Normal human α1AT, like many proteins, can be produced in high yields in bacteria and yeast. An interesting modification to α1AT replaces methionine 358 at the active site with valine to produce a molecule that is an active inhibitor but one which resists oxidation, providing a potential advantage in replacement therapy [178]. A major problem in the use of synthetic forms of α1AT

is their extremely short half-life due to the absence of carbohydrate side chains, which provide stability for the normal protein [178].

Another biotechnological approach to the production of α1AT is the use of transgenic animals. α1AT is expressed at a high level in the milk of transgenic mice, and the use of transgenic sheep or cattle could help supply large amounts of α1AT for therapeutic purposes [179].

α1AT deficiency provides a useful model for the testing of gene therapy approaches; however, it seems unlikely that this will be the preferred approach for treatment of this condition. Three potential vector systems, plasmid, retrovirus, and replication-deficient adenovirus, have been evaluated. The gene therapy approach is to remove cells from a patient and to reintroduce them after genetic modification. This approach is difficult where the product must be targeted to the lungs. Plasmids, relatively inefficient in gene transfer, are sometimes linked to a ligand to target to a particular cell type. Retroviral vectors are of concern because of the possibility of incorporation into a gene involved in tumorogenesis, leading to malignancy. Most of the retroviral DNA does not get targeted into chromosomes. Adenoviral vectors bypass the problem of slow replication of endothelial cells because the virus has avidity for epithelia of the respiratory tract. Transfer of genes into the liver has been tested as another approach. Genes transferred into hepatocytes could create a source of circulating α1AT to prevent both liver and lung damage if levels remained sufficiently high. Hepatocytes from an α1AT-deficient individual would be transfected with the α1AT gene and then returned into the peripheral circulation. Using this approach, expression of α1AT has been maintained in rats for at least four months when accompanied by partial hepatectomy [180,181]. This approach generally results in low levels of expression, which may not be adequate to protect from the development of emphysema. It is not known whether it would help avoid liver disease, particularly if such disease is due to the storage of inclusions. The simpler approach of α1AT infusion or delivery by aerosol and/or antioxidant therapy may be more feasible and cost-effective than gene therapy approaches.

Other Therapeutic Approaches

Another approach to therapy is to alter the intracellular fate of Z α1AT in the liver either by preventing degradation or increasing secretion. At the cellular level, both the protein translation inhibitor cycloheximide and the specific inhibitor of proteasome function, lactacystin, are able to prevent intracellular degradation of Z α1AT, partially restoring Z intracellular transport [182]. This observation has been made only in an experimental cell system. The use of chemical chaperones to increase secretion of mutant Z α1AT is another interesting possible route for future therapy. Chemical chaperones that reverse cellular mislocalization or misfolding have been shown in a cell-culture system and in mice to increase the secretion of α1AT, in the mouse studies producing 20–50% of the levels present in PI M mice [183].

Transplantation

There is no specific treatment for the severe liver disease that occurs in a small proportion of individuals of PI type ZZ. Fortunately, only about 3% of such individuals will experience progressive liver disease during childhood; however, a higher proportion of affected adults over the age of 50 develop liver disease. Supportive management, as for other types of liver disease, involves optimal nutrition, the prevention of fat-soluble vitamin deficiency, and diuretic treatment for ascites as required. Liver replacement provides the only definite treatment for children with end-stage liver disease associated with α1AT deficiency, a situation that will occur in only about 3% of all α1AT-deficient individuals. All of 21 PI ZZ children who received liver transplants were alive at a median follow-up of 40 months [184].

Lung transplantation has now become a feasible treatment for selected patients with end-stage lung disease. Double lung transplantation is not required as was initially believed. The survival rate may be somewhat better for individuals with single lung rather than bilateral lung transplantation [185]. Survival rates following single lung transplantation after one year have been reported as 77–90% [185,186]. Morbidity, particularly due to immunosuppression, results in a 50% five-year survival. Transplantation is a possible option when the FEV_1 falls below 30% [187]. However, a careful analysis of risk and benefit will be required. Ideally, with good nutrition, maintenance of adequate tissue antioxidants, and possibly therapy during respiratory infections, extreme measures such as transplantation can be avoided. Nevertheless, the most effective treatment of all, particularly for the lungs, remains early detection and the avoidance of smoking.

Chapter 18

Heritable Forms of Rickets and Osteomalacia

Michael P. Whyte

Center for Metabolic Bone Disease and Molecular Research, Shriners Hospitals for Children, St. Louis, Missouri 63131 and Division of Bone and Mineral Diseases, Departments of Medicine, Pediatrics, and Genetics, Washington University School of Medicine, St. Louis, Missouri 63110

SUMMARY

- **Rickets and osteomalacia are generic terms for the clinical consequences of impaired mineralization of skeletal matrix in the pediatric and adult populations, respectively. Deficiency of vitamin D, due to inadequate cutaneous biosynthesis or depletion secondary to hepatobiliary or gastrointestinal disease, causes malabsorption of dietary calcium (Ca^{++}) and explains most cases.**
- **Heritable rickets/osteomalacia usually reflects defective bioactivation of vitamin D, peripheral resistance to the hormone 1,25-dihydroxyvitamin D ($1,25(OH)_2D$), or, more commonly, hypophosphatemia due to renal phosphate (Pi) wasting. Subsequently, low extracellular levels of Ca^{++} and/or Pi compromise hydroxyapatite crystal deposition into osteoid.**
- **X-linked hypophosphatemia (XLH), the most common heritable rickets/osteomalacia, is a sex-linked dominant disorder. Short stature and bowing of the lower limbs without muscle weakness are the principal pediatric complications. Adults are troubled by osteoarthritis, pseudofractures, enthesopathy, and dental abscesses. XLH is caused by mutations in *PHEX* (phosphate regulating gene with homologies to endopeptidases on the X chromosome). An uncharacterized phosphaturic factor, "phosphatonin," seems to escape *PHEX* inactivation causing the selective renal Pi wasting. Treatment with $1,25(OH)_2D_3$ and Pi supplementation is helpful, but nephrocalcinosis and hyperparathyroidism are potential complications of treatment.**
- **Other heritable causes of "phosphate diabetes," leading to "hypophosphatemic bone disease," include autosomal dominant hypophosphatemic rickets, hereditary hypophosphatemic rickets with hypercalciuria, McCune-Albright syndrome, primary or secondary Fanconi syndrome, and X-linked hypercalciuric nephrolithiasis. This last condition is caused by deactivating mutations in the *CLCN5* gene that encodes a channel protein, ClC-5, expressed predominantly in the kidney. Depending on the specific disorder, Pi, thiazides (when there is hypercalciuria), or $1,25(OH)_2D_3$ treatment may be helpful.**
- **Vitamin D-dependent rickets, types I and II, are caused by impaired bioactivation of vitamin D due to deactivating mutations in the gene that encodes a component of the vitamin D, 1α-hydroxylase in the kidney and $1,25(OH)_2D$ resistance resulting from defects in the gene encoding the hormone's receptor (VDR), respectively. Consequently, clinical and biochemical disturbances resemble vitamin D deficiency. Treatment consists of physiologic or large doses of $1,25(OH)_2D_3$ (often with Ca^{++} supplementation), respectively.**
- **Hypophosphatasia features low serum alkaline phosphatase (ALP) activity. Premature loss of deciduous teeth is a clinical hallmark. The extreme range of disease severity reflects more than 100 different deactivating mutations in the gene that encodes the tissue nonspecific isoenzyme of ALP (TNSALP). Three phosphocompounds accumulate endogenously and therefore seem to be natural substrates for TNSALP: phosphoethanolamine (PEA), inorganic pyrophosphate (PPi), and pyridoxal 5′-phosphate (PLP). PPi inhibits hydroxyapatite crystal growth and may be a key pathogenic factor. Severe cases reflect autosomal recessive inheritance, whereas dominant-negative mutations cause relatively mild disease in successive generations. There is no established medical treatment.**

INTRODUCTION

Rickets is a generic term for the clinical consequences of impaired mineralization of matrix throughout a growing skeleton. Infants, children, and adolescents can be affected. Osteomalacia refers to the problems engendered by the same disturbance in adults (i.e., after growth plates fuse). Neither designation denotes a specific disease [1].

Often, the cause of rickets or osteomalacia is an acquired condition that diminishes endogenous stores of vitamin D. Rarely, vitamin D bioactivation or target tissue effects are impaired. Consequently, there is the cascade of gastrointestinal malabsorption of calcium, hypocalcemia, secondary hyperparathyroidism, hyperphosphaturia, and hypophosphatemia. Occasionally, however, the pathogenetic defect is kidney tubule dysfunction, leading to urinary wasting of phosphate and hypophosphatemia, sometimes associated

Connective Tissue and Its Heritable Disorders, pages 765–787

with reduced bioactivation of vitamin D. Sometimes, abnormalities of chondrocytes and osteoblasts, faulty bone matrix, or other perturbations block ionized calcium [Ca^{++}] and inorganic phosphate [Pi] entry as hydroxyapatite crystals into the skeleton [1].

The number of disorders that result in rickets and osteomalacia is considerable; most are sporadic diseases but some are heritable and comprise the subject of this chapter (Table 1) [1,2].

In rickets, all three processes of skeletal formation described below are adversely affected, whereas osteomalacia disturbs only bone remodeling [3].

Growth. For long bones to lengthen, chondrocytes in columns within growth plates (physes) proliferate, hypertrophy, and then degenerate, preparing the matrix they secrete to mineralize (endochondral bone formation).

Modeling. Correct shaping of growing bones requires simultaneous deposition and removal of osseous tissue at the outer and inner surfaces of cortical bone (subperiosteum and endosteum, respectively).

Remodeling. Trabecular (spongy) and cortical (compact) bone are resorbed and then reformed in countless microscopic areas periodically throughout life to fulfill the metabolic, structural, and repair requirements of the skeleton.

Rickets features short stature (physeal disturbances) and skeletal distortions (modeling defects) [3]. The abnormal bone remodeling (''turnover'') can appear radiographically as generalized osteopenia or, occasionally, as osteosclerosis (coarse trabecular bone) and contributes importantly to associated aberrations in mineral homeostasis. Osteomalacia will usually not deform the skeleton, unless there are fractures, because in adulthood growth plates are closed and bone modeling has essentially ceased.

Vitamin D and Mineral Metabolism

Vitamin D

Much is now known about the control of mineral homeostasis [4], including the biosynthesis, bioactivation, and physiological actions of vitamin D [5,6]. Despite the availability of supplements or the fortification of foods with vitamin D in several countries (e.g., 400 IU per quart — 0.946 liters — of milk or infant formula in the United States), antirachitic activity in most healthy people is derived primarily from cutaneous synthesis in which 7–dehydrocholesterol is converted by ultraviolet (UV) light of 290–310 nm wavelength to cholecalciferol (vitamin D_3) [7]. Ergocalciferol (vitamin D_2) is the product of UV irradiation of ergosterol extracted from plants or animals and is used as an additive or as a pharmaceutical [5,6].

Both vitamins D_2 and D_3 are prohormones that can be stored in muscle and fat or transported by vitamin D–binding protein to the liver and subsequently to the kidney for bioactivation [5,6]. First, with little regulation, vitamin D is hydroxylated in hepatocyte mitochondria by the enzyme $P450_{c25}$ to form the 25-hydroxyvitamin D derivative, 25(OH)D, called calcidiol. Then, with precise control, somehow conditioned by Ca^{++}, Pi, and parathyroid hormone (PTH) levels, 25(OH)D is further hydroxylated

TABLE 1. Heritable Causes of Rickets and Osteomalacia

	MIM No.
I. Disorders of Vitamin D Bioactivation	
A. Vitamin D dependency, type I (1α-hydroxylase deficiency)	264700
B. Vitamin D dependency, type II (hereditary Vitamin D–resistant rickets)	277420
II. Renal Tubular Acidosis, Distal (Classic, Type I)	
A. Primary (specific etiology not determined)	179800 (AD), 602722 (AR)
B. Galactosemia	230400
C. Hereditary fructose intolerance with nephrocalcinosis	229600
D. Fabry disease	301500
III. Phosphate Depletion from Impaired Renal Tubular Reabsorption (See also Table 5)	
A. X-linked hypophosphatemia	307800
B. Autosomal dominant hypophosphatemic rickets	193100
C. Syndrome of lipoatrophic diabetes, vitamin D–resistant rickets, persistent Müllerian ducts	mentioned in 277440
D. X-linked hypercalciuric nephrolithiasis	310468
E. Hypophosphatemic rickets with hypercalciuria	241530
F. McCune-Albright syndrome	174800
IV. General Renal Tubular Disorders (Fanconi Syndrome)	
A. Primary idiopathic	134600,227700, 227800
B. Cystinosis	219800
C. Fanconi-Bickel syndrome	227810
D. Lowe syndrome	309000
E. Wilson disease	277900
F. Tyrosinemia	276700
V. Primary Mineralization Defect	
A. Hypophosphatasia	146300,171760, 241500,241510
VI. Miscellaneous	
A. Axial osteomalacia	109130
B. Osteopetrosis (osteopetrorickets)	259700
C. Neurofibromatosis	162200

in renal proximal convoluted tubule cell mitochondria by $P450_{c1\alpha}$ — more commonly known as 25(OH)D, 1α-hydroxylase or simply 1α-hydroxylase [8,9]. The product is the fully active 1,25-dihydroxyvitamin D derivative, $1,25(OH)_2D$, called calcitriol. Vitamins D_2 and D_3 seem equally susceptible to these two hydroxylation steps, and their bioactivated metabolites are essentially equipotent in influencing mineral homeostasis [5,6]. $1,25(OH)_2D$ increases intestinal absorption of Ca^{++}, kidney reclamation of Ca^{++}, and bone resorption [5,6]. Rightfully, vitamin D is now regarded as a steroid hormone, not as a nutrient [4–6].

In target tissues, $1,25(OH)_2D$ has genomic and nongenomic actions [10]. It binds to the vitamin D receptor (VDR), a member of the nuclear hormone receptor superfamily [8,9], which possesses both hormone-binding and DNA-binding domains. After also combining with a retinoid X receptor, this VDR complex activates the transcription of several genes in enterocytes, kidney, and bone ultimately to augment extracellular concentrations of Ca^{++} and Pi [10].

Minerals

Extracellular concentrations of Ca^{++} and Pi are conditioned by gastrointestinal absorption, fluxes involving the skeleton and small bowel lumen, and urinary excretion [4]. Circulating levels of Ca^{++} are more tightly controlled than are levels of Pi [4]. Increments in blood Ca^{++} concentrations occur from the direct actions of PTH on the skeleton and the kidneys to accelerate bone turnover and to reclaim filtered Ca^{++}, respectively, and from the indirect action of PTH on the gut mediated by enhanced $1,25(OH)_2D$ production [5,6]. Blood Pi levels are regulated primarily by the kidney [11]. Although PTH causes phosphaturia, control of Pi homeostasis at the renal level is incompletely understood, and studies of heritable rickets and osteomalacia discussed subsequently reveal that an additional important hormonal factor(s) awaits discovery [11].

Diagnosis of Rickets and Osteomalacia

The diagnostic approach to the patient with rickets or osteomalacia is founded on an especially careful medical history and physical examination [12].

Medical History

Depending on the patient's age, disturbances in vitamin D and mineral homeostasis can cause a considerable variety of symptoms and skeletal problems. With deficiency (or impaired bioactivation) of vitamin D, the derangements can be metabolic or anatomic (Table 2) and are likely to be especially severe if extracellular Ca^{++} levels are low (Table 3).

Physical Examination

Rickets affects especially the most rapidly growing bones [13,14]. Because the neonatal calvarium enlarges particularly quickly, congenital disease sometimes causes craniotabes, with flattening posteriorly. A rachitic rosary (resulting from widened costochondral junctions) may appear during infancy. Metaphyseal flaring expands wrists and ankles. Harrison's groove is due to horizontal ridging along the inferior thorax at costal insertions of the diaphragm. Weight-bearing typically bows the lower limbs (*genu varum*). Onset of rickets later in childhood or adolescence can cause knock-knee deformity (*genu valgum*). Occasionally, the curves of the lower extremities are in the same direction ("windswept legs") [13]. Nevertheless, limb deformity may not manifest unless the patient stands. Bone pain and tenderness on palpation can reflect fracture, but they are also a prominent feature of osteomalacia due to vitamin D

TABLE 2. Vitamin D–Deficiency Rickets: Age-Dependent Signs and Symptoms

I.	Metabolic
	Hypocalcemia (see also Table 3)
II.	Neuromuscular
	Hypotonia
	Waddling gait
	Pot belly with lumbar lordosis
	Listlessness
	Proximal myopathy
III.	Dental
	Delayed eruption
	Enamel defects

	Vertebral ligament calcification

deficiency. Additional problems include a "metabolic myopathy" with reduced muscle tone and strength, leading to a waddling gait, but no (or nonspecific) changes on electromyography [13]. Proximal muscle weakness is suspected because of difficulty negotiating stairs, combing hair, and arising from a chair. Gower's sign detects this manifestation when patients must push with their hands on their thighs to stand up. Myopathy is an especially prominent feature when there are disturbances in vitamin D homeostasis.

Hypocalcemia typically results from biochemical derangements that diminish vitamin D action [5,6,14]. In infancy, floppiness, hypotonia, and failure to thrive are common. Young children are often listless and irritable [13]. Symptoms may be elicited during the medical history, and signs of overt or latent tetany appear during the physical examination (Table 3) [14].

Skull size and shape can be distorted by disturbances involving the cranial sutures. Premature fusion of the sagittal suture often causes dolichocephaly in X-linked hypophosphatemia but usually amounts only to a cosmetic concern. In hypophosphatasia, however, functional or true fusion of sutures can lead to scaphocephaly, sometimes with raised intracranial pressure [15].

There can also be lax ligaments, pectus excavatum from diaphragmatic and intercostal muscle traction, delayed eruption of permanent teeth, and enamel defects [13,14]. Alopecia is a distinctive feature in hereditary vitamin-D–dependent rickets type II [8,9]. However, it is also a manifestation of rickets from malnutrition [13].

Radiologic Studies

A posteroanterior radiograph of a wrist and an anteroposterior radiograph of a knee best document the severity of physeal and metaphyseal distortion in rickets and are used for diagnosis and to judge response to therapy [16]. Typically, physes are uniformly widened with rickets of recent onset. However, weight-bearing can asymmetrically change growth plates in the knees, sometimes masking the diagnosis (Fig. 1). Metaphyses are generally splayed, ragged, and concave, with epiphyses appearing as though they are held within cups. In osteomalacia, intervertebral disks may compress softened end plates, causing biconcave ("cod fish") vertebrae [16]. Pseudofractures (Looser's zones), often found in the femora, scapulae, and pubic rami, are a radiographic hallmark of osteomalacia (Fig. 2) [16,17].

Radiographs can provide clues concerning the etiology and pathogenesis of rickets [12,16]. Disturbances in vitamin D homeostasis, which typically engender secondary hyperparathyroidism, often lead to osteopenia and sometimes subperiosteal bone resorption. Conversely, X-linked hypophosphatemia features normal or sometimes increased skeletal radioopacity without changes of PTH excess. In hypophosphatasia, peculiar "tongues" of radiolucency project from physes into metaphyses (Figs. 3 A,B) [12,15]. Nevertheless, not all disorders that cause growth-plate distortions and extremity bowing are forms of rickets [18].

Determining how rapidly rickets responds to pharmacologic therapy may be diagnostically helpful. In primary vitamin D deficiency, radiographic improvement occurs just several weeks after a single large oral dose of ergocalciferol [13,19]. Other forms of rickets, especially those due to renal Pi wasting, often take several months to improve substantially with current medical treatments [1].

Bone scintigraphy is effective for uncovering abnormalities in the skeleton in rickets or osteomalacia but does not reveal the etiology or pathogenesis. Enhanced radioisotope uptake occurs when there is an excess of unmineralized matrix (osteoidosis); hence, rickets and osteomalacia can produce a "superscan." In osteomalacia, bone scanning is important for detecting fractures and pseudofractures. This study, however, is usually not necessary in children.

Figure 1. X-linked hypophosphatemia. Physeal widening in the knee of this 4-year-old boy with XLH is asymmetrical due to longstanding bowing deformity of his lower limbs. There is associated characteristic "beaking" of the medial femoral and tibial metaphyses (arrows).

Bone densitometry can be imprecise or misleading in rickets or osteomalacia for several reasons. Dual energy x-ray absorptiometry (DEXA) provides an areal measurement of bone mineral density (gm/cm^2) that is artifactually lowered by small body size [20]. Skeletal deformities can also compromise interpretation. Furthermore, osteoid accumulation may be recorded by various methods. Nevertheless, these techniques can be helpful to monitor responses to medical therapy, especially for individual patients with osteomalacia.

Biochemical Investigation

In acquired or heritable rickets or osteomalacia from disturbed vitamin D homeostasis, hypocalcemia can be severe [13]. Secondary hyperparathyroidism causes a mild hyperchloremic metabolic acidosis reflecting bicarbonaturia. Significant acidosis, however, suggests Fanconi syndrome or renal tubular acidosis [1,13,14]. Additionally,

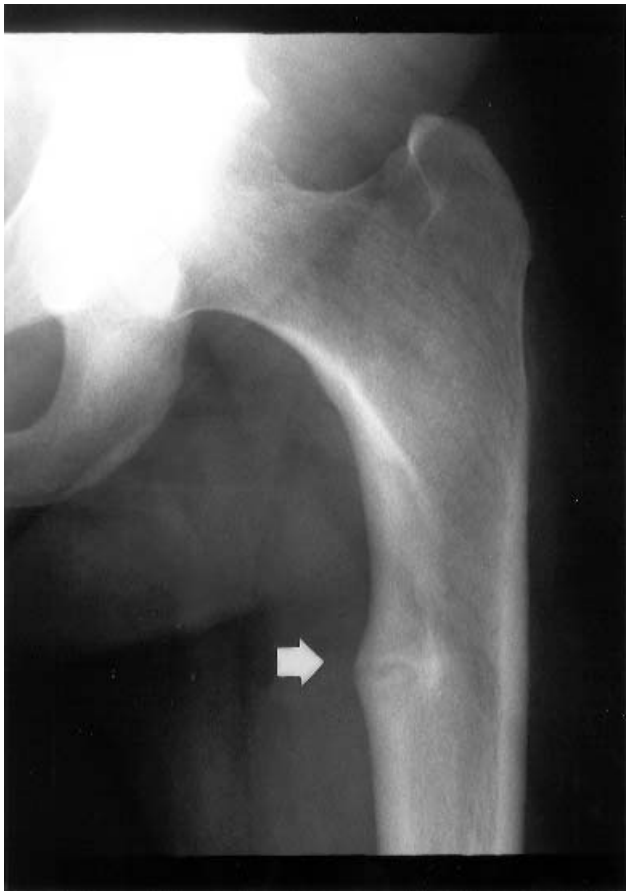

Figure 2. Pseudofracture. This 21-year-old woman with osteomalacia from XLH has *coxa vara* and a characteristic pseudofracture (Looser's zone) in the medial cortex of her left proximal femur (arrow).

nearly all forms of rickets or osteomalacia also manifest hypophosphatemia that can be due to renal Pi wasting from kidney tubule dysfunction or to excessive PTH levels.

Although quantification of circulating vitamin D_2 and vitamin D_3 levels directly evaluates vitamin D repletion, assaying these prohormones is not provided for commercially [5,6]. Instead, measuring serum 25(OH)D concentration is possible and an excellent surrogate. Assays for serum $1,25(OH)_2D$ levels are useful for diagnosing forms of vitamin D–dependent rickets and are also available on a service basis.

Serum alkaline phosphatase (ALP) activity (bone isoform) is elevated in nearly all patients with rickets or osteomalacia. A striking exception is hypophosphatasia, which features hypophosphatasemia [15]. Levels of other biochemical markers of skeletal turnover can be disturbed, depending on the precise pathogenesis of the rickets or osteomalacia [21], but need not be measured routinely.

Histopathologic Findings

Although the medical history and physical examination findings, results of routine biochemical studies, and radiographic abnormalities together usually suffice to diagnose and initiate appropriate treatment for rickets or osteomalacia, histopathologic investigation showing defective mineralization of skeletal matrix is the *sine qua non* for these disturbances [3]. A transiliac specimen obtained with a 5 mm internal diameter trephine is ideal for assessment. Both cortical and trabecular bone are sampled. Two 3-day courses (separated by a 2-week interval) of oxytetracycline or demeclocycline hydrochloride (20 mg per kg body weight daily in divided oral doses) are given to characterize *in vivo* fluorescence labeling of osseous tissue at the calcification front. The final dose is swallowed several days before biopsy.

In rickets or osteomalacia, properly stained, nondecalcified sections of skeletal tissue will reveal increased quantities of osteoid covering cortical and trabecular bone surfaces, and fluorescence microscopy will fail to show two discrete tetracycline "labels" produced by active mineralization at the osteoid-mineralized bone interfaces. Instead, absent or smeared fluorescence is noted [3]. Evidence of secondary hyperparathyroidism includes excessive numbers of osteoclasts and peritrabecular fibrosis.

Guidelines for Pharmacologic Therapy

For heritable forms of rickets or osteomalacia (Table 1), the primary pathogenic disturbance cannot be fixed. Depending on the precise diagnosis, however, it is often possible to compensate for the gene defect or to circumvent it [1].

Successful medical therapy for heritable rickets or osteomalacia must recognize the specific problem leading to aberrant mineral homeostasis [1]. Most forms of these disorders can be treated. However, an accurate diagnosis and appropriate follow-up are essential for a favorable clinical outcome while avoiding intoxication with vitamin D or mineral supplements [22]. Pharmacologic doses of vitamin D (or an active metabolite), sometimes with mineral supplementation, often effect considerable improvement but rarely achieve complete yet perfectly safe control.

As of this writing, seven sterols with vitamin D activity are prescribed worldwide [5,6,23]: vitamins D_2 and D_3, $25(OH)D_3$, $1,25(OH)_2D_3$, and three synthetic analogs of vitamin D called dihydrotachysterol (DHT) and alfacalcidiol [$1\alpha(OH)D_2$ and $1\alpha(OH)D_3$]. Vitamin D_3 and alfacalcidiol are not available by prescription in the U.S. These seven drugs differ importantly in potency, biological half-life, and cost (Table 4) [5,6,23].

Medical therapy for heritable rickets and osteomalacia can be rewarding for patient and physician. Given sufficient time before growth-plate closure, defects in the three processes of skeletal development can often be substantially corrected [3]. Relief from bone pain, reversal of deformity, correction of short stature, reduction in the risk of developing osteoarthritis, and fracture prevention are major goals of treatment [1].

Physical examination provides critical information [12]. Linear growth rate is a key parameter to monitor in infants, children, and especially adolescents. Height is best determined with a wall-mounted stadiometer. Rapid increases in body size during the pubertal "growth spurt" can significantly augment dose requirements for medical therapy. Inordinate weight gain in girls sometimes accelerates puberty, causing an early growth spurt, which, if unrecognized, can exacerbate limb deformity and compromise final height. Measurements of arm span and upper and lower body segment lengths help to quantify skeletal distortion. With heritable rickets, treatment will be necessary throughout growth, and some time can pass before control of the

Figure 3. Hypophosphatasia. A) Pathognomonic ''tongues'' of radiolucency (arrows) project from physes into metaphyses in the knee of this 2-year-old boy with the infantile form of hypophosphatasia. This finding is especially noticeable in the proximal tibia. **B**) By age $3\frac{1}{2}$ years, there has been considerable spontaneous radiographic improvement.

TABLE 4. Preparations of Vitamin D and Active Metabolites*

Preparation	Ergocalciferol	Dihydrotachysterol	Calcifediol	Calcitriol
Abbreviation	D_2	DHT	$25(OH)D_3$	$1,25(OH)_2D_3$
Trade name	Calciferol	Hytacherol, Intensol	Calderol	Rocaltrol, Calcijex
Dosage form	a. Capsules: 1.25 mg	a. Tablets: 0.125,0.200, and 0.400 mg	Capsules: 20 and 50 μg	a. Capsules: 0.25 and 0.50 μg
	b. Liquid: 200 μg/mL	b. Liquid: 0.2 mg/mL		b. Liquid: 1 μg/mL

Physiologic daily dose	2.5–10 μg	25–100 μg	1–5 μg	0.25–0.5 μg
Time to reach maximum biologic effect	4–10 weeks (oral)	2–4 weeks	4–20 weeks	$\frac{1}{2}$–1 week
Persistence of biologic effect after cessation	6–30 weeks (oral)	2–8 weeks	4–12 weeks	$\frac{1}{2}$–1 week

*Available in the U.S.

skeletal disease is achieved. Occasionally, it is a family member who sees the patient only every few months who best appreciates gradual changes in deformity. Accordingly, clinical photography, videotaping, and even gait analysis can be helpful [12].

Radiographic assessment of skeletal abnormalities, such as physeal widening and metaphyseal irregularity, is essential for monitoring rickets. In osteomalacia, there are fewer x-ray features to follow, but pseudofractures can heal with treatment. Other findings are less helpful;

osteopenia or coarsening of trabecular bone is found only in some patients [16]. Nevertheless, sequential bone density measurements should, with potential technical limitations, be worthwhile in osteomalacia.

The most important biochemical parameters for diagnosis and follow-up of rickets and osteomalacia are serum Ca^{++} and Pi concentrations, ALP activity, and PTH levels. Depending on the etiology and pathogenesis of the specific disorder, knowing serum 25(OH)D and, more rarely, $1,25(OH)_2D$ concentrations can be helpful [1]. Ca^{++} excretion in 24-hour urine collections (expressed per creatinine content) should also be assayed to guide therapy and to help monitor against vitamin D or mineral intoxication[1] [1].

The diseases that give rise to heritable rickets and osteomalacia are numerous and diverse (Table 1). Successful treatment will require an accurate diagnosis and thorough understanding of a disorder's pathogenesis [1]. Although administration of vitamin D_2 can cure vitamin D deficiency, heritable forms of rickets or osteomalacia respond best to regimens that bypass or compensate for the intrinsic metabolic defect. However, a range of effective doses must be anticipated, even among patients with a specific diagnosis. The optimal approach will likely include one of the vitamin D metabolites, perhaps with mineral supplementation. Significant adverse consequences (failed treatment, hypercalcemia, tertiary hyperparathyroidism, or renal damage) can result from an incorrect diagnosis or excessive therapy.

Treatment with an active metabolite of vitamin D has advantages and disadvantages. Importantly, these drugs can circumvent defects in the bioactivation of vitamin D [1,5,6]. Additionally, they are more potent than vitamins D_2 or D_3 and have faster onset of action (Table 4) [23]. Fortunately, toxicity can be corrected easily. However, they also have shorter biological half-lives, and more frequent dosing is necessary. Furthermore, cessation of therapy will quickly decompensate mineral homeostasis. Finally, these pharmaceuticals are expensive.

Many Ca^{++} and Pi supplements are available [23]. $CaCO_3$ given orally is least costly, but Ca^{++} citrate is best absorbed. Calcium gluconate is especially high-priced. Tablets rather than liquid preparations for Pi supplementation are more convenient, better tasting, well-absorbed, and seem less prone to cause diarrhea. Those containing high amounts of Na^+ should be avoided.

Follow-up clinic visits are essential for all types of heritable rickets and osteomalacia, but the interval should reflect the diagnosis as well as the patient's age and compliance with, and response to, therapy. Because these disorders represent deficiency of mineral content within the skeletal matrix, decreases in medication dosages are frequently necessary when healing becomes complete (i.e., acute and maintenance therapies often differ). Satiation of "hungry bones" can abruptly increase urinary Ca^{++} excretion because the skeleton no longer acts as a mineral sump [1]. Fortunately, hypercalciuria generally precedes hypercalcemia unless there is renal failure or sustained elevation in circulating PTH levels (acting to reclaim Ca^{++} from the glomerular filtrate). Correction of abnormal biochemical findings should herald hypercalciuria. Lower doses of medication may then be needed. Thus, 24-hour urine collections, not random specimens, assayed for Ca^{++} and creatinine are especially important for monitoring patients. In fact, when there is hypocalciuria but no sustained hyperparathyroidism, rising urinary Ca^{++} levels will indicate effective therapy.

Consultation and follow-up with the pediatric orthopedic surgeon is often essential for optimally managing heritable rickets. Straight lower limbs with alignment of growth plates parallel to the ground helps to prevent osteoarthritis. Leg bracing, physeal stapling (epiphysiodesis), or osteotomy may be beneficial.

Pharmacologic regimens for specific types of heritable rickets or osteomalacia are outlined in the following sections.

Heritable disorders that cause rickets or osteomalacia are listed in Table 1. Some reflect disturbances in the bioactivation or action of vitamin D; several are characterized by renal Pi wasting. As discussed below, most of these conditions have proven to be inborn errors of metabolism due to enzyme deficiencies. However, for a few of the diseases that feature renal Pi wasting, the genetic basis awaits discovery.

HYPOPHOSPHATEMIC BONE DISEASES

Most acquired and some heritable forms of rickets or osteomalacia reflect aberrations in vitamin D homeostasis leading to reduced levels of Ca^{++} in extracellular fluid [1,14]. Nevertheless, it is important to appreciate that these disorders also diminish extracellular Pi concentrations due to dietary malabsorption as well as phosphaturia from secondary hyperparathyroidism. Consequently, hypocalcemia and hypophosphatemia act in concert to decrease the extracellular $Ca^{++} \times$ Pi product, thereby impairing mineralization of newly synthesized osteoid [3].

The importance of Pi for skeletal formation is exemplified best by rickets or osteomalacia due to renal wasting of Pi ("phosphate diabetes"). Here, hypophosphatemia, without associated hypocalcemia, causes osteopathy [11,24]. "Hypophosphatemic bone disease" is a useful generic term that emphasizes the diagnostic and pathophysiologic significance of this biochemical disturbance. Many of the disorders that cause hypophosphatemic bone disease are heritable (Table 1). Although pharmacologic treatment for these types of rickets or osteomalacia has certain themes, it is important to recognize that optimal regimens differ among the various entities.

X-Linked Hypophosphatemia

X-linked hypophosphatemia (XLH) (MIM 307800) is the most common heritable form of rickets or osteomalacia [2]. Its prevalence in North America is approximately 1 : 20, 000 live births [11]. All races seem to be affected [25].

XLH was first described in 1937 after the epidemic of vitamin D–deficiency rickets, a socioeconomic scourge centered in smoggy northern industrialized cities, became treatable [26]. Discovery of vitamin D in 1919 and successful therapy and preventive measures for "nutritional" rickets was a triumph of medical science at the beginning of the last century [5,6]. Nevertheless, some patients with rickets were puzzling because they were not cured even by massive doses of vitamin D_2 [26]. XLH became the prototypic example of "vitamin D–resistant rickets" (VDRR), an acronym that survived until the disorders discussed below became sufficiently delineated and understood.

In 1958, "VDRR" was recognized to manifest sex-linked dominant inheritance [27]. Females and males are affected in a characteristic 2 : 1 ratio, although early on it was believed that the disease is more mild in females [11,24].

[1] If incomplete healing of rickets or osteomalacia is suspected, nondecalcified iliac crest histomorphometry is required [1,3].

In 1972, hypophosphatemia from selective renal Pi wasting was emphasized as a key pathogenetic factor requiring treatment [28]. In fact, XLH seems to be the best name for this disorder because of the lifelong persistence of this kidney defect [29]. In 1980, an inappropriately normal circulating level of $1,25(OH)_2D$ despite hypophosphatemia was documented but is still an enigmatic biochemical feature of XLH [30]. In 1995, an international consortium of researchers identified a gene now called *PHEX* (phosphate regulating gene with homologies to endopeptidases on the X-chromosome) that was defective in XLH [31]. More than 100 different mutations in *PHEX* have been reported worldwide [24,25].

Clinical Presentation

XLH causes bowing of the lower limbs and short stature in toddlers as they begin to bear weight (Figs. 4 A,B). Adult height Z-scores will typically be minus 2 to 3 standard deviations unless there is effective treatment [29]. Affected children can seem clumsy but are otherwise well. When skeletal disease sometimes presents later during childhood, knock-knee deformity may occur. There is no muscle weakness (in contrast to many forms of rickets). The skull often becomes dolichocephalic due to early closure of the sagittal suture, but this feature seems to be only of cosmetic concern. Deafness is not a problem in pediatric patients [32]. The chest and upper extremities are not distorted. Fractures are uncommon in children but occasionally occur later in life. Doppler and two-dimensional echocardiography of the heart is normal [33].

Adults with XLH suffer three principal complications [29,34,35]. Arthralgias, primarily involving the lower limbs and especially the knees, are usually caused by osteoarthritis. The degree of extremity deformity predicts the likelihood and severity of joint deterioration [29]. Bone pain, especially in the thighs and elicited by palpation, is often explained by pseudofractures (Fig. 2). Dental abscesses develop because brittle "shell teeth" have formed early in life due to defective mineralization of dentin [29]. Calcification of tendons, ligaments, and joint capsules, called enthesopathy, is common, but it is unclear how often enthesopathy causes symptoms [29,34]. Perhaps sensorineural hearing loss and occasionally spinal stenosis occur with increased prevalence in adults [11,24]. Obstetrical histories, however, seem benign [29].

Radiologic Findings

Radiographs of the lower limbs show physeal widening in the knees that is pronounced medially when there is bowing deformity (Fig. 1). Osteopenia and evidence of secondary hyperparathyroidism are typically absent unless dietary Ca^{++}intake is poor. In fact, the skeleton sometimes appears dense even before treatment (in contrast to other forms of rickets associated with increased circulating PTH levels). In adults, axial skeletal mass is usually normal, although sometimes the bones look sclerotic [35].

Laboratory Findings

The biochemical hallmark of XLH is hypophosphatemia [11,24]. Low blood Pi levels are documented if important age-related changes in the reference range for serum Pi are appreciated [36]. Healthy infants and children have considerably higher serum Pi concentrations (and ALP activity) than adults [36]. Because serum Pi levels may increase or decrease depending on what is eaten, fasting blood specimens are necessary for diagnosis [1]. Additionally, a considerable variety of disorders and perturbations can cause chronically low blood Pi levels and must be excluded for a correct diagnosis (Table 5). In XLH, quantification of renal Pi reclamation by calculating the tubular reabsorption of phosphorus (TRP) or, better yet, assessing the transport maximum for phosphorus corrected for glomerular filtration rate (TmP/GFR)[2] shows that hypophosphatemia is due to "phosphate diabetes" [36].

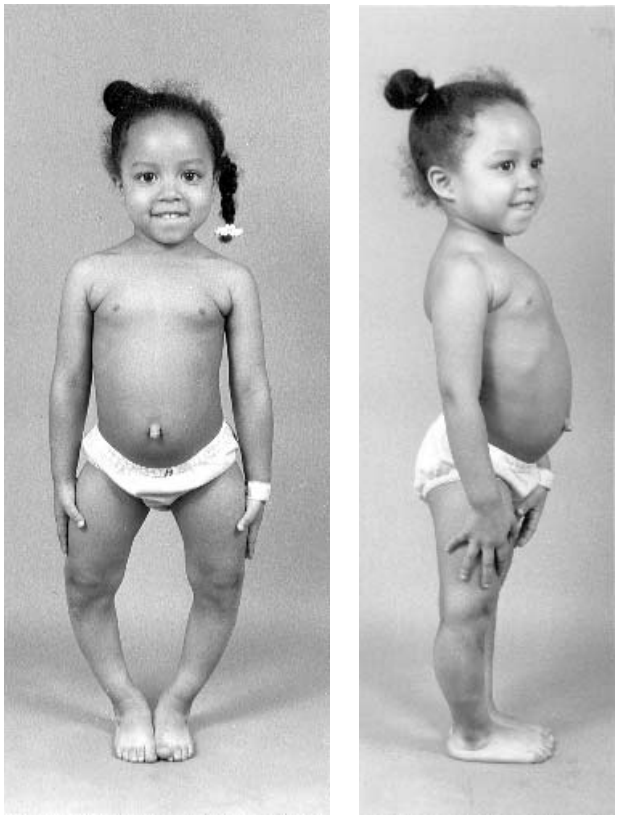

Figure 4. X-linked hypophosphatemia. A) Severe bowing deforms the lower limbs of this newly diagnosed, 4-year-old girl with a three-generation family history of XLH. **B**) Despite her hyperlordotic posture and "pot-bellied" appearance, she has no muscle weakness. Mild frontal bossing is characteristic of XLH.

Serum Ca^{++} levels are often low-normal, but not distinctly reduced, unless there are additional perturbations of mineral homeostasis [29,37,38]. Circulating $1,25(OH)_2D$ concentrations in XLH are, as a rule, normal or low-normal despite the hypophosphatemia that typically increases renal 25(OH)D,1α-hydroxylase activity in healthy individuals [11,24,30]. Unless patients receive Pi supplements insufficiently matched by doses of $1,25(OH)_2D_3$ (see below), PTH levels are also generally unremarkable [29,37,38]. Without pharmacologic treatment, serum ALP is invariably increased in children [37,38] but not always in adults [29]. Occasionally, trace glucosuria is detected; however, other reflections of renal proximal tubular function (e.g., serum K^+, HCO_3^-,

[2] $\frac{TmP}{GFR} = S_p - \left[\frac{U_p \times S_{Cr}}{U_{Cr}}\right]$ where S_p, S_{cr}, U_p, U_{Cr} are concentrations of phosphate and creatinine in serum and urine [36].

TABLE 5. Causes of Chronic Hypophosphatemia

	Pseudo-(tumor-induced) rickets
	Renal transplantation
	Respiratory alkalosis
	Severe burns
	X-linked hypophosphatemia

and uric acid levels) are normal in XLH (i.e., renal Fanconi syndrome — see later — is absent).

Histopathologic Findings

Histologic examination of the skeleton shows rickets or osteomalacia in untreated patients with XLH [28–30]. It is of interest that in appropriately stained, nondecalcified bone sections there will also be pathognomonic "halos" of osteoid surrounding individual osteocytes [29]. This peculiarity seems to be diagnostic of XLH, reflecting a mineralization defect that persists when osteoblasts become osteocytes. In fact, halos remain despite successful $1,25(OH)_2D_3$ and Pi therapy [39–43]. When circulating PTH levels are elevated, there will also be changes of hyperparathyroidism including abundant osteoclasts and peritrabecular fibrosis.

Pathogenesis and Genetics

The pathogenesis of XLH is incompletely understood [11,24]. Malabsorption of dietary Ca^{++} is a manifestation of the vitamin D resistance that requires further investigation. A murine model (*Hyp*) for XLH [44] has revealed a defect in the transport of Pi from the glomerular filtrate across kidney proximal tubule cells where PTH and somehow dietary Pi levels control urinary Pi reclamation [45]. Here, Pi transfer through the brush border membrane is the rate-limiting step. In *Hyp* mice, there is decreased activity of a high-affinity, low-capacity, Na^+-dependent, Pi cotransport system [11,24]. The transporter (NPT-2) gene in humans has been cloned from chromosome 5q35 and therefore is not a candidate for XLH [24]. Nevertheless, there is ~50% reduction in NPT-2 mRNA and protein in *Hyp* mice [11]. However, *Hyp* mice also manifest a blunted response to activators of $1,25(OH)_2D$ synthesis in kidney mitochondria [11]. In these animals, Pi deprivation and supplementation inappropriately accelerate and suppress, respectively, $1,25(OH)_2D$ catabolism [46]. Nevertheless, the precise intracellular disturbances in the kidney that diminish Pi transport and alter vitamin D bioactivation in XLH are not known.

Of great interest to the field of metabolic bone disease are observations from parabiotic and renal transplantation studies using the *Hyp* mouse that implicate a phosphaturic factor in XLH [47,48]. The nature of this factor, provisionally called "phosphatonin," is incompletely understood [49,50]. It seems to be a heat-stable protein of ~57,000 kDa with PTH-like immunoreactivity [49,50]. Additionally, however, tissue culture studies of *Hyp* and XLH bone explants suggest that osteoblast function is also intrinsically impaired [39,51,52]. Indeed, osteoblasts express PHEX and may be a source of phosphatonin [53,54].

XLH maps to chromosome Xp22.3-21.3 [25]. The gene that is defective is now called *PHEX* [2,11,24]. More than 100 different mutations affecting the coding sequence of *PHEX* have been identified in patients worldwide [24]. These defects are expected effectively to eliminate PHEX protein production. However, such mutations have been found in only ~50% of patients [25]. Defects within the noncoding regions of *PHEX* or perhaps in an additional nearby gene(s) could be the explanation for XLH in other affected individuals. In fact, preliminary analysis indicates that these essentially null mutations in *PHEX* are associated with the most severe clinical and biochemical findings among the XLH patient population [55]. Nevertheless, the putative substrate for *PHEX*, "phosphatonin," remains elusive [53,54]. Possibly, PHEX acts enzymatically at osteoblast surfaces to inactivate phosphatonin or to activate a Pi-conserving hormone [11,24].

In XLH, no gene-dosage effect emerges from comparison of prepubertal heterozygous girls versus prepubertal hemizygous boys [38]. Nevertheless, pseudofractures and enthesopathy are more prevalent and severe in men than in women [34]. Accordingly, sex (sex steroids and/or physical labor) seems to influence the long-term outcome of XLH [38].

Renal Pi wasting is a major pathogenetic abnormality in XLH [27,28]. TmP/GFR correlates positively with height Z-score and negatively with the degree of bowing deformity in untreated children and adults, respectively, with XLH [29,38]. Accordingly, this fundamental disturbance is addressed by medical therapy. Resistance to vitamin D and aberrations in renal $1,25(OH)_2D$ biosynthesis are also compensated (see below).

Treatment

A bioactive form of vitamin D together with Pi supplementation is currently the preferred medical treatment for XLH [37]. High doses of vitamin D_2 (e.g., 100,000 IU daily) improve, but will not heal, XLH rickets [26,28]. Furthermore, this therapeutic approach can prove toxic [56]. Large doses of vitamin D_2 are converted to 25(OH)D. Although the affinity of the VDR for 25(OH)D is two to three orders of magnitude lower than for $1,25(OH)_2D$ [10], excessive vitamin D_2 therapy sometimes produces sufficiently great concentrations of 25(OH)D to cause prolonged hypercalcemia, hypercalciuria, nephrocalcinosis, and renal failure [56]. The period of intoxication also reflects the long biological half-life of vitamin D itself (Table 4). In fact, vitamin D_2–induced hypercalcemia can persist for months, necessitating dietary Ca^{++} restriction and glucocorticoid treatment. Additionally, "high dose" vitamin D_2 therapy requires cessation months before osteotomy to avoid hypercalciuria or hypercalcemia if there is postoperative immobilization.

When the renal Pi wasting of XLH was first addressed therapeutically, improved clinical, biochemical, and radiographic responses became apparent [28,37]. Transient augmentation of circulating Pi levels is achieved using frequent oral Pi dosing. The amount depends on body size. About 1–2 grams of phosphorus (as Pi) are given each day for an older child or adolescent [37].

However, it is clear that combined use of $1,25(OH)_2D_3$ and Pi supplementation is important and the best regimen for XLH [37]. $1,25(OH)_2D_3$ enhances both Ca^{++} and Pi uptake from the gut. Improved dietary Ca^{++} absorption is necessary to prevent secondary or tertiary hyperparathyroidism from hypocalcemia provoked by the effect of Pi in binding Ca^{++} in the circulation or in the gut lumen. Growth hormone and $24,25(OH)_2D_3$ have been tested individually for XLH with uncertain outcome using relatively small groups of patients [57,58].

In fact, treatment of XLH requires a combined medical and orthopedic approach. Ideally, this is provided by centers experienced with XLH. $1,25(OH)_2D_3$ and Pi therapy can correct deficits in growth and restore skeletal modeling and remodeling in pediatric patients [37]. The goals of treatment are essentially twofold and clear-cut. Elimination of lower-limb deformities by the time growth plates fuse is necessary to prevent osteoarthritis later in life. Additionally, both boys and girls can achieve normal height. However, two potential complications of $1,25(OH)_2D_3$ and Pi dosing are secondary or tertiary hyperparathyroidism (compromising the clinical outcome and perhaps necessitating parathyroidectomy) and renal damage [55]. Unfortunately, the margin for error in treating XLH patients with these drugs is not great. Accordingly, medical management seems best from physicians experienced with this disorder.

Therapy should begin with affected toddlers to help avoid lower-extremity deformities that could require surgery. However, dosing and biochemical monitoring will understandably be difficult at first. Control, but not complete correction, of the rickets is a reasonable early objective. $1,25(OH)_2D_3$ is available in 0.25 and 0.50 μg capsules and in a solution of 1 μg/mL (Rocaltrol®; Hoffman-LaRoche, Inc., Nutley, New Jersey) (Table 4). Approximately 40 ng of $1,25(OH)_2D_3$ (i.e., 0.040 μg) per kg of body weight daily (divided doses are ideal) should be achieved safely over 2–3 months. Pi supplementation must be introduced at the same time as $1,25(OH)_2D_3$, with gradually increasing doses of both medications and follow-up of their biochemical effects. Pi supplementation is given three to four times daily. Tablets of Na^+/K^+ phosphate (e.g., K-Phos Neutral®; Beach Pharmaceuticals, Tampa, Florida) are convenient and generally well-tolerated, and the low Na^+ content does not cause hypertension [37,59]. Occasionally, Pi leads at first to diarrhea, but patients often tolerate the drug better after perhaps one week of treatment. If they do not, supplementation can be adjusted to acceptable levels.

In some ways, $1,25(OH)_2D_3$ and Pi produce opposite effects on Ca^{++} homeostasis, and this must be dealt with as dosages of $1,25(OH)_2D_3$ or Pi are regulated [37]. If either $1,25(OH)_2D_3$ or Pi treatment has been inadvertently stopped temporarily, both supplements should be withheld. Sudden decreases in Pi dosing should be avoided because blood and urinary Ca^{++} levels may rapidly rise [60]. Accordingly, patients should be cautioned not to go without one of the medications.

Careful biochemical surveillance is essential for XLH patient treatment because $1,25(OH)_2D_3$ and Pi supplements potently increase Ca^{++} and Pi absorption from the gut. Ca^{++}, P, and creatinine should be assessed using 24-hour urine collections (not random specimens) [1,37]. Initially, monitoring should be monthly; testing can then occur perhaps every three months when dosing becomes established. Urinary Ca^{++} to creatinine ratios of about 150–180 mg/g (424–509 mmoles/mole) demonstrate adequate gut effects of $1,25(OH)_2D_3$ and should reflect Ca^{++} absorption that will control circulating PTH levels. Unless serum PTH is nonsuppressably elevated, hypercalciuria will herald excessive $1,25(OH)_2D_3$ dosing. If PTH levels remain increased, hypercalcemia can occur before hypercalciuria. Partial parathyroidectomy can become necessary when tertiary hyperparathyroidism causes hypercalcemia and/or difficulty in controlling the skeletal disease. Fortunately, $1,25(OH)_2D_3$ has a short biological half-life, permitting rapid correction of dosing (Table 4). Reducing dietary Ca^{++} intake also works rapidly to correct endogenous Ca^{++} levels. For Pi supplementation, urine levels of 3–3.5 gP/g creatinine (8.6–10.0 moles P per mole creatinine) are efficacious yet seem reasonable to help prevent nephrocalcinosis. Renal ultrasonography, creatinine clearance, and the serum PTH level should be monitored at least yearly to screen for complications of treatment (Fig. 5). Nephrocalcinosis in XLH represents Ca^{++}-Pi deposits [61,62]. Subradiographic nephrocalcinosis, however, seems not to compromise renal function [56].

Dosage increases will be necessary as the child grows. Hypercalciuria (Ca^{++} >4 mg per kg of body weight or >220 mg per g creatinine or >628 moles/mole) can occur abruptly when skeletal mineralization is restored or when growth plates fuse. Approximately one-half the dose of $1,25(OH)_2D_3$ and Pi should then provide maintenance therapy. If hypocalciuria persists during $1,25(OH)_2D_3$ and Pi treatment, increased milk consumption or Ca^{++} supplementation may be helpful.

Orthopedic evaluation should occur at least annually during childhood and biannually during the adolescent growth spurt because bracing or epiphysiodesis can help straighten lower-limb deformities. For severe distortions, osteotomies are performed ideally after growth plates have fused to minimize the likelihood of postoperative curvatures.

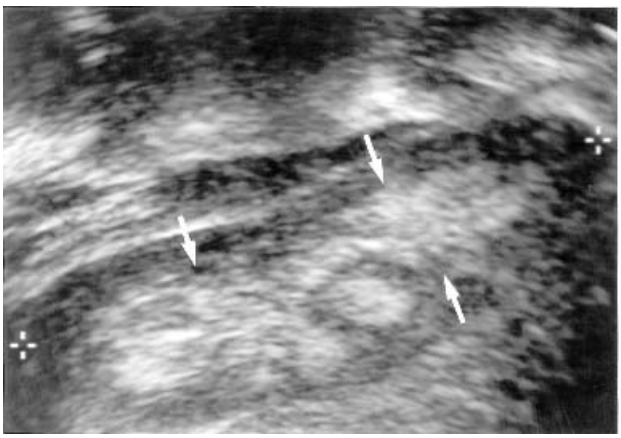

Figure 5. X-linked hypophosphatemia. Medullary nephrocalcinosis detected by renal sonography appears as patches of white material (arrows) in this 6-year-old girl with XLH receiving $1,25(OH)_2D_3$ and Pi supplementation (the symbols ⊹ help measure kidney length).

Unless patients are weight-bearing within two days of surgery (or a fracture, etc.), both $1,25(OH)_2D_3$ and Pi therapy should be discontinued temporarily to avoid immobilization-induced hypercalciuria and hypercalcemia [63].

Pubertal closure of physes does not signify that XLH is cured [29]. Renal Pi wasting persists throughout life [29]. Accordingly, affected adults should be monitored perhaps yearly. Some of these individuals seem to benefit from $1,25(OH)_2D_3$ and Pi therapy to prevent fractures or worsening deformity or to heal pseudofractures [29,64]. However, the efficacy and outcome of medical treatment for men and women with XLH is not well-understood [64]. In our experience (unpublished), five untreated adult patients tolerated knee or hip replacement well and benefited significantly. The impact of XLH during old age has not been studied, but life expectancy is probably not compromised.

Genetic Counseling/Prenatal Diagnosis

Approximately 20% of XLH patients represent new mutations [11,25]. In keeping with X-linked dominant inheritance, affected males then transmit the disorder to all of their daughters but none of their sons. Affected females pass on XLH to half of both their sons and their daughters. Prenatal diagnosis has not been reported for this treatable disease.

X-Linked Hypercalciuric Nephrolithiasis

X-linked hypercalciuric nephrolithiasis (XLHN) (MIM 310468) maps to chromosome Xp11.22 and is caused by deactivating mutations in the *CLCN5* gene involved in Cl^- transport [65,66]. It is a sex-linked recessive condition that affects males, who manifest proximal kidney tubule failure and progressive glomerular disease leading to renal insufficiency. Renal Pi wasting sometimes causes rickets [67–69]. In response to hypophosphatemia, serum $1,25(OH)_2D$ levels are elevated and associated with hypercalciuria, nephrocalcinosis, and nephrolithiasis. β_2-microglobulinuria reflects an early renal disturbance [66,68]. The severity of the hypophosphatemic rickets seems to vary considerably worldwide, and several additional names have been given to this disorder, including Dent's disease and X-linked recessive hypophosphatemic rickets [66].

Treatment of XLHN rickets is not well-established, but Pi supplementation (with caution not to induce hyperparathyroidism or to exacerbate nephrocalcinosis) has had some success [66]. Thiazide diuretics have also been used to diminish the hypercalciuria [66]. If renal failure occurs, Pi diabetes ceases and defective mineralization of skeletal matrix corrects as circulating Pi levels rise.

Autosomal Dominant Hypophosphatemic Rickets

Autosomal dominant hypophosphatemic rickets (ADHR) (MIM 193100) is an extremely rare disorder that also features isolated renal Pi wasting. It has been fully characterized in one large kindred [70], but patients with the rare disorder called "hypophosphatemic bone disease" (HBD) may also represent cases of ADHR [24]. Affected individuals manifest relatively mild rickets that can appear either during early childhood or adolescence [70]. In some patients, renal Pi wasting corrects after puberty. Serum $1,25(OH)_2D$ levels are inappropriately normal [24]. The disorder has been mapped to chromosome 12p13, but the defective gene has not been identified [71]. Medical treatment for ADHR involves the regimen used for XLH, but lower doses of $1,25(OH)_2D_3$ and Pi seem effective [24,70].

Hereditary Hypophosphatemic Rickets with Hypercalciuria

Hereditary hypophosphatemic rickets with hypercalciuria (HHRH) (MIM 241530) has been characterized in one large Bedouin kindred [72,73]. The mode of inheritance seems to be autosomal recessive [2]. Renal Pi wasting causes hypophosphatemic rickets, but circulating $1,25(OH)_2D$ levels are elevated, presumably as a physiologic response to the low Pi concentration in blood. Subsequently, patients develop hypercalciuria and kidney stones. Medical treatment of the rickets could include cautious introduction and close follow-up of Pi supplementation and the use of thiazide diuretics [24].

Fanconi Syndrome

Fanconi syndrome features proximal renal tubule dysfunction leading to low serum levels of Pi, K^+, HCO_3^-, and uric acid, as well as to aminoaciduria [74]. There are several heritable causes, including cystinosis, tyrosinemia, and Lowe syndrome (Table 1). Therapy with $1,25(OH)_2D_3$ and Pi supplementation (see XLH) seems helpful, but urinary Ca^{++} levels must be monitored especially carefully because there can be hypercalciuria.

McCune-Albright Syndrome

McCune-Albright syndrome (MAS) (MIM 174800) is a sporadic condition caused by somatic cell mosaicism involving rare gain-of-function mutations of the *GNAS1* gene (chromosome 20q13). *GNAS1* encodes the α subunit of the G protein (Gs_α) that stimulates adenyl cyclase [75]. MAS is characterized clinically by polyostotic fibrous dysplasia, café-au-lait spots, and endocrine gland overactivity, most frequently causing precocious puberty, thyrotoxicosis, or acromegaly [75].

Although the precise pathogenesis is uncertain, acquired hypophosphatemic rickets due to renal Pi wasting is not uncommon in MAS, especially when there is extensive skeletal disease (Fig. 6). We find the onset of the rickets to be at about 8 years of age [76]. The Pi wasting could reflect excessive cAMP formation in kidney tubule cells, but we speculate instead the elaboration of a phosphaturic factor, perhaps phosphatonin, from the increasing mass of fibrodysplastic tissue [76]. In fact, hypophosphatemic rickets can also complicate neurofibromatosis, ossifying and nonossifying fibroma, fibrous dysplasia that occurs with nevus unius lateris, and mixed-mesenchymal tumors (oncogenic rickets), all associated with fibrous tissue accumulation [1].

Treatment with $1,25(OH)_2D_3$ and Pi can help to minimize the added skeletal burden of rachitic disease in MAS. However, responses can be difficult to evaluate because of premature closure of growth plates when there is precocious puberty. Furthermore, the remarkable appearance of the underlying fibrous dysplasia itself can divert attention from rickets (Fig. 6). In fact, even bone histopathology may not be helpful because the defect in mineralization can be obscured if fibrous dysplasia is inadvertently sampled.

VITAMIN D–DEPENDENT RICKETS

Vitamin D–dependent rickets (VDDR) types I and II (VDDR I and VDDR II) are rare autosomal recessive disorders that mimic vitamin D deficiency [5,6,77]. However, they manifest no aberration in cutaneous synthesis of vitamin D_3 or hepatobiliary or gastrointestinal disease that can disturb vitamin D homeostasis. Despite low circulating Ca^{++}

Figure 6. McCune-Albright syndrome. The right wrist of this 9-year-old girl with MAS shows widening of the physes and irregularity of the metaphyses (especially in the distal radius) indicative of rickets. She has gradually developed hypophosphatemia with serum Pi = 2.3 mg/dl (normal 4.3–5.7). Cortical thinning and a "ground glass" appearance, characteristic of fibrous dysplasia, are present in her metacarpals.

levels, patients are replete with vitamin D, as shown by normal serum levels of 25(OH)D. In fact, there is only one report in the medical literature suggesting that a heritable defect in hepatic 25-hydroxylase occurs in humans [78].

VDDR I and II feature, respectively, diminished biosynthesis of, and target tissue resistance to, $1,25(OH)_2D$. Because there is either a block in renal conversion of 25(OH)D to $1,25(OH)_2D$ (VDDR I) or peripheral resistance to $1,25(OH)_2D$ itself (VDDR II), serum levels of $1,25(OH)_2D$ that are low and high, respectively, readily distinguish these disorders [5,6,77]. Nevertheless, both types of VDDR alter mineral homeostasis in a similar way. Dietary Ca^{++} is malabsorbed, leading to hypocalcemia, secondary hyperparathyroidism, renal Pi wasting, and hypophosphatemia. Decreased extracellular fluid levels of Ca^{++} and Pi together impair skeletal mineralization. Because the pathogenesis of VDDR I involves defective production of $1,25(OH)_2D$ by the kidney, physiologic doses of $1,25(OH)_2D_3$ easily control the disorder [79]. However, in VDDR II, even enormous doses of $1,25(OH)_2D_3$ may prove ineffective [5,6], and Ca^{++} supplementation becomes crucial [80,81]. As discussed below, both VDDR I and II are now understood at the gene level [77].

Vitamin D–Dependent Rickets, Type I

In 1961, Prader and colleagues [82] reported two children with "pseudovitamin D deficiency" who had clinical, radiographic, and biochemical features of nutritional rickets yet responded only to large doses of vitamin D. The term "vitamin D dependency" was used later for this disorder (i.e., VDDR) [77]. Subsequently, with recognition of a different entity featuring tissue resistance to $1,25(OH)_2D$, these conditions became known as VDDR I and II, respectively [5,6,77]. Early reports of affected siblings in inbred kindreds indicated that VDDR I is an autosomal recessive condition (MIM 264700) [2]. Serum levels of $1,25(OH)_2D$ are low or undetectable despite normal levels of 25(OH)D and otherwise intact renal function. Because VDDR I is now understood at the molecular level, it is also called 1α-hydroxylase deficiency [2,77,79].

Clinical Presentation

Patients appear healthy at birth. However, features consistent with nutritional rickets are usually noticed before 2 years of age and often within the first 6 months of life. There is growth retardation and poor gross motor development. Muscle weakness, irritability, pneumonia, seizures, and failure to thrive are prominent findings [77,79,82].

Radiologic and Histopathologic Features

Radiographic changes are in keeping with nutritional rickets. In addition to growth-plate abnormalities and rachitic deformities, osteopenia and other features of secondary hyperparathyroidism are present [77,79,82]. Histological examination of nondecalcified bone specimens shows defective matrix mineralization and changes of hyperparathyroidism, including osteoclastosis and peritrabecular fibrosis [79].

Laboratory Findings

Malabsorption of dietary Ca^{++} leads to hypocalcemia, secondary hyperparathyroidism, renal Pi wasting, and hypophosphatemia. Serum ALP activity is elevated. Serum concentrations of 25(OH)D are normal in VDDR I (elevated if pharmacologic doses of vitamins D_2 or D_3 or $25(OH)D_3$ are given), but serum levels of $1,25(OH)_2D$ are subnormal or remain only partially corrected by vitamin D or 25(OH)D therapy [79]. Because high doses of vitamin D or $25(OH)D_3$ produce therapeutic responses in VDDR I, it seems that 25(OH)D (or some metabolite) at sufficient levels can activate the VDR (vitamin D receptor). Theoretically, enhanced local biosynthesis of $1,25(OH)_2D$ could also occur with pharmacologic doses of the prohormone.

Pathogenesis and Genetics

VDDR I is especially prevalent in French Canadians in whom a genetic founder effect seems manifest [83,84]. In 1990, linkage studies of five such families mapped VDDR I to chromosome 12q14 [79]. Although this is the chromosomal region of the VDR gene, the molecular defect in VDDR I involves the renal mitochondrial cytochrome $P450_{cl\alpha}$ enzyme that causes rate-limiting, hormonally regulated hydroxylation of 25(OH)D to $1,25(OH)_2D$ (i.e., the 25(OH)D,lα-hydroxylase) [81]. Actually, the 1α-hydroxylase enzyme has several components: cytochrome P-450D10t, ferredoxin, and ferredoxin reductase [79]. The complete structure of the $P450_{cl\alpha}$ gene has been reported, and several mutations have been found in this single-copy gene in VDDR I patients [83–85]. French Canadians are commonly homozygous for a 958ΔG mutation. Other ethnic groups harbor a variety of $P450_{cl\alpha}$ gene changes [84]. Although

quantitative and/or qualitative defects (e.g., decreased substrate affinity) are possible for the 25(OH)D,1α-hydroxylase enzyme, to date only absent activity has been documented [83,84].

Treatment

Clinical remission has followed high-dose therapy with 1–3 mg of vitamin D_2 or with 0.2–0.9 mg of $25(OH)D_3$ given orally each day. However, physiologic doses of $1,25(OH)_2D_3$, using 0.25–1.0 μg daily, bypass the lα-hydroxylase defect and provide effective treatment [79]. Because there is no problem with hepatic conversion of vitamin D_2 to $25(OH)D_2$, vitamin D_2 rather than $25(OH)D_3$ is an effective yet cheaper therapy. Nevertheless, $25(OH)D_3$ or $1,25(OH)_2D_3$ administration, although expensive, has advantages. The physiologic half-lives of these sterols are much shorter than for vitamin D_2. Excessive dosing will therefore respond more rapidly to temporary cessation of therapy. Most patients, however, can be managed with vitamin D_2, but periodic follow-up is essential.

Vitamin D–Dependent Rickets, Type II

This disorder was characterized in 1978 when a patient with features of "pseudovitamin D deficiency" was found to have high serum levels of $1,25(OH)_2D$ [86,87]. Thus, "hereditary resistance to 1,25-dihydroxyvitamin D" or VDDR II refers to this condition [5,6]. The presence and absence of alopecia now distinguish VDDR II types A and B, respectively (MIM 277420; 277440) [2].

Clinical Presentation

Most VDDR II patients have been from the Mediterranean region [5,6,77]. Autosomal recessive inheritance is well-established, and parental consanguinity has been reported in approximately 50% of cases [5,6,77]. Affected neonates appear normal but then develop features resembling VDDR I. Additionally, ~50% of affected newborns have hypotrichosis or alopecia, or develop this manifestation during the first few months of life. Oligodontia, epidermal cysts, and cutaneous milia are further findings [5,6]. Ectodermal abnormalities tend to occur with especially severe disease. Rickets is noted before 2 years of age, although several sporadic cases have developed skeletal problems as late as their teenage years or middle age. In general, the earlier the disease presentation, the more severe the clinical and biochemical features [5,6]. Obligate heterozygotes do not have clinical manifestations.

Radiologic and Histopathologic Features

Radiographic findings in VDDR II resemble those of nutritional rickets (i.e., growth-plate changes, rachitic deformities, osteopenia, and evidence of secondary hyperparathyroidism). Bone specimens have shown normal or increased numbers of osteoclasts but with sparse areas of bone resorption. In a patient with total alopecia, hair follicles were present [88,89].

Laboratory Findings

Hypocalcemia in VDDR II causes secondary hyperparathyroidism, hypophosphatemia, and elevated serum ALP activity. Additionally, circulating $1,25(OH)_2D$ levels are increased, sometimes as much as tenfold [5,6]. This abnormality reflects peripheral resistance to $1,25(OH)_2D$, causing malabsorption of dietary Ca^{++} and the combined effect of the three activators of renal 25(OH)D,1α-hydroxylase activity (i.e., hypocalcemia, increased serum PTH, and hypophosphatemia). Furthermore, some patients seem to have diminished feedback inhibition by $1,25(OH)_2D$ on the kidney 1α-hydroxylase itself [90].

Pathogenesis

In VDDR II, the nature of the resistance to $1,25(OH)_2D$ and aberrations in the VDR effector system have largely been elucidated [5,6,77]. Molecular studies show that a variety of VDR or post-VDR abnormalities block the target tissue actions of $1,25(OH)_2D$ [91–97]. There can be absence of the VDR, diminished $1,25(OH)_2D$ binding capacity or binding affinity by the VDR, or failure of the $1,25(OH)_2D$-VDR complex to localize to the nucleus and interact with DNA [5,6,77]. Hair follicles normally contain the VDR, but the pathogenesis of alopecia is not understood [5,6]. Patients lacking VDR expression are the most difficult to treat [5,6]. Interestingly, a VDR-positive, mild variant of this condition has been reported in Colombia [98]. A mouse model has been developed by targeted ablation of the *VDR* gene [99].

Treatment

If untreated, most patients with VDDR II die in early childhood [5,6]. However, good control of the disorder is possible with medical therapy, especially in those individuals without alopecia [77,89]. Patients with VDDR IIB (normal hair) can respond fully to pharmacologic doses of bioactive vitamin D metabolites [88,89]. However, only some patients with VDDR type IIA (total alopecia) do so. Remarkably, older patients with VDDR IIA may no longer need $1,25(OH)_2D_3$ therapy, or they may require only low doses later in life [5,6]. Depending on its severity, VDDR II may require management with calciferols that enhance endogenous production of $1,25(OH)_2D$, the administration of high doses of both calciferols and Ca^{++} to compensate for the target tissue resistance to $1,25(OH)_2D$, or high doses of Ca^{++} alone (given orally or intravenously) to circumvent the target cell $1,25(OH)_2D$ resistance [80,81,100–102]. Whereas most patients respond to very high oral doses of $1,25(OH)_2D_3$ (10–40 μg daily), some can experience clinical, radiographic, and biochemical corrections with high doses of vitamin D_2 or $25(OH)D_3$ [5,6]. There can be unexplained periods of disease fluctuation.

OSTEOBLAST DISORDERS

Hypophosphatasia

In 1948, the term "hypophosphatasia" was coined by J. C. Rathbun [103] to distinguish a lethal form of rickets featuring deficient activity of alkaline phosphatase (ALP) in serum and tissues (MIM 146300, 241500, 241510). We now know that hypophosphatasia is an inborn error of metabolism characterized biochemically by low levels of activity of the tissue-nonspecific (liver/bone/kidney) isoenzyme of ALP (TNSALP) [15,104]. At least 100 different mutations in the TNSALP gene have been identified in patients worldwide [104]. Hence, hypophosphatasia is an instructive disorder. It validates the theory first promulgated in 1923 by the discoverer of ALP, Robert Robison, that ALP conditions mineralization of skeletal matrix [105]. TNSALP is ubiquitous and especially rich in liver and kidney as well as in cartilage and bone, yet hypophosphatasia seems to affect directly only the skeleton and dentition [106].

Clinical Features

Approximately 300 cases of hypophosphatasia have been described [15]. It is apparent that the severity of this disorder is remarkably variable, spanning intrauterine death from profound skeletal hypomineralization to merely premature loss of teeth [15]. Five clinical types are reported,

depending primarily on the patient's age when skeletal disease is documented. Perinatal, infantile, childhood, and adult hypophosphatasia cause skeletal and dental disease [15]. Children and adults who manifest premature tooth loss without bone defects have odontohypophosphatasia. Although artificial and somewhat imprecise, this clinical classification, reviewed below, provides a sense of the patient's prognosis and serves as the foundation for a potentially more helpful molecular nosology [104].

Perinatal Hypophosphatasia

Perinatal hypophosphatasia is diagnosed at birth and is almost invariably lethal [15]. Polyhydramnios and stillbirth are common. Profound skeletal hypomineralization with caput membranaceum and short and deformed limbs is obvious. Occasionally, bony spurs protrude from the shafts of major long bones [107,108]. Severe osteogenesis imperfecta (see Chapter 8, this volume) or cleidocranial dysplasia (see Chapter 23, Part V, this volume) may be suspected but can be distinguished by radiographic studies [17]. Failure to gain weight, irritability with a high-pitched cry, unexplained fever, seizures, anemia, periodic apnea with bradycardia, and intracranial hemorrhage can occur. Respiratory compromise from pulmonary hypoplasia and chest deformity proves fatal.

Infantile Hypophosphatasia

Infantile hypophosphatasia presents before 6 months of age with poor feeding, failure to thrive, widened fontanelles, hypotonia, and rickets [15]. Hypercalcemia and hypercalciuria may explain bouts of vomiting and nephrocalcinosis. Sometimes there is significant renal impairment. Rachitic deformity of the chest and rib fractures predispose to recurrent pneumonia. Seizures and spells of apnea may occur. Despite the impression from palpation or radiographs that fontanelles are wide open, this is a reflection of skull hypomineralization. In fact, functional craniosynostosis is common. Infantile hypophosphatasia often features progressive clinical and radiographic deterioration, and approximately 50% of patients die within the first year of life. However, the prognosis seems better if there is survival past infancy [109].

Childhood Hypophosphatasia

Childhood hypophosphatasia is particularly variable [15]. Premature loss of deciduous teeth (< age 5 years is abnormal) from dysplasia or aplasia of cementum may be the only clinical manifestation. Cementum anchors the tooth root to the periodontal ligament. Therefore, teeth are shed without the usual root resorption. Incisors are usually lost first, and some young children are rendered nearly edentulous. Enlarged pulp chambers and root canals also result in "shell teeth" that are predisposed to infection in later life. Skeletal deformity can include scaphocephaly with frontal bossing, a rachitic rosary, bowed legs or knock-knees, short stature, and metaphyseal widening causing wrist, knee, or ankle enlargement. When radiographs disclose physeal and metaphyseal irregularity, delayed walking and a characteristic but unexplained waddling gait are common. Features of a static myopathy are often present. Childhood hypophosphatasia may improve when growth plates fuse after puberty, but recurrence of symptoms is likely during middle age [15,110]. It has been noted that in some families patients manifest limb bowing *in utero* that can be mistaken for perinatal hypophosphatasia or a life-threatening bone dysplasia [107,108].

Adult Hypophosphatasia

Adult hypophosphatasia generally presents during middle age. Approximately 50% of patients, however, recall rickets and/or premature loss of teeth during childhood. Often, they are troubled by recurrent, poorly healing, metatarsal stress fractures. Painful femoral pseudofractures may then be found proximally in the lateral cortices [17]. Chondrocalcinosis is common, but Ca^{++} pyrophosphate dihydrate crystal deposition less frequently causes arthritis or pseudogout. Premature shedding of teeth can occur [15].

Odontohypophosphatasia

Odontohypophosphatasia is diagnosed when there are dental manifestations but no radiologic or even histopathologic evidence of skeletal disease.

Radiologic Findings

Radiographs are helpful for diagnosing hypophosphatasia—especially in pediatric patients. Perinatal hypophosphatasia causes pathognomonic changes. The skeleton can be so hypomineralized that only the skull base is apparent. In other affected fetuses or newborns, individual vertebrae appear to be "missing" and bony spurs protrude from the shafts of major long bones. Alternatively, severe rachitic changes are seen. Calvarial bones can be mineralized only centrally, giving the illusion that cranial sutures are widely patent. Fractures are not uncommon. In infants, abrupt transition from well-mineralized diaphyses to hypomineralized metaphyses suggests sudden metabolic deterioration. Relentless skeletal demineralization, worsening rachitic disease, and progressive bony deformity predict a lethal outcome. Bone scintigraphy showing little tracer uptake in widely separated cranial "sutures" suggests their functional closure [111]. Patients who survive infancy can have true premature pan-suture fusion, causing a "beaten-copper" radiographic appearance and raised intracranial pressure (Fig. 7). In children, characteristic "tongues" of radiolucency extend from the physes into the metaphyses of major long bones (Figs. 3 A,B). Adult hypophosphatasia can cause recurrent, poorly healing, metatarsal stress fractures as well as osteopenia, chondrocalcinosis with changes of pyrophosphate arthropathy, calcific periarthritis, and proximal femoral pseudofractures that occur laterally (rather than medially as in other forms of osteomalacia) [17].

Laboratory Findings

Subnormal serum ALP activity for age and sex (hypophosph*atasemia*) is the biochemical hallmark of hypophosphatasia. In fact, the ALP level generally reflects the disease severity [15].

Patients with odontohypophosphatasia have only mild hypophosphatasemia. Nevertheless, this finding is especially impressive because rickets or osteomalacia typically cause *hyper*phosphatasemia [1]. Several other disorders, some with skeletal manifestations, lower blood ALP levels [15], but these conditions should be readily differentiated from hypophosphatasia, and such patients do not accumulate TNSALP substrates endogenously (see below).

Serum levels of Ca^{++} and Pi are not diminished. Indeed, hypercalciuria and hypercalcemia often complicate the infantile form. The pathogenesis seems to involve a "dyssynergy" between gut absorption of Ca^{++} and defective skeletal mineralization; however, skeletal demineralization may also be a factor. Circulating levels of PTH, 25(OH)D, and $1,25(OH)_2D$ are normal unless there is hypercalcemia or renal compromise [112]. Serum Pi concentrations are above

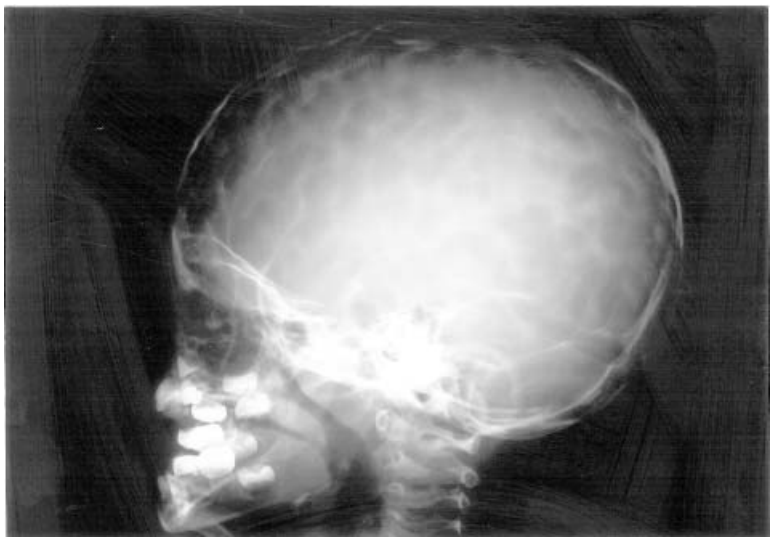

Figure 7. Hypophosphatasia. Lateral view of the skull of this 4-year-old girl with infantile hypophosphatasia shows a ''beaten copper'' appearance characteristic of pan-suture closure in the cranium.

control mean levels, and mild hyperphosphatemia is noted in approximately one-half of affected children and adults. The pathogenesis reflects enhanced renal reclamation of Pi, sometimes associated with suppressed PTH levels [113].

Three phosphocompounds, putative natural substrates for TNSALP, accumulate endogenously in hypophosphatasia: phosphoethanolamine (PEA), inorganic pyrophosphate (PPi), and pyridoxal 5′-phosphate [PLP] (Fig. 8) [15,106,114]. Preliminary evidence suggests that there may be several more [115]. Commercial laboratories will assay urinary PEA and plasma PLP. Although accumulation of PPi seems to be the key pathogenetic factor in hypophosphatasia (see below), quantification of PPi remains a research technique. Increased plasma PLP concentration is a sensitive and specific marker for hypophosphatasia [114]. However, subjects must not be taking vitamin B_6 when tested. Mild phosphoethanolaminuria can occur in several additional metabolic bone diseases, including postmenopausal or idiopathic osteoporosis [116].

Histopathologic Findings

Defective skeletal mineralization characterizes all clinical forms of hypophosphatasia except odontohypophosphatasia [15]. Unless assessment of the ALP activity in bone is undertaken, the histologic findings are those of other types of rickets or osteomalacia without secondary hyperparathyroidism [117].

Pathogenesis

ALP [orthophosphoric monoester phosphohydrolase (alkaline optimum), EC 3.1.3.1] is found in nearly all organisms as a glycosylated, plasma membrane–bound ectoenzyme [15,106]. The discovery that three phosphocompounds — PEA, PPi, and PLP — accumulate endogenously in hypophosphatasia revealed how TNSALP probably functions [15,106]. Accumulation of PLP, the principal cofactor of vitamin B_6, indicates that TNSALP acts primarily on cell surfaces [118,119]. Except for seizures in severely affected infants, patients with hypophosphatasia do not have symptoms or signs of vitamin B_6 deficiency or toxicity despite markedly increased plasma PLP levels [114]. In 1965, the discovery that urinary levels of PPi are elevated in hypophosphatasia disclosed a possible pathogenesis for the skeletal disease [120]. PPi is a potent inhibitor of biomineralization [4,120]. In patients, matrix vesicles are devoid of ALP activity but do contain hydroxyapatite crystals [121]. However, only a few isolated crystals are observed outside these extracellular structures. Hence, PPi could be blocking hydroxyapatite crystal formation in the extracellular matrix of bone [121].

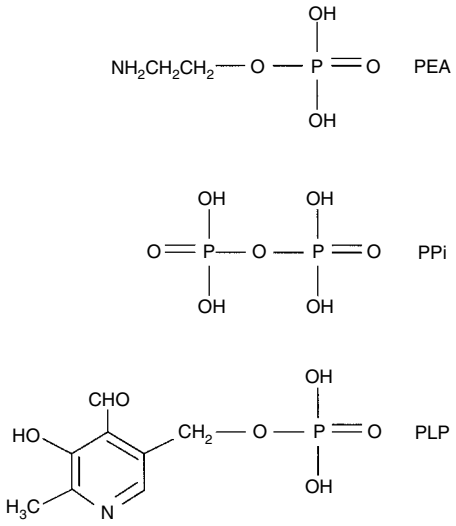

Figure 8. Natural substrates for TNSALP (tissue nonspecific alkaline phosphatase isoenzyme). Three phosphocompounds — phosphoethanolamine (PEA), inorganic pyrophosphate (PPi), and pyridoxal 5′-phosphate (PLP) — accumulate endogenously in hypophosphatasia, suggesting that they are natural substrates for TNSALP. Note: bisphosphonates are analogs of PPi in which the central oxygen atom is replaced by a carbon atom, rendering them resistant to ALP cleavage (See Chapter 1, Part III, this volume).

Genetics

Hypophosphatasia occurs worldwide. It is most common in Mennonites and Hutterites in Canada, among whom the incidence of severe disease is approximately 1/2,500 live births [122]. The incidence among the general population in Toronto is estimated to be 1/100,000 [123]. In our experience, hypophosphatasia seems to be especially rare in blacks.

Perinatal and infantile forms are transmitted as autosomal recessive traits. Obligate carriers can have diminished or low-normal levels of serum ALP activity and sometimes demonstrate elevations in plasma PLP levels, especially after a vitamin B_6 challenge [122].

The inheritance pattern(s) of the childhood, adult, and odonto forms of hypophosphatasia may be more complex [15,104]. Clearly, some cases reflect autosomal recessive inheritance. In others, however, there has been generation-to-generation transmission of biochemical features of the disorder, occasionally with mild clinical expression. Accordingly, autosomal dominant inheritance has also been reported [107,108,124,125].

The gene for TNSALP exists as a single copy in the haploid genome on the tip of the short arm of chromosome 1 (lp36.1-lp34) [126]. In 1988, a missense mutation was identified in a severely affected homozygous infant from an inbred Canadian kindred [126]. Studies of individuals with hypophosphatasia have disclosed more than 100 different mutations in the TNSALP gene [104]. Perinatal and infantile hypophosphatasia patients are homozygotes or compound heterozygotes. Molecular studies confirm that the childhood and adult forms of hypophosphatasia can indeed be the "same" disease [110]. A mouse model that recapitulates the infantile form of hypophosphatasia has been developed by TNSALP gene knockout [127].

Treatment

Conventional treatments for rickets or osteomalacia are probably best avoided in hypophosphatasia because patients are usually vitamin D replete and serum levels of Ca^{++} and Pi are not reduced [15]. Indeed, such therapies could exacerbate or provoke hypercalcemia and hypercalciuria. Hypercalcemia in infantile hypophosphatasia generally responds to reduction in dietary Ca^{++} intake but may require glucocorticoid or calcitonin therapy. Enzyme replacement by intravenous infusion of various forms of ALP has generally been disappointing [15,108,128,129]. One infant who seemed destined to die from infantile hypophosphatasia showed clinical and radiographic improvement after bone marrow and stromal cell transplantation [109].

Supportive therapy is important for hypophosphatasia. Fractures do mend, but delayed healing after casting or osteotomy has been observed. Placement of an intramedullary rod, rather than load-sparing devices such as plates, seems preferable for immediate or prophylactic treatment of femoral fractures or pseudofractures [17]. Expert dental care is especially important for children because their nutrition and speech development can be impaired by premature tooth loss. Dentures may be necessary. Craniotomy can prevent brain damage in cases with functional or true craniosynostosis. Naproxen reportedly helps pain and weakness of the lower limbs in affected children [130].

Genetic Counseling/Prenatal Diagnosis

Severely affected fetuses (perinatal form) have been detected *in utero* by ultrasonography and by assay of ALP activity in chorionic villi or amniotic fluid cells [131]. TNSALP gene mutation analysis holds promise for improved prenatal diagnosis, including for the infantile form [104].

Axial Osteomalacia

Axial osteomalacia (MIM 109130) is characterized radiographically by a coarse trabecular pattern in the axial but not the appendicular skeleton [132]. Fewer than 20 case reports have been published. Most have reflected sporadic disease, but dominant transmission is possible [133].

Clinical Presentation

Patients with axial osteomalacia generally have been middle-aged or elderly men; a few affected middle-aged women have been described. Radiographic manifestations would probably be detectable earlier in life [133]. The majority of cases have presented with vague, dull, chronic axial bone pain (often in the cervical region) that prompted x-ray studies. Family histories are usually negative for skeletal disease.

Radiologic Features

Disturbances are essentially confined to the spine and pelvis, where trabeculae are coarsened with a pattern resembling that found in other types of osteomalacia [134]. However, Looser's zones have not been reported. The cervical spine and ribs seem to contain the most severely affected bones. Two patients also had features of ankylosing spondylitis [135]. Radiographic survey of the appendicular skeleton is unremarkable.

Laboratory Studies

In four patients, serum Pi levels tended to be low [135]. In others, osteomalacia occurred despite normal serum levels of Ca^{++}, Pi, 25(OH)D, and $1,25(OH)_2D$. Serum ALP (bone isoenzyme) may be increased.

Histopathologic Findings

Iliac crest specimens have distinct corticomedullary junctions, but the cortices can be especially wide and porous. Trabeculae are of variable thickness, and total bone volume may be increased. Collagen has a normal lamellar pattern on polarized-light microscopy. There is increased width and extent of osteoid seams throughout. Tetracycline labeling confirms the defective skeletal mineralization, producing fluorescent "labels" that are single, irregular, and wide [133]. Osteoblasts are flat and apparently inactive "lining" cells, with reduced Golgi zones and rough endoplasmic reticulum, and increased amounts of cytoplasmic glycogen, but they do stain intensely for ALP activity. Changes of secondary hyperparathyroidism are absent [133].

Etiology and Pathogenesis

Axial osteomalacia is possibly due to an osteoblast defect [118]. Electron microscopy of iliac crest from one patient revealed osteoblasts that appeared inactive but had been able to release matrix vesicles within the abundant osteoid [116].

Treatment

Effective medical therapy has not been reported for axial osteomalacia. The natural history, however, seems relatively benign. Long-term follow-up of one patient showed that symptoms and radiographic findings did not change [136]. Methyltestosterone and stilbestrol have been tested unsuccessfully [136]. Vitamin D_2 (as much as 20,000 U/day for 3 years) was similarly without benefit [136]. Slight improvement in skeletal histology, but not in symptoms, was reported for calcium and vitamin D_2 therapy in a study of four cases [135].

RECENT DEVELOPMENTS

Major recent advances in relation to heritable rickets and osteomalacia include further understanding of the molecular bases of these conditions and additional insight into the phosphaturic factor(s) that cause some forms of hypophosphatemic bone disease [137].

Autosomal Dominant Hypophosphatemic Rickets

Autosomal dominant hypophosphatemic rickets (ADHR) is due to missense mutations in the gene encoding fibroblast growth factor 23 (FGF23) [138]. Proteolytic cleavage of FGF23 is prevented, resulting in its enhanced biological activity [138]. Oncogenic osteomalacia tumors have been found to contain high levels of FGF23 mRNA. Hence, this secreted protein is a candidate "phosphatonin" [139,140]. The potential role of FGF23 in acquired and inherited hypophosphatemic bone disease was reviewed in 2001 [141].

McCune-Albright Syndrome

Evidence has been published that the hypophosphatemic rickets which sometimes complicates McCune-Albright syndrome (MAS) is caused by a humoral factor [142]. Medium conditioned by lesional bone cells in culture diminished inorganic phosphate (Pi) transport in several test systems, but did not alter Pi transport in the kidney. The authors concluded "it is unlikely that the mechanism of hypophosphatemia in MAS is related to a renal phosphate leak... it is possible that the intestine is the target site..." [142]. Apparently they were unaware of our preliminary report in 1996 [76] documenting that significant Pi wasting is acquired in MAS, perhaps due to a circulating factor emanating from the expanding mass of fibrodysplastic tissue.

X-Linked Hypophosphatemia

In X-linked hypophosphatemia (XLH), phenotype-genotype correlation is difficult because of variability in pharmacologic regimens, compliance with medical therapy, and orthopedic interventions [143]. Nevertheless, as discussed in our preliminary report in 1999, *PHEX* mutations which compromise the structure of the encoded PHEX protein seem to produce the most severe clinical and biochemical disease [55]. *PHEX* mutations can lead to trapping of the encoded protein in the endoplasmic reticulum, precluding terminal glycosylation [144]. A preliminary report indicates that frizzled-related protein (FRP-4) inhibits Pi uptake and is a substrate for PHEX [145].

In children with XLH, dipyridamole treatment was found not to improve renal Pi wasting [146], and acute challenges with growth hormone only slightly altered parameters of Pi homeostasis [147]. However, growth hormone therapy given until physes fused reportedly caused a transient improvement in Pi homeostasis and had a positive effect especially on poor growth [148]. In a preliminary report, the synthetic vitamin D analog ED-71, 2β-(3-hydroxypropyl)-1α, 25-hydroxyvitamin D_3, seemed helpful for the *Hyp* mouse model of XLH [149]. Urinary oxalate and Pi concentrations are increased in XLH during $1,25(OH)_2D_3$ and Pi supplementation treatment but do not reflect supersaturation of these molecules, and the levels seem unable to predict the likelihood of nephrocalcinosis [150].

Vitamin D-Dependent Rickets

A murine model of vitamin D-dependent rickets, type I (VDDR I), has been reported as a consequence of the targeted ablation of the 1α–hydroxylase gene [151]. Reductions in CD4–and CD8–positive peripheral T lymphocytes occur, and female mice are infertile due to uterine hypoplasia and absent corpora lutea [151].

In vitamin D-dependent rickets, type II (VDDR II), specific vitamin D analogs seem promising for partially or completely restoring the responsiveness of the mutated vitamin D receptor (VDR) [152].

Hereditary Hypophosphatemic Rickets With Hypercalciuria

Hereditary hypophosphatemic rickets with hypercalciuria (HHRH) does not involve mutations in the gene encoding the type II sodium/phosphate co-transporter (NPT 2) [153,154].

ACKNOWLEDGMENTS

Supported in part by grant #8580 from Shriners Hospitals for Children and The Clark and Mildred Cox Inherited Metabolic Bone Disease Research Fund. Michelle N. Podgornik and Becky Whitener, CPS, provided expert informatics and secretarial help, respectively.

Chapter 19

Osteopetrosis

Michael P. Whyte

Center for Metabolic Bone Disease and Molecular Research, Shriners Hospitals for Children, St. Louis, Missouri 63131 and Division of Bone and Mineral Diseases, Departments of Medicine, Pediatrics, and Genetics, Washington University School of Medicine at Barnes-Jewish Hospital, St. Louis, Missouri 63110

SUMMARY

- **Osteopetrosis results from diminished osteoclast action. Defective skeletal resorption is revealed by the persistence of primary spongiosa deposited during endochondral bone formation. Consequently, enlargement of marrow spaces and neural foramina is compromised, and bone quality is reduced because skeletal remodeling is uncoupled.**
- **Complications of osteopetrosis can include myelophthisic compromise leading to anemia, infection and bleeding, cranial nerve deficits, recurrent fractures, and osteomyelitis. Severe disease can cause hypocalcemia.**
- **Infantile ("malignant") and adult ("benign") osteopetrosis, inherited as autosomal recessive and autosomal dominant traits, respectively, are best known. However, there are at least eight types of human osteopetrosis spanning a great range of disease severity. Neurodegenerative disease or renal tubular acidosis can complicate additional rarer forms.**
- **Although osteopetrosis is usually heritable, transient *in utero* and perhaps post-infectious forms of unknown etiology occur sporadically.**
- **The genetic basis is established only for a subset of patients with malignant osteopetrosis and for carbonic anhydrase II (CA II) deficiency. Mutations of the *TCIRG1* gene, that encodes a subunit of the vacuolar proton pump, and the *CA2* gene compromise acidification of the osteoclast pericellular milieu thereby impairing bone resorption.**
- **Several naturally occurring animal models as well as increasing numbers of gene knockout mice have osteopetrosis and provide insight concerning osteoclast formation and action.**
- **Malignant osteopetrosis, featuring nonfunctioning osteoclasts, can be cured by bone marrow transplantation. Pharmacologic treatment may involve high-doses of calcitriol with a diet low in calcium, interferon gamma 1b, and/or prednisone therapy. Hyperbaric oxygenation can help heal osteomyelitis.**
- **Prenatal diagnosis will require molecular information. Radiologic procedures are generally not useful.**

INTRODUCTION

In connective tissues, extracellular matrix is comprised of a rich assortment of macromolecules that together provide scaffolding for the body. While achieving its purpose, this "ground substance" also influences the metabolism and the behavior of cells embedded within this complex material that was once regarded as inert [1].

In the skeleton, the composition and physiological role of extracellular matrix is more complicated compared with connective tissue elsewhere because bone contains mineral [2,3]. Hydroxyapatite crystals become arranged in type I collagen fibers and interact with a variety of specialized noncollagenous proteins giving the body both rigid support and protection [2–4]. Furthermore, osseous connective tissue is unique because it participates in several systemic processes [5,6]. Bone is a reservoir for calcium, phosphate, bicarbonate, magnesium, and other ions [2,3], and hormonally regulated, cell-mediated events may recruit the skeleton to either release or store these constituents during health or disease [5,6]. Accordingly, among the connective tissue disorders, those that involve bone can reflect metabolic or endocrine disturbances and demonstrate novel clinical manifestations [6].

Three cell-mediated processes — growth, modeling (shaping), and remodeling (turnover) — are the foundation for the two major physiological functions of the skeleton distinguished above [2,7,8]. Structural integrity is an important reflection of the outcome of growth and modeling of individual bones [2]. Biochemical interactions are dependent on remodeling of osseous tissue [2,7,8]. The skeleton is formed when chondrocytes or osteoblasts synthesize matrix in cartilage or in bone, respectively, which then mineralizes [2,8]. Resorption occurs when multinucleated osteoclasts create an acidic pericellular milieu to leach mineral from these tissues and then immediately degrade the decalcified matrix [8–13]. Skeletal remodeling is the sequence of bone breakdown followed by bone formation occurring lifelong and involving both cortical (compact) and trabecular

Connective Tissue and Its Heritable Disorders, pages 789–807

(spongy) bone [2,7,8,13]. At the microscopic level, this process takes place in discrete bone remodeling units [2,7]. In health, turnover is precisely regulated by an intricate system of increasingly understood humoral and mechanical factors acting in concert to preserve the structural function of the skeleton while assuring mineral homeostasis [5,6,8].

A great variety of disorders disturb the skeleton by adversely affecting growth, modeling, or remodeling of bone, or by altering the biochemical environment necessary for matrix mineralization (see also Chapters 8,18,21,23, this volume) [6–8,14,15]. Among the heritable connective tissue diseases, one group of conditions features impaired resorption of skeletal tissue. Defects in osteoclast-mediated degradation of cartilage and bone limit modeling and "uncouple" remodeling, causing pathological increases in skeletal mass [11,12]. Such disturbances result clinically in *osteopetrosis*. Hypothetically, osteopetrosis could be the result of aberrations in the genesis, proliferation, differentiation, or fusion of precursor cells to form multinucleated osteoclasts or reflect inactivity of mature osteoclasts themselves [8,11,12,16–18].

This chapter provides an overview of the various types of osteopetrosis, emphasizing the forms encountered in humans.

HISTORY

Osteopetrosis was first described in a single-paragraph, unillustrated, case report published in 1904 [19] by the German radiologist Heinrich Ernst Albers-Schönberg (1865–1921) [20]. He recounted how diffusely dense bones, including some peculiar circular areas of osteosclerosis, were discovered by röntgenography in a 26-year-old man who broke his femur stepping into a shallow hole [19]. Accordingly, the eponym *Albers-Schönberg disease* increasingly refers to the mild, autosomal dominant form of this disorder (see below) [21].

Soon after Albers-Schönberg's report, the memorable but orthopedically inaccurate term *marble bone disease* captured the solid x-ray appearance of the affected skeleton. An improved alternative, *osteopetrosis*, was coined in 1926 when Karshner sought to emphasize the associated bone fragility [22].

Many conditions are now known to engender high bone mass (Table 1). Despite progress in elucidating the etiology and pathogenesis of a number of these disorders [23], the term osteopetrosis is, unfortunately, still being used generically for any type of increase in skeletal density. However, true forms of marble bone disease are caused by deficiency of osteoclast-mediated resorption of cartilage and bone (as described below) [17,18,24–26]. Hence, the term osteopetrosis reflects a specific pathogenesis and can be used with precision.

Osteopetrosis of any type is rare. Prompted by its remarkable clinical and radiographic manifestations, more than 500 case reports have been published [27]. By the 1960s, two major clinical types had been delineated: an autosomal dominant "benign" (adult) form (MIM 166600) that can be asymptomatic [25] and likely affected Albers-Schönberg's patient [19], and an autosomal recessive "malignant" (infantile) form (MIM 259700) that, unless treated, usually kills during infancy or childhood [28]. Benign osteopetrosis has an estimated prevalence of 1 per 100,000–500,000 in the United States [25]. In Europe, the figure is approximately 1 per 20,000 [29]. Malignant osteopetrosis is even rarer [30], with an incidence of about 1 per 500,000 in North America and perhaps 1 per 200,000 elsewhere [29,30]. Subsequent to these relatively early descriptions and characterizations of marble bone disease, additional phenotypes were elucidated as summarized below [31].

In 1972, osteopetrosis with renal tubular acidosis was described in three separate preliminary reports [32]. Comprehensive accounts of this syndrome were first published in 1980, when cerebral calcification was recognized to be the third principal feature [32,33]. In 1983, this disorder was discovered to be a new inborn error of metabolism characterized by carbonic anhydrase II (CA II) isoenzyme deficiency (MIM 259730) [34,35].

Beginning in 1979, cases of "intermediate" osteopetrosis were reported [36–38]. This form of marble bone disease presents during childhood with some of the symptoms and signs of the malignant type. Although survival to adulthood is likely, lifespan seems uncertain and variable [37,38]. Intermediate osteopetrosis seems to be transmitted as an autosomal recessive trait (MIM 259710) [37,38].

Even rarer types of marble bone disease have been delineated. In 1986, osteopetrosis that proved lethal *in utero* was described in stillborn siblings who were conceived by Moroccan first cousins [39]. In 1987, benign osteopetrosis was reported from Denmark to manifest in two autosomal dominant forms, types I and II [29,30]. In 1988, malignant osteopetrosis complicated by neuronal storage disease was characterized [40]. This disorder seems to be inherited as an autosomal recessive trait. In 1990, it was hypothesized that osteopetrosis in humans could follow retroviral infection [41]. Also, a "transient infantile" type of osteopetrosis, which seems to develop sporadically *in utero*, was first reported in 1991 [42]. In 1995, it was proposed that there is an autosomal dominant, type III ("centrifugal") form of benign osteopetrosis that affects primarily the limbs [43]. In fact, recent gene mapping and locus exclusion studies have demonstrated further genetic heterogeneity for benign osteopetrosis [44] (see below). Finally, osteopetrosis has occurred with other disorders [45,46], but it is uncertain whether such cases represent new diseases, or merely chance associations. Accordingly, the nosology for the human forms of osteopetrosis is becoming complex [23,31]. It seems that at least eight entities have been distinguished on the basis of their clinical/genetic features (Table 2), and other types of marble bone disease will surely be delineated or discovered.

The pathogenesis of osteopetrosis focuses on diminished osteoclast-mediated resorption of cartilage and bone as revealed many years ago by histopathologic studies that showed unresorbed primary spongiosa deposited during endochondral bone formation [7,17,18,26]. This concept was advanced significantly by the observations of Donald Walker published between 1973 and 1975, when he demonstrated that parabiosis or transplantation of bone marrow or spleen cells from normal to osteopetrotic animals cured their disease [47]. The origin of the osteoclast was revealed to be a circulating, marrow-derived cell [11,16,48].

Despite a variety of subsequent important advances in osteopetrosis — improved understanding of osteoclast ontology and function [11,16], the discovery or creation of animal models [8,9,11,12,16–18,26,48,49], and successful treatment of severe disease by bone marrow transplantation [50–57] or by hormonal approaches [23,49] — precisely why skeletal breakdown is compromised in patients remains largely unknown. Only CA II deficiency [35] and malignant osteopetrosis in some patients [58] are understood at the molecular and biochemical levels. Indeed, as noted previously, it seems that not all types of human osteopetrosis have

a genetic basis. Sporadic cases are relatively common, and some evidence suggests that a disturbance *in utero* [42] or a viral infection [41] can also cause marble bone disease (see below). The nosology for the human osteopetroses outlined in Table 2 will surely require expansion as additional variations are discovered and more becomes known about their etiology.

CLINICAL PRESENTATION

Malignant Osteopetrosis (MIM 259700)

Malignant osteopetrosis typically presents during infancy [28,52,54,57,59]. This disorder is inherited as an autosomal recessive trait (Table 2) [27]. Nasal stuffiness resulting from underdevelopment of the mastoid and paranasal sinuses is often the earliest symptom. Soon after, because cranial foramina cannot widen fully, palsies of the optic, oculomotor, auditory, or facial nerves can occur [28,59–63]. Failure of the skeleton to model properly (including formation of medullary cavities) together with marrow crowding by increased numbers of excessively large but ineffective osteoclasts and accumulation of fibrous tissue cause a myelophthisic disturbance in blood formation. Patients survive because of extramedullary hematopoiesis, but secondary hypersplenism exacerbates the marrow-based anemia [28,50,54,57,59]. Furthermore, although less well understood, hemolytic disease can occur. Leukopenia contributes to recurrent infections and thrombocytopenia leads to bruising and bleeding. There is failure to thrive. Some children are troubled by hydrocephalus [63], and sleep apnea has been described [64]. Because basal foramina in the skull do not widen properly, symptoms of cerebral ischemia can be the result of arterial stenosis [65]. Other neurological manifestations of malignant osteopetrosis include developmental delay, mental retardation, cerebral atrophy with irritability, dysarthria, and hypocalcemic tetany (see below) [63]. Vision can be impaired also by retinal degeneration, long-standing papilledema, or failure of myelinization of the optic nerves [66]. Deafness may reflect conductive defects secondary to sclerosis of middle ear ossicles or impaired drainage of the eustachian tubes [67]. Eruption and shedding of the deciduous dentition is delayed or prevented because osteoclasts fail to resorb tooth roots, or because teeth become ankylosed within a sclerotic jaw. Consequently, osteomyelitis of the mandible is a frequent complication [68]. Poor blood flow predisposes the skeleton to infection. Despite their dense appearance on radiographic study, bones are fragile and fracture is common [69]. Developmental coxa vara can be another difficult orthopedic problem [70].

Physical examination typically reveals short stature, frontal bossing with a large head, ''searching'' nystagmus, proptosis, strabismus, optic atrophy, papilledema, anosmia, facial nerve palsy, a protuberant abdomen resulting from hepatosplenomegaly, and knock-knee deformity (Fig. 1). The posterior nasopharynx may be small. Obligate mouth breathing reflects obstruction of the upper airway [28,36,59,61,63].

Children who are unsuccessfully treated usually die during the first decade of life from severe anemia, bleeding, pneumonia, or sepsis [28,59,61,71]. Hematological abnormalities with blindness by 3 months of life seem to herald a fatal outcome [71]. However, visual deficits alone do not predict early death [71]. As many as 30% of patients

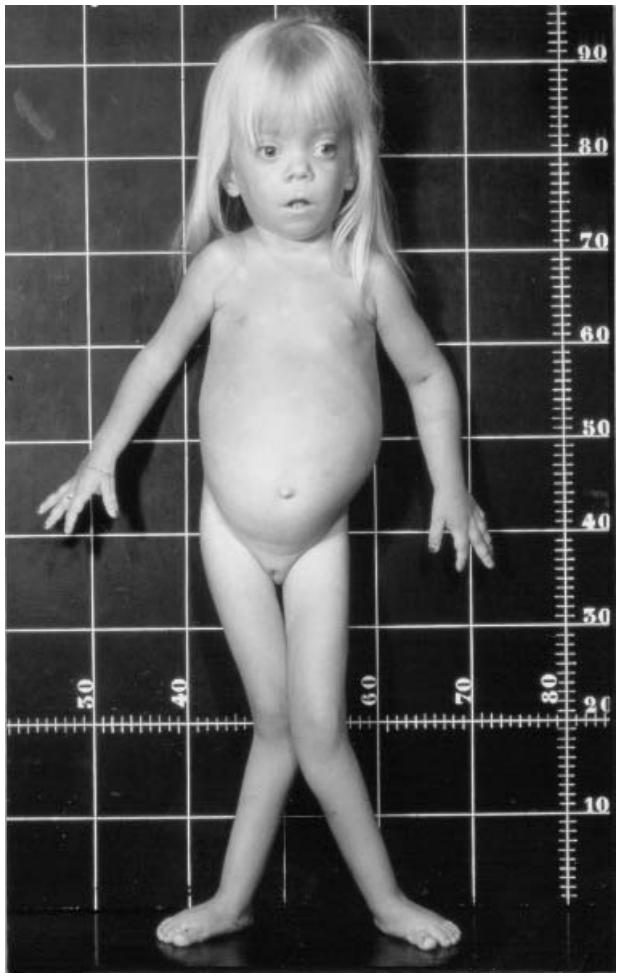

Figure 1. Osteopetrosis (malignant form). This 5-year-old girl has macrocephaly, divergent strabismus, short stature, genu valgum, a protuberant abdomen because of hepatosplenomegaly, and anemia, thrombopenia and leukopenia (Courtesy B. Steinmann, Zurich.)

given a diagnosis of malignant osteopetrosis survive to 6 years of age and, although handicapped, occasionally some live to the second or third decade of life [62,71,72].

Benign Osteopetrosis (MIM 166600)

Benign osteopetrosis features radiographic abnormalities that increase during childhood or adult life [25,30,73]. Rarely, disturbances are documented by x-ray at birth [74]. This condition is inherited as an autosomal dominant trait (Table 2) [27]. Extensive studies beginning in the 1980s of families with dense bones in Denmark suggested to the investigators that two entities were distinguishable by their clinical, radiographic, and biochemical findings [29,30,75–77]. Type II disease seems to be the disorder described by Albers-Schönberg [19]. However, the author remains uncertain whether the especially rare type I disease is truly a form of osteopetrosis. Furthermore, in 1995, a type III (''centrifugal'') form of benign osteopetrosis was proposed (Table 2), although no histopathological or biochemical evidence of impaired bone resorption was presented [43]. Indeed, in 1997, a mixture of phenotypes was reported in a Norwegian family, making subclassification of autosomal dominant osteopetrosis, discussed below, even less secure [78].

Type I disease, identified in several kindreds, features a generalized increase in bone mass, including within the calvarium [30,77]. Symptoms appear with aging and include bone pain, headache, discomfort in the back, and cranial nerve palsies, but patients are unlikely to experience fractures [30,77].

Type II disease is characterized radiographically by sclerosis of the skull base and pelvis and a ''rugger-jersey'' spine [30,73,77]. Affected individuals may be asymptomatic [25], but more often experience clinical manifestations, often including fractures (especially ''chalk-stick'' breaks in the femur) [19,73]. In fact, index cases are typically men, perhaps reflecting their predisposition to trauma compared with women [29,30]. Often, fractures manifest delayed healing or malunion [25,77]. Occasionally, there may be deafness, loss of vision, facial nerve palsy, psychomotor delay, osteomyelitis of the mandible, osteoarthritis, spondylolysis/spondylolisthesis, carpal-tunnel syndrome, or hypogonadotropic hypogonadism [25,73,79–81]. Coxa vara, sometimes with osteoarthritis of the hip, and scoliosis are common [70,73,81]. In a few kindreds, the disorder has been nonpenetrant in some individuals; i.e., they have unremarkable radiographic findings despite obvious skeletal disease in their predecessors and their offspring [25,30]. Bone densitometry may not disclose their status [82]. Conversely, severely affected children have been described in families with otherwise benign disease [83]. In Europe, the term ''benign'' is proving to be a misnomer for this type of osteopetrosis [73].

Intermediate Osteopetrosis (MIM 259710)

Intermediate osteopetrosis can cause short stature and some patients develop mild or, occasionally, moderately severe anemia, ankylosed teeth with osteomyelitis of the jaw, macrocephaly with cranial nerve palsies, and recurrent fractures [36–38]. Hepatosplenomegaly is reportedly rare [84], but can develop with myelophthisic anemia (personal observation). This disorder is inherited as an autosomal recessive trait (Table 2) [27]. The long-term outcome is poorly understood.

Osteopetrosis with Neuronal Storage Disease

Osteopetrosis with neuronal storage disease exhibits features of the malignant form but manifests additionally with cerebral and optic atrophy, ventricular dilatation, retinal pigmentary changes, hypotonia or hypertonia, central apnea, and seizures [62,71,85]. The disorder is inherited as an autosomal recessive trait (Table 2). Accumulation of ceroid lipofuscin and storage of both carbohydrates and lipids in neurons has been reported [86]. Bone marrow transplantation [62] and pharmacologic efforts to improve osteoclast function [84] are ineffective. The condition is fatal before 2 years of age [40,62,71,85]. Testing to exclude other neuronal storage disorders should be considered when osteopetrosis features early, severe, neurological abnormalities [62].

Osteopetrosis Lethal *In Utero*

Osteopetrosis lethal *in utero* is probably inherited as an autosomal recessive trait (Table 2). It causes fractures prenatally followed by stillbirth and is the one type of marble bone disease that can be detected early during gestation by ultrasonography because of dense, broken bones and hydrocephaly [39].

Carbonic Anhydrase II Deficiency (MIM 259730)

Carbonic anhydrase II (CA II) isoenzyme deficiency is an inborn error of metabolism caused by a variety of defects in the *CA2* gene [35]. This disorder is inherited as an autosomal recessive trait (Table 2) [27]. Because the etiology is certain, its manifestations, including differences between siblings and ethnic groups [35], can be described with confidence.

CA II deficiency was first reported as a distinctive syndrome in three independent preliminary publications that appeared in 1972 from the United States and Europe [32,87]. The patients had a combination of osteopetrosis and renal tubular acidosis that seemed to be a new autosomal recessive disorder [32]. Cerebral calcification was recognized to be the third principal feature of the syndrome when the first detailed descriptions were published in 1980 [32,33]. Consequently, the memorable but insensitive term ''marble brain disease'' has been used to describe this genetic disorder [33,88]. In 1983, the discovery that three American sisters had each inherited profound deficiency of CA II [34] represented our first understanding of the biochemical basis of human osteopetrosis [31]. Since 1991, when the *CA2* (''candidate'') gene was fully characterized, a variety of structural mutations have been documented in patients. We now know that specific *CA2* gene defects often cluster among ethnic groups [35,89,90].

More than 50 patients with CA II deficiency, primarily children, have been described in the medical literature [35,91,92]. Most cases have been reported from the Mediterranean region and the Middle East [35,59,92,93]. The birth history is usually unremarkable. The diagnosis is made in late infancy or in early childhood because of developmental delay, failure to thrive, fracture, and/or short stature [87,88,91]. Proximal and/or distal kidney acidification defects have been reported [94]. Hypotonia, apathy, and muscle weakness trouble some patients and may be the result of the associated renal tubular acidosis. Periodic hypokalemic paralysis can be an additional complication of the kidney dysfunction. Blindness from compression of the optic nerves and dental malocclusion occur frequently. Mental subnormality is common but not invariable [59]. Although most patients with CA II deficiency do not suffer fractures,

recurrent long bone breaks may be the source of significant morbidity [91–93]. Some patients have hypercalciuria and medullary nephrocalcinosis or recurrent nephrolithiasis [93]. Reports of the long-term outcome of CA II deficiency are lacking. In the American sibship [32], the youngest patient has developed significant sleep apnea (unpublished)—a problem that can also complicate malignant osteopetrosis [64].

Other Osteopetroses

Table 2 shows that the nosology for human osteopetrosis seems more complex than the above descriptions. A rare, transient, infantile form that is detected incidentally in the first few months of life reflects diminished resorption of skeletal tissue, apparently beginning *in utero* [42,95,96]. Severe changes are apparent on radiographic study, and there is anemia and thrombocytopenia, but no visual impairment. The abnormalities correct soon after they are discovered. The cause is unknown [42,95], but exposure to acetazolamide (a CA II inhibitor) should be considered [84]. The benign outcome of this form of osteopetrosis demands accurate diagnosis so that treatment, especially bone marrow transplantation, can be avoided. Perhaps some sporadic or inherited cases of marble bone disease result from viral infection [41]. It is uncertain whether rare occurrences of osteopetrosis with additional conditions such as Hirschsprung disease [45] or poikiloderma [46] reflect new syndromes or are merely chance associations of two disorders.

RADIOLOGIC FEATURES

Radiography

Because the pathogenesis of all true forms of osteopetrosis features a global defect in bone resorption, the growth, modeling, and remodeling of the skeleton are disturbed [97–99]. Typically, on radiographic study, there is generalized osteosclerosis (thickening of trabecular bone) and hyperostosis (widening of cortical bone) [100]. The combination of manifestations distinguish marble bone disease from other disorders that cause high bone mass, including craniometaphyseal dysplasia, pyknodysostosis, and hepatitis C–associated osteosclerosis (Table 1) [23]. However, the severity and the evolution of these abnormalities depend upon the particular type of osteopetrosis. The usual radiographic findings are described below.

Impaired bone modeling in the limbs contributes to the symmetrical increase in skeletal density because tubulation of long bones does not occur properly. Osteoclasts fail to resorb the cartilaginous and osseous tissue deposited by endochondral bone formation at the periphery of growth plates. Hence, the ends of the long bones are "undertubulated," causing a characteristic finding, i.e., metaphyses that are broad with a so-called Erlenmeyer flask or club-like deformity (Fig. 2) [97–100]. An unexplained additional aberration in some patients is a pattern of varying bone density in the pelvis and at the ends of the major long bones, i.e., perhaps the "circles" of osteosclerosis first observed by Albers-Schönberg [19]. This finding may reflect fluctuating disease activity. Rarely, the distal phalanges are inexplicably resorbed, but this irony is more common in the sclerosing bone disorder caused by defects in the cathepsin K gene [27], pyknodysostosis (MIM 265800), that increasingly seems to represent a form of osteopetrosis [23].

Rachitic-like changes occur occasionally in severe osteopetrosis (see below) [101,102]. The limb bones of affected children appear diffusely dense, yet their growth plates and metaphyses are widened and irregular, respectively. Actually, "osteopetrorickets" [102] may be the result of secondary hyperparathyroidism rather than defective skeletal mineralization (analogous to pediatric renal osteodystrophy) [97,99].

Figure 2. Osteopetrosis (intermediate form). This $4\frac{9}{12}$-year-old boy has characteristic symmetrical osteosclerosis and evidence of defective bone modeling including absence of medullary cavities and Erlenmeyer flask deformities in the distal femora.

In the axial skeleton, typically the cranium is thick and dense, especially at its base. This can cause a mask-like appearance on anteroposterior projection. The mastoid and paranasal sinuses are underdeveloped and underpneumatized. On lateral view, the vertebrae may show a characteristic "bone-within-bone" (endobone) configuration (Fig. 3) from the persistence of cartilage anlagen, or demonstrate endplate hyperostosis causing a "rugger-jersey" or "sandwich" appearance resulting from impaired modeling of the endosteal surfaces of cortices. Endobones also occur typically in the pelvis, hands, and feet [97–99] and are analogous to the "islands" of unresorbed primary spongiosa seen histologically elsewhere (see below).

In so-called autosomal dominant osteopetrosis type I, there is widening and increased density of the cranial vault with diffuse osteosclerosis of vertebrae [30]. In type II disease, there appears to be selective thickening of the skull base with typical endobone formation or a "rugger-jersey" spine [30]. In both conditions, abnormalities may be detected in infancy and progressive osteosclerosis occurs afterwards, but skeletal modeling defects are usually mild or absent [103]. Fractures are seen commonly in type II (Albers-Schönberg) disease [30]. In intermediate osteopetrosis, the radiographic changes can resemble those of the malignant form and may be found in infancy [84]. In CA II deficiency,

Figure 3. Osteopetrosis (benign form). At 2 years of age, the lumbar spine displays a ''bone-within-bone'' appearance.

Figure 4. Carbonic anhydrase II deficiency. At age 2 years, the patient shown on the extreme left in Figure 7 had diffuse osteosclerosis with absence of medullary cavities and flared metaphyses. Transverse lines (arrowheads) are present, and there are healing fractures (arrows). (Reprinted with permission from Sly et al. [91].)

skeletal radiographs have been abnormal at the time of diagnosis in all cases, although one neonate had only subtle defects [104]. The x-ray findings are generally similar to those in other forms of osteopetrosis (Fig. 4). However, cerebral calcification appears during childhood. Remarkably, the osteosclerosis and the defects in skeletal modeling noted in infancy or childhood can diminish over time in CA II deficiency [33,104]. This observation contrasts with other forms of marble bone disease in which bone density seems to increase with aging [70,97–99].

Bone Densitometry

Little has been published concerning this technology in osteopetrosis, although the various devices should be helpful for evaluating natural history and response to treatment [105]. Investigation of one individual suggests that dual energy x-ray absorptiometry (DEXA) may fail to identify nonpenetrant carriers of Albers-Schönberg disease [82].

Bone Scintigraphy

Bone scintigraphy in osteopetrosis retains its utility to disclose fractures, osteomyelitis, or other focal skeletal defects [106,107]. Recently, bone marrow immunoscintigraphy has proven helpful in assessing medullary space, especially in response to bone marrow transplantation [108].

Magnetic Resonance and Computed Tomographic Imaging

Magnetic resonance imaging (MRI) seems to be useful for monitoring the effects of bone marrow transplantation in osteopetrosis (see below) because it can document increases in medullary space [109]. MRI is crucial in malignant osteopetrosis to search for degeneration of cerebral white matter [62,67].

Computed tomography (CT) is the best technique to evaluate cranial nerve impingement resulting from narrow optic foramina [6,110,111]. In CA II deficiency, CT reveals cerebral calcification beginning at about 5 years of age [112]. Subsequently, the mineral deposits increase and affect cortical gray matter as well as the basal ganglia (Fig. 5). This calcification is similar or identical to the abnormality found in idiopathic hypoparathyroidism or in pseudohypoparathyroidism [112]. CT may also help to reveal cerebral ventricular dilatation.

LABORATORY FINDINGS

In malignant osteopetrosis, some affected infants or children experience hypocalcemia of sufficient severity to

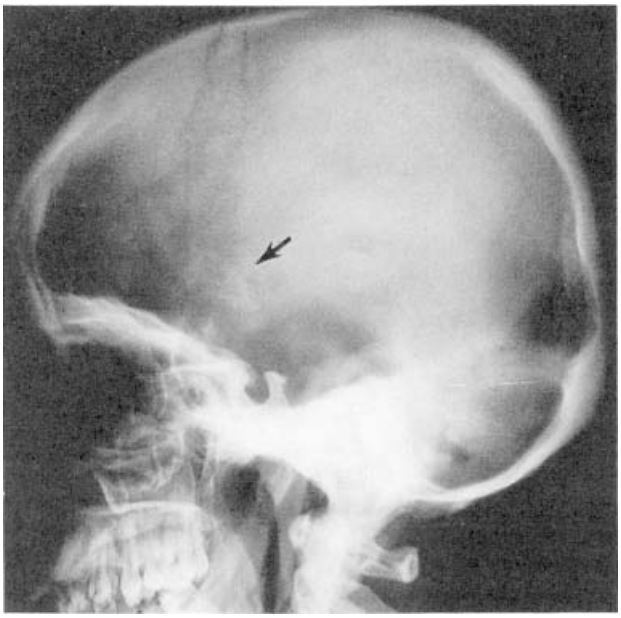

Figure 5. Carbonic anhydrase II deficiency. At age 22 years, basal ganglia calcification (arrow) is apparent in the patient shown on the extreme right in Figure 7.

cause symptoms, including seizures, and to produce rachitic changes of their growth plates [62,101,102,113]. Defective skeletal resorption likely explains the low serum calcium levels that consequently reflect dietary mineral intake [114]. Secondary hyperparathyroidism, with appropriately elevated serum $1,25(OH)_2D$ levels, is common in these cases [113–115]. Conversely, severe hypercalcemia may follow restoration of osteoclast function after successful bone marrow transplantation [116]. Heparan and chondroitin sulfate levels can be increased in patient urine [117].

Benign osteopetrosis typically demonstrates unremarkable biochemical parameters of mineral homeostasis. However, elevated serum levels of parathyroid hormone and tartrate-resistant acid phosphatase (TRAP) have been reported in Albers-Schönberg disease [30].

In 1996, from Shriners Hospitals for Children, St. Louis, Missouri, we reported that the "brain" isoenzyme of creatine kinase (BB-CK) (EC 2.7.3.2) is aberrantly present in the serum of patients with true forms of osteopetrosis, but not in that of patients with other sclerosing bone disorders [118]. Indeed, in some cases of marble bone disease BB-CK accounts for the majority of circulating CK, raising total CK values to supranormal levels [118,119]. This finding does not seem to reflect neurological damage, because it occurs in mild cases of osteopetrosis. Instead, the observation could reflect a pathogenetic biochemical defect common to each of the forms of osteopetrosis because BB-CK is the CK isoenzyme found in osteoclasts [118]. It has been suggested that anaerobic osteopetrotic bone alters osteoclast metabolism causing greater dependence upon high-energy creatine phosphate [119]. Additionally, however, TRAP from osteoclasts [11,12] can increase in serum in various forms of osteopetrosis [25,30]. Perhaps, elevated BB-CK and TRAP levels in patient serum reflect enhanced recruitment of osteoclast precursor cells [17,118].

In CA II deficiency, bone marrow appears undisturbed. When anemia is detected, it is usually mild and nutritional in origin [87,91,92]. Metabolic acidosis, featuring low serum bicarbonate levels and hyperchloremia, with increased urinary pH has been documented as early as the perinatal period [104]. Distal and/or proximal renal tubular acidosis have been reported [94,120]. Glucosuria and aminoaciduria are absent, and there is no further evidence of Fanconi syndrome [91].

HISTOPATHOLOGIC FINDINGS

For patients with severe skeletal manifestations of osteopetrosis, the radiographic features are diagnostic [97–99]. There is generalized osteosclerosis and hyperostosis causing absence of medullary space. In the mild forms of marble bone disease, however, the x-ray changes may engender less confidence. Fortunately, however, failure of osteoclasts to resorb skeletal tissue in osteopetrosis causes a pathognomonic finding that unmasks the disorder's pathogenesis [7,121–123]. Primary spongiosa (the calcified cartilage deposited during endochondral bone formation), which should be removed during skeletal modeling or remodeling, persists in osteopetrosis. Consequently, this material becomes entrapped within osseous tissue, appearing as distinctive "islands" or "bars" of cartilage. Although there seems to be a variety of pathophysiologic defects causing osteopetrosis in humans, all true forms of this disorder share this histopathologic feature. This residuum is found wherever epiphyseal or apophyseal bone formation once occurred (Fig. 6) [121,122]. In other pediatric disorders with high bone mass, there is sufficient osteoclastic activity to remove this primary spongiosa during skeletal turnover so that these cartilage remnants are not observed [23]. In CA II deficiency, cartilage bars have been demonstrated within trabecular bone in iliac crest specimens from four affected individuals representing two families [87]. However, this finding has not been reported in patients with autosomal dominant osteopetrosis types I or III. In osteopetrosis, failure of skeletal remodeling to remove this cartilage, as well as to interconnect osteons, probably contributes to the poor quality of bone tissue and thereby to recurrent fractures.

Osteoclasts are often excessive in the more common forms of osteopetrosis in humans [11,122]. Occasionally, normal counts of these cells are noted [122]. Few osteoclasts are sometimes reported, as in osteopetrosis lethal *in utero* [39], unusual cases of malignant osteopetrosis [66], and type I benign osteopetrosis [124]. Patients with few osteoclasts are of special interest because this finding also occurs in some well-understood animal models of marble bone disease (see below) [11,12]. Malignant osteopetrosis typically shows numerous osteoclasts, appropriately on the surface of trabeculae, with especially great numbers of nuclei [71,113,122,125]. Furthermore, the electron microscope generally, but not always, fails to show a "ruffled border" of the plasma membrane of these polykaryons. Ruffled borders normally form in osteoclasts that are actively resorbing bone [7,9,10]. Additionally, osteoclasts in malignant osteopetrosis usually lack the "clear zone" that normally develops between cytoplasmic organelles and the ruffled border [7,126]. Although unexplained, fibrous tissue proliferates in the medullary space in severely affected patients (Fig. 6) and further crowds hematopoietic cells [122,126]. Possibly, this abnormality reflects, in part, secondary hyperparathyroidism.

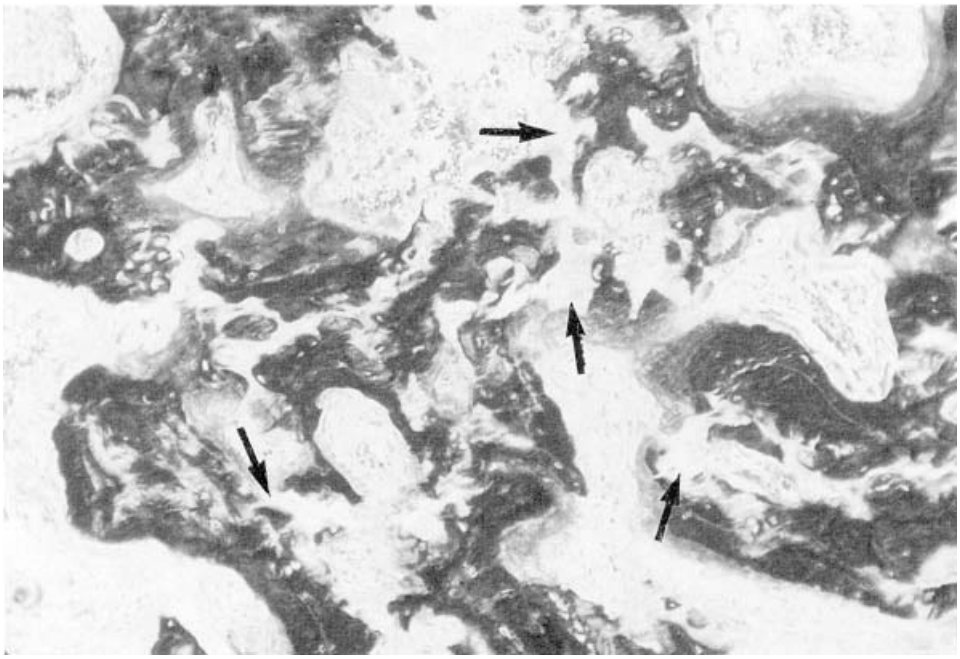

Figure 6. Osteopetrosis (malignant form). This nondecalcified section of bone shows areas of calcified primary spongiosa that stain lightly (arrows) within well-mineralized, darkly staining trabeculae. There is abundant fibrous tissue within the marrow space (Masson trichrome stain, ×160, original magnification).

Albers-Schönberg disease also features increased numbers of osteoclasts that can lack ruffled borders [76]. Unmineralized osteoid can be excessive. Woven (disorganized) bone in trabeculae and in cortices is common [76]. The histopathologic findings in other forms of osteopetrosis are less well characterized.

PATHOGENESIS AND ETIOLOGY

High bone mass can occur by several means [23,100] (Table 1). It may result from osteoclast failure, exuberant bone formation, or long-standing uncoupling of skeletal remodeling favoring net accretion of osseous tissue. Consequently, there can be focal or generalized osteosclerosis and/or hyperostosis [23,100]. Many such disorders are heritable and, like osteopetrosis, offer important clues concerning skeletal homeostasis [127].

As noted previously, osteopetrosis is caused by defective osteoclast-mediated bone resorption [17,18,24–26] (see also Chapter 1, Part III, this volume). Why this failure occurs in humans is incompletely understood. Osteoclasts are members of the mononuclear phagocyte system [11]. Their origin is a pluripotential hematopoietic stem cell that gives rise to a circulating precursor cell of monocyte-macrophage lineage [11,12,18,51]. A compelling illustration is the treatment success based upon the pioneering animal model studies of Walker [47], showing that defective osteoclast-mediated bone resorption can cause osteopetrosis and that the osteoclast progenitor is a marrow-derived cell [51,55]. Children with severe osteopetrosis have benefited dramatically from bone marrow transplantation (see below). They were cured by osteoclasts of donor origin [50,51,54,56]. However, the ontology of the osteoclast is quite complex [11,48]. A variety of growth factors, cytokines, and hormones condition osteoclast precursor cell growth, differentiation, and fusion, as well as regulate mature osteoclast function [11,18,48]. Hypothetically, therefore, many disturbances could cause marble bone disease [49]. Recently, it has become possible to generate osteoclasts using marrow cells or peripheral blood and thereby to reproduce *in vitro* fundamental pathogenetic features of osteopetrosis [128,129].

Two inheritance patterns (autosomal recessive and autosomal dominant) and several clinical phenotypes of osteopetrosis in patients (Table 2) indicate that a number of gene defects significantly impair osteoclast-mediated bone resorption in humans. Nevertheless, as reviewed below, the molecular basis for this disorder is largely unknown. Only a few patients with osteopetrosis have profoundly reduced numbers of osteoclasts [39,62]. Hence, diminished function rather than lack of these cells seems to be the more common pathogenetic disturbance [84].

Carbonic Anhydrase II Deficiency

CA II deficiency was the first form of osteopetrosis in humans for which the biochemical and genetic basis became understood [35]. The enzymopathy was discovered in 1983 [34]. In 1991, when the *CA2* gene located on the long arm of chromosome 8 had been fully characterized, mutations in patients were identified [35,89,90]. The American sisters [32] proved to be compound heterozygotes for both a splice-site mutation and a missense mutation [35]. However, the widespread geographic distribution and variable clinical severity of CA II deficiency predicted further allelic heterogeneity that is now well documented [35]. To date, a variety of *CA2* gene defects have been identified [35,89,90,130]. Accordingly, CA II deficiency is the best understood form of human osteopetrosis [35]. In the Arabian peninsula, consanguinity is a common etiologic risk factor [59,104]. Nevertheless, a range of clinical expression

occurs within sibships, and additional genetic or epigenetic factors require elucidation to fully comprehend this inborn error of metabolism [35].

The pathogenesis of CA II deficiency has been unfolding since the discovery in 1983 of a profound reduction of CA II in erythrocyte lysates of three American sisters (Fig. 7) [34]. Consistent with autosomal recessive inheritance, approximately one-half normal CA II levels were found in the red cells of their parents. Levels of CA I were undisturbed [34]. In 1985, CA II deficiency was documented in all 21 patients available for study, representing 12 unrelated kindreds of diverse ethnic and geographic origin [91]. Although autopsy investigations have not been reported, the molecular pathology of CA II deficiency establishes an important role for CA II in human bone and kidney and perhaps in brain [32–35].

Several studies show that osteoclasts substantially acidify their pericellular space during skeletal resorption [10,131]. When osteoclasts are degrading bone, ruffled membranes form an enclosure over osseous tissue in which the pH may decrease to as low as 5.5 [10,131]. At this high concentration of H^+ created by a vacuolar proton pump, mineral is solubilized. Subsequently, collagenases and other proteases become active as the pH increases, destroying the remaining matrix [132] (see also Chapter 1, Part III, this volume).

CA catalyzes the union of CO_2 and H_2O to form H_2CO_3, which then dissociates to H^+ and HCO_3^-. Accordingly, CA plays an important role in acid/base balance. CA II is the most catalytically active CA isoenzyme with the widest tissue distribution, including erythrocytes, kidney, and brain [35,130,133]. Notably, CA II is the CA of the osteoclast and is found in the cytosol [11,134–136].

In CA II deficiency, osteoclasts cannot convert CO_2 and H_2O to H_2CO_3, thereby blocking subsequent production of H^+ for acidification of the pericellular space. In fact, pharmacologic inhibitors of CA (e.g., acetazolamide) hamper skeletal resorption both *in vivo* and *in vitro* and can increase bone mass [131].

Enhanced bicarbonaturia after taking acetazolamide in CA II deficiency suggests that an additional CA isoenzyme acts importantly in renal physiology [120]. Indeed, normal levels of CA IV are detected in cell membranes shed into patient urine [137]. In CA II deficiency, intact erythrocytes seem to have sufficient CA I activity to fulfill the minimum resting requirements for respiratory gas exchange in the blood [138]. Why cerebral calcification occurs is unclear. Development of several mouse models for CA II deficiency provides tools to enhance our understanding of this inborn error of metabolism [139,140].

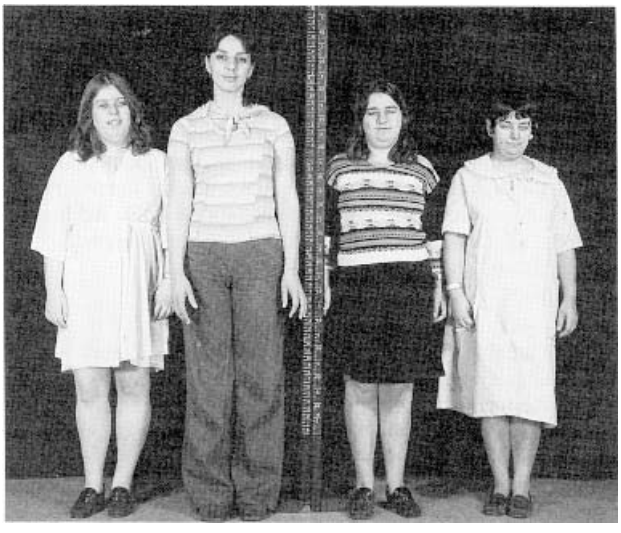

Figure 7. Carbonic anhydrase II deficiency. Three of four sisters (ages 22,24, and 29 years, left to right) are affected and have short stature. (Reprinted with permission from Whyte et al. [32].)

Malignant Osteopetrosis

The molecular basis for severe osteopetrosis remained unknown until 2000. There have been reports of diminished granulocyte and monocyte function [141], yet problems with the immune system itself seem uncommon. In 1997, malignant osteopetrosis was found to map to chromosome 11q13 in two consanguineous Bedouin kindreds [142]. M-CSF (macrophage colony-stimulating factor) production seemed to be normal [143] and in 1998, in follow-up of animal model studies (see below), the protein tyrosine kinase $p60^{c\text{-}Src}$ was found not to be implicated in malignant osteopetrosis [144]. Furthermore, there is evidence that some patients have a primary defect involving osteoblasts rather than osteoclasts [145]. In 1993, lack of expression of the osteoclast-reactive vacuolar proton pump responsible for H^+ secretion by these cells [132] was reported in a patient with craniometaphyseal dysplasia [146]. In 2000, defects in the TCIRG1 subunit of this pump were discovered in a major subset of patients with malignant osteopetrosis [58].

Osteopetrosis with Neuronal Storage Disease

In osteopetrosis with neuronal storage disease, postmortem studies show degenerative changes in brain cells, including widespread axonal dystrophy, with spheroidal bodies, storage of ceroid lipofuscin [40,84,85], and accumulation of carbohydrates and lipids [86]. Accordingly, there may be a defect(s) in lysosomal function [40].

Benign Osteopetrosis

In benign osteopetrosis, resistance to the actions of thyroid hormone and $1,25(OH)_2D$ have been reported in types I and II, respectively [74,76]. In 1997, Albers-Schönberg disease was mapped to an 8.5 cM candidate region on chromosome 1p21 in a Danish kindred, but the M-CSF (CSF-1) locus was excluded [21]. In 1999, linkage exclusion analysis of two affected families from Indiana, in the United States, indicated genetic heterogeneity [44]. Possibly, different disease loci reflect genes encoding a protein complex or a humoral factor and its receptor [44].

Other Forms

In other patients with osteopetrosis, there may be deficient production of interleukin-2 [147], synthesis of an abnormal parathyroid hormone molecule [148], or failure to generate superoxide [149]. Animal models of marble bone disease show skeletal resorption associated with induction of superoxide in cells of granulocyte/monocyte lineage in response to interferon-γ [149], M-CSF [150], and interleukin-2 [151]. Indeed, severe osteopetrosis in patients responds to recombinant human interferon-γ 1b therapy (see below) [152].

Finally, some cases of osteopetrosis may have an infectious etiology [41,153]. In 1988, electron microscopy of osteoclasts from several patients with sporadic, benign osteopetrosis revealed viral inclusions resembling the nucleocapsids of *Paramyxoviridae* [153]. Measles or respiratory

syncytial virus antigens were detected in these cells [153]. In 1990, a reverse transcriptase that resembled the enzyme made by retroviruses was discovered in the supernatant of circulating mononuclear blood cells taken from a patient with benign osteopetrosis [41]. The investigators hypothesized that retroviruses could block osteoclast action and account for some heritable forms of marble bone disease resulting from genomic integration of the virus [41]. Indeed, several animal models of "osteopetrosis" are caused by viral infection; however, they feature exuberant bone formation [84]. Whether viral inclusions observed in patients reflect the cause of their osteopetrosis or are an epiphenomenon remains unclear. Viral inclusions in osteoclasts have been seen in other bone disorders, e.g., pyknodysostosis and Paget bone disease [23]. Nevertheless, the considerable variety and growing number of animal models of osteopetrosis and their genetic heterogeneity suggest that osteopetrosis in humans will reflect abnormalities in a diversity of genes [11,12,18,82,154–159].

ANIMAL MODELS

Rapidly advancing studies using animal models provide potential clues to the etiology and pathogenesis of the human osteopetroses [11,12,18,84,154–159]. Many possible defects that could impair osteoclast action have been identified, ranging from an altered microenvironment containing osteoclast precursor cells (e.g., failure of marrow elements to produce factors that condition stem cell maturation) to skeletal tissue refractory to resorption. There could, hypothetically, be disturbances involving the proliferation or maturation of osteoclast precursor cells, fusion of progenitor cells to form polykaryons, recognition by mature osteoclasts of bone tissue for resorption, response by osteoclasts to hormones, or degradation of skeletal tissue due to lysosomal defects [11,17,18,26].

There are now more than 15 animal models of osteopetrosis involving several mammalian species [11,17,18,26, 154–159]. Mutations have either occurred spontaneously or have been induced, but each type of gene defect causes osteopetrosis that is transmitted as an autosomal recessive trait [17]. All animal models characterized molecularly reflect gene knockouts, except the *opg* mouse featuring overexpression of the osteoprotegerin gene [17].

Among the naturally occurring ("classic") mutations, the *op/op* mouse showing few osteoclasts was found in 1990 to reflect a single base-pair insertion generating a stop codon in the M-CSF gene [160]. Subsequently, in patients, however, normal serum levels of biological and immunological M-CSF activity were detected in all of 6 and 13 individuals tested, respectively [143].

The microphthalmic (*mi/mi*) mouse harbors a gene defect that affects a transcription factor [158]. Patients with an abnormality in this gene, however, have Waardenburg syndrome, type 2, which does not feature bone disease [17].

Malignant osteopetrosis maps to chromosome 11q13 in two consanguineous Bedouin kindreds — a candidate region predicted by the murine osteosclerosis (*oc*) mutation [142]. This observation led to the discovery of the *TCIRG1* defects causing vacuolar proton pump deficiency in some patients with malignant osteopetrosis [58].

Murine osteopetrosis also occurs with inactivation of the genes encoding *c-src* (a tyrosine kinase), *c-fos*, NF-κB1 and NF-κB2 (double knock-out), PU-1 (myeloid- and lymphoid-specific transcription factor), and Acp5 (acid phosphatase) [11,17,18,154,155,161]. However, defects in none of these genes have been detected in patients with marble bone disease [144,161,162].

TREATMENT AND PREVENTION

Because the outcome varies greatly for the various human forms of osteopetrosis, a correct diagnosis is critical before treatment is chosen. Radiologic investigation of the patient's family and evaluation of disease progression may be necessary. However, for malignant osteopetrosis, a "window of opportunity" for bone marrow transplantation (BMT) can close if there is a delay in diagnosis and treatment because medullary space becomes filled by excessive skeletal and fibrous tissue [57,84]. Early transplantation is considered important for such patients [57,84].

In most infants and children with severe osteopetrosis, osteoclasts are present or even numerous. BMT is designed to effect a cure by replacing these dysfunctional cells [57]. However, BMT is a complex, expensive, and potentially hazardous treatment that can be ineffective in some patients with osteopetrosis [57,84]. Currently, BMT seems appropriate only for severely debilitating or life-threatening disease. Therefore, attempting to stimulate osteoclasts has been an additional approach to therapy, especially when excellent donor matches for BMT are unavailable. The major treatment strategies for the osteopetroses in humans are discussed below and have been reviewed elsewhere [49,56].

Dietary/Hormonal Treatment

Since first used in 1965, calcium-deficient diets have reportedly had some success in treating osteopetrosis [163]. Furthermore, reduction in dietary calcium intake has been recommended when children receive interferon therapy (see below) [164]. However, liberalization of the diet or calcium supplementation may be necessary to correct symptomatic hypocalcemia, sometimes causing seizures or rachitic-like changes on x-ray [101,102]. Indeed, administration of a low-calcium diet in severe osteopetrosis has provoked rickets, which was transiently mistaken for a good response to BMT, when bone density decreased near growth plates [165].

Calcitriol [$1,25(OH)_2D$], the most potent metabolite of vitamin D, conditions the formation and function of osteoclasts [114]. Hypothetically, some cases of malignant osteopetrosis could involve either resistance to $1,25(OH)_2D$ or defective 25(OH)D, 1α-hydroxylase activity. High doses of $1,25(OH)_2D_3$ in children with osteopetrosis reportedly cause disease stabilization and, in 25% of cases, marked improvement [84,114,123]. A preliminary report of one adult, seemingly with an intermediate form of osteopetrosis, also described better hematopoiesis and decreased skeletal mass with prolonged $1,25(OH)_2D_3$ therapy [166]. Similarly, intravenous infusions of PTH appeared to be beneficial for one affected infant, perhaps by enhancing renal $1,25(OH)_2D$ biosynthesis [148].

Methylprednisolone therapy reportedly caused remission of malignant osteopetrosis in two neonates [167]. M-CSF has been assessed recently, perhaps resulting in some disease stabilization [61,84].

Bone Marrow Transplantation

Malignant osteopetrosis has been treated since 1977 [168] by transplantation of allogeneic HLA-identical marrow [50–57,169]. Retention of small numbers of donor cells is effective [84]. Successful engraftment has been followed by significant clinical, laboratory, radiologic, and histopathologic improvement in some patients [50–57]. In fact, BMT

offers the possibility of a cure. Some neurological abnormalities may improve, others are halted or prevented, but some can remain [57,62]. Indeed, visual impairment often persists despite successful marrow engraftment. Hence, BMT before 3 months of age seems best [57,71]. Permanent recovery from malignant osteopetrosis is more likely in young patients (<4 years of age) [55,56]. However, severe hypercalcemia occurs in 29% of patients who have engraftment [57,116].

Nevertheless, not all patients with malignant osteopetrosis respond well to allogeneic BMT [57]. The likely pathogenetic heterogeneity underlying malignant osteopetrosis predicts that successful engraftment of normal osteoclasts might not benefit all patients [26,55–57,62,123]. When there is primary retinal degeneration and/or generalized neurodegeneration, BMT will not stop the progressive and ultimately lethal course [62,84]. Patients whose medullary space is severely crowded by osteoclasts and fibrous tissue seem less likely to engraft [56]. Especially large osteoclasts with increased numbers of nuclei and ruffled border membranes also predict a poor response. Accordingly, histopathological study of an iliac crest specimen and electron microscopy of the patient's osteoclasts have been recommended before BMT [55,84]. The outcome of BMT is also dependent on successful HLA matching [56,57,170]. BMT from HLA-nonidentical relatives has a significantly poorer outcome [54,57,84,170]. In this situation, only about 15% of transplanted cells survive; nevertheless, there are some cures. Importantly, 30% of patients with untreated severe osteopetrosis will live. Accordingly, this is generally considered to be an unacceptable rate of failure for unmatched BMT because patient survival is well below 50% [84,170]. Recently, however, transplantation of cord blood progenitor cells, with several advantages over BMT, has been used when there is no HLA-compatible relative [56].

Interferon

Since 1992, there have been reports of treatment successes for severe osteopetrosis using recombinant human interferon-γ [84]. Predisposition to infection among these patients, attributable to diminished superoxide generation in circulating leukocytes, led to these therapeutic trials [84]. Interferon-γ 1b increases leukocyte superoxide production [152]. This treatment is followed by fewer infections, improved anemia and platelet counts, diminished trabecular bone mass with widened medullary spaces, and enlarged cranial nerve foramina [84,152,171]. There is improved survival with reduced morbidity [84,152,172]. Developmental assessment shows a wide range of cognitive and adaptive abilities in these patients [60]. Careful attention to nutritional requirements is necessary [84]. Interferon-γ 1b and calcitriol together may be especially effective [84,171].

Supportive Therapy

Hematologic problems in malignant osteopetrosis result primarily from myelophthisis. However, other factors can exacerbate the low blood cell counts. With extramedullary hematopoiesis, there is hepatosplenomegaly and secondary hypersplenism. Additional causes of hemolysis may also be present. High-dose glucocorticoid therapy helps to stabilize the hematologic situation when there is pancytopenia and hepatosplenomegaly [167]. Indeed, prednisone therapy alone, or together with a low-calcium/high-phosphate diet, can effectively treat some cases of severe osteopetrosis [173].

Hyperbaric oxygenation can be an important adjunctive treatment for osteomyelitis [174,175]. When dental sepsis is refractory to antibiotic and hyperbaric oxygen therapy, tooth extraction may be necessary, although the procedure is difficult [174,175]. Otolaryngological approaches to malignant osteopetrosis were summarized in 1998 [61]. Children with osteopetrosis are more likely to have tracheas that cannot be intubated [176]. Perioperative morbidity and mortality are increased [176].

Orthopedic complications of malignant osteopetrosis and their management were reviewed in 1999 [177]. Although technically arduous, hip replacement and correction of neuromuscular scoliosis have been performed successfully in adults with osteopetrosis [178,179]. Cervical or lumbar spondylolysis in children will generally respond to nonoperative measures [80].

Surgical decompression has benefited some patients suffering from palsies of the optic or auditory nerves [63]. The best response for optic nerve involvement occurs if retinal disease is excluded by ophthalmoscopic examination and electroretinography [65]. Transcranial Doppler ultrasonography seems promising for planning operative intervention for visual loss [180].

In CA II deficiency, whether the systemic acidosis should be corrected is unclear. In some untreated patients, skeletal density can decrease over time and radiographic changes become more normal [32]. Reversing the metabolic acidosis could diminish bone resorption, by blunting liberation of HCO_3^- from the skeleton [32]. When attempted for CA II deficiency, long-term alkali therapy seems disappointing [181,182]. Furthermore, caution is indicated because hypercalciuria, medullary nephrocalcinosis, and nephrolithiasis affect some patients [94]. In 1988, transfusion of CA II–replete erythrocytes for one of the American sisters did not improve her systemic acidosis [183]. This observation supports an acidification defect intrinsic to the kidney [120]. In CA II–deficient mice, BMT leaves the renal tubular acidosis uncorrected; however, retrograde injection of cationic liposomes complexed with a *CA2* gene transiently corrected urinary acidification [139].

PRENATAL DIAGNOSIS

In 1943, a routine x-ray examination reportedly disclosed osteopetrosis at 6 months gestation [184]. The unique sibship with osteopetrosis lethal *in utero* was evaluated by ultrasound at 18 weeks gestation [39]. Malignant osteopetrosis has been detected by ultrasound at 18 weeks gestation [185] and by x-ray [186], and can sometimes now be detected by mutation analysis of the gene coding for the TCIRG1 subunit of the vacuolar proton pump. Generally, however, radiological studies have not been helpful. CA II deficiency has been diagnosed prenatally by molecular testing [92]. Evaluation of CA II deficiency must be made at the DNA level because CA II is not expressed in fetal erythrocytes [92]. Whether cordocentesis for measurement of BB-CK or TRAP levels in serum would be helpful has not been explored.

RECENT DEVELOPMENTS

Benign Osteopetrosis

Autosomal dominant adult (benign) osteopetrosis, type I, has been localized, according to a preliminary report, to chromosome 11q12-13 [187]. This is the same region to which a high bone mass phenotype distinguishing a family from Omaha, Nebraska had been mapped [188].

Autosomal dominant adult (benign) osteopetrosis, type II (Albers-Schönberg disease), previously believed to be genetically heterogeneous, is now understood at the

molecular level. After a report that in one large Danish family the condition mapped to chromosome 1p21 [21], this region was excluded in two American kindreds [44]. The disorder was found not to map to chromosome 1p21 in an additional family [189], indicating that 1p21 is, at best, a minor locus [190]. Instead, a genome-wide search involving a large French family mapped this disorder to chromosome 16p13.3 [191]. In fact, the original Danish family [21] could not be excluded from showing linkage here, suggesting genetic *homo*geneity for Albers-Schönberg disease [191].

Malignant Osteopetrosis

Loss of the ClC-7 chloride channel as a result of mutations in the *CLCN7* gene on chromosome 16p13.3 has been reported in one of 12 patients with autosomal recessive malignant osteopetrosis [192]. Subsequently, mutations in *CLCN7* were discovered in 12 families worldwide with adult osteopetrosis, type II, and in a second patient with autosomal recessive malignant osteopetrosis [193]. This revelation of mutations in a single gene leading to two clinically distinct types of osteopetrosis has added another defect of ion transport in osteoclasts to the pathogenesis of impaired bone resorption in marble bone disease [194].

As noted previously, autosomal recessive infantile osteopetrosis had been found in a small number of patients to reflect mutations in *ATP6i* (*TCIRG1*) encoding the α3 subunit of the vacuolar proton pump [58]. It is now known that approximately 50% of such patients worldwide have deactivating mutations in this gene [195]. Accordingly, malignant osteopetrosis can be caused by *TCIRG1* and *CLCN7* (and perhaps other) gene defects. As also noted above, craniometaphyseal dysplasia was reported in one patient on the basis of monoclonal antibody studies to involve deficiency of the vacuolar proton pump [146]. Recently, however, several patients with this disorder have been discovered to have defects in the *ANKH* gene that conditions the cellular transport of inorganic pyrophosphate [196].

Other Osteopetroses

The existence of an extremely rare condition, "asynchronous asymmetric heterogeneous osteopetrosis," is supported by a report of a second patient [197].

Prenatal Diagnosis

Prenatal diagnosis of malignant osteopetrosis has recently been successful in some families using genetic testing. In several inbred Bedouin kindreds, in which the disorder had been mapped to chromosome 11q12-13 [142], linkage analysis was helpful [198]. Mutation information concerning *TCIRG1* has enabled prenatal diagnosis of malignant osteopetrosis in Costa Rican families [195]

Treatment

Advances in the treatment of osteopetrosis include a case report of apparent cure of the malignant form using prednisone therapy [199]. In 2000, interferon γ-1b received Food and Drug Administration (FDA) approval in the United States for severe osteopetrosis. Interferon-γ enhances osteoclast generation and normalizes superoxide production [200], helping, perhaps, to control infection in malignant osteopetrosis [201]. As predicted [183], bone marrow transplantation corrects osteopetrosis but not renal tubular acidosis in carbonic anhydrase II deficiency [202]. The efficacy of stem cell transplantation for severe osteopetrosis has recently been assessed [203], and the diagnosis, management, and outcome of autosomal recessive osteopetrosis has been briefly reviewed [204].

Chapter 20

Alkaptonuria

Bert N. La Du

University of Michigan Medical School, Ann Arbor, Michigan 48109-0632

SUMMARY

- **Alkaptonuria is a rare, hereditary, disease of phenylalanine and tyrosine metabolism in which the intermediary compound, homogentisic acid, cannot be further metabolized. The metabolic defect results in a characteristic triad of findings: homogentisic aciduria, connective tissue ochronosis, and arthritis of the larger joints.**
- **The cause of the disease is a lack of the enzyme homogentisic acid oxidase, normally found primarily in the liver and kidney. It requires oxygen, ferrous iron, and sulfhydryl groups to cleave the aromatic ring of homogentisic acid. No effective treatment is available, but avoiding severe stress to the spine and large joints will reduce the progress of the ochronotic arthritis.**
- **Alkaptonuria is inherited as an autosomal recessive disorder. Although no general methods are available to detect heterozygous carriers of the condition, recent advances in understanding the molecular basis of the genetic defects in alkaptonuria may permit heterozygous detection within families carrying identified homogentisic acid oxidase mutations.**
- **Exactly how this simple metabolic defect causes tissue ochronosis and arthritis is still not clear, and solving these problems will be a challenge for the future. Animal models of this disorder are now available to study the mechanism of the pathophysiology in alkaptonuria, and to assess possible approaches for treatment of the metabolic disorder.**

INTRODUCTION

Alkaptonuria (MIM 203500) is a rare, hereditary, metabolic disease in which the enzyme homogentisic acid oxidase (HGO) is deficient or missing. Homogentisic acid (HGA) produced by the metabolism of phenylalanine and tyrosine cannot be further metabolized in alkaptonuric individuals; it accumulates to some degree in the tissues, and is excreted in the urine. Urine containing HGA gradually turns dark upon standing, as the acid is oxidized to a melanin-like product. The oxidation is much faster under alkaline conditions, and is greatly retarded in acidic urine. Some alkaptonurics do not report noticing dark urine, and many are not diagnosed until they require a surgical procedure which reveals extensive ochronotic pigmentation of their cartilage and other connective tissues. However, most alkaptonuric patients do report that they pass dark urine, or urine that darkens on standing. The medical literature of the 16th and 17th centuries describes individuals who continually passed dark urine, and some of them probably had alkaptonuria [1]. An Egyptian mummy dated approximately 1500 B.C. showed the characteristic x-ray changes in the spine seen in alkaptonuric patients (extensive intervertebral disk calcification and narrowing of the hip and knee joints). Spectroscopic analysis of pigment obtained from the hip region of the mummy closely resembled the reference pigment produced by oxidation of HGA [2]. Although it was not possible positively to identify HGA in the mummy tissues, this may be the earliest case of alkaptonuria on record.

The first alkaptonuric patient diagnosed with certainty was that of Boedeker in 1859 [3]. Boedeker determined that the reducing compound in his patient's urine was not glucose, and noted the rapid darkening of the urine after alkali was added. He used this property of avid oxygen uptake in alkaline solution to name the unknown substance "alcapton" [3]. Two years later, Boedeker spelled it "alkapton" [4], and since then this condition has been called *Alkaptonurie* in the German literature and *alcaptonurie* in the French. Boedeker precipitated "alcapton" from alkaptonuric urine as the lead salt [3,4], but was unable to determine its chemical structure. About 30 years later, Wolkow and Baumann [5] identified it as 2,5-dihydroxyphenylacetic acid and named it homogentisic acid because of its similarity to gentisic acid (2,5-dihydroxybenzoic acid).

After the aromatic structure of HGA had been identified, suggestions were made about the possible metabolic sources of this unusual urinary product. Tyrosine and phenylalanine, as aromatic components of the dietary proteins, were, of course, the primary suspects. In 1891, Wolkow and Baumann demonstrated that feeding extra tyrosine or a diet high in protein greatly increased the amount of HGA excreted by an alkaptonuric patient [5]. Similar clinical investigations by several other groups allowed the construction of a metabolic pathway by which phenylalanine and tyrosine could be metabolized to HGA. It was assumed that compounds in the metabolic sequence should increase the excretion of HGA in an alkaptonuric subject, but that chemicals that were not intermediates would fail to do so. From all of these studies Neubauer suggested a sequential scheme for tyrosine metabolism in 1909 [6], the first such metabolic

Connective Tissue and Its Heritable Disorders, pages 809–825

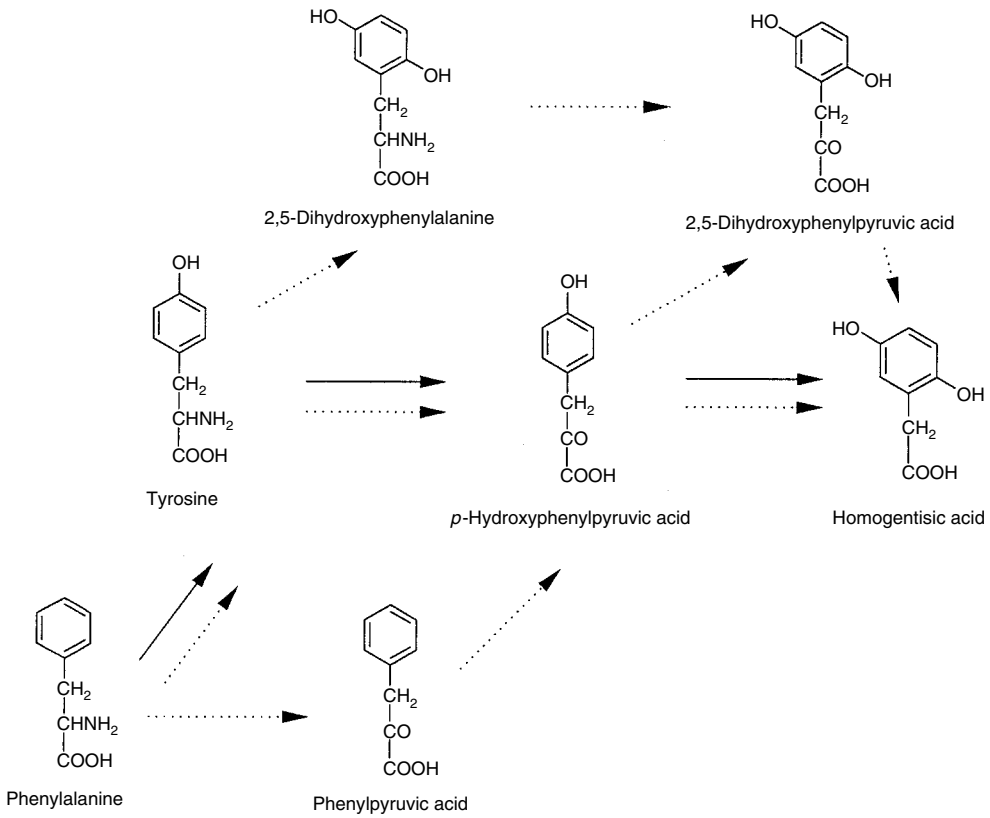

Figure 1. Scheme of phenylalanine and tyrosine metabolism to homogentisic acid based on feeding experiments with alkaptonuric patients. Dotted arrows show the possible pathways considered by Neubauer [7]; solid arrows indicate the pathway as it is believed today.

scheme proposed for any amino acid. He revised it slightly in 1928 from additional data [7] (Fig. 1), and this scheme has remained essentially unchanged over the past 70 years.

Alkaptonuria has served as a valuable model in the historical development and understanding of metabolic diseases. Garrod's brilliant concepts about inborn errors of metabolism were based on his insightful studies on alkaptonuria. In 1908, he discussed alkaptonuria in one of the Croonian Lectures [1], and in the following year he expanded his ideas more completely in his classic book *Inborn Errors of Metabolism*. [8]. He considered alkaptonuria to be an extreme example of the wide variation possible in metabolic capacity, and more like an inherited structural abnormality than an acquired, infectious disease. He predicted that some degree of metabolic variation was present in every person, according to one's hereditary background. Alkaptonuria and the other inborn errors of metabolism represented extreme examples of such variational possibilities [9]. He suspected that these variants ultimately depended on differences in the activity of specific enzymes. In this way, Garrod anticipated by many years the important interpretation of Beadle and Tatum [10] that a single defective gene is correlated with a metabolic deficiency in one enzymatic reaction. In 1909, Garrod even proposed the remarkable conclusion that the enzyme which splits the benzene ring of homogentisic acid was defective in alkaptonuric subjects, and that this enzyme was normally present in human liver [8]. This deduction was supported by all the circumstantial evidence gathered during the subsequent years, and was directly confirmed in 1958 by enzymatic assays on a biopsy sample of alkaptonuric liver [11].

CLINICAL FEATURES

The three major features of alkaptonuria are the presence of HGA in the urine, pigmentation of cartilage and other connective tissues, and nearly always, in later years, arthritis [12]. Alkaptonuria does not appear to reduce the normal life span of affected subjects [13].

Urinary Changes

Although it is generally said that people with alkaptonuria give a history of dark urine or urine which turns dark on standing, it should be noted that many reported alkaptonuric patients never observed any abnormal color of their urine during childhood [14–16], and the diagnosis was made only after they obtained medical intervention for arthritis during their later years [15–20]. For others, it may have been a false positive test for diabetes [15,19], or the finding of unusual, distinctive x-ray changes in the spine [21], or some surgical procedure revealing marked pigmentation of articular cartilage [22] that led to the diagnosis.

Alkaptonurics on a normal diet void a urine which seems to be normal, and it may not darken for several hours if it remains at an acid pH. Thus, in those instances in which freshly voided urine has been reported to darken quickly, there must have been other factors involved. Two of these are: the excretion of an alkaline urine, and the presence of a lower than normal concentration of vitamin C, or possibly

other reducing agents, in the urine. Vitamin C protects HGA against oxidation, and ascorbic acid was suggested as a therapeutic agent to prevent ochronosis because of this property [23]. The abnormal findings in alkaptonuric urine can all be attributed to the presence of HGA. No abnormal amino acid pattern [24], or other tyrosine metabolic products are found [25].

Diagnostic urinary tests for alkaptonuria are based on the detection of HGA and its unusual chemical properties. Its ease of oxidation in the presence of alkali results in the gradual darkening of the urine downward from the surface until the entire sample is dark brown. Alkaptonuric urine also reduces copper in Benedict's sugar reagent, producing an orange precipitate in a muddy-brown solution. Reduction of molybdate is the basis of the Briggs test, which has been used in the past to follow the course of urinary excretion of HGA [26]. Reduction of silver in photographic paper emulsion has also been used as a simple, qualitative test [27], and as the basis of a quantitative method to measure HGA [28]. HGA is not fermented by yeast, and it does not fluoresce under ultraviolet light.

A presumptive diagnosis of alkaptonuria can be made with the above nonspecific tests, but specific tests to identify HGA are also available. This acid has been isolated from alkaptonuric urine after precipitation as the lead salt [25,29] and the product analyzed for its chemical composition and melting point. Paper chromatography of the urine directly, or after ether extraction from acidified urine, is another simple technique to identify HGA [30]. A specific enzymatic method has been developed that permits the quantitative analysis of HGA in urine, blood, and other tissues [31,32]. Rapid analysis of HGA in urine and plasma is also possible by an HPLC method [33]. A stable isotope dilution gas chromatography-mass spectroscopic method can be used to determine the concentration of HGA in normal human plasma; normal levels are reported to be from 2.4 to 12 ng/mL, about 1/1000th of the levels found in alkaptonuric plasma [34].

Ochronosis

In 1866, Virchow first described a peculiar, generalized pigmentation in the connective tissues of a 67-year-old man [35]. The pigment was gray to bluish-black on gross examination, but ochre microscopically, and so he named this condition "ochronosis." The patient's clinical history was not available to Virchow, but there is little doubt that he had described for the first time the generalized connective tissue pigmentation that gradually develops in alkaptonuric individuals. It was nearly 40 years later that Albrecht, in 1902 [36], clearly demonstrated the causative association between ochronosis and alkaptonuria. Not long thereafter, Sir William Osler diagnosed ochronosis clinically for the first time in two alkaptonuric brothers [37]. He recognized the pigmentation of the sclerae, cerumen, and ears to be signs of the same metabolic abnormality that had previously been diagnosed only by the dark pigment in alkaptonuric urine and autopsy connective tissues.

The long delay in clinical recognition of ochronotic pigmentation as a basic feature of alkaptonuria is not surprising. Generally, the earliest external signs of ochronosis that can be detected are a slight pigmentation of the sclerae and the ears. However, these changes are rarely apparent until alkaptonuric patients are about 20 to 30 years old. Pigmentation of the eye, found about midway between the cornea and the outer and inner canthi, is found at the sites of insertion of the rectus muscles (Fig. 2). In addition, a more diffuse pigmentation may involve the conjunctiva and cornea [39]. The typical pigmentary changes in the ear cartilages also can be detected only after longstanding alkaptonuria. The cartilage is slate blue or gray and feels irregular and thickened.

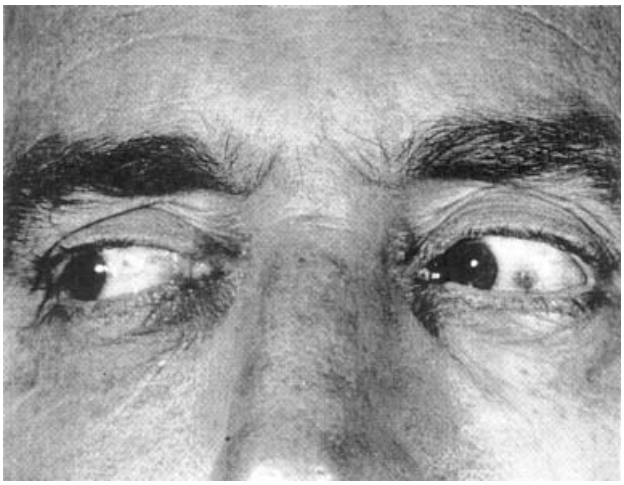

Figure 2. The bilateral deposition of ochronotic pigment in the sclerae, best seen in the left eye. From Bunim et al [38].

It is sometimes reported that a dusky discoloration, corresponding to underlying tendons, can be seen through the skin over the hands. The degree of prominence of this pigmentation is variable, and in many instances is scarcely evident at all. The pigment appears in perspiration; clothing near the axillary regions may be stained, and the skin may have a brownish discoloration in the axillary and genital regions.

In contrast to these minimal external findings, the pigmentation observed in the tissues of an elderly alkaptonuric patient at operation or postmortem is indeed striking [35,40–43]. Cartilage in many areas, such as the costal, laryngeal, and tracheal cartilage, is deeply pigmented. It has been described as being coal black in some areas (Fig. 3). Pigmentation is also present throughout the body in fibrous tissues, such as fibrocartilage, tendons, and ligaments (Fig. 4). Pigmentation is also found in the endocardium, the intima of the larger vessels, in various organs such as kidney and lung, and in the skin epidermal layer. Microscopic examination shows the pigment may be either granular or homogeneous, and is deposited both intercellularly and intracellularly [44]. Electron microscopy of alkaptonuric synovial membrane [45], hip joint tissue [46], and articular cartilage [47] shows the fragments of cartilage to be stained with yellow-brown pigment derived from HGA.

Like melanin, the ochronotic pigment can be bleached by treatment for 24 hours with hydrogen peroxide. The pigment is soluble in alkali, but only slightly soluble in hydrochloric acid. Thus, in many of its chemical characteristics the ochronotic pigment resembles melanin, which arises from the oxidation of 3,4-dihydroxyphenylalanine (dopa). To date, there is no specific stain that distinguishes between the ochronotic pigment of alkaptonuria, and melanin derived from dopa. Although Fitzpatrick and Lerner [48] had reported that Becker's silver stain for melanin was not darkened by ochronotic pigment and that the latter was stained intensely black by polychrome methylene blue,

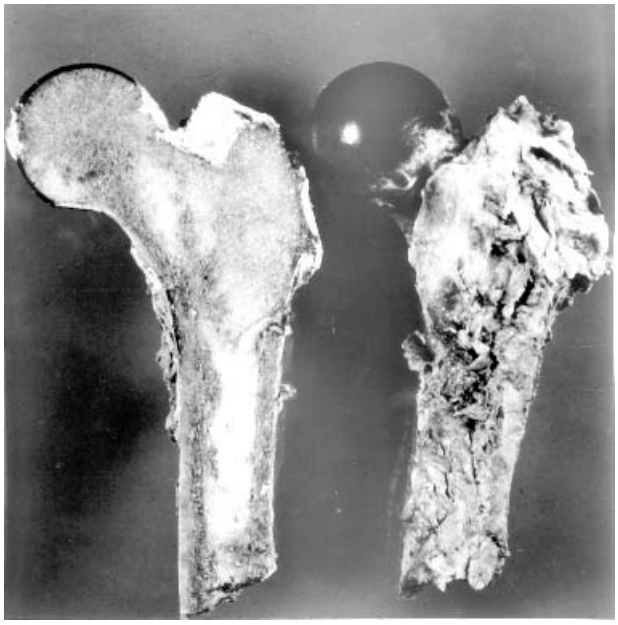

Figure 3. Ochronotic pigmentation of the femur of a 56-year-old alkaptonuric patient. (Courtesy of Dr. H.W. Edmonds of the Washington Hospital Center, Washington, D.C.)

Figure 4. Deposition of ochronotic pigment in synovial tissue from the knee joint of a 40-year-old alkaptonuric male subject. (From O'Brien et al [43].)

Cooper and Moran [42] compared the staining properties of ochronotic pigment and melanin with a number of special stains and concluded that no specific differentiation could be made with any of the stains they tested. Both pigments are best detected by the Nile blue stains of Lillie [49].

The ochronotic pigment is a polymer derived from HGA, but its exact chemical structure has never been determined. It is possible that other constituents in addition to HGA are included in the product, just as melanin pigment contains an appreciable quantity of sulfur [50] as well as polymerized dopa units.

Formation of the pigment in the tissues may be entirely nonenzymatic, as with the darkening of alkaptonuric urine. Pure HGA solutions made alkaline and aerated with air or oxygen form a dark-brown product that has an ultraviolet absorption peak at 250 nm [51]. Unfortunately, the natural pigment deposited in alkaptonuric tissues as ochronosis has not been analyzed in this way, and so the relevance of the model polymer to the *in vivo* process has not been established. Milch and Titus [52] suggested that since polymerization of pure HGA solutions does not proceed at neutral pH and low partial pressure of oxygen (as occurs in cartilage), it is likely that if molecular oxygen is involved *in vivo*, it involves the participation of an enzymatic system present locally. This conclusion assumes not only that the component steps of formation of the ochronotic pigment are the same *in vivo* as in solutions of pure HGA, but that the pigment is formed as well as deposited in the cartilage. It is not possible to say whether enzymes do play a role in the synthesis of the ochronotic pigmentation in alkaptonuria, but on the basis of their substrate specificities, it is reasonable to exclude enzymes like tyrosinase in this process.

Mammalian (human, rabbit, and guinea pig) skin and cartilage contain the enzyme homogentisic acid polyphenol oxidase, which catalyzes the oxidation of HGA to an ochronotic-like pigment [53]. Benzoquinoneacetic acid has been identified as an intermediary metabolite in that oxidation. The enzyme is a copper-protein, but it clearly is distinguished from tyrosinase. For example, tyrosine, dopa, and other catechols are not substrates for this polyphenol oxidase. Earlier studies by La Du and Zannoni [54] demonstrated that *p*-quinones, such as benzoquinoneacetic acid, can form 1,4 addition products with sulfhydryl groups, and Stoner and Blivaiss [55] observed similar derivatives with the amino groups of glycine. Binding and chemical reactions of benzoquinone (or polymers derived from the acid) with the connective tissues may produce important chemical changes that alter tissue constituents and lead to ochronosis and ochronotic arthritis [24]. A possible scheme for the enzymatic oxidation of HGA and the formation of ochronotic pigment in the connective tissues of alkaptonuric patients is given in Figure 5.

Ochronosis Not Due to Homogentisic Acid

Clinically, ochronosis might be confused with the pigmentation resulting from the antimalarial agent atabrine [56], or that secondary to use of carbolic acid dressings for chronic cutaneous ulcers [57]. Both are reversible after medication is discontinued, but both treatments are rarely used today. Long-term use of skin-lightening creams and lotions containing hydroquinone may also cause a chemically induced ochronosis [58,59]. Melanotic tumors may produce a generalized ochronosis, but such patients do not survive long enough for this to be a diagnostic problem. One case of alkaptonuria was unfortunately misdiagnosed as a melanosarcoma of the eye because of the ocular pigmentation, and the eye was removed [60].

Arthritis

"Ochronotic arthritis" is a regular manifestation of longstanding alkaptonuria. From a review of the case reports, it appears that alkaptonuric arthritis occurs earlier and is more severe in males than in females [61], even though the sex incidence of alkaptonuria is approximately equal. According to Hench [62], ochronotic arthritis resembles rheumatoid arthritis clinically but is like osteoarthritis radiographically. The earliest symptoms are likely to be

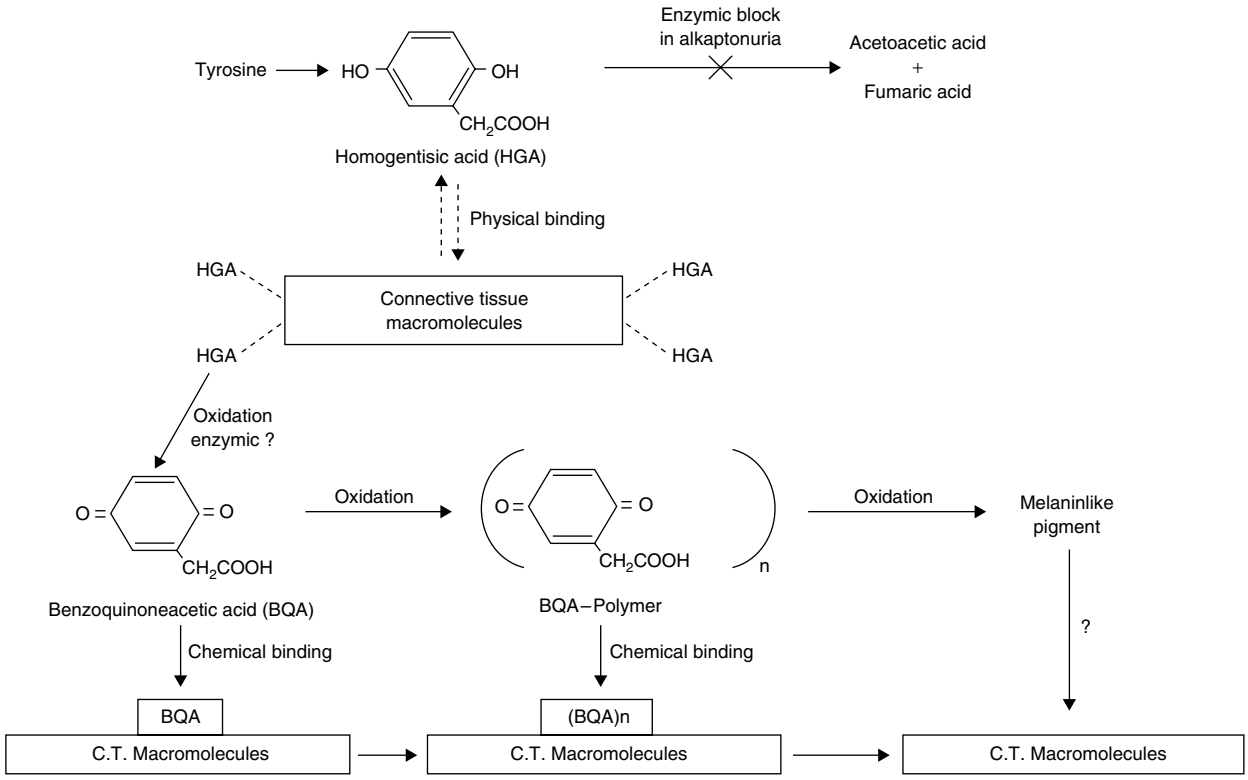

Figure 5. Postulated scheme for the formation of ochronotic pigment in alkaptonuric tissues (From Zannoni et al. [53].)

some limitation of motion of the hip, knee joints, and occasionally, the shoulders. Periods of acute inflammation resembling rheumatoid arthritis are common, followed by rather marked limitation of motion and ankylosis in the lumbosacral region.

X-ray changes of the spine are considered almost pathognomonic for alkaptonuria [21]. The vertebral bodies of the lumbar spine show degeneration of the intervertebral disks and a narrowing of the intervertebral space and dense calcification of the remaining disk material (Fig. 6). There is also a variable degree of fusion of the vertebral bodies. From x-ray changes in the lumbar spine alone, it is often possible to diagnose alkaptonuria. In contrast to rheumatoid spondylitis, alkaptonuria shows little osteophyte formation and minimal calcification of the intervertebral ligaments. The large peripheral joints involved in alkaptonuria differ from those involved in osteoarthritis in that degenerative changes are most commonly found in the shoulder and hip joints, but the sacroiliac region may be completely spared.

Calcification of the ear cartilage is another sign of alkaptonuria that may be seen on x-ray films. Occasionally, free intra-articular bodies are found [63]. In contrast, the smaller joints usually show little or no abnormality.

The common occurrence of arthritis in the population and the long interval before it occurs in alkaptonuric patients probably account for the failure of earlier investigators to connect arthritis with alkaptonuria. The first case of Boedeker [3] was said to have neuralgia of the lower lumbar spine. The early investigators considered alkaptonuria to be a completely benign disorder without symptoms and of clinical importance only because it might be misdiagnosed as diabetes, because of the nonspecific copper-reduction tests on urine used many years ago. Review of the earlier case reports shows that in most instances osteoarthritis was mentioned, and, in fact, arthritis developed in nearly all alkaptonuric patients during their later years. The arthritic complications are often severe and painful, and may lead to a completely bedridden existence in later life.

The relationship between the deposition of ochronotic pigment in the connective tissues and the degenerative changes which occur in some areas of the connective tissues, particularly the cartilage and the intervertebral disks, remains unknown. It has been suggested that the pigment acts as a chemical irritant which accelerates a degenerative process in the cartilage, with pathological changes similar to those seen in osteoarthritis [18,63]. Intra-articular injection of HGA into the knee joints of rabbits produces local lesions of the cartilage and soft tissues resembling those seen in alkaptonuria [64]. Presumably, either the ochronotic pigment or HGA itself inhibits some of the enzyme systems involved in cartilage metabolism. Greiling [65] found that low concentrations of the artificial pigment prepared by treating HGA with alkali inhibited the action of hyaluronidase on chondroitin sulfate, and hyaluronan. However, HGA itself did not inhibit hyaluronidase at equivalent concentrations. Dihlmann et al. [66] extended these studies to show inhibition of several additional enzymes, particularly glutamic dehydrogenase, hexokinase, and malate dehydrogenase, by the oxidized, polymerized pigment derived from HGA.

Inhibition of lysyl hydroxylase [67] (see also Chapter 2, Part I, this volume) could be particularly important, if

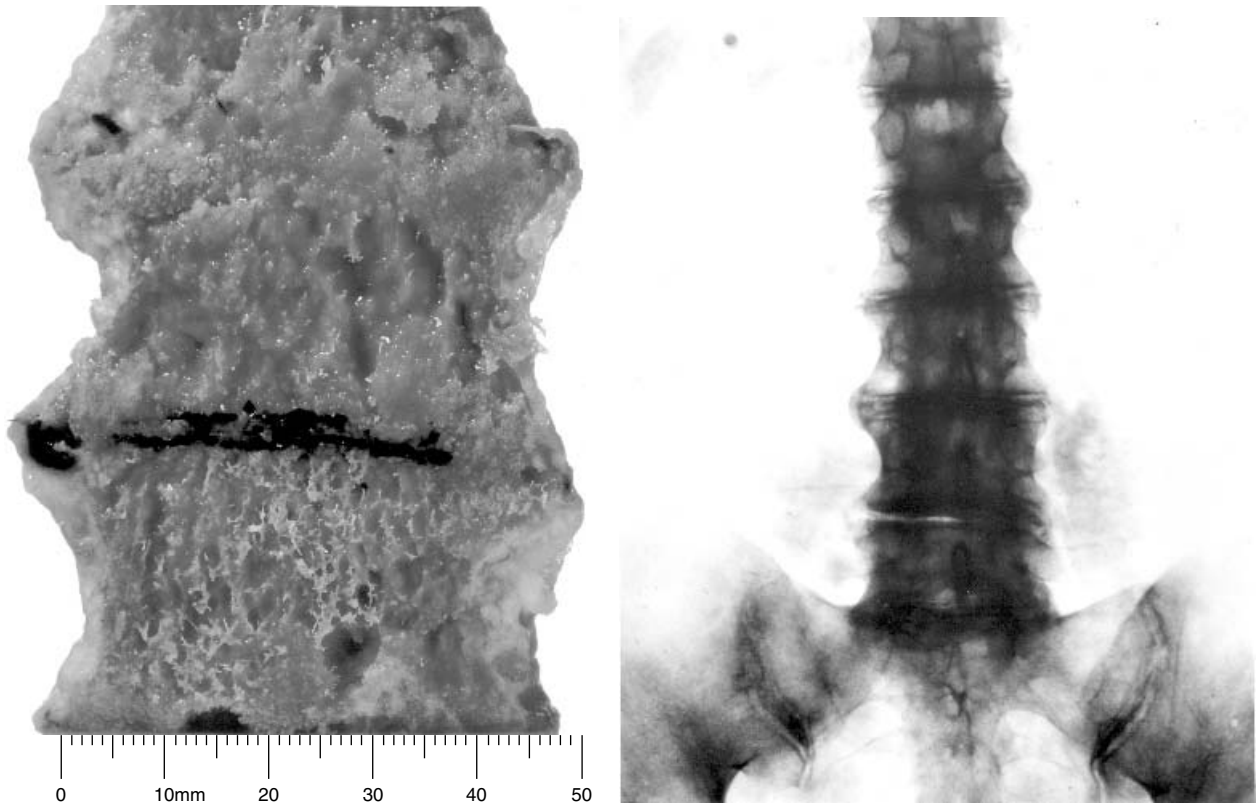

Figure 6. Alkaptonuric spines showing the typical narrowing and calcification of the intervertebral disks (Photograph on the **left**, see also Legend to Figure 9, courtesy of Dr. B. Bode, Department of Pathology, University Hospital, Zurich, Switzerland; radiograph on the **right**, from Bunim et al [38]).

this were to reduce the number of hydroxylysine residues and the nature of the cross-links essential to give tensile strength to collagen fibers. Recent studies [67a] question this hypothesis, based on the finding of normal urinary ratios of lysyl pyridinoline / hydroxylysyl pyridinoline residues in three alkaptonuric patients. Reducing agents, such as ascorbic acid and 1,4-dithiothreitol, competitively protect against inhibition of lysyl hydroxylase by HGA in the chick embryo [67], so the actual inhibitory agent in this model system might be an oxidation product of HGA, such as benzoquinoneacetic acid.

In recent years the techniques of molecular biology have made it possible to discover a number of molecular mutations that affect the structure of collagen [68](see also Chapters 8,9, and 23, Part II, this volume); some of these are responsible for hereditary forms of arthritis [69]. Whether HGA or its metabolites are responsible for inducing a similar defect in the collagen structure by altering the nature of the cross-links and thereby decreasing its resistance to shearing stress in alkaptonuric subjects remains to be established. If the arthritic complications in alkaptonuric subjects could be prevented or greatly reduced, the major clinical burden of this disorder would be eliminated.

Other workers have evaluated the effects of HGA on articular chondrocytes [70]. Cytotoxic effects were noted with rabbit adult articular chondrocytes at HGA concentrations of 5 μg/mL or above; cytotoxic effects were seen with fetal articular chondrocytes at concentrations of 1 μg/mL. Another laboratory [71] has shown that hyaline cartilage incubated with the polymerized products of HGA oxidation develops an increased hardness and decreased elasticity. It is suggested that these structural changes, as well as the mechanical stress to the large joints, lead to cartilage destruction [72].

Other Findings in Alkaptonuria

In addition to the features mentioned above, some other complications seem to occur in alkaptonuric patients with a greater frequency than might be anticipated in the general population. A relationship between ochronosis and cardiovascular disease has not been clearly established, but a review of the case histories of alkaptonuric patients indicates there to be a relatively high incidence of heart disease [19]. In 1910, Beddard [73] tabulated the autopsy findings in eleven patients with ochronosis and found that eight had chronic mitral and aortic valvulitis, one had an aortic aneurysm, and one had an aneurysm of the left ventricle. Other investigators [40,74] have noted generalized arteriosclerosis and calcification in the heart valves and of the annulus of the aortic and mitral valves [41,75]. Myocardial infarction was a common cause of death in this group.

Other complications regularly found in alkaptonuric patients are ruptured intervertebral disks [76], prostatitis, associated with prostatic stones [14,19,77], and renal stones [77]. One patient with alkaptonuria also had polycythemia [78], one had nephrocalcinosis [79], and one had severe renal disease called "ochronotic nephrosis" [42], but these are probably examples of chance association with

the other diseases. Conditions that favor the expression of alkaptonuria, such as consanguineous marriage, would also favor the presence of other recessive but unrelated traits.

SYNTHESIS AND DEGRADATION OF HOMOGENTISIC ACID

In mammals, most of the dietary phenylalanine and tyrosine is oxidized to acetoacetic acid by enzyme systems localized primarily in the liver and kidney. The scheme of this metabolic pathway is shown in Figure 7. As mentioned above, the scheme is based on the earlier studies with alkaptonuric patients and many animal experiments *in vivo*. Studies with isotopically labeled phenylalanine and tyrosine showed the fate of each of the carbon atoms in the aromatic ring and the side chain [80–82], and the distribution of the isotope in the products — CO_2, acetoacetic acid, and fumaric acid. Two of the four carbon atoms of acetoacetic acid were derived from carbon atoms 2 and 3 of the side chain and the other two came from the aromatic ring. Furthermore, the position of the isotope from the ring carbon atoms indicated that the side chain migrated during the oxidation, in agreement with the scheme postulated earlier by Neubauer (see Fig. 1), to account for the 2,5-dihydroxyphenyl intermediary product, HGA, from the 4-hydroxyphenyl precursors. This rearrangement involves a quinol intermediate, so hydroxylation of the ring, and migration, and oxidative decarboxylation of the side chain all take place as a complicated single step [83–86].

The present scheme of tyrosine oxidation is therefore very much like that of Neubauer (Fig. 1) in the steps leading to the formation of HGA, with the notable exception that neither 2,5-dihydroxyphenylalanine nor 2,5-dihydroxyphenylpyruvic acid is now considered to be an intermediate. Both compounds do produce extra HGA when fed to alkaptonuric patients [6,28], but were found to be inactive as substrates when tested with mammalian liver preparations which oxidize tyrosine or *p*-hydroxyphenylpyruvic acid to homogentisic acid [80–82].

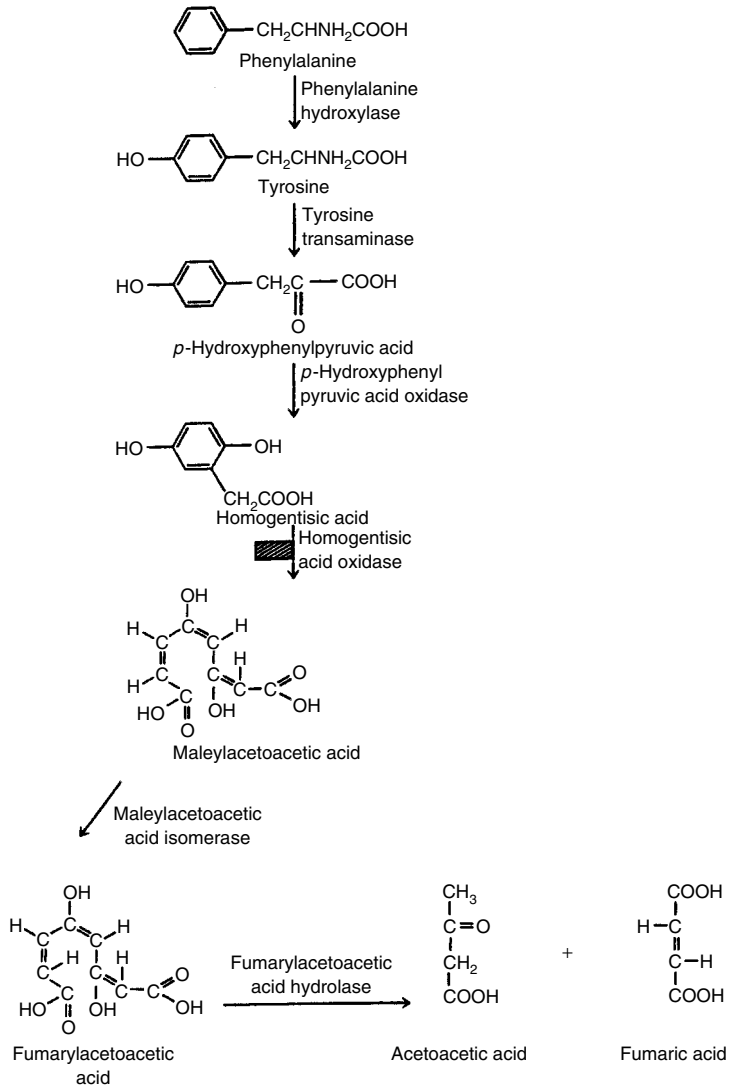

Figure 7. Enzymatic steps in the oxidation of phenylalanine and tyrosine to acetoacetic acid. ▨ = block in alkaptonuria.

TABLE 1. Activity of Tyrosine Oxidation Enzymes in Homogenates from Alkaptonuric and Nonalkaptonuric Human Liver

Enzymes	Enzyme Activity (μmol Substrate Oxidized per hour per gram Liver)	
	Nonalkaptonuric	Alkaptonuric
Tyrosine transaminase	36	32
p-Hydroxyphenylpyruvic acid oxidase	67	46
Homogentisic acid oxidase	268	<0.048
Maleylacetoacetic acid isomerase*	960	780
Fumarylacetoacetic acid hydrolase	288	222

*Units calculated as Δ log density (hour per 0.1 g) wet weight liver [87].
(From La Du et al. [11])

METABOLIC DEFECT IN ALKAPTONURIA

Garrod suggested in 1909 [8] that the metabolic defect in alkaptonuria was the absence of a liver enzyme catalyzing the oxidation of HGA, but other possible explanations were suggested from time to time after that by other workers. However, direct analysis of the enzymes involved in tyrosine metabolism in biopsied normal and alkaptonuric liver in 1958 showed that only HGO was missing in the alkaptonuric liver. All the other enzymes involved in tyrosine metabolism to acetoacetic acid were present at about the same level of activity as in normal liver [11,38] (Table 1). Evidence was also obtained that the lack of activity was not due to the presence of inhibitor or to the lack of any known cofactor [11]. Later, autopsy samples of kidney tissue from two alkaptonuric patients made it possible to show that HGO is also absent from alkaptonuric kidney [88], and presumably from any other tissues where it is usually found.

It is now reasonable to define the defect in alkaptonuria as the failure to synthesize active HGO and to attribute all the findings in alkaptonuria to this specific enzymatic defect. Recent cloning of the gene coding for HGO and the identification of specific mutations affecting the structure of the enzyme protein now provide a molecular basis for classifying various HGO deficiencies in different alkaptonuric patients.

The metabolic abnormality in alkaptonuria is present essentially from birth. Garrod noted in 1901 that staining of the diapers was scarcely evident 38 hours after birth, although after 52 hours they were deeply stained and continued to be thereafter [89]. The reason for the delay in the excretion of HGA in newborn alkaptonuric patients is probably because the enzyme systems involved in tyrosine oxidation are not completely developed at birth and increase in activity during the first few days thereafter [90]. Once established, the defect continues relentlessly throughout life. No therapeutic agent has been found that substantially alters the degree of the defect. The amount of HGA excreted per day is usually from 4 to 8 g; it can be altered by changing the content of phenylalanine and tyrosine in the diet. In starvation there is a marked decrease in HGA excretion [91], as would be expected, although Mittlebach [92] showed that on a diet very low in protein, an alkaptonuric patient continued to excrete some HGA, presumably from the breakdown of endogenous tissue proteins.

HOMOGENTISIC ACID OXIDASE

The enzymatic step missing in alkaptonuric subjects is the further metabolism of HGA by an oxidative cleavage of the benzene ring to yield maleylacetoacetic acid [93], which, in turn, is isomerized enzymatically to fumarylacetoacetic acid [87,94,95] (see Fig. 7). Human maleylacetoacetic acid isomerase has recently been cloned [96] and shown to have an identical amino acid sequence to another enzyme, glutathione S-transferase [97]. The next step is hydrolysis to fumaric and acetoacetic acids by a hydrolase which appears to be the same as that shown to hydrolyze a number of α-γ-diketo acids by Meister and Greenstein [98] and to hydrolyze triacetic acid [99,100]. In 1950, Suda and Takeda [101] solubilized an enzyme from *Pseudomonas* adapted to tyrosine which catalyzed the oxidation of HGA, and named it homogentisicase. They also studied the properties of a similar enzyme from rabbit liver [102]. Homogentisicase, or, as it is now generally called, homogentisic acid oxidase (HGO)(EC 1.13.11.5), has been purified and characterized by several laboratories [93,103–105]. It is an oxygenase, and both atoms of oxygen come from atmospheric oxygen in the cleavage of the benzene ring, based on experiments with ^{18}O. The enzyme contains essential sulfhydryl groups and requires ferrous iron [102,106]. It resembles other oxygenases involved in ring cleavage reactions, such as pyrocatechase [107,108], hydroxyanthranilate oxidase [109], and protocatechuic acid oxidase [110]. No other cofactors have been clearly implicated in this reaction, and ascorbic acid simply maintains iron in its reduced form. HGO activity in isolated rat hepatocytes depends on the oxygen tension [111]. The enzyme is inhibited by various quinones [104], sulfhydryl-binding agents [106], and metal-chelating agents such as α,α′-dipyridyl and *o*-phenanthroline [112] which react with ferrous iron.

HGO activity has been measured manometrically, because the oxidation requires the uptake of two atoms of oxygen, and spectrophotometrically [113], by following the absorption of the product maleylacetoacetic acid at 330 nm (provided that product is stable and not further metabolized under the assay conditions). HGO is localized in the soluble fraction of liver and kidney [114], as are all other mammalian enzymes involved in the conversion of tyrosine to acetoacetic acid [115,116]. The level of HGO activity in the rat is highest in liver, and appreciably lower in kidney, and there is no significant activity in any other tissues so far examined [105,106], such as blood, salivary glands, germinal epithelium, and muscle. A similar tissue distribution pattern was observed in rats, rabbits, guinea pigs, and pigeons [105]. In humans, too, HGO is highest in liver [11], with appreciable activity also present in kidney [88]. The optimal pH for HGO is about 7 [102,103], and it is very specific for HGA. Such closely related compounds as *o*-hydroxyphenylacetic acid, *p*-hydroxyphenylacetic acid, and gentisic acid are not

oxidized [103], nor are homogentisic acid ethyl ester and homogentisic acid lactone. The quinone formed by oxidizing HGA (benzoquinoneacetic acid) does not appear to be an intermediate in the oxidation [103]. In fact, this quinone is a strong inhibitor of HGO [6,103]. The requirement for ferrous iron cannot be satisfied by other bivalent metals, such as Co^{++}, Zn^{++}, Mg^{++}, or Mn^{++} [102].

Metabolism of Homogentisic Acid

One might expect elevated plasma levels of HGA in alkaptonuric patients in view of the large quantities of this acid excreted each day. Neuberger et al. [25] found, however, that in a 7-year-old alkaptonuric girl, the fasting plasma level was not more than about 3 mg/100 mL plasma, and this level did not increase significantly following the oral administration of 3 g L-phenylalanine. Nevertheless, within 6 hours approximately 85% of the administered amino acid could be accounted for as extra HGA in the urine. Neuberger et al. [25] made very significant observations in regard to the excretion of HGA during their investigation. The plasma clearance data indicated that unless a large fraction of the urinary HGA was both synthesized and excreted within the kidney, the glomerular filtration rate alone could not possibly account for the efficient rate of HGA excretion. Indeed, the renal clearance of HGA approached 400 to 500 mL/min, approximately equal to the rate of renal blood flow. Even though it is very unusual for a normal intermediary metabolite to be actively secreted by the kidney, this is obviously true for HGA. This conclusion is in accord with the earlier observation of Katsch and Metz [117] that giving intravenous HGA to an alkaptonuric subject did not increase the plasma concentration of this acid significantly. Experiments using an enzymatic assay to estimate plasma HGA concentrations have also confirmed these conclusions [31]. Alkaptonuric and nonalkaptonuric individuals were both found to excrete HGA very rapidly after oral administration, and the renal clearance indicated active secretion by the kidney.

It appears that two factors help to keep the plasma and presumably the tissue concentrations of HGA at a low level: the great capacity to metabolize this acid in the liver and kidney, and the rapid renal tubular secretion of HGA. In the alkaptonuric patient, the renal secretory mechanism is sufficient to keep the plasma HGA level very low, even when extra HGA is given. This renal defensive mechanism is very significant, and probably explains why it takes so many years before ochronosis appears in alkaptonuria subjects. It is quite possible that the tissues are only occasionally flooded with HGA and that this must be repeated many times over the years before tissue pigmentation occurs to a significant extent. Benzoquinoneacetic acid may be an intermediate in this process.

EXPERIMENTAL ALKAPTONURIA AND OCHRONOSIS

Genetic Animal Models

Spontaneous alkaptonuria has very rarely been reported in species other than human beings. A Cynomolgus male monkey caught in the wild was found to excrete appreciable amounts of HGA, positively identified by gas chromatography-mass spectrometric analysis [118]. Another report describes a mutant mouse with undetectable liver HGO and homogentisic aciduria. However, no ochronotic pigment deposits were present in the tissues. The authors suggested that the lack of ochronosis might be explained by the relatively high concentrations of endogenously produced ascorbic acid in the mouse [119]. In contrast, an earlier paper by Lewis [120] described a rabbit with urine that darkened on exposure to air and showed some other qualitative tests for HGA. Unfortunately, HGA was never isolated or positively identified, and the rabbit died without leaving offspring. In addition, there are a few reports of generalized ochronosis in the bones and connective tissues of cattle, dogs, and horses in which the tissues are described as being as black as coal; again, HGA was never positively identified in the urine of any of these animals [17,121,122].

Induced Alkaptonuria in Animals

Experimental alkaptonuria has been produced in rats and mice by feeding large quantities of phenylalanine or tyrosine. It has also been reported that vitamin C-deficient guinea pigs fed extra phenylalanine [123,124] or tyrosine [123] excreted HGA, as well as *p*-hydroxyphenylpyruvic acid and *p*-hydroxyphenyllactic acid, but the methods used in these studies for urinalysis do not distinguish between *p*-hydroxyphenylpyruvic acid and HGA [125]. Other workers have found only the two *p*-hydroxy compounds and no HGA in similar experiments with vitamin C-deficient guinea pigs [126].

Experimental alkaptonuria has, as noted, been produced in rats and mice by feeding large quantities of phenylalanine and tyrosine. There is also one report of transitory HGA excretion after feeding a human volunteer large amounts of L-tyrosine [127]. Another type of experimental alkaptonuria has been induced in rats by a diet deficient in the sulfur-containing amino acids [128], which was not corrected by giving ascorbic acid but was reversed by giving cysteine [129]. In this type of experimental alkaptonuria, proportionately less *p*-hydroxyphenylpyruvic acid is excreted than in the type that responds to ascorbic acid.

In addition to the above methods, the fact that HGO requires ferrous iron has been exploited. Inhibition of HGO by the injection of α,α′-dipyridyl and feeding extra tyrosine were used by Suda and Takeda [102] to induce experimental alkaptonuria in guinea pigs. The excretion of HGA in these animals was not corrected by giving vitamin C.

It can be concluded that most of the methods of producing experimental alkaptonuria have relied on either direct inhibition of HGO or the creation of an imbalance in the various enzyme reactions sufficient to cause an accumulation of HGA and its urinary excretion. Attempts to produce experimental alkaptonuria and ochronosis in animals by feeding special diets have met with only limited success. In most instances the inhibition of HGO has been inadequate, and only a small fraction of normal HGO activity is sufficient to prevent the accumulation of HGA and deposition of ochronotic pigment.

Prolonged feeding of L-tyrosine has produced some degree of ochronotic pigmentation of the connective tissues in animals. Bondurant and Henry [130] maintained rats on a diet supplemented with 12% tyrosine for 40 days. Gross examination of the dissected knee and hip joints revealed no structural abnormalities, but these tissues showed the deposition of pigment in the articular cartilage of the head of the femur and in opposing tibial and patellar surfaces of the knee joint. Microscopic examination showed focal accumulations of dark-brown pigment in the cytoplasm of chondrocytes in the epiphyseal cartilage in some animals.

Blivaiss et al. [131] induced experimental ochronosis in 4-week-old rats by supplementing their diet with 8%

tyrosine for up to 28 months. After this time there were ochronotic-like pigment deposits in cartilage, such as the joint capsules, condyles, sternum, and trachea. Pathologic changes were found in the articular cartilage, which included abnormal alignment of chondrocytes with pigment inclusion, fibrillation, and fragmentation, as well as bone denudation. By histochemical techniques, they found an increase in nonsulfated glycosaminoglycans in the connective tissues. The histochemical changes were similar to those observed in the patella from a patient with alkaptonuria.

HEREDITARY ASPECTS

The first description of the inheritance of alkaptonuria was by Garrod in 1902 [9]. He presented evidence that this condition was congenital and familial, and that it occurred more often in families in which there were consanguineous marriages. He suggested that alkaptonuria was transmitted as a simple recessive Mendelian trait, and believed that HGA arose in the normal course of tyrosine metabolism. In 1902, Bateson and Saunders [132] also suggested that the inheritance of a rare recessive factor might explain the incidence of alkaptonuria. These studies on the mode of transmission of alkaptonuria were among the very first of any on human hereditary metabolic disorders. During the subsequent years, several examples were recorded of direct transmission of alkaptonuria (i.e., parent and offspring both affected), but Garrod suggested that these were examples of a heterozygous individual mating with a homozygous alkaptonuric, rather than representations of a dominant form of the disorder. As more family histories were described, the general conclusion about the recessive nature of the disease remained unchallenged.

In 1932, Hogben et al. [133] carefully reviewed all the known cases of alkaptonuria reported up to that time. The recessive character of the disease was confirmed in nearly all the families, and at least half of all affected individuals were offspring of consanguineous matings. Although there was an unequal sex distribution in their cases — 100 males and 46 females — the authors did not interpret this as an indication that the condition was semilethal in females. They noted that males were more often the probands in affected families and suggested that the higher incidence in males might be explained by the more frequent medical examination of males. They also noted that among infants there were slightly more females than males, in agreement with this explanation.

Among the families summarized by Hogben et al. [133] were a few in which a dominant form of alkaptonuria had to be considered. In one family studied by Pieter [134], the author felt compelled to conclude that a dominant type of alkaptonuria existed. Such a conclusion depends on the predicted opportunity for marriage between homozygous and heterozygous individuals, and the frequency of the heterozygote in the population sample under study. The incidence of alkaptonuria in the general population can only be roughly estimated. It is reasonable to assume, however, that it is less rare than was believed 50 years ago. A study in Northern Ireland by A.C. Stephenson reported the incidence of alkaptonuria to be from 3 to 5 per million individuals (see [135]). This would give a considerably higher incidence of heterozygous individuals in the general population than assumed by Hogben et al. [133]. At present, most, if not all, cases appear to represent the inheritance of a single autosomal recessive gene. This is supported by the biochemical finding that a single enzyme system is inactive in this condition and that only one clinical form of alkaptonuria is known.

An unusually high incidence of alkaptonuria has been observed in the Trencin District of Czechoslovakia, near the Slovakian-Bohemian border [136]. Nearly 200 alkaptonuric individuals have been identified among the 16,000 inhabitants [137,138]. Genetic analysis of the affected families shows a concentration of alkaptonuric patients within specific localities, and the authors propose that this is due to a founder effect, with genetic drift and inbreeding in the specific isolated hamlets of that region [139].

Rare diseases with recessive inheritance are regularly encountered more frequently in selected inbred populations, and this complicates any estimation of the incidence of heterozygotes in the general population. It would be helpful if a diagnostic test were available to detect the carrier state. One would hope to find approximately half the normal amount of enzyme in the tissues of heterozygous individuals, but obligatory heterozygous carriers of alkaptonuria do not excrete HGA after an oral loading dose of L-tyrosine [140], and measurements of the ability to metabolize HGA by an oral HGA tolerance test have so far shown no differences between presumed carriers and normal controls. These results are not unexpected in view of the tremendous capacity of the liver to metabolize HGA. Even if this reserve were reduced to one-half, it might not be exceeded by any oral tolerance test. It is interesting to calculate the potential reserve capacity to metabolize HGA: assuming a liver weight of 1500 g and also assuming that the liver HGO is as efficient *in vivo* as found under assay conditions *in vitro*, it may be calculated that the normal adult liver should be able to metabolize over 1600 g of HGA per day.

MOLECULAR BIOLOGY OF THE GENETIC DEFECT

Considerable progress has been made within the last few years in our understanding of the genetic defects in alkaptonuria at the molecular level, and this has been well summarized by Scriver [141]. On the basis of the coinheritance of alkaptonuria with other Mendelian diseases, chromosome 3 was suspected to be the likely location of the gene causing alkaptonuria. Homozygosity mapping with polymorphic markers in two consanguineous families suggested further that the most likely region was 3q2 (combined lod score = 4.3) [142]. Another laboratory also assigned the alkaptonuria gene (*AKU*) to human chromosome 3q [143]. Further supporting evidence came from quite another source, when the murine alkaptonuria gene (*Aku*) was mapped to mouse chromosome 16 in a region of synteny between human chromosome 3 and that mouse chromosome [144]. The structural gene for human HGO was cloned in 1996 [145]. The investigators concerned also demonstrated that specific mutations of the *HGO* gene were associated with the alkaptonuria phenotype, and that these mutations followed the expected pattern within alkaptonuric family pedigrees. The same laboratory also showed that the *HGO* gene mapped to human chromosome 3q21–q23, the location of the *AKU* locus [145]. Their unusual approach to cloning the human *HGO* gene began by first cloning the homologous *hmgA* gene in *Aspergillus nidulans* after growing the mold on phenylalanine [146]. As described by Scazzocchio [147], success with the *Aspergillus* genetic analysis led to similar success cloning the human *HGO* gene, using probes derived from the mold *hmgA*

and a spectrophotometric method to measure HGA by its absorption after conversion to maleylacetoacetic acid [148].

The human *HGO* gene has 14 exons encoding 445 amino acid residues which extend over nearly 60 kb of DNA. The gene is expressed in the liver, prostate, colon, and small intestine in particular, and there seems to be only one copy of the gene [145]. Two pedigrees were analyzed for mutations that might be expected to result in the loss of catalytic function. One mutation, Pro230Ser, was present in both parents in family M, and in one parent in family S. Another mutation, Val300Gly, was present in the other parent in family S. The affected children all had either a double dose of Pro230Ser, or were compound heterozygotes with both of these mutations. Expression experiments in *E. coli* of the wild type and Pro230Ser mutant forms of human HGO demonstrated that this single amino acid change in the protein structure caused a complete loss of enzymatic activity [145].

A more complete description of the human *HGO* gene has recently been published by the same laboratory [149], with further details about the regulatory regions, and the intronic and exonic characteristics. Several simple sequence repeats (SSRs) in the introns were polymorphic in their Spanish population sample, and these markers should be very useful in tracing particular *HGO* mutations in different ethnic groups and geographic areas in the future.

Researchers at the University of Würzburg recently reported the cloning of the mouse *HGO* gene [150]. In collaboration with Slovak investigators at the Komensky University they used the high degree of homology (93%) between human and mouse *HGO* to clone independently the human *HGO* gene [151]. They found the same 14 introns and coding sequence published by the Spanish group [145]. In four alkaptonuric patients from the Slovakian region they found two novel mutations: Gly481Ala, in exon 8, and a single base insertion in exon 7 (454–457insG), which leads to a stop codon, 21 codons farther downstream [151]. The relatively high prevalence of alkaptonuria in Slovakia (up to 1 in 19,000) will be explored with these new molecular probes to look for founder effects and the distribution of *HGO* mutations within this special population.

The Madrid laboratory has reported on the *HGO* mutations in 14 representative alkaptonuric subjects from six European countries, Algeria and Turkey. Point mutations believed to produce nonfunctional enzyme have been identified in 11 of the 14 exons, and several intronic defects are also believed to be responsible for this metabolic disorder phenotype [152]. They have recently added six additional mutations, bringing the total of known *HGO* mutations at this time to 27 [155]. These mutations and those found in the Slovak individuals and other locations are illustrated in Figure 8.

The associated polymorphisms and repetitive sequences found associated with the *HGO* gene and its mutations permit the designation of several distinct haplotypes, five of which are the most representative. These haplotypes will be very useful in exploring the long history and migration of the alkaptonuria mutations in different populations throughout the world.

DNA tests may also be used in the future in the detection of carriers among relatives of identified alkaptonuric patients, as well as the identification of variant forms of the disorder which would be expected to show some clinical differences from the standard phenotype.

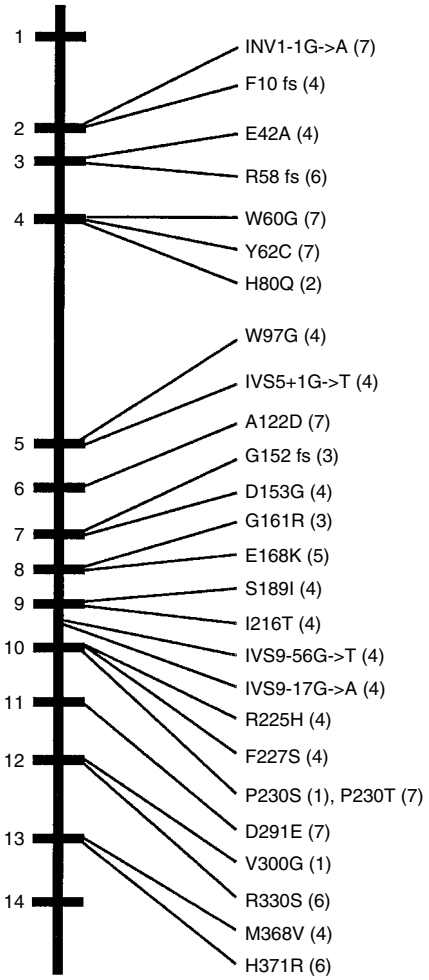

Figure 8. Locations of mutations causing alkaptonuria in the human homogentisic acid oxidase (*HGO*) gene. Mutations reported in [145] are indicated by (1); in [149] by (2); in [151] by (3); in [152] by (4); in [153] by (5); in [154] by (6); and in [155] by (7). The 14 exons of the *HGO* gene are represented roughly to scale.

TREATMENT

Attempts to treat alkaptonuria have been directed either toward correcting the underlying metabolic defect or preventing or reversing the pigmentation and arthritic changes. Galdston et al. [40] administered several vitamins, brewers' yeast, tyrosinase, insulin, and adrenocortical extract without altering the daily amount of HGA excreted by an alkaptonuric patient. Several groups have studied the effectiveness of vitamin C [40,156,157]. Although ascorbic acid corrects the alkaptonuria induced in guinea pigs by feeding large amounts of tyrosine [158], it does not change the defect in the hereditary type of human alkaptonuria. Other agents, such as vitamin B12 [159], and cortisone [160,161] are also without benefit, as far as correcting the metabolic defect is concerned.

At times, it has been suggested that dietary phenylalanine and tyrosine be reduced to decrease the output of HGA, but a severe restriction in the intake of these amino acids is not practical except for brief periods, and probably would

be dangerous to the alkaptonuric patient if continued for very long.

Since, from a practical standpoint, the important consequence of this metabolic disorder is that it leads to pigmentation and arthritis, an effective therapeutic measure could be aimed at preventing or correcting these outcomes. It is possible, as Sealock et al. pointed out [23], that increased tissue concentrations of ascorbic acid might prevent or greatly reduce the deposition of ochronotic pigment, even though this treatment would have no impact on the basic enzymatic defect.

The observation by Murray et al. [67] that ascorbic acid protects lysyl hydroxylase from inhibition by HGA (possibly via benzoquinoneacetic acid [162]), leads to the obvious suggestion that prolonged maintenance of relatively high tissue concentrations of ascorbic acid might delay, and possibly reduce, the degree of pathologic changes in the connective tissues. At least, extended clinical experience giving a gram or so of ascorbic acid per day in divided doses is worth investigating [163,164]. It has been claimed that an alkaptonuric patient with arthritis showed symptomatic improvement after taking 2 g of ascorbic acid per day [165]. Megadoses of ascorbic acid, however, should probably be avoided and could be counterproductive, since, at very high levels, ascorbic acid may compete with and compromise the active secretion of HGA by the kidney.

NTBC (mesotrione), [2-(2-nitro-4-trifluormethylbenzoyl)-cyclohexane-1,3-dione], a potent inhibitor of *p*-hydroxyphenylpyruvate oxidase (*p*HPPO), is used to treat hereditary tyrosinemia (MIM 276700). Recently, this inhibitor has also been suggested as a possible treatment for alkaptonuria, since it should theoretically shift the metabolic block from HGO to the preceding metabolic step, *p*HPPO (see Fig. 7), and prevent the formation of HGA. However, many uncertainties remain, such as the safety of long-term use of NTBC, at what age the treatment of alkaptonurics should start, and whether a complete metabolic block would be necessary. Although metabolic inhibitors for treating severe disorders, like tyrosinemia, have gained ready acceptance because of the dire consequences of no treatment, great care must be taken in the chronic treatment of disorders that are less

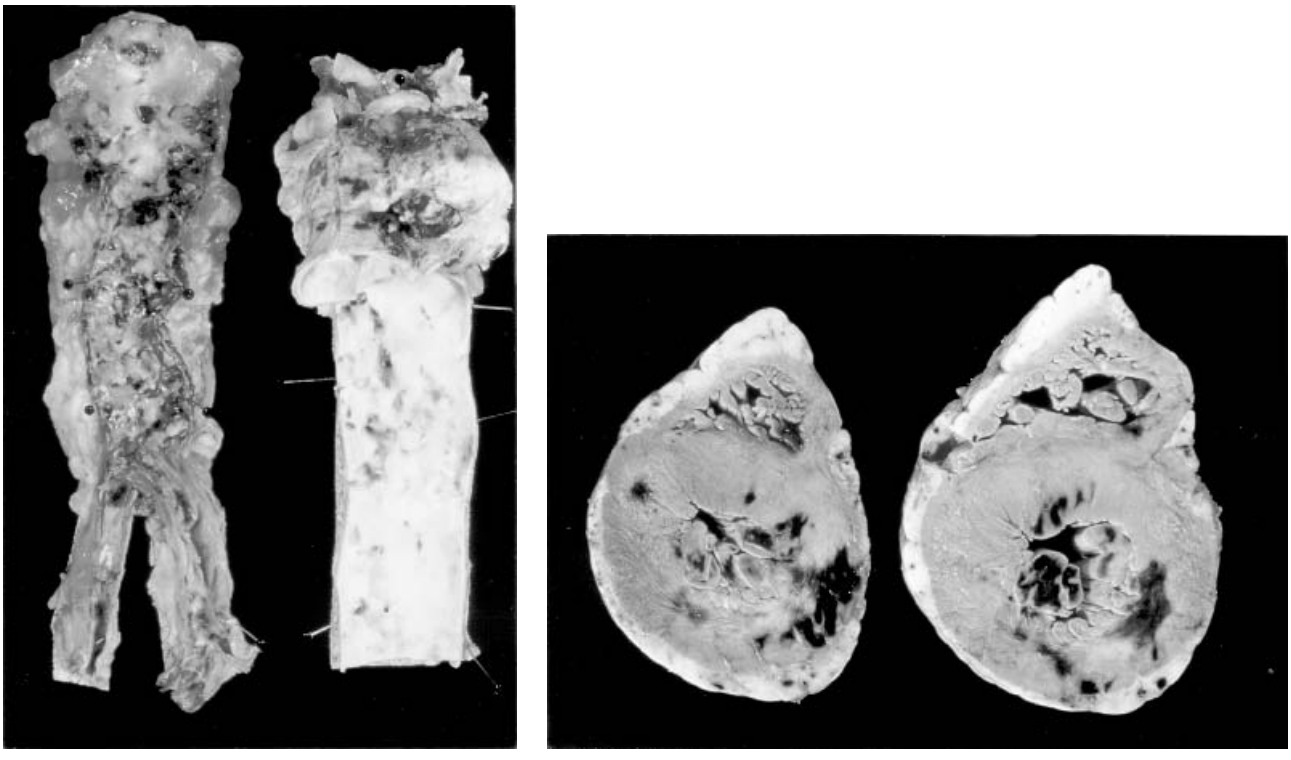

Figure 9. The 68-year-old woman whose tissues are shown, died of cardiac insufficiency 2 weeks after an aortocoronary bypass operation and aortic valve replacement for coronary heart disease and severe aortic stenosis. Both mammary arteries had to be used for the procedure because the leg veins were damaged as a result of the multiple orthopedic operations she had previously undergone (see below). Dissections of both mammary arteries, probably due to alkaptonuria-related vessel wall changes, were found at autopsy. The patient had a long-standing history of generalized arthritis, and total prostheses had been implanted in both knee and both hip joints. Endarterectomy of both carotid arteries, as well as percutaneous transluminal angioplasty of the right femoral artery for symptomatic arteriosclerosis, had been performed on different occasions within the previous 15 years. She reported that her urine darkened in contact with air and her underwear often displayed dark stains. On clinical examination marked blueness of the sclerae as well as dark conchae and anthelixes could be seen. Marked arteriosclerosis of the abdominal aorta with dark pigmentation on the left, compared with the less severely affected thoracic aorta on the right (**A**). Pigment deposition in the infarcted myocardium (**B**) and in the cerebellum at infarcted areas which showed histologic signs of cellular organisation (**C**). The surface of the kidneys was irregular and presented dark spots (**D**). (For alkaptonuric spine changes in the patient, see Fig. 6, left panel.) (Courtesy of Dr. B. Bode, Department of Pathology, University Hospital, Zurich.)

severe and have slowly acquired pathology, like alkaptonuria. It is probable, however, that this approach for treating alkaptonuria will be tried and evaluated during the next few years.

The recent advances in our understanding of the molecular defect in alkaptonuria will, no doubt, encourage the application of genetic engineering to replace the missing enzyme by recombinant techniques. While it may be possible to achieve such a result at some time in the future, it is important now to be aware of the potential toxicity of some of the intermediary compounds that occur later in the tyrosine metabolism pathway, particularly maleylacetoacetic acid and fumarylacetoacetic acid. Extensive conversion of HGA to these later metabolites in inappropriate environments, where they may not easily be further metabolized, might result in even greater toxicity for the patient than that produced by HGA, itself [166].

RECENT DEVELOPMENTS

Details have been received of a 47-year-old man with alkaptonuria who exhibited progression of his ochronosis much more rapidly than his two affected siblings. In fact, his skin was extremely dark. It was determined that he suffered from diabetic nephropathy with glomerular insufficiency. His plasma HGA level was approximately twice that encountered in other alkaptonuric patients, while his urinary HGA level was typical of the disorder. After receiving a renal allograft from his homozygously normal sister, his renal function normalized, and his plasma HGA level fell by approximately one-half, as did his 24-hour urinary output of HGA. This suggests that the transplanted kidney provided secretory function, and may also have provided HGO activity; (personal communication, W. Introne, C. Phornphutkul, I. Bernardini, W. Gahl. 23 October 2001).

Fibrodysplasia Ossificans Progressiva

Frederick S. Kaplan, Eileen M. Shore and J. Michael Connor

Departments of Orthopaedic Surgery (F.S.K., E.M.S.) Medicine (F.S.K), and Genetics (E.M.S.), The University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania 19104; Department of Medical Genetics, Duncan Guthrie Institute, University of Glasgow, Yorkhill, Glasgow G3 8SJ, United Kingdom (J.M.C.)

SUMMARY

- **Fibrodysplasia ossificans progressiva (FOP) is a rare autosomal dominant disorder of connective tissue.**
- **The classic phenotype of FOP includes the diagnostic triad of congenital malformation of the great toes; progressive heterotopic ossification of skeletal muscles, tendons, ligaments, and fascia in an endochondral process; and progression of disease activity in characteristic anatomic patterns (dorsal to ventral, axial to appendicular, cranial to caudal, and proximal to distal).**
- **Ectopic ossification in FOP usually begins in the muscles of the neck or back as soft tissue swellings that look like tumors. The lesions appear rapidly, tend to be asymmetric, and are variable in both size and shape, frequently leading to misdiagnosis of a neoplastic process.**
- **Cells from FOP patients show increased expression of bone morphogenetic protein-4 (BMP-4).**
- **A genome-wide linkage analysis using four families with inheritance of FOP revealed consistent linkage of FOP with the 4q27-31 region of chromosome 4. The *BMP4* gene is not within this locus, but genes involved in the BMP signalling pathway, as well as other candidate genes, have been identified in this interval.**
- **There is no established medical treatment for FOP. Creative use of BMP technology will likely have important applications in the inhibition of heterotopic ossification in diseases such as FOP. Soluble BMP receptors, dominant negative receptors, and BMP antagonists may show promise in binding and physiologically inactivating BMP where it is not needed or wanted.**

INTRODUCTION

Fibrodysplasia ossificans progressiva (FOP) (MIM 135100) (synonym: myositis ossificans progressiva) is a rare autosomal dominant disorder of connective tissue in which severe disability due to progressive soft tissue ossification accompanies characteristic skeletal malformations. Early case reports were provided by Guy Patin in 1692 [1] and by John Freke in 1736 [2], but it was not until 1879 that Helferich described the characteristic associated malformation of the big toes [3]. By 1918, Rosenstirn [4] was able to identify 115 definite cases of FOP in the world literature. The number of reported cases now exceeds 600 and includes several large series [5–10] in addition to multiple single case reports. Two attempts at complete ascertainment have been made. A minimum point prevalence of 1 patient per 1.64 million of the population was found in the United Kingdom [11], and a similar point prevalence was recently found in France (Le Merrer, Hôpital Necker, Paris; personal communication). The sex ratio is equal, and FOP has been reported in all ethnic groups.

CLINICAL FEATURES

The principal clinical features of FOP are skeletal malformations and soft tissue ossification. Although malformations may be demonstrated radiologically at a number of sites in the skeleton, they are evident clinically only in the hands and feet [7]. Characteristically (90% of patients), the big toes are short with malformations of the first metatarsals, and contain only a single phalanx which may be deviated laterally (Fig. 1). Less commonly (10% of patients), the big toes are of normal length, but are stiff from early childhood or become rigid in adolescence. Rarely, severe reduction defects of all toes are present [7,8].

Short thumbs, due to short first metacarpals, are seen in about 50% of FOP patients, and incurved little fingers are seen in a similar percentage of individuals. Occasionally, shortening or stiffening of other digits may be apparent. All of these digital malformations in FOP are bilaterally symmetrical [7,8].

The pregnancy, birth history, and birth weight of FOP patients are unremarkable. The shortened big toes may be noted at birth, but tend to be misdiagnosed as isolated congenital hallux valgus. The child is otherwise asymptomatic until soft tissue ossification begins.

Ectopic ossification in FOP usually presents as a series of lumps in the muscles of the neck or back [8,12] (Fig. 2). Typically, these lumps are first noted at 2–6 years of age,

Connective Tissue and Its Heritable Disorders, pages 827–840

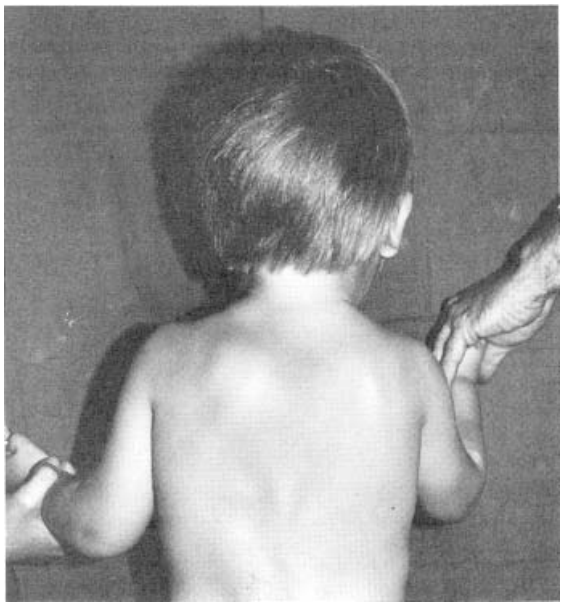

Figure 2. Early paraspinal ossifying lumps.

but they may occasionally be present at birth, or be first noted only after adolescence [9,13,14]. Soft tissue swellings that look like tumors appear over several hours, tend to be asymmetric, and are variable both in size and shape leading to suspicion of a neoplastic process [15]. They may or may not be painful and the overlying skin may be warm and reddened, leading to suspicion of an infective process [10]. Lumps are usually firm in texture and gradually shrink in size over several days or weeks. They may be succeeded by other lumps, and this often gives the patient the mistaken impression that the lumps are moving about [8]. Occasionally, fever or malaise accompanies the appearance of new lumps, but in general constitutional disturbance is absent [16]. The lumps themselves cause stiffness, which improves as they subside, but the disease process continues, and when ectopic bone forms, irreversible limitation of movement becomes apparent [9]. Mature heterotopic bone replaces skeletal muscle, tendon, ligaments, and fascia, locking joints in place, and rendering movement completely impossible [13] (Fig. 3). Flare-ups in limb musculature and soft tissues can often be mistaken for thrombophlebitis [17].

The majority of episodes of ectopic ossification occur spontaneously, although local trauma may result in an exacerbation. Local trauma may include intramuscular injections [18], lump biopsy [19], operations to excise ectopic bone [10], accidental injury [20], falls [21], dental therapy [22,23], and careless venepuncture.

Ectopic bone in FOP has a predilection for certain sites. The axial musculature bears the brunt of the disease. Limb involvement tends to be most marked proximally; with proximal muscle involvement preceding distal involvement, axial involvement preceding appendicular involvement, and dorsal involvement preceding ventral involvement [9]. Limited jaw opening is also extremely common [22–25]. In contrast, involvement of the muscles of the face is uncommon. Certain muscles, including the tongue, the extraocular muscles, the diaphragm, heart, sphincter muscles, and visceral smooth muscle are never involved [8,9].

Ectopic bone formation also occurs in ligaments, fasciae, aponeuroses, tendons, and joint capsules [5]. Skin is not directly involved, as in a related condition, progressive osseous heteroplasia (POH) (MIM 166350), but ulceration over a projecting mass of bone may occur [19].

Stiffness of the cervical spine is a common early finding [26]. Later, fixation of multiple major joints in a variety of positions results in a progressive loss of mobility [13]. Ultimately, the patient becomes virtually immobilized, with residual movements possible only in the distal limbs, tongue, face, and eyes [13]. Submandibular swelling can be a life-threatening complication especially when associated with massive anterior neck swelling and difficulty in swallowing [22]. Special measures to decrease swelling, including a course of glucocorticoids may be warranted [22].

Hearing impairment, first noted by Lutwak [27], is a common feature of FOP [6,8] occurring in 52% of patients [28]. The onset is usually in adolescence or early adult life, and develops over a period of some weeks, but is then nonprogressive. The hearing loss is usually conductive and may be due to middle ear ossification, but in the only patient who has had surgical exploration of the middle ear, a mobile ossicular chain was found with no evidence of stapedius ossification [29].

Ocular problems do not occur in FOP and mental development is usually normal. Two patients in the series of Connor and Evans [8] were mildly mentally retarded and, interestingly, these two also had the most severe hand and foot malformations with reduction defects of all digits.

Other highly variable features include diffuse scalp baldness, excessive skin seborrhea, menstrual irregularities, and premature menopause [8]. Sexual development is usually normal, although lack of breast development in females appears to be a common feature of the condition. Longitudinal growth appears to be normal, although severe scoliosis may develop, especially when asymmetrical heterotopic ossification of the spine occurs early in life [30].

RADIOLOGICAL FEATURES

The radiological findings in FOP illustrate the combination of skeletal malformations, ectopic ossification, and skeletal changes secondary to immobilization and activity [31].

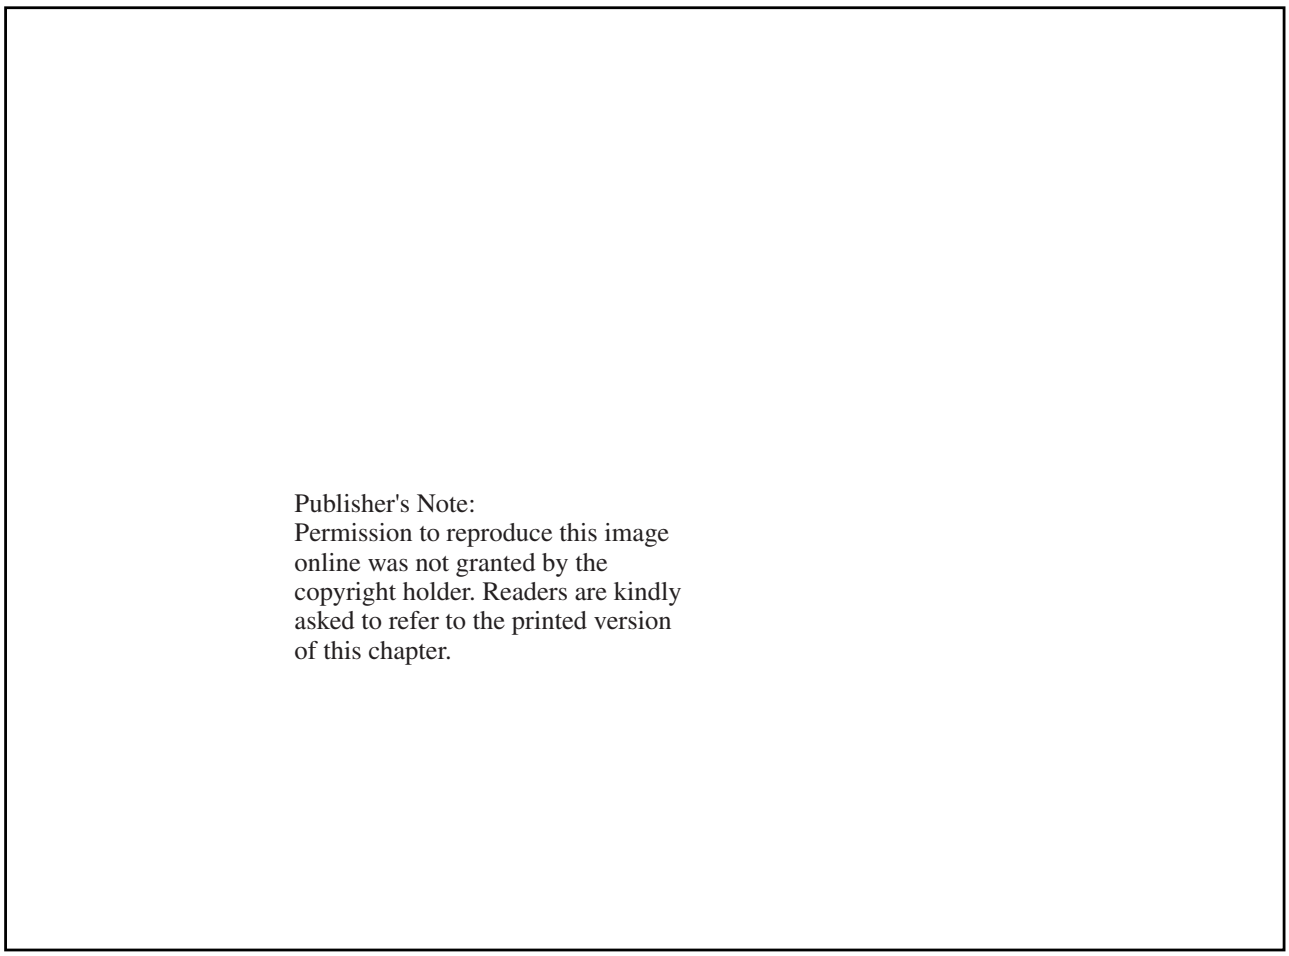

Figure 3. Clinical photograph and skeleton of a man with fibrodysplasia ossificans progressiva. The rigid posture noted in this 25-year-old man with fibrodysplasia ossificans progressiva is due to ankylosis of the spine, shoulders and elbows. Plates and ribbons of ectopic bone contour the skin over the back and arms (**A**), and can be visualized directly on the skeleton (**B**) (following death from pneumonia at age 40 years). In addition to malformations of the digits, other skeletal malformations may include the following: short, broad, femoral necks; shallow acetabula; small mandibles and osteochondromas, especially along the medial borders of the proximal tibiae; a narrow anteroposterior lumbar spinal canal; a decreased humeral epicondylar angle; and misshapen cervical vertebrae [12,32,33]. The malformations of the cervical spine are characteristic and consist of small vertebral bodies, enlarged pedicles, and large spinous processes. Progressive fusion of both the bodies and the apophyseal joints may occur and may actually represent segmentation defects [26] (Fig. 4).

In the hands, common findings are short first metacarpals and malformed middle phalanges of the fifth finger, occasionally with an accessory epiphysis. The changes in the feet are more variable. Commonly, only a single phalanx is present in each big toe, though in early childhood there may also be an accessory epiphysis near the head of the first metatarsal, which later fuses with either the metatarsal or the single phalanx [7] (Figs. 5, 6).

Some patients have two malformed phalanges in each big toe, which later fuse (Fig. 7), while occasionally the initial radiographs of the feet are entirely normal. Synostosis of the phalanges, both of the big toe and of the thumb, often occurs in later childhood and may also occur in the other toes [7]. Patients occasionally have severe reduction defects of all digits (Fig. 8).

Ectopic bone is apparent on radiographs as early as six weeks after the initial appearance of an ossifying lump. Ectopic bone matures through an endochondral process, develops normal trabecular architecture, and eventually develops secondary synostoses to the normotopic skeleton [31] (Figs. 9–11). Radionuclide bone scans show increased uptake at ossifying sites before new bone can be documented radiologically [34,35]. Reinig et al [36] have investigated 12 FOP patients with serial computerized

tomography (CT) scans. Initially during a flare-up, swelling is observed in the muscle fascial planes (corresponding to the active phase on the bone scan) and subsequently ectopic bone is seen.

Benign chondro-osseous neoplasms, including osteochondromas and enchondromas, have been reported [12,37].

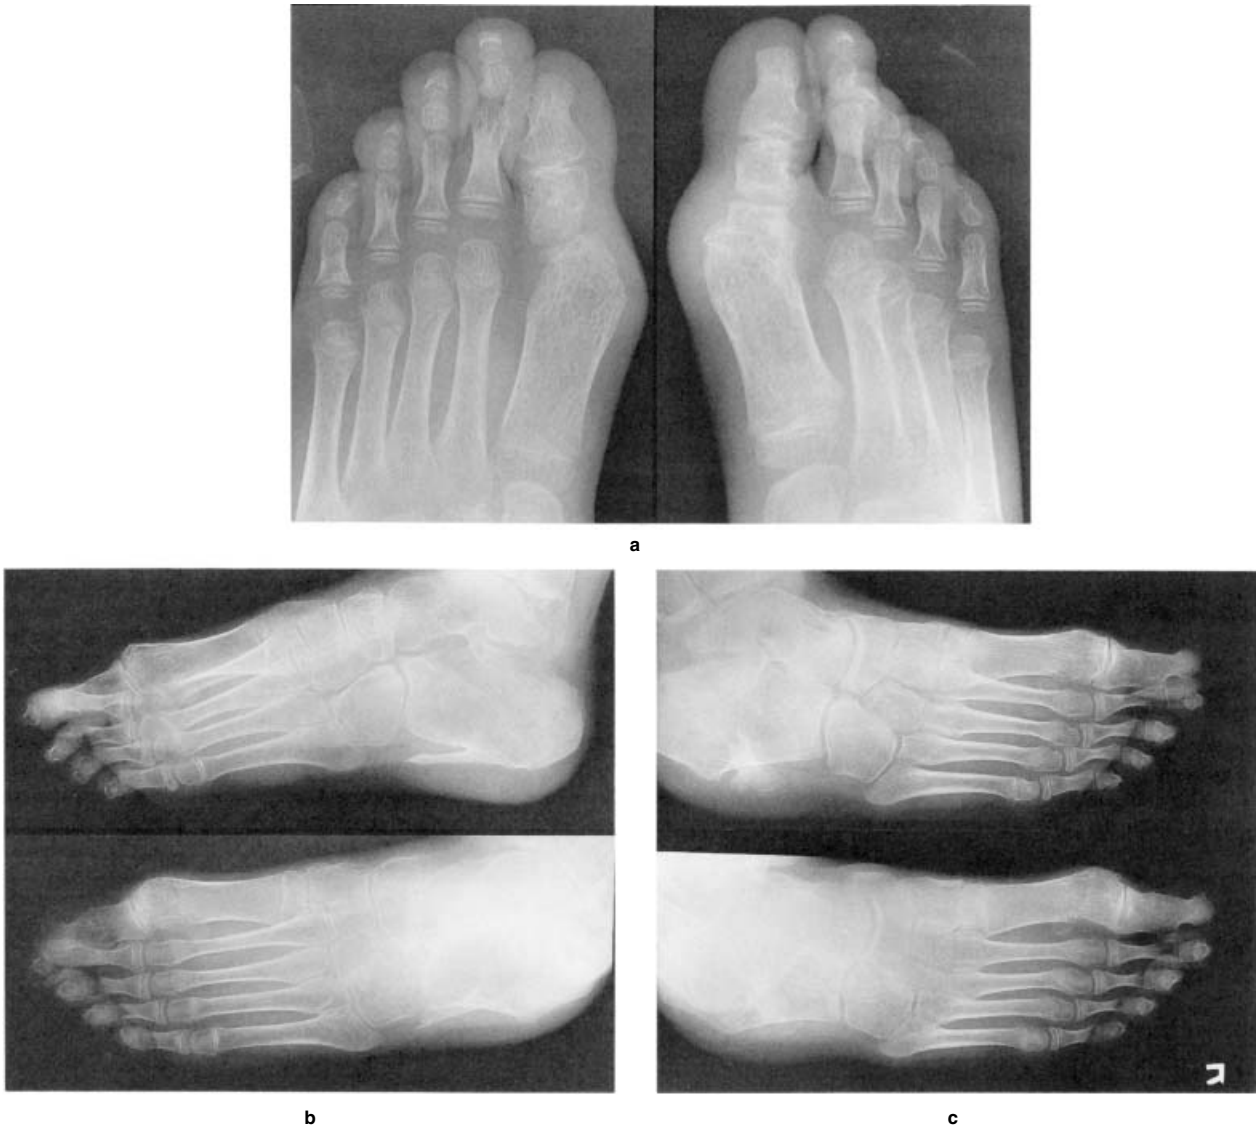

Figure 7. Progressive fusion of two malformed phalanges in the big toes at 7 years (**a**) and at 14 years (**b**). Note ossification of the ligamentous insertion of a muscle or aponeurosis into the calcaneum of the left foot, and of the soft tissue beneath the calcaneum of the right foot.

Immobilization results in disuse osteoporosis, and this is most marked in the region of ankylosed joints [31] (Fig. 11). Therapy may also produce radiological changes, e.g., osteoporosis in patients on corticosteroids, and widening of the physis and disorganized metaphyseal bone growth in patients on long-term sodium etidronate [38].

LABORATORY STUDIES

Routine biochemical and hematological investigations are normal in FOP, as is urinary excretion of hydroxyproline [10,39]. Abnormal electrocardiograms are often noted and include bundle branch blocks, ST segment changes, and evidence of right ventricular dysfunction [40,41]. Pulmonary function tests, even in childhood, reveal a restrictive ventilatory defect and reduced lung volumes, but arterial blood gases have been normal in the few patients in whom they have been measured, until late in the course of the disease when mild chronic carbon dioxide retention has been noted [40,41].

NATURAL HISTORY

Erratic progression of disability is usual in FOP. Patients typically have long periods of apparent disease inactivity, but, in general, limitation of the spine and both shoulders is present by 10 years of age. One or both hips are generally involved by 20 years of age, and most patients are chair-bound or bed-bound by 30 years of age [8,9,13]. Ectopic ossification, though generally less frequent in adults, does not stop completely and continues into old age [8,13]. The ultimate level of disability does not appear to be related to the patient's sex, age of onset of heterotopic ossification, or type or extent of skeletal malformations. Once present, disability is permanent [13].

Figure 11. Ankylosis of the hip in a 24-year-old female. Disuse osteoporosis of the femur is contrasted dramatically with ossification of the adductor muscle, which shows well-formed cortical bone. (Reprinted, with permission, from Giedion [105].)

Although life span is reduced in FOP, most patients will reach adult life. The average age at death of 33 patients was 34.7 years [42] and several patients have survived into old age [14]. Pneumonia has been reported to be the usual terminal illness and this is promoted by the chest wall restriction. However, the more recent anecdotal experience of the authors suggests a high incidence of sudden death syndrome associated with sleep apnea, late in the course of the disease. Formal sleep studies with prospective

measurement of blood gases have not been performed, but patients should be cautioned not to use oxygen therapy in an unmonitored setting, especially during sleep. Some patients have died from starvation secondary to jaw fixation, brain injury following a fall, or suicide [21]. Although lesional biopsies are commonly misdiagnosed as sarcomas, there does not appear to be an increased incidence of malignant disease in FOP patients [15].

PATHOLOGICAL STUDIES

Biopsy specimens of FOP lesions are exceedingly rare. Tissue samples are available only rarely from nonelective surgical procedures or from biopsies taken prior to the diagnosis of FOP.

Early FOP lesions exhibit an intense perivascular lymphocytic aggregation followed by invasion of lymphocytes into the surrounding muscle with subsequent myocyte death. Interfascicular fibroproliferative tissue follows with extensive neovascularity [43]. Levels of basic fibroblast growth factor (bFGF), an extremely potent angiogenic peptide, are markedly elevated in the urine of patients with FOP during times of disease flare-up [44], correlating with the appearance of the vascular fibroproliferative lesion. A role for hematopoietic cells in heterotopic osteogenesis has been suggested [45]. Immunohistochemical evaluation of lymphocyte markers revealed a predominance of perivascular B-lymphocytes and a mixed population of B-lymphocytes and T-lymphocytes weakly positive for bone morphogenetic protein-4 (BMP-4) invading the skeletal muscle [43]. Whether the early lymphocytic infiltration is a causative or reactive event, or both, cannot be determined from the observations in the small sample of patients examined.

Intermediate stage FOP lesions cannot be distinguished histologically from aggressive juvenile fibromatosis, a condition that does not progress to form bone [15], but immunohistochemistry can be useful [12,46]. BMP-4 expression has been detected in cultured fibroproliferative cells and in intact tissue specimens from pre-osseous FOP lesions, but not in aggressive juvenile fibromatosis lesions [15,47]. Later stage FOP lesions show characteristic features of endochondral ossification including chondrocyte hypertrophy, calcification of cartilage, and formation of lamellar bone with marrow elements, almost identical to the pattern seen in a normally developing growth plate or in fracture repair.

INHERITANCE

Genetic Transmission

Most described cases of FOP result from new mutations, with the mutation rate estimated to be $1.8\ (SE \pm 1.04) \times 10^{-6}$ mutations per gene per generation [11]. The rarity of FOP suggests the likelihood of a single mutated locus causing the disorder in all or most individuals, and recent genome-wide linkage analysis in four small multi-generational families suggests linkage to a region on the long arm of human chromosome 4 [48].

Reproductive fitness in FOP is low, and only a few examples of inheritance of FOP within a family have been documented [5,11,20,27,40,49–51]. Previous major reviews of FOP reported no clear examples of dominant transmission [6,8]. The autosomal dominant inheritance of FOP was first suggested in 1886, in a 7-year-old boy with characteristic features of FOP, whose father had the same congenital deformity of the great toes but no other features of this disorder [52]. Similar occurrences were reported soon after [53–56].

Kaplan et al. [20] reported a father, two daughters, and a son affected by FOP. This family showed little variability in phenotype between affected individuals. Connor et al. [57] reported a three-generation family with FOP with a wide range of phenotypic severity, ranging from disabling ectopic bone formation and premature death to an asymptomatic adult whose only manifestation was a malformation of the big toes.

Two case reports of FOP in identical twins [58,59] have been noted. The parents had no sign of the condition. The first suggestion of gonadal mosaicism in FOP was reported in two half-sisters with the same unaffected mother and different unaffected fathers [60], raising the possibility that the mother had a mutant gene for FOP in multiple ova but that the mutant gene was present in few or no somatic cells. Gonadal mosaicism is a proven cause of recurrence in sibs of other autosomal dominant disorders [61].

Although variable expressivity of the FOP phenotype is widely accepted, there is little evidence that the condition is nonpenetrant [11]. However, a report of one family with affected cousins does suggest the remote possibility of nonpenetrance [5,49].

Risk of Inheritance

There is a 50% percent chance that any child of a person with FOP will themselves have the condition. There is no documentation of successful prenatal diagnosis of FOP [62]. Theoretically, ultrasound may be able to identify skeletal changes, but it is unknown whether these are apparent early enough in the pregnancy when termination is generally considered acceptable. An increased paternal age has been suggested as an associated risk factor for occurrence of FOP [11,63,64].

Counseling a family that has one child with FOP requires that both parents be examined thoroughly. Examples of a parent with mild features, such as short, laterally deviated great toes, with a child showing the complete FOP phenotype have been observed [52,53,57]. The possibility of gonadal mosaicism [60] means that the parents cannot be absolutely reassured, but can be given a very low recurrence risk.

MOLECULAR GENETICS

Candidate Gene Approach

Positional cloning was, until recently, impractical for FOP due to the small number of affected individuals and the lack of multigenerational families showing inheritance of the disease. The candidate gene approach has been pursued as an alternative indirect method in an attempt to identify the mutated gene. In selecting a candidate gene for FOP, the main diagnostic criteria (congenital malformations of the great toes, heterotopic endochondral ossification, temporal and spatial patterns of ectopic bone formation) must be considered. The candidate gene for FOP must be functional during normal embryonic development (to account for the malformations of the big toe), as well as being active postnatally to induce heterotopic ossification in tendon, ligament, fascia, and skeletal muscle.

Bone Morphogenetic Protein (BMP) Genes

The genes that best fit the criteria of an FOP candidate gene are those that encode the bone morphogenetic protein (BMP) family and other components in the BMP signal transduction pathways [65–72].

The BMP genes, members of the larger transforming growth factor beta (TGF-β) superfamily of peptides, have been highly conserved throughout evolution [65], and genes with a high degree of homology with members of the mammalian BMP family have been found in the fruit fly, *Drosophila melanogaster* [65,69,71]. The *BMP2* and *BMP4* genes, which produce proteins that are about 90% homologous to each other, are also homologous to the *Drosophila decapentaplegic* (*dpp*) gene. The DPP protein shows ~75% amino acid identity to BMP-2 and BMP-4 in the mature carboxyl-terminal region, which is the mature functional domain of these proteins.

In *Drosophila*, the *dpp* gene is an essential gene in early embryonic development, as well as later in development when it provides necessary information for limb formation [65]. The pattern of *dpp* expression is analogous to the expression of BMP-2 and BMP-4 in vertebrate development [65,69,71]. These BMPs play critical roles both in early embryogenesis and in skeletal formation, important criteria for FOP candidate genes. BMP-4 and DPP both appear to function by directing cell fate [65,73]. The absence of BMP-4 in a transgenic knockout mouse is lethal in early embryogenesis, resulting in little or no mesodermal differentiation, and no hematopoiesis [70,74]. BMP-4 has also been implicated in patterning of the developing mouse and human limb [75–77]. Over-expression of BMP-4 in the chick embryonic limb bud is associated with ectopic osteogenesis and polarizing defects in limb formation [78].

BMP Expression in FOP

Although early FOP lesions are histologically identical to those of aggressive juvenile fibromatosis, these two disorders can be distinguished by immunohistochemistry with BMP-2/4 antibodies [15]. Tissue from aggressive juvenile fibromatosis lesions (which do not progress to form bone) shows no binding of BMP-2/4 antibody, while FOP lesional tissue binds the antibody, indicating the presence of the BMP proteins within early stage FOP lesions that will progress to endochondral ossification.

Cells derived from a pre-osseous FOP lesion and from immortalized lymphoblastoid cell lines established from FOP patients showed increased expression (by Northern analysis and ribonuclease protection assay) of BMP-4 but not BMP-2 compared to controls. In addition, correlation of BMP-4 expression with FOP was observed in a family showing inheritance of FOP: the affected father and three affected children expressed BMP-4, while the unaffected mother did not [47]. Further studies have verified that BMP-4 protein is synthesized in lesional cells from patients who have FOP [15].

Steady-state levels of mRNA expression for BMP-4 and the BMP receptors were evaluated using semi-quantitative reverse transcription polymerase chain reaction (RT-PCR) and documented the presence of Type I and Type II BMP-4 receptor mRNAs in FOP lesional tissue as well as in unaffected muscle tissue [79]. In lymphoblastoid cell lines of affected individuals in a family that exhibited autosomal dominant inheritance of FOP, the previous finding of elevated steady-state levels of BMP-4 mRNA was confirmed [79], but no differences in the steady-state levels of mRNA for either the Type I or Type II BMP-4 receptors were observed between affected and unaffected individuals in the same family.

Recent results have indicated that the increased levels of BMP-4 mRNA in FOP cells result from an increased rate of transcription of the *BMP4* gene [80]. The increased activation of BMP-4 in FOP cells may be due to a mutation within the *BMP4* gene itself or to a mutation in another genetic locus that causes over-expression of BMP-4 in the cells of FOP patients. The structure and function of the human *BMP4* gene is currently being examined in order to understand how it is regulated [81]. An examination of the exon-coding sequences of the *BMP4* genes of patients with FOP has identified no mutations in these transcribed regions [82].

Linkage analysis of two small families with autosomal dominant transmission of FOP has been performed using a highly polymorphic microsatellite marker near the *BMP4* gene locus [83], in order to determine whether the *BMP4* gene is consistent with or excluded from linkage with FOP in these two families. In one family [20], which showed the classic phenotypic features of FOP (as described above), the results were consistent with linkage to *BMP4* and the lymphoblastoid cells of affected members expressed high levels of BMP-4 mRNA. In the second family [57], in which affected members showed mild phenotypic features of FOP, linkage of FOP and *BMP4* was excluded; interestingly, BMP-4 expression levels were not elevated in affected members of this family.

Recently, a genome-wide linkage analysis using four families showing inheritance of FOP revealed consistent linkage of FOP with the 4q27-31 region of chromosome 4 [48]. The *BMP4* gene is not within this locus, but genes involved in the BMP signaling pathway, as well as other candidate genes, have been identified in this interval.

Genetic mutations in FOP could reside anywhere in the BMP-4 signaling pathway [48], or in other molecular pathways that affect the level of BMP-4 expression. Additional information about the cellular and molecular events that occur during the progression of FOP lesion formation, as well as a better understanding of the events that induce bone formation during normal embryonic development and fracture healing, will both expand the list of candidate genes and focus on the most likely causes of this disorder.

ANIMAL MODELS OF FOP

A fibrodysplasia ossificans progressiva-like condition has been recognized in cats, and six sporadic cases have been reported [84–87]. The disease occurs in both males and females, and is seen in both the domestic short-hair and domestic long-hair cat. At diagnosis, affected cats ranged from 10 months to 6 years of age. Unlike the disease in man, affected cats do not have congenital malformations of the distal limbs. Radiography revealed multiple foci of heterotopic ossification within affected muscles. Intense perivascular lymphocytic infiltration at the advancing edge of fibroproliferative lesions was nearly identical to that seen in human FOP lesions. There is marked proliferation of connective tissue followed by cartilage and bone formation within epimysium, tendons, and fasciae. The clinical course of the feline disease is rapid, with the development of severe disability within weeks to months. The FOP-like disease in the cat closely mimics FOP in humans, and may serve as an animal model for this disorder. Unfortunately, all evaluations performed to date have been post-mortem studies on pet cats, and no live animals are currently available for examination.

In a compelling transgenic animal model, murine embryonic overexpression of the *c-fos* proto-oncogene leads to postnatal heterotopic chondrogenesis and osteogenesis, with phenotypic features similar to those seen in children who have FOP [88]. The over-expression of Fos protein

in embryonic stem cell chimeras leads to heterotopic endochondral osteogenesis mediated, at least in part, through a BMP-4 signal transduction pathway. In contrast, early FOP lesions express abundant BMP-4 without over-expression of c-Fos, suggesting that the primary molecular defect in FOP may be independent of sustained Fos effects on chondrogenesis and osteogenesis [88,89].

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Patients with FOP are frequently diagnosed incorrectly, most often with aggressive juvenile fibromatosis, prior to the correct diagnosis of FOP (MIM 135100). The diagnosis of FOP should be suspected from the appearance of the toes at birth and from the emergence of soft tissue swellings on the neck and back during the first decade of life, even before the appearance of radiographically demonstrable heterotopic ossification. If the correct identity of the disease eludes the observer and an unfortunate biopsy is performed, the appearance of a highly vascular fibroproliferative lesion should provoke suspicion of FOP. The radiographic appearance of segmentation defects of the cervical spine, or the clinical appearance of asymmetric fibroproliferative swelling in a sternocleidomastoid muscle could mistakenly provoke diagnostic consideration of Klippel-Feil syndrome (MIM 148900) or idiopathic torticollis (MIM 128100; MIM 602124), respectively.

In children who present with heterotopic ossification of the skin and progressive involvement of deep connective tissue and skeletal muscle, the diagnosis of progressive osseous heteroplasia (POH) must be considered (MIM 166350). POH is a recently described genetic disorder of mesenchymal differentiation characterized by dermal ossification during infancy and by progressive heterotopic ossification of cutaneous, subcutaneous and deep connective tissues during childhood [90]. The disorder can be distinguished from FOP by the presence of cutaneous ossification, by the absence of congenital malformations of the skeleton, by the absence of tumor-like swellings, by the asymmetric mosaic distribution of lesions, by the absence of predictable regional patterns of heterotopic ossification, and by the predominance of intramembranous rather than endochondral ossification. POH can be distinguished from Albright's hereditary osteodystrophy (AHO) (MIM 103580) by the progression of heterotopic ossification from skin and subcutaneous tissue into skeletal muscle, by the absence of morphologic features associated with AHO, and by the presence of normal endocrine function.

PREVENTION AND MANAGEMENT

Preventive measures are directed at avoiding trauma that might stimulate the induction of a new lesion. Once FOP is diagnosed, all intramuscular injections and all dental blocks using local anesthetic must be avoided [18,23]. Assiduous attention should be directed to dental hygiene to decrease the necessity for therapeutic dental intervention [23,91].

Falls are a common cause of severe morbidity in patients with FOP [21]. The head is a common site of injury in FOP, and the injury profile includes traumatic brain injury, intracranial hemorrhage, and death. Deficiencies in coordinate gait and upper limb protective function likely account for the severity of head injuries in the FOP population. Precautions are intended to minimize the risk of injury without compromising a patient's functional level or independence. These include limitation of high-risk activities, the use of protective head gear, and the institution of safety improvements in living environments.

There is no established medical treatment for FOP [92–94]. The rarity of the disorder, its variable severity, and the fluctuating clinical course are substantial difficulties in evaluating potential therapies.

Physical therapy may be harmful and may provoke new lesions [11]. Surgical release of joint contractures is generally unsuccessful and risks new, trauma-induced heterotopic ossification [11]. Osteotomy of ectopic bone to mobilize a joint is usually counterproductive because of robust heterotopic ossification at the operative site. Spinal bracing is ineffective, and surgical intervention is associated with numerous complications [30]. Dental therapy should avoid mandibular blocks and stretching of the jaw [23,95]. Newer dental techniques for focused administration of anesthetic are available. Guidelines for general anesthesia have been reported [96]. All intramuscular injections should be avoided [18].

Adrenocorticotrophic hormone, corticosteroids, binders of dietary calcium, intravenous infusion of ethylenediaminetetraacetic acid (EDTA), nonsteroidal anti-inflammatory agents, radiotherapy, oral disodium etidronate, and warfarin (to inhibit gamma-carboxylation of osteocalcin) are generally ineffective [97,98]. Two recent studies suggest possible, very limited, benefits from a course of intravenous etidronate [99] or prophylactic use of 13 *cis*-retinoic acid [99,100]. Accordingly, medical intervention is currently supportive.

Creative use of BMP technology will likely have important applications in the inhibition of heterotopic ossification in diseases such as FOP. Soluble BMP receptors, dominant negative receptors, and BMP antagonists may be promising in binding and physiologically inactivating BMP where it is not needed or wanted [101]. The hope for an effective treatment for FOP has been increased by the recent discovery of BMP-4 overexpression in the condition [47,102,103]. "With so much being discovered about how the BMPs act," says Brigid Hogan, a developmental geneticist at Vanderbilt University in Nashville, Tennessee, "it might be possible to develop drugs that would block some part of the BMP-4 pathway — and therefore prevent the progression of what is a horrible nightmare disease" [104].

RECENT DEVELOPMENTS

Identification of the Genetic Cause of FOP

Because of the typically debilitating nature of FOP, few examples of inheritance from parent to child are known. Four small multigeneration families were identified, however, and have been used in a genome-wide linkage analysis [106]. This analysis linked the FOP phenotype to markers in a 36 cM region of 4q27–31 (with a lod score of 3.10 at recombination fraction 0), supporting an earlier study [83] that excluded linkage of FOP to the *BMP4* gene on chromosome 14. Several candidate genes for FOP have been identified within the chromosome 4q27–31 linkage interval and the coding regions of several of them, including *SMAD1*, have been examined for mutations in FOP patients; however, mutations that correlate with the disorder have not been identified.

The BMP antagonist noggin had been considered as a candidate gene for FOP, but genetic studies have indicated the absence of linkage of the noggin gene to FOP [107]. There are two reports [108, 109] of mutations in the noggin gene in patients with FOP, but extensive mutational analysis in some of the identical patients, as well as in more than 30

additional FOP patients, failed to detect any mutations in the noggin gene ([107]; own unpublished data).

BMP Antagonists in FOP

Differential mRNA and protein expression of several BMP pathway components, including BMP antagonists, has been examined in FOP-derived and control cells to try and uncover additional clues to the identity of the genetic defect in FOP [110].

BMP-4 mRNA and protein are uniquely overexpressed in lymphocytes and lesional cells from patients with FOP. The cellular effects of BMPs are determined in part in a dose-dependent fashion by tightly-regulated morphogenetic gradients of BMPs and secreted antagonists such as noggin, chordin, and gremlin. Although the various BMP antagonists are unique proteins, they share the functional property of binding specifically to extracellular BMPs, preventing them from interacting with their transmembrane receptors. Several studies have indicated that BMP-4 upregulates the expression of noggin and gremlin, thereby establishing an autoregulatory negative feedback loop. A defect in the feedback pathway between BMP-4 and one or more of its extracellular antagonists could plausibly contribute to elevated BMP-4 activity in FOP and, therefore, basal and BMP-4-induced expression of noggin, chordin, and gremlin mRNA in control and FOP lymphoblastoid cell lines was investigated [111]. Control cells exhibited marked increases in noggin and gremlin mRNA expression in response to a BMP stimulus (as measured by RT-PCR), whereas patient-derived cells exhibited a dramatically attenuated response. This suggests that a loss of negative feedback due to an insufficient BMP antagonist response may account in part for increased BMP-4 activity in FOP. The findings support the importance of a critical balance between an inductive morphogen and its secreted antagonists and suggest the potential of BMP antagonist-based strategies in the therapy of FOP.

Mast Cells in FOP Lesions

Postnatal heterotopic ossification in FOP is often heralded by hectic episodes of severe post-traumatic connective tissue swelling and intramuscular edema, followed by an intense and highly angiogenic fibroproliferative mass. The abrupt appearance, intense size, and rapid intrafascial spread of the edematous pre-osseous fibroproliferative lesions implicates a dysregulated wound response mechanism, and suggests that cells and mediators involved in inflammation and tissue repair may be conscripted in the growth and progression of FOP lesions. The central and coordinate role of inflammatory mast cells and their mediators in tissue edema, wound repair, fibrogenesis, angiogenesis, and tumor invasion led to the investigation of the potential involvement of mast cells in the pathology of FOP lesions and the discovery that inflammatory mast cells are present at every stage of the development of FOP lesions, and most prominent at the highly vascular fibroproliferative stage [112]. Mast cell density at the periphery of FOP lesional tissue is 40 to 150-fold greater than in normal control skeletal muscle or in uninvolved skeletal muscle from FOP patients, and 10 to 40-fold greater than in any other inflammatory myopathy examined. These findings document the mobilization and activation of inflammatory mast cells in the pathology of FOP lesions, and provide a novel and previously unrecognized target for pharmacologic intervention.

Influenza B Infection and FOP

Influenza B and other viral infections are known to cause a broad range of myopathies, especially in children. These muscle syndromes range from mild, self-limiting myalgias to life-threatening rhabdomyolysis. The etiology of muscle injury in influenza infection is unclear. Possibilities include direct invasion of muscle by the virus, activation of pro-inflammatory transcription factors, and autoimmune processes. FOP flare-ups may be stimulated by blunt soft tissue injury, surgical trauma, intramuscular injections, or myotoxic local anesthetics.

Mounting anecdotal evidence from patients, families, and physicians has suggested that a relationship exists between viral infections (such as influenza) and FOP flare-ups. A case study has been conducted of a family in which all three sisters (two affected with FOP and one unaffected) developed influenza symptoms (fever, cough, sore throat, headache, and myalgias) [113]. Both of the sisters with FOP experienced signs of a FOP flare-up (severe soft tissue swelling, erythema, warmth, and pain) within 6–12 hours of the onset of influenza symptoms. These are the first cases in which a documented viral infection has served as a trigger for an FOP flare-up. A larger retrospective study investigating the temporal relationship between influenza infection and FOP flare-ups further supports a connection between influenza infection and the progression of FOP.

Metalloproteinase (MMP) Activity in FOP

Although heterotopic angiogenesis is important in the pathogenesis of FOP lesions, its mechanism in FOP patients is not well understood. MMP-2 and MMP-9 (see also Chapter 7, this volume) have been shown to be critical for the extracellular matrix degradation that is necessary for endothelial cell invasion and for new capillary sprouting in wound healing and a variety of diseases. The role of MMP-2 and MMP-9 in the angiogenesis of pre-osseous lesions in FOP has been examined [114]. Urine samples from FOP patients experiencing flare-ups exhibited levels of MMP-9 activity significantly higher than in normal controls, suggesting that MMPs may play a role in angiogenesis during the development of FOP heterotopic ossification, thereby possibly representing a target for anti-angiogenic therapy.

Therapy

The ultimate goal of research into FOP is the development of treatments that will prevent, halt, or even reverse the progression of the condition. An updated and comprehensive review of the management of FOP can be found on the IFOPA website at *www.ifopa.org* under "Research/Treatment Guidelines" (see also "Patient Support and Information", below).

PATIENT SUPPORT AND INFORMATION

The International Fibrodysplasia Ossificans Progressiva Association (IFOPA) is a nonprofit organization that supports research and education for patients with FOP. The IFOPA was founded in 1988 by Jeannie Peeper, an adult with FOP, in order to end the social isolation imposed by this rare and debilitating disease. Today, the IFOPA has nearly 200 members in over 15 countries. The IFOPA's home page on the World Wide Web contains information about FOP, the IFOPA, and the international collaborative research project. "What Is *FOP*? A Guidebook for Families" is also available on the website. The address for the site is *www.ifopa.org* Those using email can contact the IFOPA at ifopa@vol.com.

The address of the IFOPA is: Ms. Jeannie Peeper, President, IFOPA, PO Box 196217, Winter Springs, FL 32719-6217.

ACKNOWLEDGMENTS

The authors are indebted to Drs. Judah Folkman, William Gelbart, Richard Harland, Victor McKusick, Maximilian Muenke, John Rogers, Vicki Rosen, Roger Smith, Neil Stahl, Marshall Urist, John Wozney, and Michael Zasloff for their enduring intellectual contributions to this field and to the evolution of the work presented here.

The authors dedicate this work to Jeannie Peeper (President of The International Fibrodysplasia Ossificans Progressiva Association) and to all of the patients worldwide affected with FOP in appreciation of their continuous inspiration and in admiration of their steadfast courage. This work was supported in part by grants from the International Fibrodysplasia Ossificans Progressiva Association, the Medical Research Council (UK), The Ian Cali Fellowship, The Gund Foundation, The European Neuromuscular Center, The Isaac & Rose Nassau Professorship of Orthopaedic Molecular Medicine, and The National Institutes of Health (R01-AR-41916).

Chapter 22, Part I

Disorders of Lysosomal Enzymes: General Considerations

Ulrich N. Wiesmann

Inselspital Bern, Medizinische Universitäts-Kinderklinik, 3010 Bern, Switzerland

INTRODUCTION

The connective tissues consist of two main components, the collagens and the proteoglycans. Both are situated in the extracellular compartment and are secreted by resident cells of the connective tissues. The proteoglycans of the extracellular matrix are molecules with a molecular weight of several million (see Chapter 4, this volume). They consist of core proteins to which glycosaminoglycan (GAG) subunits are covalently linked in a fern-like pattern. The core proteins themselves are noncovalently bound to stringlike molecules of hyaluronan (hyaluronic acid). The presence of numerous anionic groups such as carboxyl and sulfate groups is responsible for the acid characteristics of glycosaminoglycans and for their property of binding certain dyes such as toluidine blue. These dyes change their colors metachromatically into colors of longer wavelength. In spite of their high molecular weight, the proteoglycans are readily water-soluble and therefore frequently escape histochemical visualization because they are lost into the aqueous phase during tissue fixation. Therefore, the histochemical demonstration of extracellular proteoglycans is difficult and requires special methods.

Connective Tissue Homeostasis

Similarly to all other structures in the organism, the extracellular constituents of the connective tissue matrix are continuously renewed. In part, the metabolism of these high molecular weight structures occurs extracellularly through the activity of enzymes such as hyaluronidase, which are secreted by the connective tissue cells into the extracellular matrix. Through the action of hyaluronidase, the proteoglycans are depolymerized. The next degradation step consists of the degradation of core proteins by proteinases, which are also secreted by the cells. An uncontrolled degradation of matrix constituents is prevented by several types of inhibitors of proteinases present in the extracellular space. Extracellular matrix degradation is discussed extensively in Chapter 7 (this volume). The glycosaminoglycan chains and polypeptides resulting from partial extracellular degradation and/or the soluble proteoglycans are finally taken up into the cells of the connective tissues and degraded in the lysosomes, their degradation occurring in a step-wise manner through several lysosomal hydrolases. These maintain a strict order in the sequence of their actions, which cannot be bypassed. For this reason, any deficiency of a single individual lysosomal hydrolase, usually the result of a genetic defect or, rarely, of inhibition by a lysosomotropic drug (e.g., chloroquine), stops lysosomal degradation of the substrate at the point where the missing enzyme should act. This is the reason for the existence of as many different genetic mucopolysaccharidoses and oligosaccharidoses as there are enzymatic steps in the degradation of glycosaminoglycans and oligosaccharides.

Regulation of the rates of extracellular matrix degradation and synthesis by the resident cells of the connective tissues is responsible for there being an equilibrium between the secretion of newly synthesized material and the uptake and degradation of older, previously secreted material [1]. Recently, new developments in our understanding of the regulation of connective tissue homeostasis have been described. Heparan sulfate proteoglycans at cell surfaces and in the extracellular matrix bind diverse molecules, including growth factors and cytokines, and it is suggested that the activities of such molecules may be regulated by the metabolism of heparan sulfate [2]. Proteoglycans seem to be involved in feedback signaling from the extracellular matrix to the cells synthesizing it. Various cytokines and growth factors have been found able to penetrate the extracellular matrix and to inhibit or stimulate proteoglycan biosynthesis. The degradation of proteoglycans can also be enhanced or inhibited by several different cytokines. Proteoglycans may function as receptors, protectors, inactivators, and storage ligands of cytokines. Agonistic or antagonistic cytokines are both involved in the regulation of proteoglycan turnover during balanced or unbalanced metabolism in normal and pathological situations, respectively [3].

Extensive data on glycosaminoglycan (GAG) composition and the distribution of collagen fibril diameters have been collected for a diverse range of connective tissues. It has been shown that tissues with collagen fibrils of smaller diameter (average diameter less than 60 nm) have high concentrations of hyaluronan while those with larger diameter collagen fibrils (average diameter approximately 200 nm) have high concentrations of dermatan sulfate. It has thus been suggested that the lateral growth of fibrils beyond a diameter of about 60 nm is inhibited by the presence of an excess of hyaluronan, but that this inhibitory effect is diminished by an increasing concentration of dermatan sulfate. It has also been postulated that high concentrations of chondroitin sulfate will inhibit fibril growth beyond an average diameter of approximately 150 nm. Such an inhibition may, in turn, be diminished by

Connective Tissue and Its Heritable Disorders, pages 841–848

an increasing concentration of dermatan sulfate, such that this becomes the dominant GAG present in the tissue [4].

Invasion by nonresident cells such as macrophages, granulocytes, and other cells mediating inflammation, or of tumor cells, may severely disturb the equilibrium between synthesis and degradation. In most instances this disturbance results in increased degradation, because the invading cells secrete lysosomal enzymes such as hyaluronidase or cathepsins as well as inflammatory cytokines. This process often results in a diminution of the extracellular substance and the formation of defects. On the other hand, resident cells may start to divide and multiply as a reaction to local inflammation due to the secretion of cytokines, e.g., IL-6 (interleukin 6). The increase in cell number, or the reactions of the cells to factors resulting from local inflammation, may mediate an increased secretion of both types of molecule that form the matrix: collagens and proteoglycans. This may result in an excess of extracellular material and/or in a qualitative change of the composition of matrix components, offering a probable explanation for the formation of connective tissue scars and the so-called keloids of the skin, or for the formation of callus in bone and osseous fibrosis. Again, the regulation of these mechanisms is mostly unknown. In the formation of keloids, which often occur after dermal burns, genetic factors may play a role, since they are more frequent and prominent in dark-skinned individuals than in the white population [5].

Equally unknown and unclear is the cause of the disturbed regulation of the metabolism of the extracellular matrix in the mucopolysaccharidoses. In these disorders, the lysosomal storage of nondegradable glycosaminoglycans is explained by specific enzyme deficiencies. However, the increase of these compounds extracellularly, e.g., in the skin, bones, and cartilage, which is often the basis of the clinically visible symptoms in patients, still remains to be adequately explained. Gene expression and the synthesis of extracellular matrix components might directly or indirectly be related to lysosomal storage. In aspartylglucosaminuria, a lysosomal storage disease, the ultrastructure of collagen fibrils in the skin of patients has been shown to be abnormal. *In vitro*, fibroblasts from these patients show reduced synthesis of collagens due to decreased steady-state concentrations of mRNA and an imbalance in proteoglycan synthesis [6].

INTRACELLULAR HANDLING OF CONNECTIVE TISSUE COMPONENTS

Reasons for, and Specificity of, Cellular Lysosomal Accumulation

The composition of the proteoglycans in the extracellular matrix is different in different types of connective tissue. In particular, there are differences between the loose connective tissue of skin and the highly organized structures of the matrix in bone and cartilage. As a consequence, skin, bone, cartilage, tendon, and fascia may be differently affected depending on the specific type of lysosomal enzyme defect. Genetic defects of lysosomal enzymes that catalyze degradation steps common to all glycosaminoglycans, such as β-glucuronidase, may result in morphological changes in many different tissues and locations. Again, a deficiency of an enzyme that is responsible for a step in the degradation of just one type of glycosaminoglycan, but one that is present in many different types of connective tissues, e.g., dermatan sulfate, will also express itself in a broad range of clinical symptoms. On the other hand, if a genetic defect results in the deficiency of a lysosomal enzyme that catalyzes one step in the degradation of a glycosaminoglycan that is only a minor component of the connective tissue matrix, e.g., heparan sulfate, the involvement of skin, bone, and cartilage may be minimal, as in Sanfilippo disease. Heparan sulfate, however, plays an important role in the brain and, therefore, the clinical expression of this disorder, in which heparan sulfate degradation is disturbed, is mainly linked to progressive behavioral and intellectual deterioration.

Lysosomal Function

Lysosomes are cellular organelles that maintain a pH of between 4.5 and 6.5 by an ATP-dependent proton pump. They contain a large number of hydrolytic enzymes that have a pH optimum in this acidic range that are able to disassemble macromolecules such as proteins, glycopeptides, glycosaminoglycans, and glycogen, as well as nucleic acids and complex lipids, into their individual constituents, e.g., monosaccharides and their derivatives, amino acids, fatty acids, and cholesterol, as well as inorganic acids like phosphate and sulfate. These low molecular weight molecules either diffuse through the lysosomal membranes or are transported across them by energy-dependent mechanisms into the cytosol. They may either be released from cells into the extracellular fluid or be reutilized by them for energy production or macromolecular synthesis.

The substrates for lysosomal degradation originate either from the cells themselves during the process of intracellular renewal of macromolecules and membrane lipids, or may arise from the extracellular environment from which they are internalized into the cells by pino- or phagocytosis.

In this chapter are described heritable genetic diseases that originate from single or multiple deficiencies of lysosomal enzymes that are normally responsible for the degradation of the glycosaminoglycan components of the extracellular matrix. The dysfunction of lysosomal degradation on the basis of such enzyme deficiencies inevitably results in an arrest of sequential lysosomal substrate degradation and the accumulation of nondegraded or partially degraded glycosaminoglycans within the lysosomes. This storage of substrates leads to vacuolization and swelling of the cells and to changes in homeostasis of the extracellular matrix.

Intracellular Uptake of Substrates

The intracellular uptake of components of the connective tissue matrix is the prerequisite for intracellular lysosomal degradation. The mechanism comprises cellular incorporation, intracellular vesicular transport, incorporation of the substrates into the lysosomes, and, finally, lysosomal degradation.

Intracellular Incorporation

The uptake of macromolecular components of the extracellular matrix usually occurs by pinocytosis, rarely by phagocytosis. Both are energy-requiring, temperature-dependent processes. Extracellular proteinase activity, together with extracellular hyaluronidase activity, results in the disassembly of the large glycosaminoglycan structures that then become soluble and can be taken up by resident connective tissue cells. During endocytosis, extracellular molecules enter the cell interior in vesicles that are formed by the invagination and inward fusion of plasma membranes. These macromolecules may be in solution, loosely bound to the membrane, or bound to specific receptors at this stage [7]. Receptor-mediated endocytosis is effectively used by many cell types to internalize macromolecules for

lysosomal breakdown. The macromolecular ligands bind to specific cell surface receptors that then move to, and cluster within, specialized regions of the plasma membrane termed "coated pits." Once receptors bound to appropriate ligands are within the coated pits, coated vesicles are formed that are internalized. As soon as the coated pits have lost their connection with the extracellular space, the clathrin coat that specifies the coated vesicles disassembles, and the smooth-surfaced uncoated vesicles, together with their contents of ligands and receptors, are now delivered into the endosomal compartment [8,9]. The degree of binding of molecules to the plasma membrane regulates their rate of uptake and is paralleled by the rate of degradation of molecules like proteins, some glycoconjugates, and proteoglycans in the endocytosing cells [7].

Little is known about the control of endocytosis and pinocytosis. Rates of endocytosis vary according to the cell cycle, nutritional conditions, and in response to certain hormones, such as growth factors [7], but, on the whole, the rate of degradation of endocytosed molecules correlates with variations in the rate of uptake. In conditions in which the intracellular vacuolar system becomes enlarged, the availability of receptors at the cell surface will be decreased and, therefore, the uptake of a particular ligand may be decreased.

There are examples of feedback inhibition that may control ligand entry during endocytosis into the cells and lysosomes, and there may be secondary feedback inhibition of endocytosis, as a consequence of lysosomal storage or the resecretion of endocytosed material or the inhibition of endosomal/lysosomal fusion. All of these mechanisms may result in a disequilibrium of connective tissue homeostasis, as is found in many of the lysosomal connective tissue disorders [10].

Intracellular Transport of Endocytosed Substrates

Endosomes are small plasma membrane vesicles which may have a shuttle function between the larger vacuoles in the interior of a cell and the plasma membrane, in both directions. The endosomal compartment is composed of a network of tubules and vesicles which may form a reticulum within the peripheral cytoplasm of the cells. In this complex structure, ligands dissociate from their receptors, and receptors sort themselves from each other. The interior and the material contained within endocytic vesicles, as well as the interior of the coated vesicles previously mentioned, are acidified by proton pumps that exist within the membranes of the vesicles. Acidification seems to be responsible for the dissociation of ligands and receptors and plays a central role in redirecting the receptors back to the plasma membranes by means of receptosomes [8].

Mode of Access of Macromolecules to the Lysosomal Interior

One of the controlling steps in lysosomal function is the entry of substrates into the lysosomal compartment. Lysosomes contain numerous hydrolytic enzymes capable of degrading biological macromolecules taken up by endocytosis, pinocytosis, or phagocytosis. In the process of remodeling hypertrophic cartilage and bone, however, lysosomal enzymes are also secreted by clastic cells into a localized acidic extracellular compartment [11]. For most macromolecules (proteins, nucleic acids, or glycosaminoglycans), entry into the lysosomal compartment involves membrane fusion. Acidification of the intracellular vesicles and endosomes seems to be a prerequisite for subsequent fusion with lysosomes. This fusion can be inhibited by low temperature and by weak bases such as amines [12]. Such weak bases may also interfere with the processing of lysosomal enzymes, as a consequence of which they may be secreted into the extracellular space instead of being incorporated within the lysosomes. Significant progress has been made in recent years toward elucidating the pathways by which lysosomal membrane proteins are delivered to late endosomes and lysosomes. While some lysosomal membrane proteins follow the constitutive secretory pathway and reach lysosomes indirectly via the cell surface and endocytosis, others exit the *trans*-Golgi network in clathrin-coated vesicles for direct delivery to endosomes and lysosomes. Sorting from the Golgi or the plasma membrane into the endosomal system is mediated by signals encoded by the short cytosolic domains of these proteins [13].

In the regular process of endocytosis, most of the endosomal membranes are rescued and recycled back to the plasma membrane, although some may enter the lysosomal compartment and become degraded. As the flow from endosomes to lysosomes by vesicle/lysosome fusion is bidirectional, a certain proportion of the endocytosed molecules may leave the cells by a secretory process accompanying membrane recycling [14]. This may be important in lysosomal storage diseases, in which the intracellular storage of material may favor this secondary secretory route into the extracellular fluid and interfere with extracellular matrix homeostasis.

Intralysosomal Degradation

After the fusion of the endocytic vesicles containing endocytosed material with primary or secondary lysosomes, hydrolytic degradation commences. As well as proteoglycans that have been taken up from the extracellular compartment, newly synthesized glycosaminoglycans and proteoglycans are also diverted from the secretory route into lysosomes. Both *in vivo* and *in vitro* it has been shown that more than half of newly synthesized proteoglycans fail to be secreted from the cells, and are segregated into lysosomes and degraded [15]. This degradation of newly synthesized material may represent another important function devised to regulate net synthesis and secretion and ensure homeostasis of the extracellular matrix.

SYNTHESIS, SORTING, AND TRANSPORT OF LYSOSOMAL ENZYMES

The targeting of lysosomal enzymes from their site of synthesis in the rough endoplasmic reticulum to their final destination in lysosomes is directed by a series of protein and carbohydrate recognition signals on the enzymes.

Lysosomal enzymes act only within a relatively narrow acid pH range of between 4.5 and 6.5. At neutral pH they may be mostly inactive. It is generally the case that lysosomal enzymes mediate only degradative processes. However, there are certain exceptions. One of these is an enzyme (acetyl-CoA-α-glucosaminide N-acetyltransferase) that catalyzes the N-acetylation of amino sugars within heparan molecules, which at the time of their entry into lysosomes are not acetylated. Acetylation of amino sugars seems to be a prerequisite for hydrolytic release from their linkage with uronic acid to be achieved. This N-acetylating lysosomal enzyme is deficient in Sanfilippo disease type C [16].

It is generally assumed that lysosomal enzymes of different types are present together in the same lysosomal vacuoles.

Activities are very stable at the low lysosomal pH, but the enzymes are very sensitive to irreversible inactivation at alkaline pH, both *in vivo* and *in vitro*. They are greatly resistant to tryptic digestion and, in general, proteinases that rapidly degrade nonlysosomal proteins do not act against undenatured lysosomal enzymes, many of which remain quite stable and have half-lives of days to weeks. They also seem to be stabilized by the presence of their substrates. All of the properties mentioned may contribute to the fact that the pattern of lysosomal enzyme activity differs greatly from cell type to cell type and between different organs.

Synthesis of Lysosomal Enzymes

Lysosomal enzymes are synthesized on membrane-bound polysomes in the rough endoplasmic reticulum (RER). Lysosomal enzymes, along with secretory and plasma membrane proteins, contain amino-terminal signal sequences that direct the vectorial discharge of the nascent proteins into the lumen of the RER [17]. The three classes of proteins also share a common peptide signal for asparagine glycosylation involving the transfer of large, preformed oligosaccharide-dolichol-diphosphates to the nascent polypeptides. The responsible enzyme (dolichyl-P-Glc:$Man_9GlcNAc_2$-PP-dolichyl glucosyltransferase) is deficient in carbohydrate-deficient glycoprotein syndrome (CDGS type V) [18]. In the RER the signal peptide is cleaved, and the processing of the asparagine-linked oligosaccharides begins with the excision of three glucose and one mannose residues. The proteins then move by vesicular transport to the Golgi stack, where they undergo a variety of post-translational modifications [19,20]. The next signal is unique to lysosomal enzymes and permits their high-affinity binding to a specific phosphotransferase that catalyzes the formation of a mannose 6-phosphate recognition marker. This carbohydrate determinant allows binding to specific receptors that translocate the lysosomal enzymes from the Golgi complex to an acidified prelysosomal compartment. There the lysosomal enzymes are discharged for final packaging into lysosomes. Two distinct mannose 6-phosphate receptors have been identified, and cDNAs encoding their entire sequences have been cloned. An analysis of the deduced amino acid sequences of the receptors shows that each is composed of four structural domains: a signal sequence, an extracytoplasmic amino-terminal domain, a hydrophobic membrane-spanning region, and a cytoplasmic domain. The entire extracytoplasmic region of the small receptor is homologous to the 15 repeating domains that constitute the extracytoplasmic portion of the large receptor [21].

The acquisition of phospho-mannosyl residues occurs through the concerted action of two enzymes. First, UDP-N-acetylglucosamine-1-phospho-transferase transfers N-acetylglucosamine-1-phosphate from the nucleotide sugar UDP-N-acetylglucosamine to selected mannose residues on the lysosomal enzyme to give rise to a phosphodiester intermediate. Then, another enzyme, N-acetylglucosamine-1-phosphate, α-N-glucosaminidase, removes the N-acetylglucosamine residue. The resultant mannose 6-phosphate phosphomonoester serves as a central recognition marker that leads to high-affinity binding to mannose 6-phosphate receptors in the Golgi complex [22,23]. After addition of the recognition marker, the sorting and diversion of lysosomal enzymes take place through the binding of the enzymes to mannose 6-phosphate receptors, which are concentrated in *cis*-Golgi cisternae, coated vesicles located near the *cis*-most Golgi cisternae, and endosomes or lysosomes, and also at the cell surface of some cell types in coated pits [24]. The *cis*-Golgi cisternae, coated vesicles, and endosomes or lysosomes are assumed to represent the sorting site, carrier vesicles, and delivery site, respectively, for lysosomal enzymes.

By this mechanism, enzymes directed toward lysosomes are segregated from homologous proteins that are destined for secretion. The ligand (lysosomal enzyme)-receptor complex is delivered to the prelysosomal staging area, where dissociation of the ligand occurs through acidification of the compartment. The receptors then cycle back to the Golgi apparatus to pick up further ligand molecules, whereby the lysosomal enzymes are packaged into lysosomes. Small amounts of the lysosomal enzymes are secreted into the extracellular space before their delivery to lysosomes. They may bind to mannose 6-phosphate receptors at the cell surface and be internalized again, to be delivered to the lysosomes together with substrates. This secretion-recapture mechanism may account for 5–10% of total lysosomal enzymes delivered to the lysosomes. This alternative route to the lysosomes provides the rationale for lysosomal enzyme therapy in cells and in patients with lysosomal enzyme deficiency. Its practical use so far has been restricted to enzyme therapy with recombinant glucocerebrosidase in visceral Gaucher disease patients and to bone marrow replacement therapy in mucopolysaccharidosis patients.

Some of the lysosomal enzymes, such as acid phosphatase and β-glucosidase, and lysosomal membrane proteins, may be transported to the lysosomes by a mannose 6-phosphate-independent mechanism [25,26].

Intracellular Turnover of Lysosomal Enzymes

Simultaneously with oligosaccharide processing, lysosomal enzymes undergo proteolytic processing. They are synthesized as pre-proenzymes with amino-terminal extensions. The pre-piece, which is the signal sequence, is cleaved immediately after transport into the endoplasmic reticulum. The pro-piece is cleaved later, usually over the course of several hours to several days. This processing appears to be initiated in the prelysosomal compartment and continues in the lysosomes [27]. Most lysosomal enzymes are already active as proenzymes. In some cases, however, such as cathepsin D, the pro-sequence functions as an activation peptide. In the other lysosomal enzymes that are synthesized as active enzymes, the function of this processing is not clear. The pro-piece may have a stabilizing effect and may contain sorting information for the targeting of lysosomal enzymes by the mannose 6-phosphate-independent pathway.

The degradation of lysosomal enzyme polypeptides begins during their biosynthesis [28]. Once the lysosomal enzymes reach the lysosomes, they undergo decay according to first-order kinetics. The turnover of lysosomal enzymes is heterogeneous, the lifetimes of individual enzymes being different from one another and from the turnover of lysosomal membrane proteins, but being of the order of several days to several weeks [29]. In some lysosomal disorders, the degradation of mutated but metabolically active enzyme protein may be greatly accelerated, resulting in a functional enzyme deficiency [30]. An excessive degradation rate with the loss of functional enzyme activity may also be due to the lack of a stabilizing protein, as in the combined deficiency of β-galactosidase and glycoprotein sialidase. Loss of enzymatic function may result from difficulty in hydrolase packaging in the prelysosomal compartment, as suspected for the late-onset form of glycogenosis type II [31]. The longevity of lysosomal

enzymes may also be altered by defects in the synthesis of their carbohydrate moiety, as in CDGS, a hypothesis rendered feasible by experiments with drugs interfering with glycosylation such as tunicamycin [32].

LYSOSOMAL ENZYME DEFICIENCIES

Genetic deficiency of a lysosomal enzyme leads to the lysosomal accumulation of its nondegraded substrate. Usually, an enzyme deficiency is caused by failure to synthesize a catalytically active form of a particular enzyme, due, for example, to a point mutation. Another reason for a missing lysosomal enzyme activity is an inability to transport the active enzyme from its site of synthesis to the lysosomes [22,23,27].

Glycogenosis type II was the first genetic disorder to be identified as a lysosomal storage disease [33], since when about 40 different lysosomal storage diseases have been identified as being due to single or multiple enzyme deficiencies [34].

Those enzyme deficiencies in which there are clinical manifestations of lysosomal dysfunction can be attributed to mutations within the genes coding for one or other of the polypeptide chains of lysosomal enzymes. This may lead to an abortive polypeptide chain that is instantly degraded and never reaches the lysosomes, an enzyme lacking catalytic activity, or an enzyme that is more sensitive to inactivation. Lysosomal enzymes are glycoproteins and the formation and trimming of carbohydrate side chains is responsible for the targeting of lysosomal enzymes to the lysosomes. The formation of mannose 6-phosphate groups in the oligosaccharide side chains mediates the binding of lysosomal enzymes to specific receptors. For this recognition marker two enzymes are required: N-acetylglucosamine-phosphotransferase and phosphodiester-glycosidase. The deficiency of the phosphotransferase is the basic defect underlying I-cell disease and pseudo-Hurler polydystrophy (Part II, this chapter).

A deficiency of the phosphodiester-glycosidase has been discovered in one particular family [35]. The absence of mannose 6-phosphate groups in lysosomal enzymes may also be due to mutations in the genes for the lysosomal enzymes themselves, as has been shown for α-glucosidase [36]. Defects interfering with the correct structure of the carbohydrate chains in lysosomal enzymes result in a multiple enzyme deficiency of all enzymes that are dependent on the mannose 6-phosphate pathway for reaching the lysosomes. Not all lysosomal enzymes, however, require the presence of the mannose 6-phosphate recognition group and binding to the appropriate receptors in order to be transported into the lysosomes. Some of them, which are not absent or deficient in I-cell fibroblasts, such as acid phosphatase and β-glucosidase, seem to require a conversion of the high-mannose type to complex type oligosaccharide to be transported to the lysosomes [37].

In summary, the following mechanisms may lead to deficiencies of lysosomal enzymes [34,38]:

1. The precursor of the enzyme is not synthesized, or is synthesized at a diminished rate.
2. Following synthesis of a normal amount of the precursor, rapid degradation of the unstable enzyme occurs.
3. The precursor lacks the mannose 6-phosphate recognition marker, resulting in deficient targeting to lysosomes. This may be due to: (a) N-acetylglucosamine-1-phosphotransferase deficiency; (b) N-acetylglucosamine-1-phosphodiester-N-acetylglucosaminidase deficiency; (c) change of the Ser/Thr–X–Asn sequence functioning as glycosylation site as a result of amino acid substitution.
4. Either the precursor or the mature enzyme may have altered physicochemical and/or enzymological properties.
5. The enzyme may be degraded too rapidly because of the absence of protective protein required for its stabilization.
6. Absence of a factor required for normal enzymic activity.
7. The product accumulating as a result of a deficiency of one enzyme may inhibit the activity of (an) unrelated enzyme(s).

PATHOGENESIS OF LYSOSOMAL DISORDERS OF CONNECTIVE TISSUE

Any condition that interferes with the intralysosomal activity of an enzyme involved in disassembling connective tissue components (glycoproteins and GAGs), as well as the abnormal extracellular secretion of one or more lysosomal enzymes, will eventually lead to a connective tissue disorder. This will manifest itself primarily in organs that contain large proportions of collagen and proteoglycans such as skin, bone, and cartilage. Other organs in which proteoglycans may play a functional role, such as the developing brain, may also be involved, as may be organs and tissues such as the heart and cornea, of which an essential part is comprised of connective tissue components.

The quantity and composition of proteoglycans, particularly keratan sulfate, in organs may change with age [39]. This may, in part, explain why the urinary excretion of keratan sulfate in MPS IV and oligosaccharide excretion in patients with oligosaccharidoses may be reduced or even disappear with increasing age. It also may provide an explanation for the observation that the enlarged liver in patients with mannosidosis may normalize with increasing age.

Reasons for Central Nervous System Involvement

Glycosaminoglycan (GAG) metabolism seems to play an important role in neuronal maturation and synaptogenesis [40,41]. Any imbalance may interfere with neuronal migration, differentiation, and function, especially in the early stages of development. This explains why any rational treatment, for example, enzyme substitution, should be initiated as early as possible, preferably before the patient presents major symptoms of central nervous system involvement. However, this may create severe ethical problems, since the available and developing treatments are by no means without acute risk.

The repertoire of the lysosomal system extends beyond its function in degrading biological macromolecules for energy and recycling purposes. Controlled shifts in lysosomal activity help neurons to regulate their cytoplasmic volume and to remodel local cellular domains [42]. Therefore, the pathogenesis of brain damage in lysosomal disorders may originate from as yet unexplored aspects of lysosomal function.

Lysosomal accumulation of GAGs may also interfere with the orderly metabolism of other components of

the brain. It has been shown that these accumulating substances inhibit the activity of β-galactosidase, which is responsible for the degradation of gangliosides. The accumulation of gangliosides in neurons is manifested by the typical "zebra" bodies seen in gangliosidosis. Some glycosaminoglycan storage products may be more inhibitory, and this may be why brain function, for example, is more disturbed in Hunter disease than in Hurler disease, and may even be spared in milder cases as a result of residual activity.

Thickening of Bones and Skin, and Hirsutism

Thickening of the skin in some of the mucopolysaccharidoses may well be explained by an excess of GAGs in the skin, this being the expression of an imbalance between synthesis, secretion, and degradation of GAGs interfering with the orderly array of collagen fibrils. Hirsutism is frequently observed in older patients with MPS I, II, VI, or VII. This may be the result of the direct effect of a changed microenvironment on hair growth [43] or due to the increased binding of androgenic steroids from the adrenal glands by GAGs.

In MPS I, II, and VII, there seems to be a surplus of GAGs in connective tissues resulting in thickening of the skin and bones, while in others, such as MPS IV, there is, in contrast, something of a shortage due to an imbalance of keratan sulfate and heparan sulfate or dermatan sulfate. Not much is known of the collagen counterpart that may also be increased or reduced.

Glycosaminoglycans are constituents of larger proteoglycans that may or may not be associated with collagens. The glyco-moieties of the proteins contain glucose, galactose, mannose, fucose, and sialic acid as well as amino sugars. This explains why the oligosaccharidoses on the one hand are phenotypically connective tissue disorders, while on the other hand they involve noncollagen structures in other organs, particularly the CNS.

Reasons for Phenotypic Variation

Identical lysosomal enzyme defects may vary greatly in their phenotypic expression, this phenomenon usually being thought to be linked to different residual functional enzyme activities.

The more is known about the molecular genetics of lysosomal enzyme deficiencies, the more it becomes evident that point mutations, even at the same locus, may result in different phenotypes. Polymorphism within genomic DNA may modulate the severity of a point mutation by interfering with enzyme processing and intracellular transport, thereby determining the amount of enzyme present at the intralysosomal site and thus influencing its residual activity. Another reason for the differential involvement of cells and organs in lysosomal disorders may stem from the fact that processing and routing of lysosomal enzymes may vary among different cells (see, for example, I-cell disease, Part II of this chapter). Thus, different lysosomal enzyme activity patterns may ensue, and different residual enzyme activities may protect or damage cells.

Enzyme deficiencies due to single base mutations within the same triplet may vary greatly in the severity of their clinical phenotypes because of variations in transcription; for example, the mutation may lead to another amino acid with consequent inhibition of dimer formation, loss of a glycosylation site, or a stop codon.

PROSPECTS AND OUTLOOKS FOR NEW TREATMENTS

The prenatal diagnosis of lysosomal storage disorders may acquire new relevance in the light of the efficacy of early treatment. Once a diagnosis is confirmed in an index case, either by enzyme analysis of a variety of available specimens of fetal origin, by ultrastructural observation, or by molecular genetic studies, pseudodeficiency of a lysosomal enzyme must be excluded before early therapy or elective abortion can be instituted. A combined approach to prenatal diagnosis involving biochemical, molecular genetic, and morphological studies is recommended [44].

Enzyme replacement for genetic defects of lysosomal hydrolases should be evaluated in animal models first. Substantial progress in this area has been achieved. In mice and dogs lacking β-glucuronidase, homologous to human MPS VII (Sly disease), autologous implants of genetically modified cells (fibroblasts, myoblasts) embedded in collagen lattices (neo-organs) have been implanted for the continuous *in vivo* production of enzyme. All animals expressed β-glucuronidase from the vascularized neo-organs that developed after implantation and the lysosomal storage lesions in their livers and spleens greatly improved [45–47].

In a canine model of MPS I, infusions of recombinant human α-L-iduronidase resulted in decreased lysosomal storage in liver, kidney, spleen, lymph nodes, synovium, adrenals, and lungs. Detectable enzyme activity was present in brain and decreased glycosaminoglycan storage was apparent, although histologic improvement was not evident. Cartilage and heart valve did not show any detectable improvement [48]. Animal models occur naturally, but may also specifically be created by knocking out the gene responsible for a certain lysosomal enzyme as with the targeted disruption of the murine α-L-iduronidase gene in mice [49].

Another feasible approach may be to correct cells from patients *in vitro* using viral vectors to result in overexpression of a deficient enzyme, and then to reimplant the enzyme-secreting cells in the patients [50,51].

Allogeneic bone marrow transplantation for the mucopolysaccharidoses has been explored, and visceral features in patients so treated were ameliorated after transplantation. Transplant-related mortality was 10% if an HLA-identical sibling marrow donor was available and 20–25% if mismatched tissue was used. Bone marrow transplantation was not effective if severe neurological symptoms were already present at the time of transplantation [52]. Microglia invading the brain may have been responsible for successful enzyme replacement in brain after bone marrow engraftment [53].

Chapter 22, Part II

Disorders of Lysosomal Enzymes: Clinical Phenotypes

Jules G. Leroy

Children's Hospital "C. Hooft," Gent University Medical School, 9000 Gent, Belgium

SUMMARY

- Both the structural integrity and normal function of connective tissues are progressively affected in many lysosomal enzyme deficiency disorders. Hydrolases are normally involved in the metabolism of mucopolysaccharides (glycosaminoglycans), oligosaccharides, lipids, and even some proteins. In many of the "lysosomal disorders" connective tissue disease is associated with the adverse effects of substrate storage in brain and visceral organs. Target connective tissues include the skeletal system in general and metaphyseal cartilage and bone in particular, in addition to joints, ligaments, tendons, fasciae, meninges, cardiac valves, skin, and gingivae.
- The mucopolysaccharidoses are a group of lysosomal storage disorders caused by deficiency of one or other of the lysosomal hydrolases involved in glycosaminoglycan metabolism. Consequently, storage of dermatan sulfate and/or heparan sulfate or keratan sulfate and their excessive urinary excretion are observed in patients. Identification of the compound(s) excreted remains of orienting value for the diagnostic assay of the deficient enzyme and ultimately for the characterization of the encoding gene mutation.
- The mode of inheritance of all mucopolysaccharidoses is autosomal recessive, except for mucopolysaccharidosis (MPS) II, Hunter disease, an X-linked recessive trait. Several clinical features are common to all mucopolysaccharidoses and thus of little diagnostic value. All disorders have a progressive clinical course and many a fatal outcome between early infancy and mid-childhood. Even in the milder clinical types morbidity is considerable and life expectancy significantly reduced. Mental deficiency is important in MPS IH, MPS IIA, and MPS VII but in none of these is as early and severe as in the four genetically distinct, clinically indistinguishable types of Sanfilippo disease (MPS III). Mental retardation is absent or of minor consequence in the Morquio diseases (MPS IV A and B) and Maroteaux-Lamy disease (MPS VI). Facial and general body features show gradual coarsening. Progressive skeletal abnormalities noticeably different from the dysostosis multiplex expressed with variable severity in the other entities are specific only to Morquio type A disease (MPS IVA).
- For each of the mucopolysaccharidoses the mutant gene has been mapped and cloned, and its nucleotide sequence partially or fully determined. Most often patients are compound heterozygotes for two different mutations.
- In multiple sulfatase deficiency, several lysosomal and microsomal sulfatases are deficient. They are nonfunctional because a specific type of post-translational modification, common to all sulfatases, does not occur. A particular cysteine residue in the nascent glycoprotein is not transformed into 2-amino-3-oxopropionate, thus precluding the maturation of catalytically active sulfatases.
- The oligosaccharidoses (OS) result from the defective metabolism of carbohydrates in glycoproteins and glycolipids. Excessive urinary excretion of oligosaccharides is the common hallmark of all. Clinically these disorders resemble both the mucopolysaccharidoses and the lipidoses.
- The sialidoses are due to significantly decreased activity of glycoprotein sialidase. Even the most common type, childhood dysmorphic sialidosis, formerly called mucolipidosis type I, is rare. Normosomatic sialidosis, or cherry-red spot myoclonus syndrome, shares a slowly progressive clinical course with the former but lacks dysmorphic features. The latter designation points to decreasing visual acuity and progressive nervous system involvement. In neonates, sialidosis may cause nonimmune hydrops and lead to early fatal outcome.
- Among the four clinical phenotypes delineated in patients with isolated deficiency of β-D-galactosidase, three are known as G_{M1}-gangliosidosis, the fourth as Morquio disease type B (MPS IVB). Except for the latter, it is preferable to view the clinical phenotype as continuously variable, ranging between the severe infantile form with early fatal outcome and the chronic late or adult onset form. Dysostosis multiplex is severe in infantile G_{M1}-gangliosidosis and mild or absent in the adult type patient. This is in contrast to the radiographic findings in MPS IVB in which the mutant enzyme retains some activity toward G_{M1}-gangliosides but none toward keratan sulfate and oligosaccharide substrates, thus explaining the mild central nervous system effects and the serious connective tissue disease.

Connective Tissue and Its Heritable Disorders, pages 849–899

- **In the mannosidoses the clinical course is slow and connective tissue involvement mild. α-Mannosidosis is the result of a severe deficiency of the lysosomal acid α-mannosidase. Genetic heterogeneity is more extensive than the variability among phenotypes. β-mannosidosis has an inconsistent phenotype in the few patients reported. The human gene encoding β-D-mannosidase has been cloned and sequenced.**
- **The central nervous system is involved much more prominently than connective tissue in fucosidosis, a quite rare but more severe oligosaccharidosis with infantile onset. A quickly evolving disease (type l) and an almost nonprogressive albeit equally severe disorder (type 2) have been discerned. Patients with both phenotypes have been observed in the same pedigree.**
- **Aspartylglucosaminuria has a high incidence in Finland. It is a chronic disorder not easily recognizable before the age of 5 years, with mental deficiency a major component and a gradually coarsening facies and inguinal herniae signs of connective tissue disease. Most patients live well into adulthood. A number of mutations in the gene encoding aspartyl-β-glucosaminidase have been identified. Schindler disease, a chronic but very rare oligosaccharidosis, due to a deficiency of N-acetyl-α-D-galactosaminidase causes mainly severe neurologic deterioration similar to neuroaxonal dystrophy.**
- **Both I-cell disease (mucolipidosis II) and the milder pseudo-Hurler polydystrophy (mucolipidosis III) are due to a deficiency of N-acetylglucosamine-phosphotransferase by which intracellular transport and compartmentalization of the majority of lysosomal hydrolases is considerably disturbed. The cultured fibroblasts of patients contain numerous dense inclusions and are termed inclusion cells (I-cells). Clinically, I-cell disease is reminiscent of Hurler disease, but has an earlier onset and more severe morbidity. The onset of pseudo-Hurler polydystrophy occurs in early childhood. The disorder has a more chronic course. Growth rate, severely deficient in the patient with I-cell disease, is less affected in pseudo-Hurler polydystrophy.**
- **Galactosialidosis encompasses three disorders with a clinical resemblance to G_{M1}-gangliosidosis and sialidosis. Both glycoprotein sialidase and β-D-galactosidase are deficient. In all instances, galactosialidosis is a severe disease with consistent involvement of the nervous system, the retina, the skeleton, and other organ systems. The primary defect is a deficiency of the lysosomal 32 kDa β-D-galactosidase protective glycoprotein and/or its 54 kDa precursor, because of which sialidase is not activated, β-D-galactosidase is left unprotected against intralysosomal degradation and cathepsin A catalytic activity is abolished.**
- **The primordial metabolic defect in pyknodysostosis, a rare osteochondrodystrophy, is cathepsin K deficiency. Many different mutations have been identified in the cathepsin K gene in the few unrelated patients already studied.**
- **Gaucher disease type I (almost 80% of Gaucher disease patients), the most prevalent lysosomal storage disease, is the only sphingolipidosis with significant skeletal involvement. The central nervous system is spared. Glucosylceramide accumulates in typical reticuloendothelial cells, called Gaucher cells, as the result of glucosylceramide-β-glucosidase (glucocerebrosidase) deficiency. A number of different mutations, mostly single nucleotide substitutions, have been identified. The disease occurs with high frequency in Ashkenazi Jewish subjects in whom the large majority carries one of four more common mutations. Significant therapeutic progress has been achieved in Gaucher type I disease.**

INTRODUCTION

Many of the lysosomal disorders were originally delineated as storage disorders of childhood rather than as disorders of connective tissue. In fact, most such entities are both. In some, the lysosomal accumulation of macromolecules and the ensuing cell and parenchymal organ damage, including that to brain, is of major clinical importance. In others, the extracellular connective tissue is most adversely affected. In this chapter, only those lysosomal disorders with significant involvement of connective tissues such as bone, cartilage, and soft tissue will be discussed.

THE MUCOPOLYSACCHARIDOSES

Recognized as disorders of connective tissue as early as 1960 [1], the mucopolysaccharidoses and their study have played an important role in promoting clinical and scientific knowledge about amorphous connective tissue. In Table 1, the milestones in our understanding of the glycosaminoglycan (GAG) storage disorders are set out. Because, in each, elucidation of the enzyme defect has preceded insight into the gene mutation responsible, the

TABLE 1. Milestones in Understanding the Mucopolysaccharidoses (MPS)

1917; 1919	Clinical descriptions by Hunter and Hurler
1952	Discovery of storage of acid mucopolysaccharides (glycosaminoglycans[GAGS])
1957	Excessive urinary excretion of acid mucopolysaccharides noticed in patients; urinary test for group diagnosis
1962–63	Additional MPS entities delineated: Scheie, Sanfilippo, Maroteaux-Lamy diseases
1965	First McKusick classification; toluidine blue metachromasia observed in fibroblasts
1968–74	''Corrective factors'' in metabolism of GAGs; main primary enzyme deficiencies known
1975–90	Assignment of lysosomal enzyme genes to chromosomal locations; molecular biology of lysosomal enzymes involved in the mucopolysaccharidoses; monoclonal antibodies; processing; intracellular routing
1990–	Molecular biology of genes; molecular diagnosis; genotype-phenotype correlation; animal models: experimental gene therapy; bone marrow transplantation; enzyme substitution strategies

sequence of events outlined represents a classic example of functional genetics, in which knowledge of a gene product and its function precedes and contributes to the identification, cloning, and characterization of the gene.

The mucopolysaccharidoses (MPS) are a group of heritable disorders characterized by intralysosomal storage of GAGs, previously termed acid mucopolysaccharides. In each entity, this is due to the deficiency of a single specific lysosomal enzyme involved in the hydrolytic breakdown of GAGs. All of the disorders have a slow course but interfere significantly with normal life expectancy. Except for Hunter disease with its X-linked recessive mode of inheritance, all types of MPS are autosomal recessive disorders.

At present, at least a dozen different clinical entities characterized by excessive urinary excretion of GAGs have been formally delineated. They are listed in Table 2. Several of the fully developed phenotypes, though superficially similar, can be differentiated clinically. The features most useful for this differentiation, as well as signs and symptoms rather common to all diseases, are shown in Table 3.

Mucopolysaccharidosis I

Hurler Disease; MPS IH (MIM 252800)

Hurler disease, MPS IH, has served as a point of reference in the process of detection and delineation of several clinically related disorders. This prototype among the mucopolysaccharidoses, due to α-L-iduronidase deficiency, can be diagnosed clinically in the first 6 months of life, even though most of its features in infancy are but retrospectively recognized as relevant components of the syndrome. The neonate or young infant with Hurler disease has noisy breathing and is hypotonic. In males, often postoperative scars are indicative of earlier surgical treatment of inguinal herniae or hydroceles, which may recur. Restricted motion in the shoulders is observed from infancy. Corneal cloudiness, if equivocal on clinical inspection, is confirmed by slit lamp examination. As infancy progresses, the head becomes more scaphocephalic, and its circumference enlarges excessively. There is frontal bossing. Between 6 and 15 months of age, the child's growth and weight gain are excessive, resulting in plots which may cross over onto higher centile curves. Upper respiratory infections and otitis recur frequently. Some reduction in the range of motion of the large and small joints and some broadening of the wrists and hands may already be apparent. The abdomen becomes increasingly prominent, and hepatosplenomegaly is a regular finding. There is a moderate degree of hirsutism. Delay in psychomotor development is only moderate. An umbilical hernia, a constant feature, is rarely of clinical importance before the age of 3 years (Fig. 1). From 18 months onward, growth decelerates considerably and usually ceases during the fourth year of life, from which time also the head circumference no longer increases. Independent walking is usually achieved with delay. Speech, often with a hoarse voice, remains elementary. As toddlers, Hurler disease patients continue to make slow progress in psychomotor development, but in

TABLE 2. Catalog of the Mucopolysaccharidoses (MPS) [1]

			Primary Metabolic Defect				
Abbreviation	Eponym	MIM No.	Enzyme	Gene Symbol	EC No.	Main Metabolite Affected	Location of Gene on Chromosome

MPS VII	Sly	253220	β-D-glucuronidase	*GUSB*	3.2.1.31	DS, HS, CS	7q11.21-q11.22

DS, dermatan sulfate; HS, heparan sulfate; KS, keratan sulfate; CS, chondroitin sulfate.

[1] Allied to the mucopolysaccharidoses is mucosulfatidosis or multiple sulfatase deficiency (MSD); MIM 272200; see text.

[2] In still a third type of MPS IV the enzyme defect remains unknown.

TABLE 3. Mucopolysaccharidoses (MPS): Clinical Features of Differential Diagnostic Importance

	MPS I[1]			MPS II[1]		MPS III[2]	MPS IV		MPS VI[1]		MPS VII[4]
Symptoms	Hurler	Scheie	Compound	A	B		A[3]	B	A	B	
Neonatal problems	Several	None	None	Few if any	None	None	None	None	Several	None	Few if any
Final stature	Severely dwarfed	Nearly normal	Reduced	Dwarfed	Reduced	Almost normal	Severely dwarfed	Reduced	Severely dwarfed	Reduced	Dwarfed
Coarse facies	Severe; family features eliminated	Slight	Flat, receding chin	Moderate to severe	Mild	Mild or absent	Mild or absent	Absent	Moderate to severe	Mild	Severe
Cornea	Cloudy	Cloudy	Cloudy	Clear	Clear	Clear	Cloudy	Cloudy	Cloudy	Cloudy	Cloudy
Kyphosis	Frequent, dorsolumbar	None	None	Rare, mild	None	None	Constant, dorsal	Mild, rare	Frequent. dorsolumbar	Rare, mild	Frequent, dorsolumbar
Psychomotor retardation	Severe	None	Probably none	Severe	None to mild	Extreme	None	None	None to mild	None	Moderate
Behavior	Calm, friendly	Normal	Normal	Stubborn, destructive	Normal	Restless, with-drawn, early dementia	Normal	Normal	Normal	Normal	Normal
Dysostosis	Early, severe	Minimal	Moderate	Severe	Moderate	Minimal	Severe, typical	Moderate	Early, severe	Mild to moderate	Moderate to severe

Several important clinical features, though usually of consistent severity within one syndrome, are of less or no differential diagnostic value. They are macrocephaly, herniae, hepatosplenomegaly, cardiac and great vessel valve disease, hirsutism, upper respiratory infections, otitis and/or hearing loss, restriction of motion in all joints.

[1]The clinical entities first delineated represent but reference types in a continuous spectrum of severity; frequency spectrum skewed toward the more severe phenotypes.

[2]Four genetic entities known within one overall phenotype with inconsistent pattern of variation.

[3]Besides the MPS IVA outlined, both an intermediate and a mild phenotype exist.

[4]Several clinical forms distinguishable as more patients are reported, ranging from neonatal immune hydrops to late childhood onset disease.

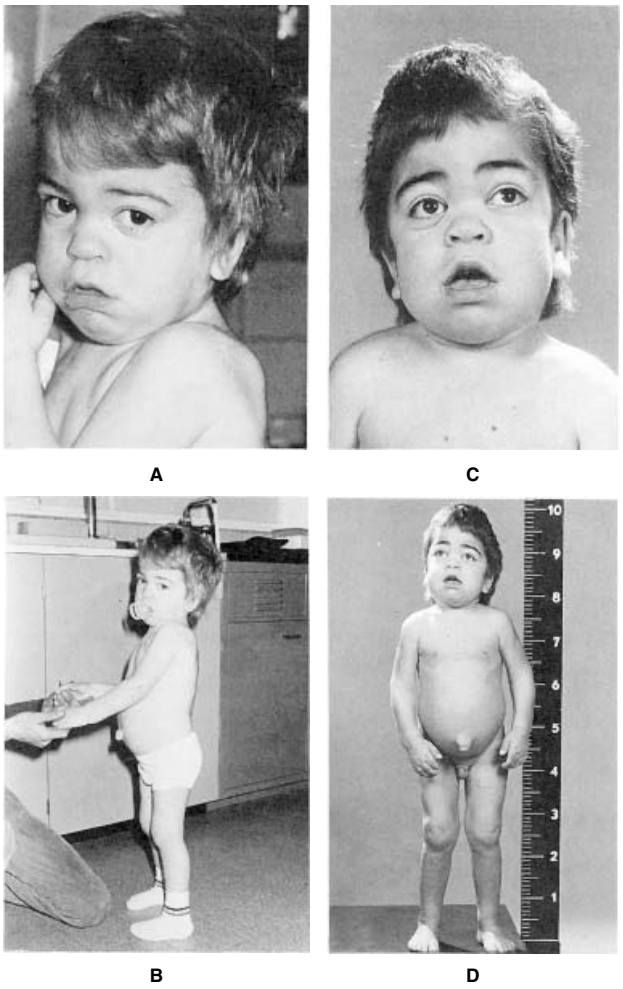

Figure 1. A,B: Patient with Hurler disease (MPS IH) at age $3\frac{7}{12}$ years, with rather mild abnormality of facial and general body configuration, hirsutism, persisting epicanthal folds, a low nose bridge, broad hands, and moderate restriction of joint mobility range, an umbilical hernia, and a prominent abdomen. **C,D**: Same patient at age $7\frac{3}{12}$ years. Features of MPS IH have progressed considerably. Final standing height (101 cm [3rd centile: 113 cm]) is rather tall in this mucopolysaccharidosis. Clouding of corneae not visualized photographically.

subsequent years increasing physical disability, conductive hearing loss, and respiratory infections represent additional hindrances impairing their progress. From the moment unaided sitting is achieved, or even before, a thoracolumbar kyphosis may be evident. It soon becomes fixed and rarely requires orthopedic treatment.

Mean life expectancy is about 10 years. Before such fatal outcome due to cardiac valve disease and mainly mitral stenosis and insufficiency and to bronchial and lung sclerosis, facial features have become increasingly grotesque, their resemblance to Gothic gargoyles leading to the now-obsolete term "gargoylism". The skin has become thick and stiff. Increasing deafness becomes more of the sensorineural type. Mental function and social contacts have meanwhile gradually declined. Finally, in the last stage, ambulation becomes limited, partly because of increasing stiffness of the large joints with fixation in flexion, and partly because of cardiorespiratory insufficiency and lack of mental and social initiative.

The radiographic features of the Hurler patient's skeleton have been termed succinctly dysostosis multiplex [2]. They are evident from birth and evolve from mild to severe by the time growth ceases. All bones are affected. The most obvious abnormalities already evident at the age of clinical onset of the disease are listed in Table 4. Dysostosis multiplex, defined as a particular pattern of radiographic changes, is not pathognomic for Hurler disease. Qualitatively similar abnormalities are observed in some of the other mucopolysaccharidoses, and in several of the oligosaccharidoses. In these entities, dysostosis multiplex is either more or less severe and evolves either more quickly or more slowly. In each instance, the following radiographs should preferentially be taken: skull (lateral), spine (lateral), pelvis and hips (anteroposterior), hands and wrists, and at least one example of a long bone. Fig. 2 illustrates various aspects of dysostosis multiplex in a patient with fully developed Hurler disease. Inherent to the recognition of the autosomal recessive mode of inheritance of Hurler disease, was the original view that all patients are homozygous for a mutant MPS IH gene with severe phenotypic effect [3]. The advent of molecular biology has meanwhile shown that most of them are compound heterozygotes for different mutations in the α-L-iduronidase gene. (See below).

Scheie Disease; MPS IS (MIM 252800)

The second phenotype due to α-L-iduronidase deficiency is represented by the patient with Scheie disease, which is a milder condition than Hurler disease. The first complaints arise in late childhood and relate to fine motor clumsiness in the hands due to decreasing motility of the finger joints. Clinical examination brings to light a decreased range of motion at the shoulders and slight clouding of the corneae, which may become troublesome and require corneal transplants that, however, provide only temporary relief. Often pes cavus is observed. Inguinal herniae may have been repaired earlier in life. Growth and intelligence are not significantly impaired. Subclinical to moderate hearing loss is noticed. Interference with life expectancy is usually

TABLE 4. Early Signs of Dysostosis Multiplex: Radiographic Features at the Clinical Onset of Hurler Disease[1]

Calvarium	Large, elongated (scaphocephalic head)
Spine	Ovoid vertebrae and /or hook-shaped hypoplastic vertebra(e) T_{12}, L_1, L_2
Pelvis, hips	Hypoplastic narrow iliac body; shallow acetabula
Long bones	Failure of tubulation (wide diaphyses)
Ribs	Broad
Hands (metacarpals)	Pointed bases, widened diaphyses, coarse trabeculation; wide proximal and middle phalanges

[1] Dysostosis multiplex, quantitatively different or similar, is observed in several other mucopolysaccharidoses (MPS); in MPS IV it differs qualitatively. For similarities and differences in the oligosaccharidoses, see text and [2]

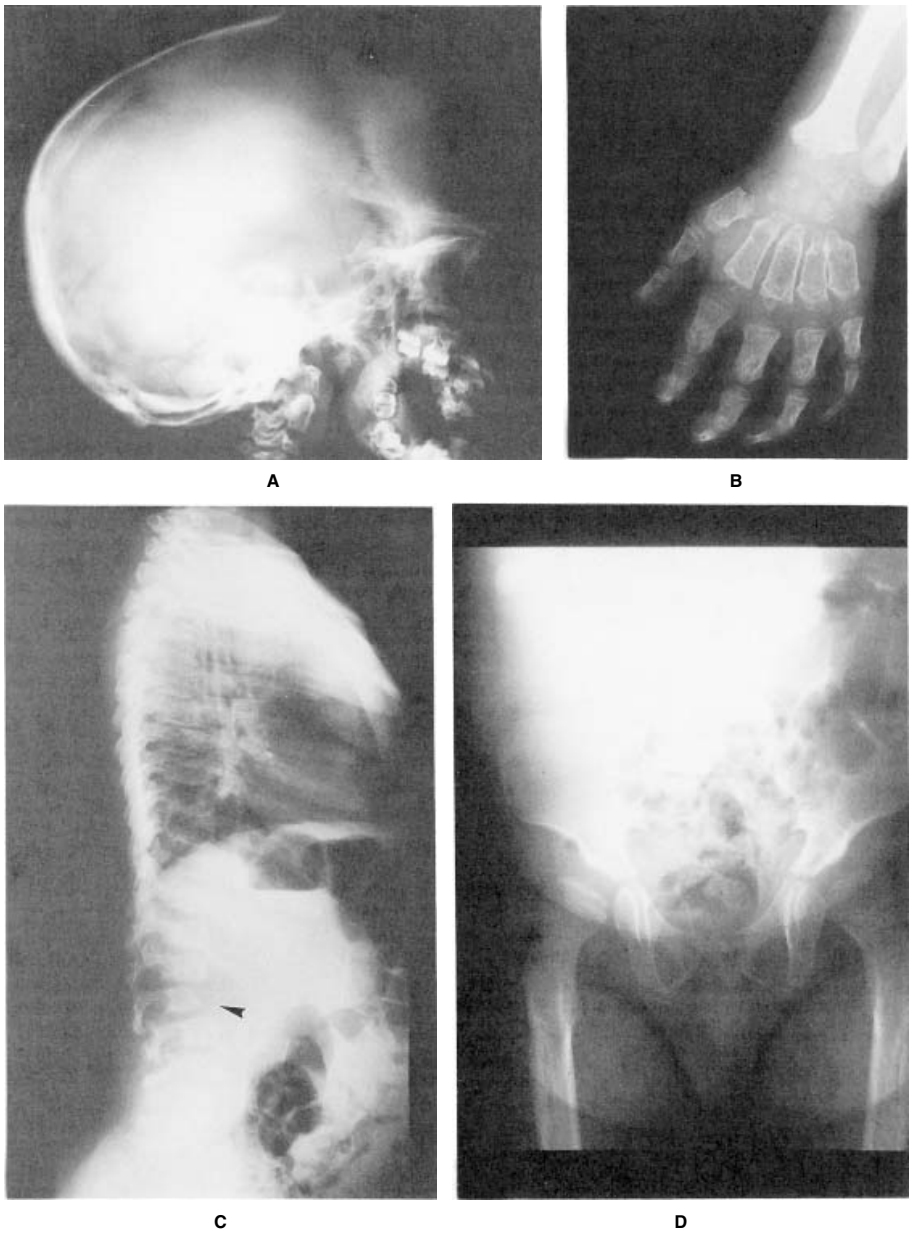

Figure 2. Roentgenographic dysostosis multiplex in fully developed MPS IH as documented at 7 3/12 years in the patient shown in Figure 1. **A**: Enlarged cranial vault with elongated sella turcica. **B**: Left hand and wrist: tilted, irregular distal radial and ulnar metaphyses; dysplastic small carpal bones; metacarpals with proximal pointing, widened diaphyses, and coarse trabeculation; phalanges shortened and widened; claw hand deformity shown by flexion of fingers. **C**: Spine; small L_3, with anterior–inferior beaking (arrow). **D**: Pelvis: narrow iliac bodies and flaring wings; oblique, shallow acetabula; coxa valga; flattened proximal femoral epiphyses.

mild in Scheie disease, except when aortic valve thickening and stiffening leading to stenosis and insufficiency causes progressive cardiac failure. Complications include retinopathy, glaucoma, and, rather often, carpal tunnel syndrome. On radiographic examination, only mild dysostosis multiplex is noticed, even in patients with rather advanced Scheie disease.

Following the discovery of the same enzyme defect as in Hurler disease [4–6], Scheie disease patients, originally classified as representing MPS V, were at first considered as being homozygous for a MPS IS mutant gene with only mild effect [3], but have more recently been recognized as compound heterozygotes [7–9].

MPS IHS (Formerly Hurler-Scheie Compound MPS) (MIM 252800)

This third phenotype among the α-L-iduronidase mutants is intermediate between MPS IH and MPS IS with regard to both time of appearance and severity of signs and symptoms. The majority of patients survive until young adulthood (Fig. 3). Final stature, though below normal, is significantly taller than in the Hurler disease patient. Despite considerable physical limitations, patients may be successful pupils in

Figure 3. Patient with MPS IHS at 18 years of age, and a successful high school student; corneal clouding severe but barely visualized photographically; prominent maxillar part of facies.

regular grade and high school. The term "compound form of MPS I" was coined on the basis of the hypothesis that these patients are compound heterozygotes for the allelic mutations, MPS IH and MPS IS, at the MPS I locus [10], even though MPS IHS patients born to consanguineous parents have been observed [3]. Meanwhile, in the majority of compound MPS-IHS patients heterozygosity has been proved [7–9].

Molecular Defect in MPS I and Diagnosis

Patients with Hurler disease (MPS IH), Scheie disease (MPS IS), or MPS IHS excrete excessive amounts of dermatan sulfate and heparan sulfate in the urine. In the cytoplasm of lymphocytes, large vacuolar structures, when stained with toluidine blue, show red metachromasia, demonstrating the glycosaminoglycan nature of their contents. Since the 1970s, formal confirmation of the clinical diagnosis has been achieved by the finding of nearly absent activity of α-L-iduronidase in leukocytes and cultured fibroblasts [5,6]. Assay of this enzyme in chorionic villi or cultured amniotic fluid cells also allows the prenatal diagnosis of MPS I [5]. In Fig. 4, the role of α-L-iduronidase in the physiologic degradation process of glycosaminoglycans is schematically presented. Although but one of many lysosomal acid hydrolases involved, its deficiency precludes their concerted catabolic action in the patient. Although the severely affected Hurler disease patients usually lack both immunodetectable α-L-iduronidase protein and α-L-iduronidase activity, a correlation between residual enzyme activity and severity of the phenotype has only been partially possible [11,12].

Knowledge of the α-L-iduronidase (*IDUA*) gene and its mutations may be useful in establishing genotype-phenotype correlations. The *IDUA* gene maps to chromosome 4p16.3 [13] in close proximity to the genes for Huntington disease and fibroblast growth factor receptor 3 (FGFR3), which is mutated in achondroplasia and related osteochondrodystrophies [14] (see Chapter 23, Part IV, this volume). The gene is approximately 19 kb in length and contains 14 exons. Exons 2 and 3 are separated by a large intron of nearly 13 kb, which contains an *Alu*-repeat element and a highly polymorphic VNTR repeat. This latter was an important point of reference in the identification of the gene itself. The promoter region of the *IDUA* gene contains several possible transcription start sites consistent with the maintenance of low levels of transcription. At its 5′ end, the *IDUA* gene is flanked by another *Alu* repeat sequence [14–16].

α-L-iduronidase mRNA has a length of only 2.3 kb. Alternative splicing of exons 2 and 3 has been reported [14], but its clinical significance remains unclear at present. The 1959-bp open reading frame in *IDUA* is represented by 653 amino acids in a single polypeptide containing six potential N-glycosylation sites [15]. A signal peptide of 25 amino acids is cleaved off upon leaving the endoplasmic reticulum, placing the N-terminus at alanine 26.

Genotype-Phenotype Correlation in MPS I

To the present, several hundred mutations including nonsense, missense, and splice site mutations and small deletions or insertions have been identified within the *IDUA* gene [7–9,14,17–19]. In addition to cataloging the *IDUA* mutants [14], the earlier described and most frequently encountered ones have been given allelic variant subnumbers of MIM 252800 [20]. Intragenic polymorphisms have also been found. They may be helpful in identifying founder effects as they account for high frequencies of alleles in some ethnic groups and not in others.

Some genotypes reliably predict the clinical phenotype. Null mutations and the effects of either premature termination of the gene product, frameshifts, or major sequence rearrangements, invariably cause severe disease (MPS IH) in the homozygous patient, and usually also in the compound heterozygote. This is true for the mutations Trp402Stop and Gln70Stop accounting for approximately 50% of patients of Northern European origin [7–9]. Because of the degree of allelic heterogeneity, not only patients with MPS IHS but also many with Hurler or Scheie phenotypes are genotypically compound heterozygotes. It is now well understood that rather than the discontinuous set of three clinically delineated phenotypes — severe, intermediate, and mild — a continuous spectrum of severe to mild clinical expression more accurately describes the variability of phenotypes among MPS I patients and reflects the expected consequence of multiple alleles at the *IDUA* locus. Obviously intrafamilial clinical variability is significantly more restricted than the wide overall variability. Unless a large proportion of mildly affected Scheie type patients had not been ascertained, the distribution of MPS I patients would have been considerably skewed toward the severe Hurler phenotype.

The consequences of simple amino acid substitutions are inconsistent, as some produce a severe phenotype while others result in intermediate or even mild disease. Some of the amino acid polymorphisms probably modulate the directly deleterious effect of amino acid substitutions. The mutation Arg89Gln found with high frequency in Japan, but not in Europe, produces reduced stability and activity of the mutant α-L-iduronidase. It is found often in Scheie disease, and may have its deleterious effect potentiated by the presence of the Ala361Thr polymorphism and thus produce an intermediate phenotype. Besides the steady improvement in the molecular documentation of genetic heterogeneity in MPS I, detailed genotype-phenotype correlation with high predictive value is

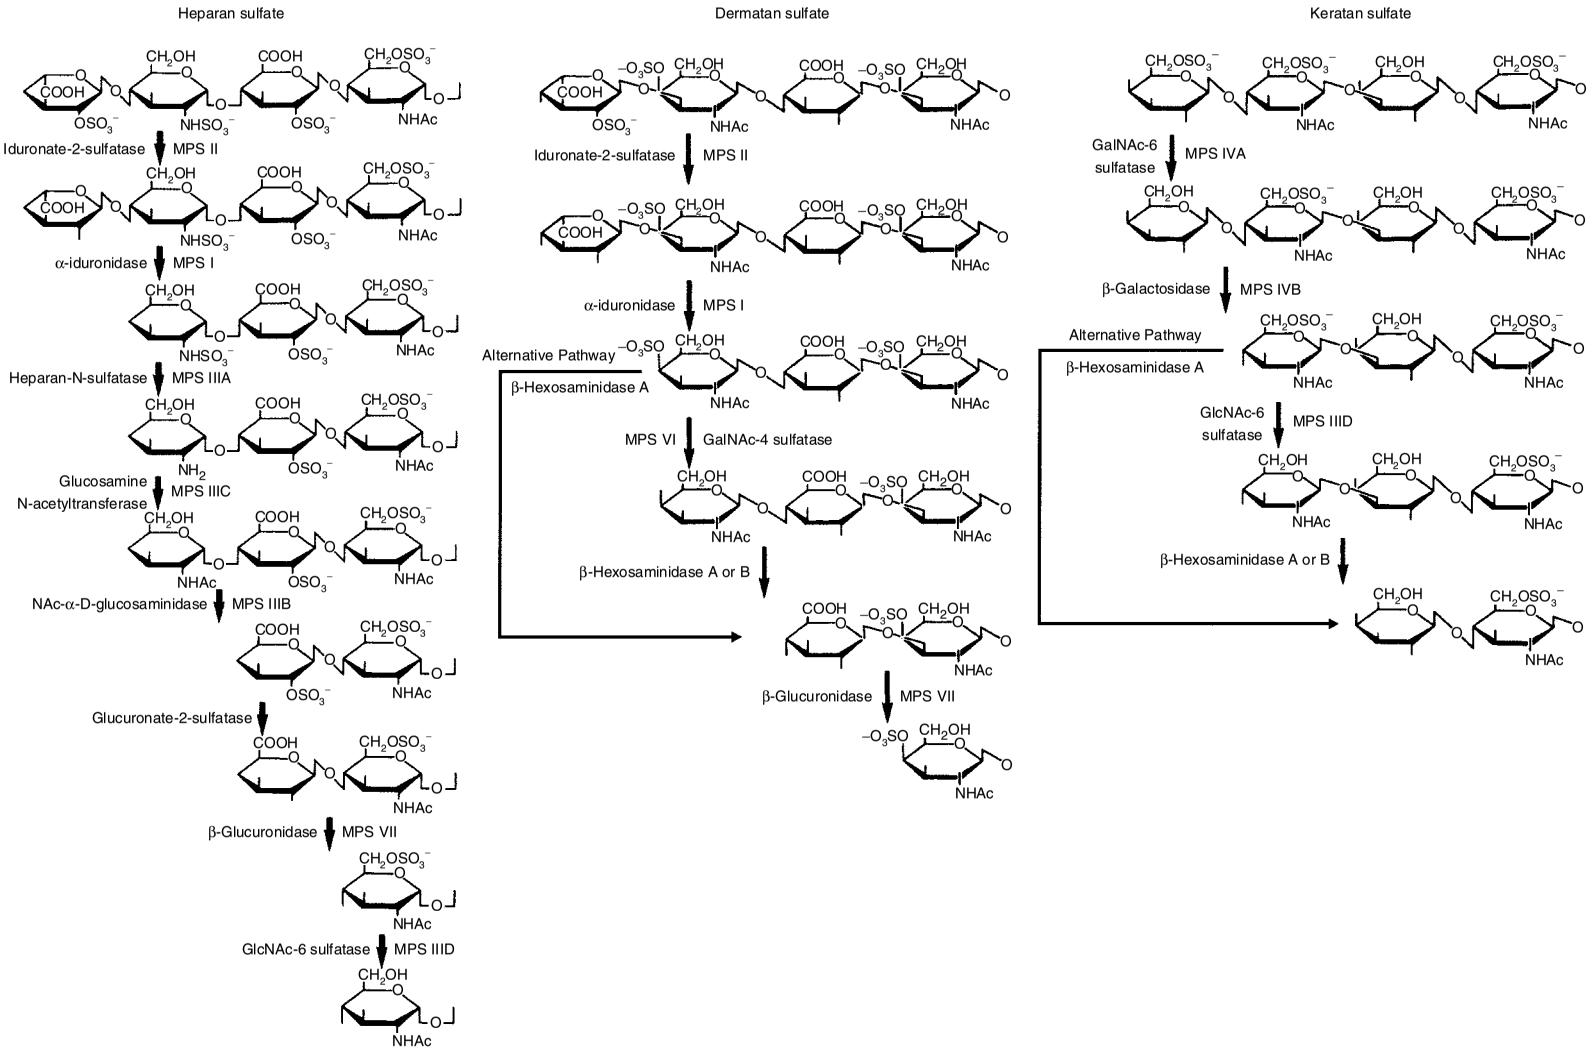

Figure 4. Schematic degradation of glycosaminoglycans by the concerted catalytic action of exoglycosidases and sulfatases having the effect of stepwise removal of glycosyl moieties and sulfate groups and provision of the appropriate substrate for the next enzyme action. Normal catabolism is specifically interfered with in each mucopolysaccharidosis by the primary enzyme defect indicated. For abbreviations, see text and Tables 2 and 3. Structures shown are qualitative representations only as the relative proportions of iduronate/glucuronate moieties, the degree of hexosamine acetylation, and the type and number of sulfate groups differs from tissue to tissue. **Dermatan sulfate (DS)**: polymer of disaccharide repeats of 2-sulfated iduronate (glucuronate) α 1,3 (β 1,3) residues linked to GalNAc sulfated at C4; each repeat is joined by β 1,4 linkage to the next. **Keratan sulfate (KS)**: polymer of disaccharide repeats of galactose joined by β 1,4 linkage to GlcNAc; each repeat is joined by β 1,3 linkage to the next; nearly all GlcN moieties are sulfated at C6. **Heparan sulfate (HS)**: polymer of α-glycosidically linked disaccharide repeats consisting of iduronate (glucuronate), some of it 2-sulfated, joined by α 1,4 (β 1,4) linkage to GlcNAc, itself sulfated at C6 and/or at its free NH-substituent on C2. Glycosaminoglycans are components of large proteoglycan complexes in cartilage matrix and other connective tissues, mostly O-linked onto proteins. For further information, see Chapter 4 (this volume). (Figure adapted from [116].)

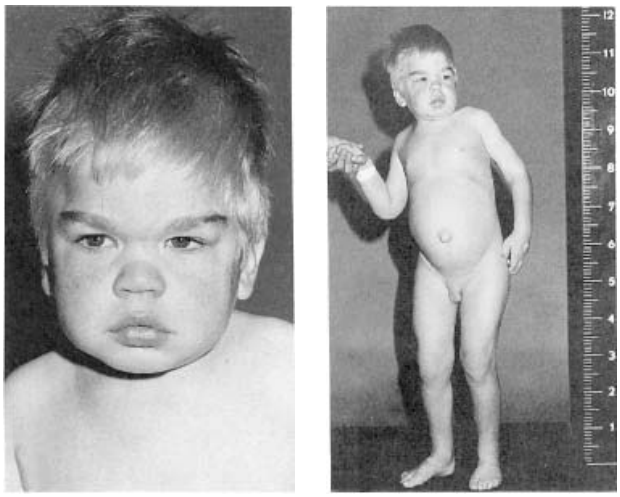
still to be achieved. In this respect, the lack of systematic description of phenotypes, including their natural courses, is at present at least as large a flaw as the lack of knowledge of the amount and quality of α-L-iduronidase mRNA produced and the incomplete understanding of enzyme processing, intracellular routing and kinetics, the rate of substrate accumulation in different tissues, and residual specific organ catalytic activity *in vivo*. The strategy and success of attempts at enzyme and gene therapy will much depend on such knowledge about the individual patient.

Matters of genetic heterogeneity at the *IDUA* locus are further complicated by the existence of rare pseudodeficiency alleles. Such mutations result in low or unmeasurable α-L-iduronidase enzyme activity when assayed with artificial substrates, but produce a normal phenotype. Irrespective of the unknown physiopathologic significance of this additional molecular heterogeneity, its existence has implications in particular in prenatal diagnosis [21].

Hunter Disease; MPS II (MIM 309900)

Usually the patient with Hunter disease does not come to medical attention before his third birthday, when parents may be concerned about slow development of speech and short attention span. Often, recurrent respiratory infections, including bouts of otitis, will have troubled the affected toddler. Rather frequently he will already have been operated upon for inguinal herniae. He has quite noisy breathing and excessive nasal discharge. The patient is described as increasingly disobedient, destructive, and stubborn. Complaints about loose stools soon become regular. Upon clinical examination, the boy has coarse facial and stocky body features. The head is large, but often not scaphocephalic. The bridge of the nose is low. The corneae are clear. At this early stage of the disorder the patient's height is tall, and sometimes exceeds the 97th centile. The abdomen is prominent. There is hepato- and often also splenomegaly. If cooperation is adequate, limitation of the range of movement at the shoulders can be demonstrated. The hands are broad and the fingers slightly stiff (Fig. 5).

For the inexperienced clinician, the early diagnosis of Hunter disease, of great importance for the purpose of prevention, is a major challenge. At 3 or 4 years of age, physical features in the Hunter disease patient are much milder than those in Hurler disease, which, at that age, is already fully developed. However, the completely developed clinical phenotype of MPS II becomes quite similar to that of MPS IH, hence the obsolete term Hurler-Hunter syndrome. Whereas Hurler disease patients remain good-natured and of calm disposition, Hunter disease boys have a short attention span and are impatient and agitated. Their growth slows down from about 4 years of age, but does not come to a complete halt until about 6 or 7. Deafness is of major importance. Initially of the conductive type, by age 5 it is compounded by an increasing sensorineural component, which thereafter becomes the sole reason for total lack of hearing. Facial features gradually coarsen and mental and motor handicap and joint stiffness increase gradually. The eyebrows become heavy, the hair more coarse. Hirsutism increases over the back and the limbs. Kyphosis is rather rare in Hunter disease. Patients may show patches of nodular skin. Heart murmurs due to thickened and stiffened cardiac valves are often heard in older patients. Hunter disease frequently has a fatal outcome, usually between the ages of 10 and 15 years, due to either cardiorespiratory complications refractory to treatment, or brain stem disease,



A B

Figure 5. A, B: Patient with Hunter disease type A (MPS IIA) at the age of $5\frac{10}{12}$ years. A stocky, strong boy with coarse hair and facial features, a low nose bridge, increasing limitation of range of movement in large and small joints, a claw hand deformity, and a prominent abdomen with a small umbilical hernia. Growth decelerating but stature still at 50th centile.

or both. Dysostosis multiplex in Hunter disease does not differ qualitatively from that in Hurler disease, but is less pronounced at any age [2].

In a minority of patients, Hunter disease has a much milder clinical course. In such patients, its clinical onset can be at a variable age, but is usually not after mid-childhood. Deafness, respiratory infections, and stiffening of the hands are the most frequent initial complaints. Survival to adulthood is the rule. Growth, although adversely affected, leads to short stature rather than true dwarfism. Dysostosis multiplex remains quite mild. Usually, patients can attend regular grade school and even high school in some instances. The majority of patients with the milder form of the disorder die in young adulthood of acute complications of slowly progressive cardiac valve disease.

It is obvious that the severer and milder forms of the disease, previously often called MPS IIA and MPS IIB, respectively [20], are but the extremes of a continuum of overall clinical variation. However, the phenotypes of affected boys within a single family or pedigree are rather consistent.

Molecular Defect in MPS II and Diagnosis

Iduronate 2-sulfatase (IDS) deficiency is the primary metabolic defect in Hunter disease [22]. The role of the enzyme in glycosaminoglycan degradation is illustrated in Fig. 4. No *in vitro* complementation has been observed between cultured fibroblast strains derived from patients with severe and mild disease, confirming that all *IDS* mutations are functionally allelic. It is clear, however, that besides the effects of mutations affecting the iduronate sulfatase glycoprotein itself, its intracellular processing and compartmentalization, already well known in human fibroblasts [23], must depend on still other genes. The *IDS* gene spans 24 kb near the telomeric region of the X-chromosome at Xq27-Xq28. Its transcriptional orientation is from telomere to centromere. [20,24–26].

Carrier detection in clinically normal females, a major challenge in any X-linked disorder when relying on enzyme specific activity, becomes straightforward provided the mutation in the proband has been identified. If not, hair root enzyme studies [27] or *in vitro* inhibition of intercellular cross-correction by fructose 1-phosphate [28] must still be resorted to. Occasionally, full Hunter disease has been reported in girls with a normal karyotype. Most such observations have been explained by nonrandom inactivation of the X-chromosomes probably induced by either autosomal translocation, Xq deletion [29,30], or the zygotic process of twinning [31].

The isolation, cloning and sequencing of a 2.3 kb iduronate 2-sulfatase cDNA represented a major step in effectively achieving the molecular diagnosis of Hunter disease [32,33], demonstrating its extensive genetic heterogeneity, and providing answers to questions of genotype-phenotype correlation. The *IDS* gene contains 9 exons, the complete base sequences of which have been elucidated [34,35]. Patients in whom the *IDS* gene has been deleted completely or grossly rearranged invariably have the severe form of Hunter disease [29,36–38]. They may represent as many as 20% of all *IDS* gene mutations. As many as half of all patients have missense or nonsense mutations. A large majority of these are severely affected, while the remainder have either an intermediate form or are more mildly affected. Mutations with a severe clinical effect usually involve amino acids that are conserved between human and murine iduronate sulfatases. They do not usually involve amino acids identified as homologous in several other sulfatases. As expected, mutations in patients with mild disease are compatible with slight residual iduronate sulfatase activity. However, in more than 20% of MPS II patients with a deletion of even a single or two or three base pairs, the majority of which lead to a frameshift and premature polypeptide termination, a total loss of enzyme function is found. These are therefore called null mutations. Also, several splice site mutations have been documented, mostly causing relatively small insertions or deletions in the mRNA [34–38].

A second gene, called *IDS2*, has been identified. It is presumed to be a pseudogene containing base sequence stretches related to exons 2 and 3 and introns 2,3, and 7 of the *IDS* gene [39]. Its location is telomeric to the latter. It is probable that in about 10% of the more severely affected Hunter disease patients, a *cis* intergenic (gene-pseudogene) recombination with the primary *IDS* gene has occurred, resulting in the disruption and inversion of the intervening DNA within the primary *IDS* gene. In the rearranged gene, pseudogene intron 3- and intron 7-related sequences are found [40]. This apparent "hot spot" type of chromosomal rearrangement is probably based on crossing over between fairly homologous stretches of nucleotides.

The entire *IDS* region telomeric to the *IDS2* gene contains a number of as yet unknown genes that may also be deleted in the more severely affected Hunter disease patients, in particular those with atypical additional symptoms such as ptosis of the eyelids, obstructive sleep apnea, and seizures. Thus, such patients may be affected by a contiguous gene deletion syndrome of which Hunter disease and a disorder causing some type of epilepsy are components [33,37,41–43].

In one patient with moderate to severe Hunter disease, no intragenic *IDS* mutation but a large deletion 178 bp upstream of *IDS* exon 1 was detected spanning an *IDS* promoter and resulting in the total loss of IDS function [44]. The continuously enlarging list of mutations within and around the *IDS* gene [45] makes systematic tabulation of allelic variants an increasingly formidable task [20]. If, in the original reports, systematic description of the corresponding phenotypes remains scanty at best, any attempt at genotype-phenotype correlation remains a daunting assignment.

Sanfilippo Disease; MPS III A (MIM 252900), III B (MIM 252920), III C (MIM 252930), and III D (MIM 252940)

As shown in Table 2, no less than four different enzyme defects have been demonstrated in various patients with Sanfilippo disease, all of whom excrete mainly or exclusively large amounts of heparan sulfate in the urine. For the specific role of each of the enzymes involved in glycosaminoglycan catabolism, see Figure 4. Clinically and chemopathologically, all types of MPS III can hardly be considered disorders of connective tissue, and, therefore, they are not discussed here at length. Their main clinical features are listed in Table 3. The heads of these patients are large, but skeletal growth remains approximately normal. Nevertheless, the thickening of the mitral valve leaflets and chordae tendineae, mitral regurgitation, mild mitral stenosis, asymmetric septal hypertrophy, and aortic insufficiency known to occur in the natural course of any type of MPS are frequently apparent also in MPS III patients. In some they lead to congestive cardiomyopathy, as has been pointed out by Dangel [46]. These findings known in MPS I, II, and the rest of the entities are the more surprising in MPS III, which is known to affect mainly and foremost the central nervous system. For extensive discussion of clinical phenotypes, pathology, and chemopathology, the various enzyme defects, and molecular aspects known to date, the reader is referred to excellent reviews elsewhere [47,48].

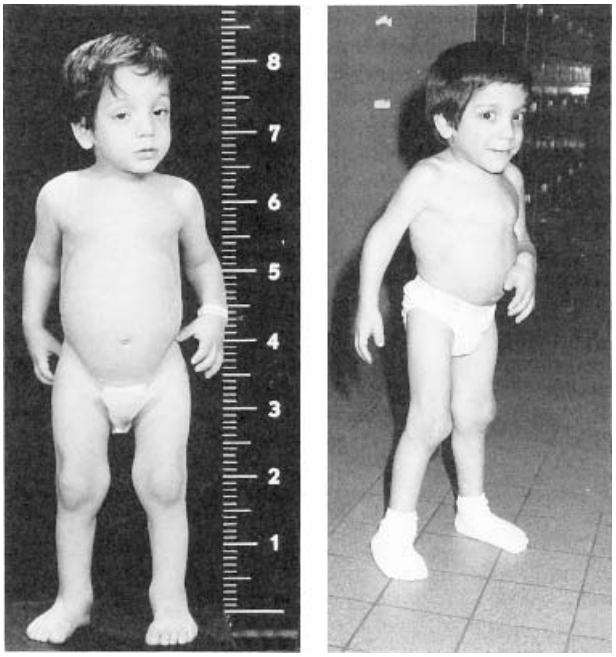
Morquio Disease; MPS IV

MPS IVA (MIM 253000)

The clinical features of this severe short-trunk type dwarfism do not appear until the second or third year of life, when pectus carinatum and growth failure become parental complaints and medically observable (Fig. 6). Genua valga and thoracolumbar kyphosis may be the presenting symptoms. Throughout its clinical course, Morquio disease does not affect mental functioning. Before the age of 6 years, the full clinical picture has developed and consists of a rather large head consistently held in slight retroflexion; facial features that, except for a rather prominent maxilla and mandible, are rather unremarkable; cloudy corneae, at least upon slit lamp examination; widely spaced teeth with hypoplastic enamel; a short neck; protruding sternum; joint laxity; conductive hearing loss; progressive physical disability and easy fatigue for both mechanical and neurological reasons. Vibration sense and muscular tone in the lower limbs become inadequate. Multiple arthroses also compound the clinical picture in older patients [10,20,48,49].

Life expectancy within each type of Morquio disease is determined by the probability of complications, mainly cervical myelopathy, which is unavoidable if careful orthopedic fusion of the cervical spine is not performed sufficiently early in childhood. Luxation of the first cervical vertebra due to odontoid hypoplasia and hyperlaxity of ligaments can cause sudden death due to major damage to the lower brain stem [50].

The radiographic features are those of a spondyloepiphyseal dysplasia with coxa valga. They may also be recognized



A **B**

Figure 6. A: Patient with Morquio A disease (MPS IVA) at age $2\frac{4}{12}$ years. Rapidly decelerating growth. Prominent knees with mild limitation of range of movement without stiffness of weak connective tissue. Rather proportional body configuration. Slight cloudiness of corneae. **B**: Same patient at $4\frac{8}{12}$ years of age. Increase in stature has been minimal. Progressive deformation of sternum and thoracic cage, wrists with radial deviation, and knock knees. Many bouts of upper respiratory infection throughout.

as an unusual form of dysostosis multiplex with, as main added features, odontoid dysplasia and ensuing atlantoaxial instability leading to increased risk of cervical spinal cord compression; moderate to severe platyspondyly; and marked shortening of tubular bones without diaphyseal widening.

Molecular Defect in MPS IVA and Diagnosis. The excessive urinary excretion of keratan sulfate, initially of orienting value in diagnosis, decreases considerably after adolescence. A deficiency of N-acetylgalactosamine-6-sulfate sulfatase (GalNAc-6-sulfate sulfatase) is detected not only in severely affected patients but also in those with an intermediate or even mild phenotype [51–53]. How the enzyme deficiency interferes with keratan sulfate metabolism may be deduced from Fig. 4. The mild form of MPS IVA is to be distinguished in the laboratory from that caused by a nonallelic mutation at the β-D-galactosidase locus (see Morquio disease type B, below).

In normal subjects, GalNAc-6-sulfate sulfatase is synthesized as a precursor glycopeptide of 120 kDa. After the removal of the N-terminal signal peptide and some carbohydrate modification, the precursor is enzymatically cleaved giving rise to the mature heterodimeric enzyme consisting of two subunits of 40 kDa and 15 kDa, respectively [54]. As might be predicted from the clinical variability of MPS IVA, various mutations in the GalNAc-6-sulfate sulfatase (*GALNS*) gene affect to varying degrees either the synthesis, maturation, stability, subunit association and/or kinetic properties of the enzyme [55].

Genomic sequences and full length cDNA encoding N-acetylgalactosamine-6-sulfate sulfatase have been cloned and characterised [56,57]. The gene, mapped by *in situ* hybridization, is located at 16q24.3 [58,59]. It is approximately 35 kb in length and contains 14 exons. The open reading frame in the cDNA consists of 1566 bp encoding 522 amino acids [57]. In addition to multiple polymorphisms useful in haplotype identification [60], the several types of gene mutation detected include not only missense, frameshift, and splice-site mutations, but also large structural alterations such as a rather common double gene deletion, 8.0 and 6.0 kb in size, respectively [61], so far found only in Japanese patients [60]. The 8.0-kb deletion results from an *Alu-Alu* recombinational event, while the 6.0 kb deletion involves intragenic recombination between short incomplete direct repeats at the two breakpoints. Although mutation analysis of the *GALNS* gene demonstrates rather extreme allelic genetic heterogeneity, a characteristic mutation common to each ethnic population studied appears to emerge, except in the case of patients of continental European origin [62,63]. In Colombia, 16 out of 19 patients (68%) have been shown to carry the Gly301Cys missense mutation [64]. Two mutations, Ile113Phe and Thr312Ser, represented 32% of a sample of patients from Ireland and Australia [63]. The former has not yet been found in Japan. The skewed prevalence in some of the populations studied and the results of haploid type analysis within the *GALNS* gene point at ethnic group-specific founder effects. Emerging also is the impression that missense mutations resulting in the replacement of glycine by amino acids interfering with the tridimensional conformation of the enzyme and those in regions of the gene conserved among all sulfatases, have a severe clinical effect. Some mutations have consistently been associated with a mild phenotype. Patients with an intermediate phenotype are often compound heterozygotes for two *GALNS* mutations. At the present time, any conclusions relating to phenotype-genotype correlations must remain tentative.

MPS IVB (MIM 253010)

This is a milder form of Morquio disease, radiographically resembling moderate spondyloepiphyseal dysplasia [64]. In most patients, direct involvement of the central nervous system cannot be demonstrated. In some, however, mental regression is observed [65]. The condition is due to deficiency of β-galactosidase [66–68] (Fig. 4). The mutations involved are known to be allelic to the β-galactosidase mutations causing the various types of G_{M1}-gangliosidosis (Table 6). They affect mainly the affinity of β-galactosidase for keratan sulfate and oligosaccharides and not, or only slightly, that for gangliosides and other lipid-soluble substrates [66]. Cell hybridization studies have shown that MPS IVB and the various forms of G_{M1}-gangliosidosis belong to the same complementation group [67]. (See G_{M1}-gangliosidosis in "Disorders Due to Deficiency of β-D-Galactosidase", below).

MPS IV C; Non-Keratan Sulfate-Excreting MPS IV (MIM 252300)

In addition to the various clinical phenotypes of MPS IVA and MPS IVB patients, children and adolescents with mild manifestation of the disease and radiographic features also qualitatively within the range of MPS IV have been described, in whom no deficiency of either N-acetylgalactosamine-6-sulfate sulfatase or β-D-galactosidase has been found [69]. Thus, it is likely that in some patients with "Morquio disease," the primary enzyme defect has not yet been elucidated [52]. As pointed out by McKusick [20], many

types of spondyloepiphyseal dysplasia have been incorrectly labeled Morquio syndrome. Because lack of keratansulfaturia is common in the older MPS IVA patient, the unaffected function of both N-acetylgalactosamine-6-sulfate sulfatase and β-D-galactosidase stands as a requirement for the diagnosis of MPS IVC.

Maroteaux-Lamy Disease; MPS VI (MIM 253200)

Both severe (VIA) and mild (VIB) clinical phenotypes are generally recognized among patients with Maroteaux-Lamy disease, who are physically quite similar to patients with MPS 1H or children with pseudo-Hurler polydystrophy, discussed among the oligosaccharidoses below, respectively. As a rule, however, developmental retardation and mental deficiency are not features of Maroteaux-Lamy disease.

The MPS VIA patient comes to medical attention somewhat later in infancy and usually has milder craniofacial features than the Hurler patient. Growth is often equally deficient and dysostosis multiplex quite severe. Some patients may survive into early adulthood. Clinical recognition of the MPS VIB patient is often delayed until more than 5 years of age. Growth and facial features are only mildly affected and dysostosis multiplex is minimal. In both types of patient, almost exclusively dermatan sulfate is excessively excreted in the urine [49]. Metachromatic granules in lymphocytes and granulocytes are more easily demonstrated in MPS VI than in the other types of mucopolysaccharidoses.

Molecular Defect in MPS VI and Diagnosis

Both clinical forms of MPS VI are specifically associated with a severe deficiency of N-acetyl-galactosamine-4-sulfate sulfatase (arylsulfatase B), most likely due to functionally allelic mutations. In fact, the clinical expression of deficient arylsulfatase B activity represents a continuous range of phenotypes with regard to both intrinsic severity and clinical course between the better known MPS VIA and milder MPS VIB. The molecular basis for this phenotypic spectrum remains to be clarified but is clearly related to genetic heterogeneity. The enzyme defect was elucidated a quarter of a century ago [70,71]. Its metabolic role in dermatan sulfate degradation is depicted in Figure 4. In patients, arylsulfatase B protein is not only significantly decreased but also structurally altered. Its degree of modification shows some correlation with the severity of clinical presentation [72,73]. This trend toward a low level of cross-reacting material using polyclonal-based sandwich ELISA has also been confirmed by protein assay and immunochemical analysis in other types of MPS patients. Information on enzyme processing and targeting is, however, an essential prerequisite in correlating overall residual catalytic activity with clinical phenotype [74]. The arylsulfatase B enzyme has been purified from various sources [75]. It is synthesized as a 64 kDa precursor polypeptide, which is subsequently phosphorylated and enzymatically processed into two major mature forms. Only form I, composed of a 47 kDa and an 11.5 kDa polypeptide, appears to exert catalytic activity toward the artificial substrate *p*-nitrocathecol sulfate [76].

The gene has been assigned to chromosome 5q13-q14 by *in situ* hybridization [77]. The cloning and characterization of genomic DNA and full-length cDNA has established the human *ARSB* gene as containing 8 exons [78,79]. This has opened the route to accurate testing for the heterozygous genotype and to studies on genotype/phenotype correlation. Various gene mutations have already been documented, comprising mostly missense mutations, some nonsense nucleotide substitutions, and some single nucleotide deletions with frameshift consequences. Few have been observed in more than single families. In homozygous patients the degree of severity is rather consistent, but in heterozygous genotypes is difficult to predict. The biochemical phenotype does not necessarily reflect the intralysosomal molecular events that one would want to see correlated with the clinical features [73,80–82].

Sly Disease; MPS VII (MIM 253220)

This disorder was clinically delineated simultaneously with the discovery of the underlying defect of β-D-glucuronidase [83]. The patient with Sly disease does not differ clinically from the one with Hurler disease, although the clinical course starts somewhat later and may last well into adulthood. Rather extensive variability is noticeable among patients described, varying from the now classic MPS VII (Sly disease) patient to mildly affected individuals with asymptomatic thoracic kyphoscoliosis without organomegaly, corneal clouding or dwarfing, but with β-D-glucuronidase activity only 10% of normal in cultured fibroblasts [84,85]. At the opposite end of the phenotypic spectrum, several examples of nonimmune fetal hydrops have been observed before or at birth [86–88]. As glucuronic acid is a building block in several glycosaminoglycans, the deficiency of β-D-glucuronidase impairs the catabolic breakdown of heparan as well as dermatan sulfate (Fig. 4).

The lengthy process of determining the precise chromosomal location of the human gene at 7q11.21-q11.22, was completed relatively recently. The fluorescence *in situ* hybridization technique applied, simultaneously revealed two pseudogenes located at 5p13 and 5q13, respectively [89]. Cloning and molecular characterization revealed that the human β-D-glucuronidase gene (*GUSB*) is 21 kb long and contains 12 exons. Through alternative splicing, two different transcription products arise. In the shorter of the two types of mRNA, a major part of exon 6 is lacking [90]. Complete sequencing was achieved by Tomatsu et al. [91]. Once again, the expected genetic heterogeneity has been amply documented by the finding in homozygotes, severely affected compound heterozygotes, and hydropic neonates, of missense, frameshift, and premature splice site-introducing mutations [88,89,92].

Multiple Sulfatase Deficiency; Mucosulfatidosis (MIM 272200)

The clinical and pathological phenotype of this rare but severe disorder is a composite of features found in the mucopolysaccharidoses and metachromatic leukodystrophy [93,94]. First described by Austin et al. in 1965 [95], it is due to the deficiency of several lysosomal and microsomal sulfatases. The disease has its clinical onset in the first year of life, when psychomotor retardation, hepatosplenomegaly, recurrent respiratory infections, inguinal herniae in males, moderate dysostosis multiplex, and increased urinary excretion of glycosaminoglycans as well as sulfatides is observed. Craniofacial changes are less severe than in Hurler disease, but as neurodegenerative symptoms become overwhelming in the second year of life, the facial features are soon those of a child with severe mental retardation. By the third birthday, loss of the few acquired skills, progressive quadriplegia, ataxia, nystagmus, convulsions, and loss of vision and hearing are apparent. The corneae remain clear. In most patients, dermal scaling or moderate ichthyosis is observed as a result of steroid sulfatase deficiency, as in X-linked isolated steroid sulfatase deficiency (MIM 308100). Multiple sulfatase deficiency ends fatally between early and late childhood. Most

of the few clinical reports available agree closely with the average phenotype described. However, other clinical types, including a neonatal [96,97] and a late-onset variant [98], have been reported. Multiple sulfatase deficiency in the fetus is also a cause of low urinary estriol in pregnancy [99]. No less than five different phenotypes including metachromatic leukodystrophy and various types of MPS may be recognized initially at the time of the clinical onset of the disorder [94], yet all mutations causing multiple sulfatase deficiency are allelic. Formal diagnosis of the condition is achieved by the demonstration in leukocytes or fibroblasts of simultaneous deficiencies of the lysosomal arylsulfatases A (cerebroside sulfatase) (EC 3.1.6.8) and B (EC 3.1.6.1) and the microsomal arylsulfatase C (steroid sulfate sulfohydrolase) (EC 3.1.6.2). Other sulfatases, in particular those known to be primarily deficient in Hunter disease, Sanfilippo diseases A and D, and Morquio A disease, respectively (Table 2), are also equally and concomitantly deficient [93,100]. *In vitro* complementation studies have provided no indication that the genes for the sulfatases involved are affected [101]. However, in expression studies of sulfatase cDNA in multiple sulfatase-deficient fibroblasts, sulfatase polypeptides were found to have significantly reduced catalytic activity [102]. Subsequently, a genetic defect in posttranslational arylsulfatase modification has been demonstrated. The conversion of cysteine residues 69 in arylsulfatase A and 91 in arylsulfatase B into 2-amino-3-oxopropionic acid, which is required for the generation of catalytically active sulfatases, does not occur in multiple sulfatase deficiency. This lack of sulfatase posttranslational modification causes multiple sulfatase deficiency [103]. The cysteine residues in question are located within an amino acid sequence highly homologous among human sulfatases. This entire sequence is also conserved in four lower eukaryote sulfatases.

THE OLIGOSACCHARIDOSES

Because of the adversely affected metabolism of carbohydrate in glycoproteins and glycolipids of oligosaccharidosis patients, there is an excess of oligosaccharides in their tissues and body fluids. At present, this group of disorders is also called the glycoproteinoses because of the defective catabolism of glycoproteins (Fig. 7). Excessive urinary excretion of oligosaccharides is the common hallmark of all

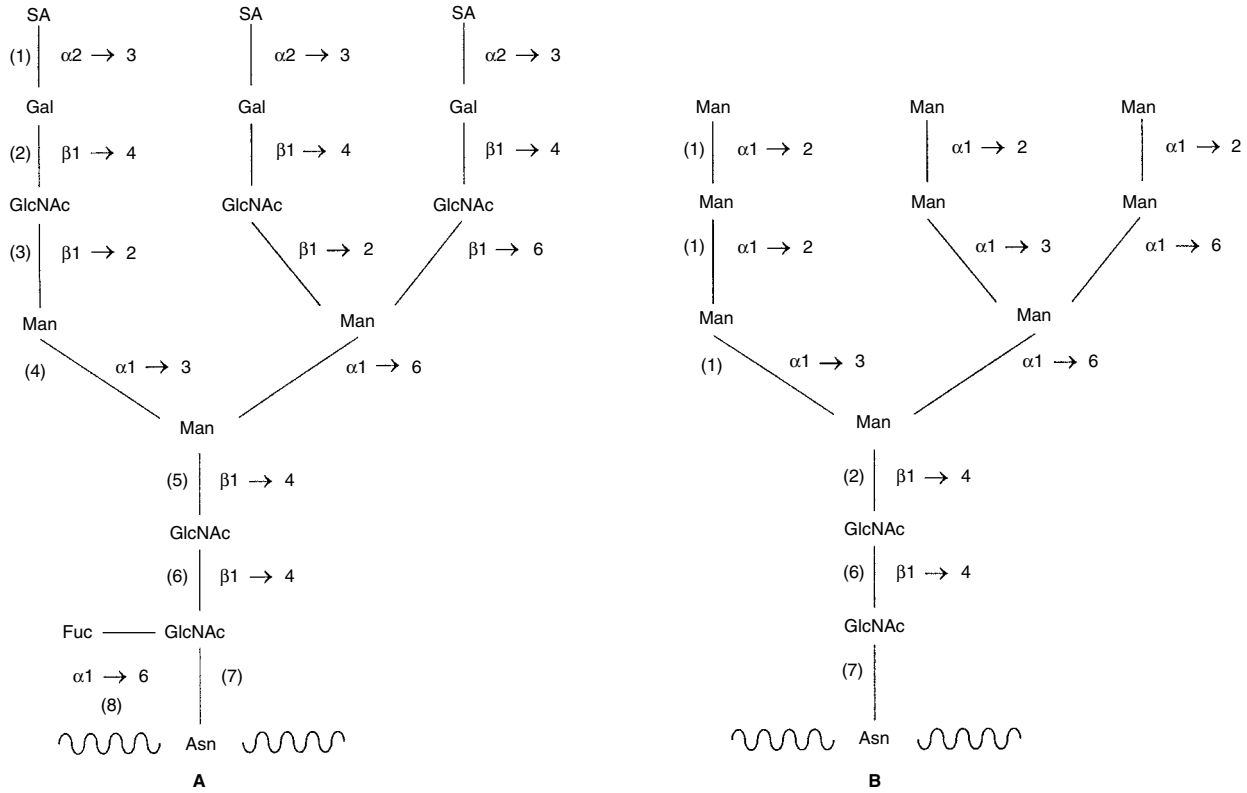


Figure 7. Catabolism of glycoproteins A: Complex N-linked (asparagine-linked) glycan in glycoproteins (lysosomal hydrolases) directed toward secretion into the extracellular fluid. (For biosynthesis, see refs. [105,115,116]. Concerted metabolism of the chemical bonds indicated occurs by stepwise catalytic action of (1) glycoprotein sialidase; (2) β-D-galactosidase; (3) β-hexosaminidase; (4) α-D-mannosidase; (5) β-D-mannosidase; (6) endo-β-N-acetylglucosaminidase; (7) aspartylglucosaminidase; and (8) α-L-fucosidase. **B**: Representative example of high-mannose type N-linked (asparagine-linked) glycan in glycoproteins (lysosomal hydrolases), fit for the phosphorylation reaction at the C6 position of the terminal mannose moiety. This phosphorylation is catalytically mediated by GlcNAc-phosphotransferase (see section on I-cell disease in text and legend to Figure 13) and required for recognition by the lysosomal hydrolase and binding to specific Man-6-P receptors in the prelysosomal compartment. Physiologic metabolism of the specified chemical bonds in this glycan structure is stepwise with the concerted catalytic involvement of (1) α-D-mannosidase; (6) endo-β-N-acetylglucosaminidase; and (7) aspartylglucosaminidase. Various types of hybrid glycan structures have been observed in lysosomal glycoproteins. SA, sialic acid; Gal, galactose, GlcNAc, N-acetylglucosamine; Man, mannose; Fuc, fucose; Asn, asparagine residue in polypeptide chain.

oligosaccharidoses. This term is the preferred substitute for the name ''mucolipidosis'' proposed in the first comprehensive paper on a number of hereditary disorders clinically related to both the mucopolysaccharidoses and the sphingolipidoses [104]. Progress in understanding and delineating the oligosaccharidoses is summarized in Tables 5 and 6. All oligosaccharidoses are inherited as autosomal recessive traits and may be due to the deficiency of a single lysosomal hydrolase or to altered processing or protection of lysosomal enzymes. While awaiting effective treatment, management also of this group of disorders lies in prevention, with early diagnosis, genetic counseling, and prenatal diagnosis, available for all oligosaccharidoses, as main strategic measures. Comprehensive reviews are available [105,106].

The Sialidoses (MIM 256550)

At present, at least four different disease entities (Table 6) have been given the common name of sialidosis, coined in 1977 [107]. This term should be reserved exclusively for the clinical conditions discussed here and due to the isolated primary deficiency of glycoprotein sialidase (NAc-neuraminic acid hydrolase).

Childhood Dysmorphic Sialidosis

This disorder was originally called lipomucopolysaccharidosis by Spranger [108], who provided its clinical delineation. It was subsequently named mucolipidosis I [104]. Complaints of slow psychomotor development usually come in early childhood, when coarse facial features and thoracolumbar kyphosis are also noted. At first, a puffy face, depressed nasal bridge, and broad maxilla are reminiscent of MPS IH or hypothyroidism. Developmental milestones are reached with delay. Intellectual development and physical growth are slower than normal, with height being below the third centile between the ages of 3 and 5 years, when similarity of the facies to that in Hurler disease becomes more striking. The nose has a bulbous shape with anteverted nostrils. Gingival hypertrophy is mild to moderate. The teeth are widely spaced, the tongue is enlarged, and the maxillary part of the face prominent. The thoracic cage is barrel shaped, with pectus excavatum and thoracolumbar kyphosis. Hepatomegaly, although an early feature in some patients, is inconsistent or absent in others. Splenomegaly is rare. Herniae may be present. Sensorineural deafness is already present in early childhood. The clinical picture is

TABLE 6. The Oligosaccharidoses

Clinical Designation • Type	MIM No.	Metabolic Defect: Enzyme	Gene Symbol	EC No.	Metabolic Features	Gene Chromosomal Location
Sialidosis						
• Neonatal (hydropic) • Infantile, nephrosialidosis • Childhood dysmorphic • Normosomatic	256550	Glycoprotein sialidase	*NEU1*	3.2.1.18	—	6p21.3
G_{M1}-gangliosidosis

only fully developed in late childhood, with the appearance of progressive ataxia and nystagmus, muscle wasting and loss of strength. By then ophthalmologic examination reveals a cherry-red macular spot, often strabismus, and, inconsistently, cataract and corneal opacity. Subsequently, a coarse tremor and myoclonic jerks complete the neurologic syndrome. Mental deterioration is not a feature and seizures have not been observed, but sensory deficits and decreased nerve conduction velocity are indications of peripheral nerve involvement. Of interest is that limitation of large joint movements is only minimal and that the small joints of the hands are not affected. Progression of dysmorphic sialidosis is slow. Patients become chair-bound from adolescence. Adverse effects of the neurologic deficit and pneumonia have been considered the causes of death in adolescence or early adulthood [109–112]. Careful consideration of the diagnosis of α-mannosidosis is, however, necessary in patients considered to have childhood dysmorphic sialidosis, because its clinical phenotype, including its natural course, may be similar [109]. The radiological manifestations of childhood dysmorphic sialidosis may be summarized as slowly progressing to a mild to moderate degree of dysostosis multiplex.

Peripheral lymphocytes contain abnormal vacuoles. In bone marrow smears, histiocytic cells have a foamy cytoplasm. Histopathologic changes are noticed in neurons, as well as in mesenchymal and visceral cells. Hepatocytes and Kupffer cells are filled with cytoplasmic vacuoles and granules. Electron micrographs show enlarged, membrane-bound lysosome-like organelles filled with reticulogranular material. These vesicular structures fill major portions of the cytoplasm [109]. The discovery of an increased urinary excretion of several oligosaccharides [113,114] stimulated their structural elucidation as glycoprotein-derived sialyloligosaccharides in which sialic acid residues occupy the terminal nonreducing position [115] (Fig. 7). The urinary oligosaccharide pattern in sialidosis patients [114] is similar to that found in patients with I-cell disease or pseudo-Hurler polydystrophy, and hardly differs from that in galactosialidosis patients. In contrast to the results obtained by routine diagnostic methods, the various compounds found in the urine differ in their detailed chemical structure depending on the particular enzyme defect, as may be shown by more sophisticated chemical and molecular analytic methods [115,116].

The demonstration in fibroblasts of a deficiency of glycoprotein acid sialidase active against water-soluble substrates establishes the diagnosis in the sialidoses. Here, this deficiency is associated with neither defective β-D-galactosidase (see "Galactosialidosis", below) nor with deficiency of several other lysosomal hydrolases (see I-Cell Disease and Pseudo-Hurler Polydystrophy, below). The parents of patients with childhood dysmorphic sialidosis have intermediate sialidase activity [117]. The enzyme defect in patients can also be demonstrated in freshly isolated leukocytes.

Normosomatic Sialidosis; Cherry-Red Spot-Myoclonus Syndrome

Almost simultaneously with the discovery of the primary metabolic defect in childhood dysmorphic sialidosis, a deficiency of glycoprotein acid sialidase was found also to be the enzyme defect in the cherry-red spot-myoclonus syndrome [118].

The designation, cherry-red spot-myoclonus syndrome, correctly refers to the main clinical features: a slowly progressive reduction of visual acuity, with onset in some patients before 10 years of age, and a crippling, often generalized action myoclonus appearing in the second decade of life. A macular cherry-red spot is almost consistently found, but the time of its first appearance cannot be determined without prospective observation in younger affected sibs of index cases. Although the absence of dysostosis multiplex, even in patients with mild scoliosis, the absence of psychomotor retardation and mental deficiency, except for terminal deterioration, the absence of corneal clouding even by slit-lamp examination, and the absence of facial coarsening make the inclusion of this entity among connective tissue disorders a matter for discussion, these features are important in differentiating patients from those with the juvenile or adult type of galactosialidosis.

As the enzyme diagnosis in patients with the normosomatic sialidosis or cherry-red spot-myoclonus syndrome is sometimes delayed until adulthood, oligosaccharidurie may no longer be detectable at that time. The residual activity of acid sialidase is higher in fibroblasts from juvenile normosomatic sialidosis patients than in those from patients with childhood dysmorphic sialidosis. The parents of patients have intermediate levels of sialidase activity. Somatic cell hybrids between childhood dysmorphic sialidosis and juvenile normosomatic sialidosis fibroblast strains do not show enzymatic complementation, providing evidence of allelism [119].

Infantile Sialidosis; Nephrosialidosis

This variant, described originally in two sibs with early appearing and severe clinical features of childhood dysmorphic sialidosis with an identical isolated deficiency of glycoprotein acid sialidase [120], may be called infantile sialidosis. It has subsequently been observed by Aylsworth et al. [121]. Because the glomerular nephropathy, considered an essential component of this type of sialidosis, was fatal in one of the original patients described by Maroteaux, it has also been termed nephrosialidosis [120].

Neonatal (Hydropic) Sialidosis

Glycoprotein sialidase deficiency may apparently result in fetal and/or neonatal non-immune hydrops, ascites, and hepatosplenomegaly. The findings of excessive excretion of urinary oligosaccharides and specific glycoprotein sialidase deficiency establish the diagnosis in these very sick infants [122,123].

Molecular Biology of Sialidase and Its Gene

Glycoprotein sialidase performs an essential role in removing terminal sialic acid residues from the complex carbohydrate side chains in mature sialoglycoconjugates. The allelic mutations responsible for sialidosis cause a continuously variable spectrum of phenotypes. The excessive urinary excretion of oligosaccharides in addition to the spectrum of phenotypes is rather similar to what is observed in patients with any type of galactosialidosis or with disorders due to GlcNAc-phosphotransferase deficiency, both of which are described further in this chapter. The two subunits of glycoprotein sialidase have been isolated and purified: the larger one, a 76 kDa polypeptide is associated with a smaller 32 kDa subunit. The latter is a trifunctional protein, which functions simultaneously as the activator of acid sialidase, as the "protective protein" for β-galactosidase, which is deficient in galactosialidosis, and as cathepsin A [124,125]. The gene coding for the 76 kDa subunit of glycoprotein sialidase has been mapped to 6p21.3. A full-length cDNA clone representing the gene and predicting a 415 amino acid polypeptide with considerable homology to other neuraminidases in nature has been characterized and

sequenced [126,127]. The gene coding for the protective protein with cathepsin A activity (PPCA) is located on chromosome 20 [128]. Already a few missense and nonsense mutations have been found to be associated with various types of sialidosis. Irrespective of their phenotype, most patients are compound heterozygotes for two different mutations [20].

Disorders Due to Deficiency of β-D-Galactosidase

Disorders due to acid β-D-galactosidase deficiency are better known as G_{M1}-gangliosidoses [129]. This term implies only defective ganglioside degradation and progressive brain disease, and is therefore not an appropriate label for the classification of patients with only or mainly a spondyloepiphyseal dysplasia such as Morquio disease type B.

Infantile G_{M1}-Gangliosidosis; Landing Disease; G_{M1}-Gangliosidosis Type 1 (MIM 230500)

The onset of this devastating disease is at or soon after birth. Feeding difficulty, hypotonia, edema of hands and feet, weak sucking and other primitive reflexes, poor weight gain, and/or failure to thrive are the usual early signs and complaints. Psychomotor development is minimal and head control remains poor. Sensory responses of and social contact with the patient are limited. The cranial and facial features are reminiscent of those encountered in both Hurler disease and I-cell disease (see below). The corneae are clear. Gingival hypertrophy and sometimes macroglossia are present. Cardiomyopathy, muscular weakness, and hypotonia are occasional manifestations. Recurrent respiratory infections complicate the clinical course throughout. Retinal cherry-red spots similar to those observed in Tay-Sachs disease are found in about half of the patients. Already in infancy, rather generalized angiokeratoma [130,131] may be observed, as illustrated in Figure 8. Hepatosplenomegaly is a regular feature, as are moderate thoracolumbar kyphosis and enlargement of most peripheral joints [131,132] (Fig. 8). Already before 1 year of age, generalized convulsions and spastic quadriplegia are found. In the second year of life, blindness, deafness, and decerebrate rigidity compound the clinical picture. Patients rarely survive beyond their second birthday, the fatal outcome being due to either brain stem dysfunction or infectious respiratory disease.

Radiographically, the skeletal changes are moderate to severe dysostosis multiplex [2], similar to that seen in I-cell disease. In the infant patient, temporary periosteal cloaking of the long bones is regularly seen, a feature shared with the I-cell disease patient in infancy.

In the urine there is excessive excretion of oligosaccharides, mainly those with terminal β-galactose residues [133]. The pathological changes due to storage of G_{M1}-gangliosides are not fully described here. They include neuronal lipidosis and general visceral histiocytosis due to intralysosomal

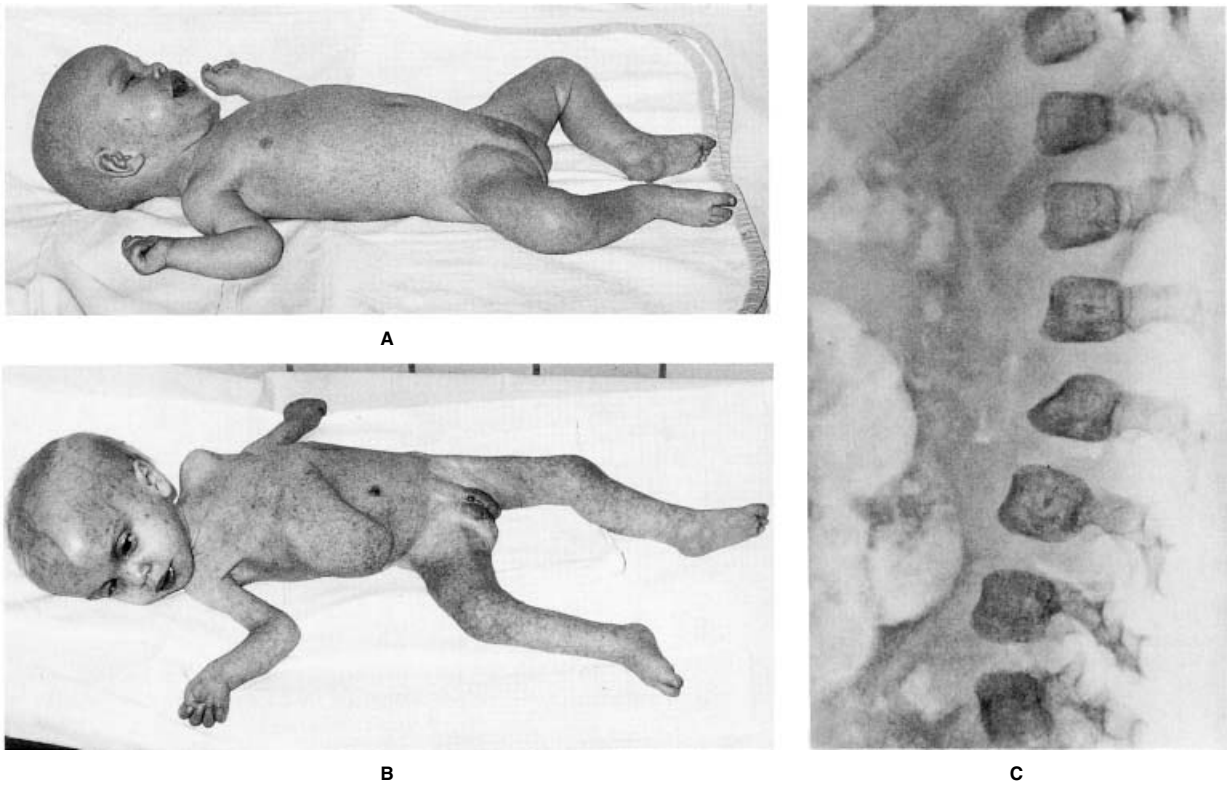

Figure 8. Patient with type 1 G_{M1}-gangliosidosis (Landing disease). **A**: General features at 9 months of age: macrocephaly; hypotonia; bilateral macular cherry-red spots in the retina; pronounced formation of angiokeratomas over large areas of skin. Head control never achieved; convergent strabismus; prominent mouth. **B**: Same patient at 18 months of age. Macrocephaly; extreme hypotonia and dystrophia; hepatosplenomegaly. **C**: Typical aspect of dysostosis multiplex in lumbar spine already apparent at 9 months of age. (Reprinted from [131] with kind permission of S. Karger AG, Basel, Switzerland.)

storage of loose heterogeneous material, obviously a tissue type-dependent range of galactoproteins in addition to gangliosides. The diagnosis is made formally by the finding of a severely deficient acid β-D-galactosidase [129] in leukocytes or cultured fibroblasts. The mutation apparently affects the catalytic activity of acid β-galactosidase toward all galactoconjugates in a similarly profound fashion [133]. Figure 4 and Figure 7 illustrate the role of β-D-galactosidase in connective tissue galactoconjugates.

Late Infantile or Juvenile G_{M1}-Gangliosidosis; G_{M1}-Gangliosidosis Type 2 (MIM 230600)

For details, the reader is referred to a review elsewhere [133]. The phenotype, also with considerable morbidity and a lethal outcome in middle to late childhood, has a later onset at around l year of age and features milder facial, skeletal, and visceral abnormalities. Cardiac involvement may be a regular albeit inconsistent feature in the late infantile as well as infantile type of G_{M1}-gangliosidosis [134,135]. Dysostosis multiplex is mild or may even be absent. Neurological dysfunction, known to be the rule in infantile G_{M1}-gangliosidosis, gradually but consistently becomes also here part of the clinical syndrome as it fully develops. The mutant β-galactosidase is qualitatively similar to the abnormal enzyme in the infantile form. It has, however, preserved two to five times greater residual activity toward all natural substrates [136], which consequently are stored at a slower rate. Confirmation of diagnosis is by assay of acid β-D-galactosidase as in the infantile form.

Adult G_{M1}-Gangliosidosis; G_{M1}-Gangliosidosis Type 3 (MIM 230650)

A few patients have been documented in whom a childhood-onset neurological disorder with slowly progressive paralysis, dystonic posture, cerebellar dysfunction, and, years later, gradual loss of intellectual and social functioning as main components, is apparently due solely to a deficiency of acid β-D-galactosidase [137]. As connective tissue appears to be uninvolved, the responsible mutation apparently produces an enzyme with catalytic activity toward galactoproteins sufficiently preserved but with that toward gangliosides seriously impaired.

Molecular Biology of β-D-Galactosidase and Its Gene

Although the activity of β-D-galactosidase is relatively deficient in any patient tissue, cultured fibroblasts, and body fluid, the extent of substrate storage is directly correlated with the severity of the disorder and inversely so with residual enzyme activity [138]. Comparison of data from different laboratories is, however, difficult. The enzyme in question is different from galactosylceramidase (EC 3.2.1.46), which is deficient in globoid cell leukodystrophy (Krabbe disease), and the gene for which is on chromosome 14. The mature β-galactosidase occurs in tissues in either monomeric, dimeric or multimeric form, the latter comprising aggregates of the monomer [66]. In fibroblasts, the enzyme is synthesized as a high molecular weight precursor of 85 kDa that is processed via an intermediate form to the 65 kDa mature protein that contains about 8% carbohydrate. Most of the latter is of a complex oligosaccharide nature. In the lysosome, β-D-galactosidase is stabilized through its association with its protective lysosomal glycoprotein, which also activates glycoprotein sialidase. For more about protective protein with cathepsin A activity and its gene *PPGB* (Table 6) see under "Galactosialidosis", below. The catalytic hydrolysis of G_{M1}-gangliosides and other lipid substrates by β-galactosidase also depends on the presence of the low molecular weight sphingolipid activator protein 1 (SAP-1), also called saposin B, a physiologic detergent that facilitates enzyme-substrate interaction [133].

In the MPS IVB patient (previously considered under the mucopolysaccharidoses), β-D-galactosidase activity has been found reduced to about 5% of its normal level using both artificial substrates and G_{M1}-gangliosides. However, its hydrolytic activity toward keratan sulfate and oligosaccharides from patients' urine samples is totally lacking [68,139]. In liver and fibroblasts from many patients with G_{M1}-gangliosidosis or Morquio B disease, cross-reacting material has been demonstrated in immunologic studies using antisera against purified human β-galactosidase [67,140]. Gradually, the *in vitro* effect of specific mutations has become more specifically related to enzyme phosphorylation, processing, sorting to lysosomes, aggregation into multimeric form, binding to protective protein, catalytic properties, optimum pH, thermostability, and electrophoretic mobility [133]. The gene coding for β-D-galactosidase has been fine mapped to 3p21.33 by *in situ* hybridization [141], although it had previously been assigned to chromosome 3 over 20 years ago [142]. The gene coding for lysosomal β-galactosidase protective protein is located on chromosome 20 (see under "Galactosialidosis", below).

Human nascent placental β-galactosidase consists of 677 amino acids, including 23 signal sequence residues. This is the *in vitro* functional expression product of cDNA in COS cells and virally transformed mutant fibroblasts [133,143,144]. The human gene coding for β-galactosidase extends over 60 kb and contains 16 exons [145]. A steadily increasing number of mutations is being identified, providing one more example of genetic heterogeneity [133,146]. The mutations are classified either as "allelic variants" [20] or according to their main phenotypic effect [133]. Most frequently, single nucleotide substitutions are observed in either homozygous or compound heterozygous genotypes. The clinical effect is mostly severe and evident from early infancy. The more chronically evolving late infantile and adult G_{M1}-gangliosidoses are less frequent phenotypic consequences. Interestingly, the Arg457Stop (*C*GA to *T*GA transition) nonsense mutation in exon 14 in the homozygous state introduces a premature stop codon and results in severe infantile G_{M1}-gangliosidosis, whereas the Arg457Gln (CGA to C*A*A transition) missense mutation combined in the heterozygote with Ile51Thr yields the chronic adult phenotype. A few larger structural rearrangements within the gene, including duplications and insertions, have also been detected. The largest group of patients with known mutations is from Japan, probably due to the keen and effective work of Japanese scientists rather than a significantly higher prevalence of β-D-galactosidase-related disease in that part of the world. At least five different missense mutations causing MPS IV B have also already been documented [20,133,147].

α-Mannosidosis (MIM 248500)

A severe clinical form with late infantile onset and a less severe, slower evolving type of α-mannosidosis may be discerned. The precise age of onset of the latter, which occurs in late childhood or adolescence, is often uncertain because of its slow and gradual nature. Mannosidosis also comprises a wide range of phenotypes, rendering delineation of separate clinical disorders rather irrelevant, in particular because variability of clinical course has been observed even among sibs [148,149].

Clinical Phenotype

The neonatal period is uneventful in α-mannosidosis, but even during the patient's first year of life, recurrent respiratory infections and otitis require hospital admissions. Psychomotor progress slows in the second year and walking is usually achieved with delay. Belated onset of speech and psychomotor retardation are the usual reasons for clinical evaluation. In childhood, signs and symptoms are normal stature, macrocephaly, a prominent forehead, a coarse facies, clear corneae, persistent epicanthic folds, a low nasal bridge, noisy breathing, thick lips, and a prominent jaw and mouth. Joint mobility is minimally impaired. The abdomen is protuberant with an umbilical hernia as a rule. In boys, inguinal herniae or hydroceles are common. Hepatosplenomegaly is mild to moderate in young patients, but disappears in adolescence. Mild kyphosis is common. Hearing loss of both the conductive and the sensorineural type, a clumsy broad-based gait and a deficiency of motor skills are almost always present from later childhood on [150,151]. Speech and language remain at an elementary level. The patient's disposition is usually agreeable, but sudden episodes of anger or aggressiveness and periods of sleep disturbance are regularly reported. Ophthalmologic examination does not reveal any retinal changes but regularly detects cataracts. Infectious complications are the main reasons for a fatal outcome in mid-childhood.

In most patients, the onset occurs some time in mid-childhood. The clinical course is rather mild and barely progressive, with slowly coarsening facial and general body features. A patient is shown in Figure 9. Data on life expectancy are scarce, but most patients apparently survive well into adulthood. In sibs reported from Israel [152], corneal clouding was apparent. These patients also showed marked limitation of joint mobility. Hearing loss has remained moderate in the patient shown (Fig. 9), but from the age of 21 she has shown severe mental deterioration without significant physical disability. The radiographic findings can be summarized as mild, representing slowly progressive dysostosis multiplex.

Figure 9. Girl with α-mannosidosis at the age of 10 years with normal general body features, a minor reduction of range of movement in large and small joints, and a decreasing growth rate. Mildly coarse facies; large skull; hearing aid reveals moderate sensorineural deafness. Patient, a young adult in 1998, has intermittent but lengthening periods of dementia.

Molecular Defect in α-Mannosidosis and Diagnosis

α-Mannosidosis is an oligosaccharidosis as demonstrated by the excessive urinary excretion of mannose-containing oligosaccharides in simple screening tests using silica gel thin-layer chromatography [113,114]. Many of these mannose-rich compounds have been isolated and structurally characterized [105] (see also Fig. 7).

Vacuolization in peripheral lymphocytes is prominent in all patients reported. In liver tissue, numerous clear vacuoles are seen in hepatocytes and Kupffer cells. The cytoplasmic inclusions also exist in histiocytes in bone marrow, endothelial cells of sinusoid vessels, and lymphocytes in spleen and lymph nodes. Throughout the central nervous system the cytoplasm of neurons is distended, being packed with an abundance of single, membrane-bound vacuoles with remarkably clear, sparsely dispersed reticulogranular material [151]. The severe morphologic changes in hepatocytes and neurons are not due to storage of large macromolecules but to the accumulation of abnormal amounts of mannose-containing oligosaccharides derived from improperly degraded carbohydrate chains in glycoproteins.

The diagnosis of mannosidosis is based on the demonstration in tissue or body fluids of a severe deficiency of lysosomal α-D-mannosidase, which has optimal activity near pH 4.5 [153,154]. The activity of α-D-mannosidase can be determined most easily in total homogenates of leukocytes or cultured fibroblasts, where, at pH 4.2, interference by neutral isozymes is negligible, and the specific activity of α-D-mannosidase in mannosidosis is but a few percent of that in controls. Similar results in cultured amniotic fluid cells and postmortem organs, respectively, establish prenatal diagnosis and confirmation of mannosidosis. α-D-mannosidase exists in two forms termed A and B, which have identical catalytic and immunological properties. They are products of the same gene [105]. In human plasma or serum, an "intermediate" or "neutral" form of α-D-mannosidase is predominant, and the lysosomal "acid" enzyme much less abundant. The former is thermolabile at 56 °C and most active at pH 5.5–6.0 [155], but the latter is thermostable. Serum or plasma lysosomal mannosidase can be measured at its pH optimum of 4.6 most reliably only after thermoinactivation (56 °C) of samples dialyzed against phosphate-buffered saline [156,157]. The mannosidase activity in tissues and body fluids of patients with mannosidosis is mainly due to unaffected isozymes with neutral or intermediate pH optima. The kinetic and physicochemical properties of the residual mutant enzyme studied in many patients may differ from those of the wild-type enzyme. Changes encountered especially in mutant tissues with high-residual mannosidase activity may be particular to specific patients and thus document enzymatically the existence of genetic heterogeneity. Often thermostability is decreased and Km values for artificial substrates increased [158,159].

Molecular Biology of α-D-Mannosidase and Its Gene

The synthesis of lysosomal α-mannosidase has been studied in normal and mannosidosis fibroblasts by immunoprecipitation [160–162]. Results may differ according to tissue studied, but may also be influenced by proteolytic degradation of the gene product. The enzyme is synthesized as a

large, 110 kDa precursor protein. Subsequently, proteolytic processing results in 65 and 27 kDa subunits.

The gene encoding α-mannosidase, termed *MANB*, has been mapped to the region 19p13.2-q12 [163]. It was assigned to chromosome 19 by studies in mouse-human hybrid cells [164]. The first cDNA clone representing the *MANB* gene was isolated from retina/muscle cDNA libraries [165] and subsequently differentiated from cDNA derived from spleen, lung, and fibroblasts [166,167]. Riise et al. [168] have established the overall structure and organization of the *MANB* gene which spans 21.5 kb and contains 24 exons. The corresponding transcription initiation sites have been sequenced for a few hundred nucleotides upstream from the gene. By Northern blot analysis, a single mRNA species of approximately 3.5 kb was apparent and a corresponding 962 amino acid-containing polypeptide identified. This has led to the detection of a heterogeneous collection of nonsense and missense mutations [20,67,169,170]. Homozygous as well as compound heterozygous patients have been described. Thus, α-mannosidosis is recognized as another lysosomal enzyme disorder in which clinical heterogeneity is matched by genetic heterogeneity. More mutations need to be known before questions regarding genotype-phenotype correlation can be answered.

β-Mannosidosis (MIM 248510)

First recognized as causing a severe affliction of the central and peripheral nervous systems with a rapidly fatal outcome in goats [171], a comparable human β-mannosidosis was not detected until 1986. Then, a boy with a slowly coarsening facies, mild bone disease, and developmental retardation on the one hand [172], and adults with a mild and slowly evolving condition on the other [173], were reported to have profound β-mannosidase deficiency. By sheer coincidence, the boy reported by Wenger et al. [172] apparently also had Sanfilippo disease and therefore may be phenotypically rather atypical. To date, only about a dozen patients have been described, mostly at various stages of the disorder's natural course. In infancy, a disease-free interval is usually observed, although one instance has been reported of rapidly evolving CNS disease with status epilepticus by 1 year and a fatal outcome by 15 months of age [174]. In another infantile patient, seriously delayed and impaired speech development has been documented [175]. More often, gradually coarsening facial features, consistent mental deficiency and sometimes neuropathy [176] have been reported. In older patients, behavioral problems have been encountered as have angiokeratomata [173,177]. Hearing loss is also a feature in the chronic disease [178]. Organomegaly has not yet been reported, and cerebral atrophy has been observed inconsistently on MRI scan.

Routine oligosaccharide urinary screening does not easily detect β-mannosidosis. Therefore, quantitative analysis of disaccharide excretion, in particular of the specific Manβ(1–4)GlcNAc, is required. This compound accumulates in patients with β-mannosidase deficiency because only the innermost mannosyl residue in any N-linked oligosaccharide in glycoproteins is in β-linkage [172,179] (Fig. 7).

Molecular studies of the caprine gene encoding β-mannosidase [180] have contributed to the molecular biological investigation of its human counterpart. The human gene is located in the region 4q22-q25. The entire coding region of this *MANBA* gene has now been sequenced and shown to consist of 3293 nucleotides, of which 2640 represent the true coding region. One acceptor splice site mutation that upon translation yields a truncated enzyme in the sib patients reported by Kleijer et al. [181] has already been identified [182].

Fucosidosis (MIM 230000)

This disorder also, more a disease of the nervous system than of connective tissue, was originally recognized as an atypical mucopolysaccharidosis with normal urinary excretion of glycosaminoglycans [183]. With the demonstration that the vacuoles visible in peripheral lymphocytes and Kupffer cells are abnormally swollen lysosomes, a search among the lysosomal hydrolases for the responsible metabolic defect led to the finding of a profound deficiency in tissues and body fluids of α-L-fucosidase [184].

Clinical Phenotype

An initial symptom-free period of 6–12 months is followed by frequent upper respiratory tract infections at the time when delay in psychomotor development becomes overt. Physical examination at this stage reveals a slightly coarse facies, thickened lips and tongue, thick skin, and generalized hypotonia with depressed deep tendon reflexes. Some patients never learn to walk alone. Abundant sweating with increased salinity of the sweat has been noticed in young patients. Slowing of linear growth occurs from about the age of 2 years [183,185,186]. Mild hepatosplenomegaly, inconsistently observed in early childhood, is absent in older patients. Mild thoracolumbar kyphosis and cardiomegaly are more often radiographic than clinical findings. The corneae are clear. Before 3 years of age, and earlier in some patients, the clinical course is characterized by progressive loss of motor skills, apathy, hypertonia and spasticity with hyperreflexia, sometimes seizures, increasing mental deterioration, and finally dementia and decerebrate rigidity. A minority of patients with this natural course, which extends over only a few years to a slightly longer period, succumb to complications of their neurodegenerative disease. The phenotype described has been termed fucosidosis type 1.

The observation of several patients with severe mental deficiency, an almost nonprogressive disease, mild radiographic abnormalities, angiokeratoma, and telangiectasia, reported when in their teens or twenties [186–190], prompted the suggestion of a second phenotype, fucosidosis type 2. These patients, surviving beyond adolescence and into early adulthood, represent the majority of cases. Late in their disease they may have recurrent attacks of dehydration due to inability to control body temperature [186].

As more information on the natural course and extent of the clinical spectrum of fucosidosis becomes available, the hypothesis of two distinct clinical phenotypes cannot be maintained. Patients with both types of disease have been observed in one large pedigree [191] and in single sibships [192,193]. In somatic cell hybridization experiments with fibroblast cultures derived from both types of patient, no mutual complementation is observed.

Radiographic changes are either absent or mild in young patients. Skeletal age lags behind the patient's chronological age. Lumbar vertebrae are either slightly hypoplastic or normal in the presence of dorsolumbar kyphosis. Thus, true dysostosis multiplex is not encountered in fucosidosis. Instead, mild spondyloepiphyseal dysplasia is often found in longer surviving patients.

Molecular Defect in Fucosidosis and Diagnosis

Fucose-containing oligosaccharides are excreted excessively in the urine [113,114]. Simple screening by thin-layer

chromatography can distinguish the pattern of oligosaccharide excretion in fucosidosis from that in other oligosaccharidoses, provided the appropriate control samples are included in the study [105,113].

No less than 25 fucosylglycoasparagine-containing compounds in the urine of fucosidosis patients have been separated and characterized. Their consistent feature is the $\alpha(1 \rightarrow 6)$ fucose to GlcNAc linkage [194] (Fig. 7). This is precisely the one which through lack of functional α-L-fucosidase remains unhydrolyzed in patients. One of the glycolipids accumulating in the CNS and other tissues of patients is the H-antigen glycolipid (Fuc $(\alpha 1 \rightarrow 2)$ Gal $(\beta 1 \rightarrow 4)$ GlcNAc-α-Gal-ceramide). The relationship between the clinical severity of fucosidosis and the quantity and quality of the fucosyltransferase(s)-dependent blood group antigens (H, Le^a, Le^b) remains largely unresolved.

Assay of α-L-fucosidase in leukocytes using the fluorescent 4-methylumbelliferyl-α-L-fucopyranoside as a substrate remains the method of choice for establishing or excluding the diagnosis of fucosidosis [195]. The profound deficiency of α-L-fucosidase found in tissues [186,189,190] is similar both in patients with rapidly advancing disease and in those with a more protracted course. Determination of α-L-fucosidase activity in serum is of no value in the diagnosis of fucosidosis because in about 12% of normal individuals the average serum enzyme activity is only about 5% of that in the rest of the population [196,197]. In these normal individuals with variant α-L-fucosidase in serum, the enzyme in leukocytes has normal activity.

Molecular Biology of α-L-Fucosidase and Its Gene

The lysosomal enzyme, α-L-fucosidase, hydrolytically removes fucose from the non-reducing end of many types of glycoproteins and glycolipids. The enzyme occurs predominantly in a homotetrameric form but also exists in multiple other combinations of its common subunit of 50–60 kDa. It has been purified from a variety of tissues. Glycosylation of the enzyme appears to be quite important, as a 51 kDa precursor molecule is processed to the mature 59–60 kDa end product [198]. From studying the mutant residual fucosidase, genetic heterogeneity among patients has been inferred: in many patients, barely any or no cross-reacting material is detectable, while in some the precursor protein remains unprocessed [199].

Fucosidosis is worldwide a rare disorder. Often parental consanguinity (40% of cases) is observed [200]. In both Italy and the United States, more patients have been observed than in any other country, which finding may not entirely be related to prevalence.

By the use of somatic cell hybrids, the gene locus (*FUCA*) for human α-L-fucosidase was located on chromosome 1 [201] and later on its short arm at band p34 [202]. The existence of a pseudogene of *FUCA* has also been established [203]. This latter was confirmed and more precisely mapped to 2q31-q32 by fluorescence *in situ* hybridization and confocal microscopic measurement [204].

The gene for human fucosidase comprises 8 exons spanning 23 kb. The nucleotide sequence in the pseudogene is 80% identical to the *FUCA* cDNA but has no open reading frame [205]. By Northern blot analysis, an mRNA of 2.3 kb has been demonstrated. These results have led to the identification and characterization of a variety of mutations in the *FUCA* gene. These are listed as allelic variants [20], and include base transitions or transversions, each leading to a premature stop codon, and single- and two-base deletions resulting in frameshifts. At least one splice site mutation and a large deletion involving two exons have been characterized [200,206–208]. Most of the patients concerned had an early onset and a clinically severe course of their disease. Only one of these mutations, Gln351Stop [206], has been observed in several families, while the others have been identified only in isolated patients or pedigrees. One recently characterized missense mutation resulting in the substitution of the conserved leucine 405 by arginine (Leu405Arg) [209] was observed in an adult with fucosidosis. Although her longevity is unusual, her disease, however, is one of extreme mental and physical severity.

Aspartylglucosaminuria (MIM 208400)

Although discovered in a British sibship [210] and observed worldwide as a rare metabolic disorder [20], aspartylglucosaminuria has the particularly high minimal incidence of 1/18,500 in Finland [211]. It is thus of no surprise that the detailed phenotypic description, including natural course, as well as the metabolic and molecular elucidation of aspartylglucosaminuria has been contributed mainly by Finnish clinicians and scientists.

Clinical Phenotype

The disorder is rarely recognized in infancy, although hypotonia and weak sucking are sometimes recorded retrospectively. In toddlers and young children, frequent upper respiratory and middle ear infections and umbilical and inguinal herniae are the most prominent complaints. The infections decrease in frequency after the age of 6 years. Aspartylglucosaminuria is not an easy clinical diagnosis before the age of 5 years [212]. Mental retardation, a consistent feature from later childhood on, is not usually recorded formally before the diagnosis of aspartylglucosaminuria is made. Gross motor development proceeds within normal limits, but delay in speech development, clumsiness, short attention span, and restlessness are the usual sources of initial concern. Besides the gradually coarsening facial features and the herniae, abnormal connective tissue signs are hardly noticeable. Developmental delay is gradually more apparent. From adolescence, the loss of mastered skills is observed, and is followed by a more consistent decline from early adulthood. Middle-aged adult patients have adaptive skills inferior to those in the average mentally retarded patient. In one quarter of cases, bouts of behavioral unrest may compound the clinical picture [213,214].

Molecular Defect and Diagnosis

This oligosaccharidosis results from the deficiency of aspartyl-β-glucosaminidase, a lysosomal amidase that hydrolyzes the amide bond between asparagine and N-acetyl-glucosamine in glycoproteins [215]. As a consequence, 2-acetamido-1-L-β-aspartamido-1,2-dideoxy-β-D-glucose, trivially named aspartylglucosamine (GlcNAcAsn), accumulates in tissues and is excreted excessively in patients' urine [216] (Fig. 7). First trimester prenatal diagnosis of aspartylglucosaminuria is possible [217]. For routine use the abnormal metabolite is easily discerned by high voltage electrophoresis/ninhydrin technology. A highly sensitive liquid-chromatographic method for the detection of GlcNAcAsn in urine and a fluorometric enzyme assay for aspartylglucosamine in lymphocytes have been developed [218,219].

Molecular Biology of Aspartyl-β-Glucosaminidase and Its Gene

The gene for aspartyl-β-glucosaminidase (*AGA*) has been mapped to 4q32-q33 by deletion mapping [220] and *in situ* hybridization [221]. Purification of the enzyme led

ultimately to the isolation and cloning of cDNA and its complete nucleotide sequencing [222,223]. The overall 13 kb sequence of the human *AGA* gene has an open reading frame distributed over 9 exons [224]. The growing list particularly of point mutations resulting in either single amino acid substitutions or reading frameshifts, but also of small deletions, and splice site nucleotide substitutions resulting in larger deletions involving complete exons, is ever more impressive [212,225–227]. The most common "Finnish" mutation located in exon 4 and resulting in a Cys163Ser substitution eliminates an all important intrachain disulfide bond, with resultant misfolding and faulty compartmentalization of the enzyme [228]. The mature enzyme normally forms a heterotetrameric (2α,2β chain) structure, following cleavage of the nascent precursor into α and β subunits [229]. In addition to *in vitro* mutagenesis, the identification of mutations has contributed substantially to understanding their steric effects on enzyme structure as well as the important posttranslational regulation of aspartyl-β-glucosaminidase production and function [230,231]. The considerable genetic heterogeneity notwithstanding, significant phenotypic differences among aspartylglucosaminuria patients have not been recorded.

Schindler Disease; Neuroaxonal Dystrophy Schindler Type; Kanzaki Disease; N-Acetyl-α-D-Galactosaminidase Deficiency (MIM 104170)

Schindler disease is characterized by neurologic deterioration, progressive joint contracture and the appearance of subcutaneous and submucous nodules, which lead to progressive and characteristic hoarseness [232]. Schindler disease was first observed in two German male sibs of consanguineous parents [233]. The clinical onset was in late infancy, starting with the cessation of development, hyperacusis, and the subsequent regression and loss of skills acquired earlier. Other early manifestations included general and axial hypotonia, grand mal seizures, poorly coordinated movements, visual impairment, strabismus and nystagmus. This period of rapid regression resulted by 4 years of age in considerable mental and neurologic deficit compounded by cortical blindness, myoclonus, rigidity and flexion contractures, and by decorticate posturing. The subsequent course was but a stable vegetative state with nearly complete lack of contact with the environment. More recently, two Dutch sibs have been reported: a girl with a milder neurodegenerative disorder and her younger brother, considered still to be presymptomatic, had the same enzyme defect [234,235].

Almost simultaneously with the original report, an adult, mildly retarded Japanese female with disseminated angiokeratoma and glycopeptiduria was shown to have numerous cytoplasmic vacuoles in kidney and skin cells [236]. The angiokeratoma lesions had appeared on the lower trunk and spread slowly over the body surface. This patient had consanguineous parents, but she had two unaffected children of her own. Telangiectatic lesions were found also in the ocular conjunctiva and in the fundus of the eye. Endoscopy demonstrated telangiectasia in the gastric mucosa. The clinical picture of this patient was completely different from that found in Schindler disease. It has been called Kanzaki disease [20,106]. That it is also different from any other known oligosaccharidosis or mucopolysaccharidosis, and also from Fabry disease and fucosidosis, was confirmed enzymatically. Similar patients have since been reported [237]. Neuropathological findings show that Schindler disease is principally a disorder of the central and peripheral nervous systems with a remarkable lack of any visceral abnormality [232,233]. The clinical course and the similar axonal ultrastructural findings are rather reminiscent of the Seitelberger type of infantile neuroaxonal dystrophy (MIM 256600) or of some aspects of Hallervorden-Spatz disease (MIM 234200). It is not unlikely that some patients reported earlier with either of these disorders and in whom no enzyme studies were performed may have been examples of Schindler disease.

The abnormal thin-layer chromatographic urinary oligosaccharide profile was the first indication pointing to a metabolic disorder. The blood group A trisaccharide, GalNAc α (1 → 3) Gal (2 → 1) α Fuc, represented a major compound among other glycoconjugates excessively present, all of which had terminal α-NAc-galactosaminyl moieties. The latter were found in both the N- and the O-linked accumulated glycopeptides, glycoproteins, and glycosphingolipids. In addition, keratan sulfate was found stored in various biopsied tissues and cultured fibroblasts. Therefore, a specific deficiency of lysosomal α-NAc-galactosaminidase was predicted and confirmed in Schindler disease [233,238]. It was subsequently demonstrated also in Kanzaki disease [239]. Residual activity was well below 2% of normal in the former, and below 5% of normal in the latter. Immunoblotting using monospecific rabbit anti-human enzyme antibody showed an absence of cross-reacting material in patients. Studies on the biosynthesis of normal and the Schindler mutant enzyme showed that the mutation did not interfere with the synthesis of the 52 kDa precursor protein, and probably also not with the generation of the mature 48 kDa enzyme protein. The latter was, however, more readily denatured in the German patients than in the Kanzaki-type patients. An interesting account of the relationship between α-N-acetylgalactosaminidase, first recognized as α-galactosidase B, and the true α-galactosidase A is found in the review by Desnick and Wang [232]. The enzyme had initially been considered an isozyme of α-galactosidase A, deficient in Fabry disease (MIM 301500) [240].

The gene encoding α-NAc-galactosaminidase is located at 22q13 [241]. The full-length 2.2-kb cDNA and subsequently the entire genomic DNA encoding the enzyme has been isolated, sequenced, and expressed in COS-1 cells [242,243]. Remarkable similarity with α-galactosidase A has, indeed, been established. The gene contains 9 exons and an open reading frame of 1236 bp encoding 411 amino acids.

Specific point mutations have been detected in the Schindler disease patients and in Kanzaki disease. The German patients were homozygous for a G → A transition at nucleotide 973 resulting in a lysine for glutamic acid substitution at position 325 (Glu325Lys) [242]. In the cDNA of the Kanzaki proband, also, a missense mutation was found at amino acid position 329. A C → T transition at nucleotide 985 resulted in an arginine to tryptophan substitution (Arg329Trp) [244]. At present, the reason for the large phenotypic difference between the two types of patient harboring a functionally allelic mutation only 3 amino acids apart in the defective enzyme remains unresolved.

Disorders Due to N-Acetylglucosamine-Phosphotransferase Deficiency

I-Cell Disease (Mucolipidosis II) (MIM 252500)

I-cell disease is a slowly progressive disorder with clinical onset at birth and a fatal outcome in childhood. The neonate with I-cell disease has a low birth weight, a plump and

swollen facies, and skin that is thick and particularly stiff about the ears. Congenital herniae are consistently present in males. One or more orthopedic abnormalities are common: e.g., clubfoot, dislocation of the hip(s), thoracic deformity, or kyphosis. Despite generalized hypotonia, the range of movement in the shoulders is already limited.

Unlike Hurler disease (MPS IH), there is no temporary period of excessive skeletal growth during the first and second years of life. Instead, the poor growth decelerates fast within 6 months of birth and often ceases before 15 months. Growth failure is always severe and a final height of 80 cm is rarely exceeded. The head is not scaphocephalic. Stiffening of all joints occurs from the first year of life. Psychomotor retardation is extreme in some patients, but rather mild in others. Upper respiratory infection and otitis recur frequently, and breathing is noisy. The facies is rather flat. It resembles that of patients with MPS IH but shows consistent differences: small orbits and hypoplastic supraorbital ridges, prominence of the eyes, a tortuous pattern of periorbital veins, telangiectatic capillaries over the midface and cheeks, impressive gingival hyperplasia, and a prominent mouth. Hepatosplenomegaly is moderate or absent. The corneae are clinically clear, and haziness is found only on slit-lamp examination [245]. In the longer surviving patients there is a coarsening of facial features and a broadening of the hands and wrists. Cardiac murmurs appear gradually. The abdomen is protuberant with an umbilical hernia often present (Fig. 10). Bronchopneumonia and congestive heart failure are the usual causes of death.

The radiological abnormalities in I-cell disease are qualitatively indistinguishable from those in MPS IH and G_{M1}-gangliosidosis type 1. Excessive periosteal new bone formation along the long tubular bones before 1 year of age is a feature shared with patients with infantile G_{M1}-gangliosidosis. This phenomenon is mainly a radiographic observation and has been called periosteal cloaking (see also G_{M1}-gangliosidosis, above). In I-cell disease, dysostosis multiplex is quantitatively more severe at any given time in the clinical course than in any of the mucopolysaccharidoses or oligosaccharidoses [2,246].

Molecular Defect in I-Cell Disease and Secondary Deficiency of Hydrolases. The name "I-cell" disease originated from the observation in the phase-contrast microscope of a large number of cytoplasmic granular inclusions in patients' skin fibroblasts cultured *in vitro*. These cells were called "inclusion cells" or "I-cells" (Fig. 11), and the corresponding disorder I-cell disease [247]. It has also been called mucolipidosis II [104].

In I-cells, the activity of a large number of lysosomal acid hydrolases is considerably reduced or absent [248–250]. The activity of the same acid hydrolases is greatly increased in the culture medium of I-cells and also in the patients' extracellular fluids [251,252]. In postmortem tissues, the specific activities of β-D-galactosidase and glycoprotein sialidase are reduced, but those of other acid hydrolases are within normal limits [249,250]. Findings in leukocytes are inconsistent but rather similar. The *in vitro* findings mentioned are also to be found in amniotic fluid and cultured amniocytes as well as in chorionic villi, and have been used successfully in the prenatal diagnosis of I-cell disease [106]. The secondarily impaired degradation of glycoproteins is sufficiently extensive *in vivo* to result in excessive urinary excretion of several sialyloligosaccharides [113,114] (Fig. 7). It should be noted that the excretion pattern in the sialidoses is qualitatively similar.

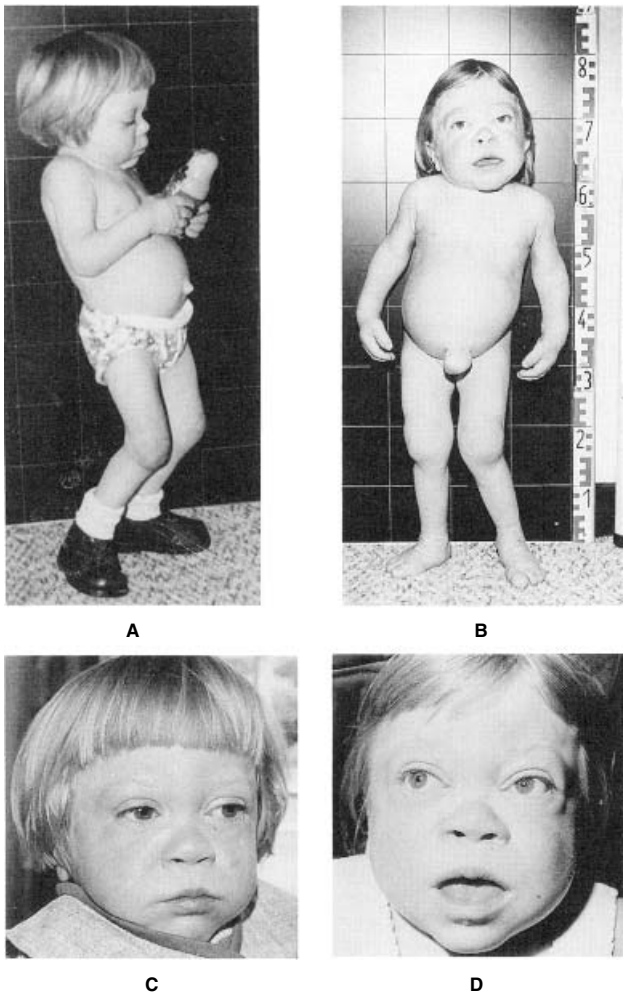

Figure 10. Girl with I-cell disease. **A**: Lateral view at $3\frac{1}{2}$ years of age. **B**: Frontal view at $8\frac{1}{2}$ years. Growth had ceased completely at 2 years (scale in dm). Progression of clinical features as described in text, readily apparent. **C**: Facies of same patient at $3\frac{1}{2}$ years and (**D**) at $8\frac{1}{2}$ years of age. Puffy eyelids; proptosis of eyes and shallow orbits; epicanthic folds; low nose bridge; prominent mouth; mental handicap rather mild.

In I-cell disease, connective tissue cells are primarily affected. Whereas in cultured fibroblasts the cytoplasmic granules are filled with pleiomorphic material, the corresponding *in vivo* inclusions in mesenchymal cells are either empty or contain only sparse granulofibrillar material. The single most characteristic pathological feature is the presence of a large number of cytoplasmic, unit membrane-bound vacuoles in connective tissue cells, irrespective of the organ in which they are located. Such abnormal cells are particularly abundant in skin, gums, heart valves, and the zones of endochondral and membranous bone formation. Pericytes of capillaries, adventitial cells, and Schwann and perineural cells are affected. In the renal glomeruli, there is foamy transformation in only the visceral and not the parietal cells of Bowman's capsule. Changes in neurons and glial cells are minimal, inconsistent, and possibly of a secondary nature [253,254].

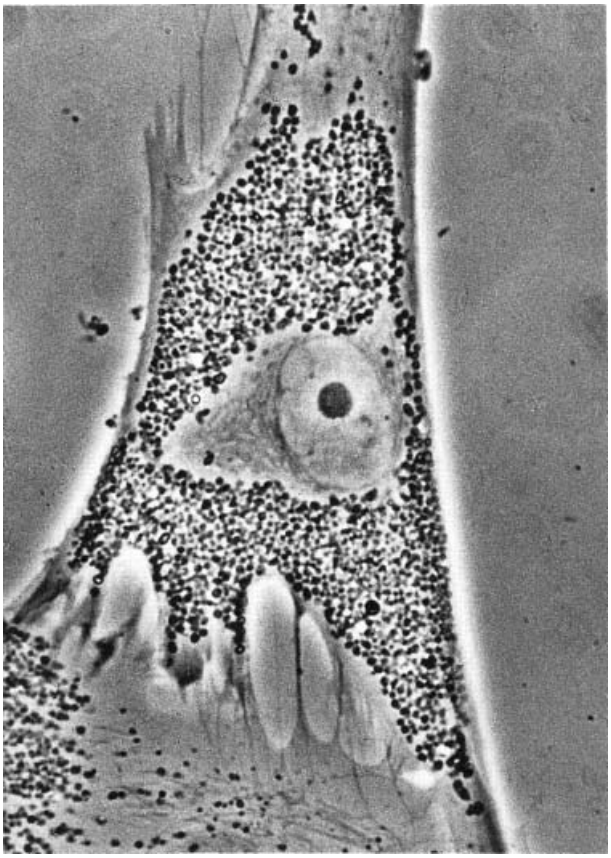

Figure 11. Phase-contrast micrograph of living "inclusion" cell (I-cell): normal nucleus; numerous optically dense granular inclusions fill the cytoplasm except for the juxtanuclear hypertrophic Golgi apparatus. All cells in fibroblast cultures derived from I-cell disease and pseudo-Hurler polydystrophy patients have similar phase-contrast features.

The primary metabolic defect in I-cell disease is responsible for the lack in lysosomal hydrolases of a common recognition marker essential for their binding to specific receptors and subsequent proper intracellular routing. The carbohydrate nature of the common recognition marker was shown by Hickman et al. [255]. Subsequently, mannose 6-phosphate and phosphorylated mannans were found to be effective inhibitors of adsorptive pinocytosis of hydrolases, and pretreatment with alkaline phosphatase abolished receptor-mediated pinocytosis of hydrolases, underscoring the role of phosphate in the recognition marker [256]. In I-cells, phosphorylation does not occur or is only partially achieved. Also, processing of the newly synthesized precursor proteins is incomplete. The enzymes encountered in I-cell disease culture medium are unphosphorylated, and are also of larger molecular size than the mature intracellular hydrolases. They possess no phosphate-containing recognition marker [257,258], which is needed to gain access to the lysosomal compartment or to enter the cells by absorptive pinocytosis. In normal fibroblasts, a major proportion of $^{32}P_i$ groups in newly phosphorylated high mannose-type oligosaccharides in biosynthetic intermediates of lysosomal enzymes are blocked by N-acetylglucosamine, rendering the mannose 6-phosphate-containing carbohydrate chains insensitive to alkaline phosphatase [259,260]. The mere finding of these phosphodiester-structures in the nascent intracellular glycoproteins suggested their formation by enzymatic transfer of N-acetyl-glucosamine-1-phosphate to C_6 of mannose. This reaction is highly deficient in fibroblasts and parenchymatous organs from patients with I-cell disease or pseudo-Hurler polydystrophy (see below), and constitutes the primary metabolic defect in these disorders: i.e., there is a deficiency of UDP-N-acetylglucosamine: lysosomal hydrolase N-acetyl-glucosaminyl-1-phosphotransferase [261–263], for which the term GlcNAc-phosphotransferase is adopted here as a trivial name (Fig. 12; see also the section on synthesis of lysosomal enzymes in Part I of this chapter). The enzyme has been formally adopted by the "Enzyme Commission" as EC 2.7.8.17. A phosphodiesterglucosidase, unaffected in both I-cell disease and pseudo-Hurler polydystrophy, subsequently removes the N-acetyl-glucosamine moiety and uncovers the phosphate, thus rendering the mannose 6-phosphate recognition marker functional [264] (Fig. 12). Normal lysosomal enzymes, having acquired the active recognition marker, can be recognized by specific receptors that direct their transfer to lysosomes. There are two distinct mannose 6-phosphate receptors, which have been purified and structurally characterized by cloning of the corresponding cDNAs [265–268].

Both receptors are normal in I-cell disease and pseudo-Hurler polydystrophy. This conclusion is presumed because of the observation that the internalization of normal lysosomal hydrolases by I-cells is normal [269]. The pathway of enzyme transport from the cell surface to the lysosomes, although discovered first, has since been shown to be of only secondary importance in the routing of these enzymes. Both mannose 6-phosphate receptors are integral membrane proteins containing an aminoterminal extracytoplasmic domain, a unique transmembrane region, and a cytoplasmic carboxyl-terminal domain. One is a large molecule (275 kDa), comprising 15 homologous domains

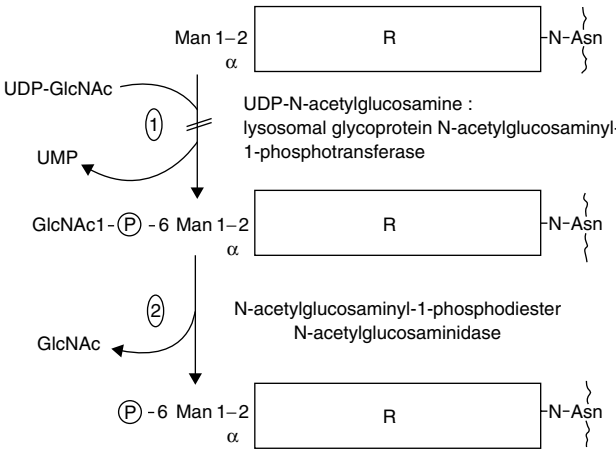

Figure 12. Enzymatic biosynthesis of the mannose 6-phosphate (P) recognition marker in oligomannosyl-type N-linked oligosaccharides (R) in glycoproteins. The step 1 enzyme is totally or partially deficient in I-cell disease and pseudo-Hurler polydystrophy, respectively [261–263]. The step 2 phosphodiesterglycosidase is unaffected. The normal two-step process results in the formation of a 6-mannose phospho-monoester, the central component of the recognition marker leading to high-affinity binding to mannose 6-phosphate receptors in the Golgi complex and thus ensuring proper routing to the lysosomal compartment.

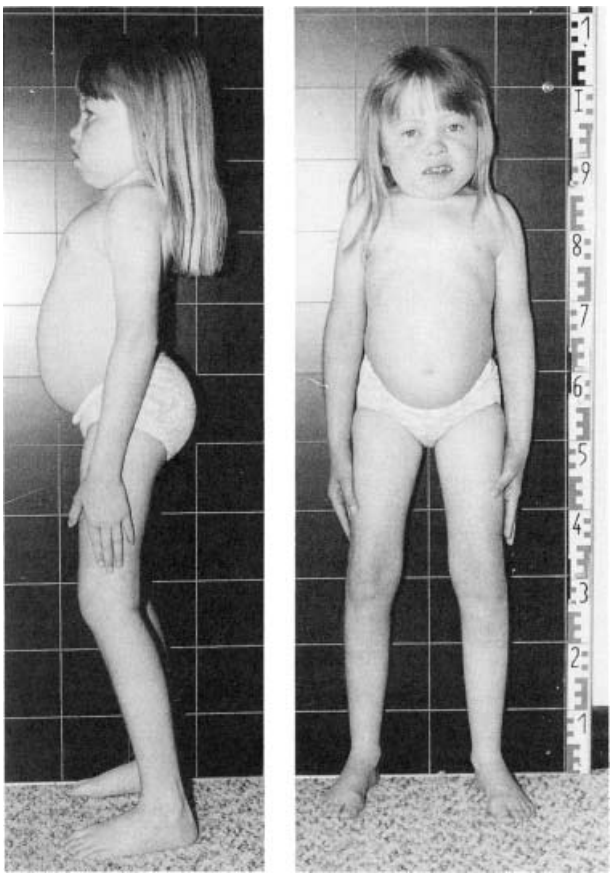
each of about 154 amino acids in the extracellular domain, while the other is much smaller (46 kDa) and contains only a single domain, homologous to those in the larger receptor. The smaller receptor occurs mainly in homodimer form. The larger receptor binds mannose 6-phosphate markers irrespective of the presence of divalent cations. It is, therefore, called the cation-independent mannose 6-phosphate receptor (CI-MPR). The smaller receptor requires cations for the optimal binding of ligand (Man-6-P) and is referred to as the cation-dependent mannose 6-phosphate receptor (CD-MPR). The molecular biology of the mannose 6-phosphate receptors has been reviewed elsewhere, and their primary role in targeting newly synthesized lysosomal enzymes to the lysosomal compartment in fibroblasts and in their own intracellular recycling demonstrated [270,271]. Their three-dimensional structure has also been elucidated [272]. Observations in mutant mice have proved that either type of receptor can only partially compensate for the functional absence of the other, and that the absence of both is barely compatible with survival [273–276]. The ligand binding of either type of receptor has some degree of specificity, the CI-MPR being the most effective [277].

The delineation of I-cell disease and the discovery of the primary and secondary enzyme deficiencies have been of major importance in allowing the elucidation of the mannose 6-phosphate/mannose 6-phosphate receptor-dependent intracellular routing of lysosomal hydrolases, at least in fibroblasts, and probably in other connective tissue cells [248–252]. Although the primary deficiency of GlcNAc-phosphotransferase is found in all tissues examined [263], the secondary enzymatic [249,250] and pathologic [253,254] features are only partially or not at all demonstrable in lymphoid cells and tissues and in parenchymal organs such as liver and spleen. Therefore, alternative pathways for intracellular trafficking of lysosomal enzymes to lysosomes must exist besides the mannose 6-phosphate/mannose 6-phosphate receptor–dependent pathway [263,278]. Such alternative mechanisms of inter- and intracellular transport of lysosomal enzymes have been noted in Part I of this chapter.

Pseudo-Hurler Polydystrophy (MIM 252600)

This disorder was delineated and named pseudo-Hurler polydystrophy by Maroteaux [279]. It has also been called mucolipidosis III [104]. Complaints of physical slowness, joint stiffness, and slow mental development around the age of 3 years mark the clinical onset. The patient's facies is coarse, and the range of movement in shoulders and hips already reduced. The growth rate is slower than normal and the head circumference remains proportional to stature, which is well below normal in adults (Fig. 13). The corneae are clear by inspection but show opacities on slit-lamp examination. The liver and spleen are not usually enlarged [280,281]. Mental deficiency in pseudo-Hurler polydystrophy patients is mild and nonprogressive. The course of the disease is slow and characterized by increasing joint stiffness and by joint pain, in particular of the hips. Pseudo-Hurler polydystrophy patients of advanced age have been reported [280], but comprehensive data on life expectancy are not yet available.

There is generalized osteoporosis and bone age is considerably delayed. Dysostosis multiplex, though variable between patients, is generally mild, except for the severe and progressive lesions in the hips [2,280], where secondary arthrotic changes represent a considerable problem. Stiffness in the shoulders is of soft tissue origin. Urinary excretion of glycosaminoglycans is normal, while that of sialyl-oligosaccharides is excessive, complex, and indistinguishable from that found in I-cell disease urine [113,114]. This finding is nevertheless of orienting value for diagnosis.



A B

Figure 13. A,B: Patient with pseudo-Hurler polydystrophy at 10 years of age: prominent maxillar part of facies. Severe hip dysplasia with hips fixed in partial flexion; compensatory exaggerated sagittal curvature of back, small stature (scale in dm); normal slender hands; intelligence low normal range.

The I-cell phenomenon is apparent in pseudo-Hurler polydystrophy fibroblasts, as in I-cell disease cultures [282]. The activity of many acid hydrolases is considerably reduced in the cells and elevated in culture medium [283]. The residual activities of β-D-galactosidase [284] and sialidase [285] are higher in "I-cells" from pseudo-Hurler polydystrophy patients than in those from I-cell disease donors. Contrary to findings in I-cell disease, in oligosaccharides isolated from pseudo-Hurler polydystrophy acid hydrolases, some degree of phosphorylation has occurred [258]. These findings correlate with the milder clinical phenotype in pseudo-Hurler polydystrophy. Of direct diagnostic importance is the fact that in the serum of patients there is also greatly increased activity of many acid hydrolases.

The dividing line between pseudo-Hurler polydystrophy patients and "I-cell disease" patients with mild mental handicap and protracted course may not be clear, but differences in growth rate, final height, and degree of dysostosis multiplex are the better criteria for distinguishing

between the two disorders. However, several patients have been reported who demonstrate the continuously varying distribution of clinical severity of which I-cell disease and pseudo-Hurler polydystrophy are but the points of reference [286].

The I-cell phenomenon in fibroblasts derived from either type of patient has pointed from the start toward a common pathogenesis for both disorders, as was subsequently underscored by the finding of the same enzyme defect [262].

Molecular Biology of GlcNAc-Phosphotransferase and Its Genes

The phenotypic heterogeneity of patients with GlcNAc-phosphotransferase deficiency initially led to the delineation of I-cell disease on the one hand and pseudo-Hurler polydystrophy on the other [245,279]. More recently, the clinical heterogeneity has rather been interpreted as a continuum of severity with regard to age of clinical onset, natural course and final outcome. The degree of secondary deficiency of hydrolases has also been correlated with the clinical variability encountered [284–287]. In addition, the primary GlcNAc-phosphotransferase deficiency is more complete in I-cell disease than in pseudo-Hurler polydystrophy [258,287,288]. However, even in pseudo-Hurler polydystrophy patients there is heterogeneity of GlcNAc-phosphotransferase activity. Because of the consistency of the abnormal phenotype in multiply affected sibships, the phenotypic variability must reflect genetic heterogeneity of either an allelic or a nonallelic nature, indicating that I-cell disease and pseudo-Hurler polydystrophy may be disorders resulting from mutations in different genes.

That at least pseudo-Hurler polydystrophy must be due to more than one nonallelic gene mutation has been implied for some time by the results of *in vitro* complementation tests [287,289,290]. Complementation in heterokaryons following pairwise *in vitro* fusion of two different mutant fibroblast strains results in the restoration of intracellular lysosomal hydrolase activity and the correction of qualitatively abnormal physicochemical properties. Complementation has been observed to result also in the restoration of GlcNAc-phosphotransferase activity [291].

Three complementation groups (A, B, and C) were recognized in pseudo-Hurler polydystrophy [287,292]. Complementation group A cell strains had considerably reduced GlcNAc-phosphotransferase activity irrespective of whether the phosphate acceptor substrate used was a purified lysosomal hydrolase or the artificial α-methylmannoside. Only one, rather atypical patient represented complementation group B. Complementation group C comprised variant pseudo-Hurler polydystrophy donors with deficient GlcNAc-phosphotransferase activity when assayed with lysosomal enzymes or glycoproteins as phosphate acceptors, but normal activity of the enzyme when the α-methylmannoside acceptor was used [287–289]. Thus, GlcNAc-phosphotransferase must be an heteromeric enzyme with a catalytically active subunit and, in addition, a subunit for substrate recognition. In pseudo-Hurler polydystrophy type C patients, the causal mutation yields an enzyme subunit defective in recognizing its natural substrates but apparently does not affect the catalytic subunit. On the other hand, the enzyme in I-cells of pseudo-Hurler polydystrophy group A is catalytically defective, even when it properly recognizes its natural acceptor substrates. The same applies to the majority of I-cell disease patient cell strains.

More recently, bovine GlcNAc-phosphotransferase has been isolated and purified from lactating mammary glands and its subunit structure determined [293,294]. The enzyme is a 540 kDa complex of disulfide-linked homodimers, each of which is composed of a 166 kDa α subunit and a 51 kDa γ subunit. With these dimers, two identical, 56 kDa β subunits are noncovalently associated. The enzyme complex may be symbolized as $\alpha 2\beta 2\gamma 2$.

This important stride led to the isolation of the human GlcNAc-phosphotransferase γ subunit cDNA and its localization to chromosome 16p, in the study of a large Druze pedigree in which the variant or type C pseudo-Hurler polydystrophy was segregating [295]. The entire sequence of the 1219 bp cDNA has been elucidated. It contains an open reading frame of 915 bp, predicting a mature protein product of 281 amino acids. Transient expression of the human GlcNAc-phosphotransferase γ polypeptide (35 kDa) has been achieved in transfected COS cells, in which it also forms disulfide-linked homodimers as has been found for the γ subunit in the bovine enzyme complex. Following RT-PCR amplification and sequencing of the cDNA from type C pseudo-Hurler polydystrophy patients in two families, the insertion of a single cytosine at codon 167 has been detected. It results in frameshifted translation and premature termination of the polypeptide [295].

The purification and molecular characterization of the bovine GlcNAc-phosphotransferase has also been of major importance for the isolation of human cDNA clones encoding the α and β subunits of this oligomeric enzyme. These clones were shown to be derived from a single cDNA clone, itself the reverse transcribed product of a 6.2 kb α/β transcript. Following translation into an α/β precursor polypeptide, the α and β enzyme subunits are generated by proteolytic cleavage at a lysine-asparagine bond. The N-terminal α subunit, the larger of the two, consists of 928 amino acids, while the β subunit, C-terminal in the α/β precursor, contains 328 amino acids [296]. The α and β subunits are weakly homologous to yeast chitin synthetase 2, strongly suggesting that they represent the catalytic portion of the enzyme. In fibroblasts from four I-cell disease patients no α/β-mRNA was found by Northern blot analysis, while in I-cell strains derived from two pseudo-Hurler polydystrophy patients (complementation group A) this α/β-transcript was present in significantly reduced amounts. In both types of fibroblast strain, the 1.3 kb γ subunit transcript was found to be normally present [296]. The human α/β-subunit gene has been shown to reside on chromosome 12q. It spans 76 kb and is genomically organized in 22 exons. Polymerase chain reaction amplification has demonstrated that all individual exons are present in all patients so far studied. Small insertions and deletions causing frameshifts and substitutions that disrupt splice junctions have been found. These either prevent transcription or alter the stability of the message [296] as the causal factors in I-cell disease and pseudo-Hurler polydystrophy patients.

Galactosialidosis (MIM 256540)

The designation "galactosialidosis" [297] has been applied to three more or less clinically delineated "disorders" or types, with resemblance, both clinical and metabolic, to generalized G_{M1}-gangliosidosis and sialidosis, but genetically distinct from each. With similar oligosaccharidiuria and β-D-galactosidase deficiency established in patients, early reports already either stressed their unique combination of clinical features [298] or made attempts at classifying cases with a long follow-up into different groups [299]. Objective classification became feasible following the discovery by

Wenger et al. that in this type of patient glycoprotein sialidase was deficient in addition to β-D-galactosidase [300].

In addition to the most frequent, juvenile (adult) type of galactosialidosis, so far mostly reported from Japan [297,301–303], both late infantile [298,304] and neonatal (hydropic) [305–309] forms have been discerned. Galactosialidosis is a disease with severe manifestations in nearly all patients, who, in fact, represent a continuum of phenotypes heterogeneous with respect to age of onset (pre- or perinatal until late adolescence), rate of progression, severity, and prognosis. For clinical purposes and for genotype-phenotype correlation studies, the alternative division into a type I form with generalized and severe manifestations and perinatal or early infantile onset and a type II form with later (late infantile, juvenile, adult) onset and protracted course, has at least an equally heuristic value [302,303]. The latter type then needs further subdivision into subtypes IIA (severe expression) and IIB (mild expression). Galactosialidosis is a rare metabolic disorder with a frequency distribution of phenotypes, at least in Japan, skewed toward the later onset and chronic course types.

Juvenile (Adult) Type Galactosialidosis

The clinical onset of this form occurs from late childhood until early adult life [299,301–303]. Intrafamilial variation between patients is smaller than interfamilial differences. The composite clinical picture of the fully developed syndrome consists of the following signs and symptoms: (1) slowly progressive cerebellar ataxia, tremor, and action myoclonus, pyramidal but no extrapyramidal signs, and no nystagmus; (2) decreasing visual acuity and cherry-red spot in the macula; (3) mild dysostosis multiplex, mild coarsening of facial features, and moderately short stature; and (4) moderate intellectual impairment, which is unusual in the initial stages of the disease. Any one of the components may be of prime and/or early concern or may instead be lacking. Angiokeratoma is frequently observed in older patients. On slit lamp examination most patients show corneal opacities. Hearing loss is occasionally present. In some instances, mild facial coarsening, neuromotor developmental delay, slow physical growth and physical impairment or discomfort may be found retrospectively before "the age of onset" [310]. Cardiac abnormalities have been observed in juvenile galactosialidosis [311]. This type of galactosialidosis corresponds to type II in the clinical division proposed by the Japanese authors [302].

Late Infantile Galactosialidosis

Only a few patients with clinical onset of galactosialidosis during or before the second year of life have been reported [297,298,303,305]. In them, coarse facial features, hepatosplenomegaly, dysostosis multiplex, and developmental delay are noted initially, without ophthalmologic or neurologic signs which may develop further along in the natural course, which usually is quite prolonged. Too few detailed and long-term follow-up reports are available. One patient followed over more than 18 years has developed fibrotic thickening of the cardiac valves and required aortic valve replacement [304]. In this group of patients, the rate of clinical progression of galactosialidosis is remarkably heterogeneous [312]. The rather consistently protracted course makes the older patients indistinguishable from those with the juvenile (adult) onset type of galactosialidosis.

Neonatal (Hydropic) or Early Infantile Galactosialidosis

Neonates presenting with a condition clinically almost indistinguishable from G_{M1}-gangliosidosis type 1 but with extensive edema and ascites have been diagnosed as having a combined deficiency of glycoprotein sialidase and β-galactosidase. They have a coarse facies, a depressed nasal bridge, cloudy corneae, a macular cherry-red spot, and conjunctival telangiectasia with similar lesions over the lower abdomen. Some succumb in early infancy [303,305–307,309]. Some show severe nonimmune hydrops *in utero* or at birth with early fatal outcome [306,307]. In the longer surviving patients, respiratory infection recurred frequently and both congestive heart failure and renal failure were the compounding causes of death, in addition to anemia and thrombocytopenia. Radiographically, the skeletal changes were identical to those in G_{M1}-gangliosidosis and I-cell disease [306]. The classification of galactosialidosis patients according to the Suzuki group of authors [302,303], places the neonatal (hydropic) or early infantile cases into their galactosialidosis type I.

Pathological Features and Diagnosis

Patients with any type of galactosialidosis have vacuolated peripheral lymphocytes, aligning them with all other storage disorders due to a lysosomal hydrolase deficiency [309]. Detailed reports on post-mortem examinations of galactosialidosis patients remain few in number [313,314]. Numerous cytoplasmic membrane-bound vacuoles are readily apparent in hepatocytes, Kupffer cells, Schwann cells associated with peripheral nerves, and fibroblasts. Under the electron microscope, concentric or wavy lamellar as well as fine granular material is found within the swollen lysosomal structures in neurons throughout the central nervous system and in connective tissue cells in parenchymal organs. Similar abnormalities are detectable in cultured fibroblasts. In the central nervous system, the storage material encountered within neurons is reminiscent of what is found in G_{M1}-gangliosidosis. However, G_{M1} and other ganglioside species are less abundant. The several oligosaccharides in glycoproteins or glycolipids accumulating are of the N-acetyllactosamine type, with the mannose β 1–4 GlcNAc sequence preserved at their reducing termini (see Fig. 7). The structures of the oligosaccharides excreted are very variable, but quite similar to those of the compounds excreted excessively in the urine of patients with sialidosis [315].

As indicated in the introduction, the demonstration of the combined deficiency of β-D-galactosidase and glycoprotein sialidase in fresh leukocytes and cultured fibroblasts provides objective confirmation of the clinical diagnosis of galactosialidosis. A deficiency of the former enzyme is not found in all tissues, nor in plasma, and, where detectable, is less profound than in patients with G_{M1}-gangliosidosis. In obligate heterozygotes, glycoprotein sialidase activity is intermediate but β-D-galactosidase is normal [316]. The significance of cathepsin A specific activity for diagnostic purposes is discussed below.

The Metabolic and Molecular Defect

The enzyme deficiencies encountered in each type of galactosialidosis do not mutually complement one another *in vitro* and thus must be caused by allelic mutations. Immunoprecipitation with anti-β-galactosidase antibody has revealed that the 85 kDa β-galactosidase precursor polypeptide is synthesized as in normal fibroblasts, but is only partially processed into its 66 kDa monomeric form.

The defective product does not aggregate into high molecular weight complexes and has a much faster than normal turnover following its synthesis [317–319]. In the pulse-chase experiments performed in these initial studies, attention was paid to three polypeptides of 54 kDa, 32 kDa, and 20 kDa, respectively, the first apparently being the precursor of the latter two species, because all three were absent in fibroblasts from patients with the early infantile type of galactosialidosis.

The primary defect in galactosialidosis is the absence or profound deficiency of the lysosomal 32 kDa β-galactosidase protective protein and its 54 kDa precursor. It is normally required for the aggregation of the 66 kDa β-galactosidase monomers and their protection against intralysosomal degradation. This protein is an essential factor also for the activation of glycoprotein sialidase [317–321]. The molecular characterization of the 32 kDa protective protein was greatly aided by the cloning of its corresponding cDNA [322], from which its amino acid sequence was deduced. A hydrophobic signal peptide of 28 amino acids is proteolytically cleaved from the N-terminus of the 298 amino acid sequence of the 32 kDa component that represents the larger of two functional domains within the 54 kDa precursor, or proform, of the protective protein. The 32 kDa polypeptide is separated by endoproteinase cleavage from the N-terminus representing the 20 kDa polypeptide. Subsequently, the larger polypeptide is trimmed starting from its COOH-terminus. The two proteins are held together as a heterodimer by the formation of disulfide bridges. Glycosylation of the two asparagine residues is completed before the polypeptide complex dimerizes (95 kDa) and acquires its multifunctional role [323]. Only the glycosylation site in the 32 kDa polypeptide becomes phosphorylated and thus acquires the mannose 6-phosphate recognition marker needed for correct routing toward the prelysosomal vesicles [324]. Part of this maturation process needed for activation takes place in the lysosomal compartment itself. This sequence of events has been elucidated by studying the transient expression of human protective protein cDNA in COS-1 cells.

Extensive molecular homology is found between protective protein and two yeast carboxypeptidases, including, in particular, the conserved amino acids which, although belonging to different subunits, constitute the active enzymatic site in the human protein. The protective protein was found to have cathepsin A activity [322]. In fibroblasts derived from infantile galactosialidosis patients less than 1% of normal cathepsin A activity is detected [316], whereas there is 2–5% residual activity in cells from patients with the late infantile or juvenile/adult types. Heterozygote values for cathepsin A activity were, on average, half of normal. This carboxypeptidase shows amply sufficient specific activity in chorionic villi and amniocytes to allow it to be used in prenatal diagnosis. A sign of warning against the possibility of a mutation interfering substantially with the protective function of the protective protein without affecting its cathepsin A activity must, however, be posted. Thus, demonstration of the coexisting secondary enzyme deficiencies may remain the more reliable assay method for diagnostic purposes [321].

Molecular Pathology: Genetic Heterogeneity

Somatic segregation of human chromosomes from man-mouse hybrid cell lines allowed localization of the gene encoding the protective protein (PPGB) to chromosome 20 [325] and its more precise assignment to 20q13.1 [326]. Immunoprecipitation with specific antibody has shown that in fibroblasts from patients with the early infantile type of galactosialidosis, there is either a marked reduction or absence of the 52 kDa precursor species and a total lack of protective protein itself [318,327]. There is even an absence of the corresponding mRNA [322]. It appears that in at least some patients the precursor protein is wholly or partially retained in the endoplasmic reticulum. Recently elucidated simple point mutations may have this effect for various reasons, such as the prevention of phosphorylation of the protective protein and subsequent disturbed enzyme routing and early 32 kDa breakdown, as caused by the Val104Met, Leu208Pro, and Gly411Ser substitutions [324]. In the juvenile (adult) onset type of galactosialidosis, an increased amount of 52 kDa precursor was actually found, but there was no active 32 kDa protein, suggesting a block in the maturation process. Frequent among the mutations in Japan is the deletion of exon 7 in the *PPGB* gene, symbolized as IVS7DS, A-G +3, Ex7del, which is due to a splice site alteration 3 bp downstream from exon 7. Homozygotes for this mutation have a mild, adult type of galactosialidosis, probably due to some alternative production of mRNA and some residual mature protective protein. This mutation results in a much earlier clinical onset if in compound heterozygous constellation with the missense Trp65Arg mutation. In fibroblasts from patients with the late infantile type of galactosialidosis with early onset and chronic course, accumulation of the immature 52 kDa precursor was often also noticed. It was, however, accompanied by a much reduced but measurable amount of active 32 kDa glycoprotein. Treatment of the fibroblast strain with the protease inhibitor, leupeptin, led to an increase of the active protective protein/cathepsin A species [327]. Such a form of galactosialidosis is found in the case of a Phe412Val substitution. The patients reported by Chitayat et al. [310] and Strisciuglio et al. [304] are of this type. In Japan, the homozygous state for the missense mutation Tyr395Cys is also common among severely affected patients, although the mutation results in a somewhat milder clinical course in the compound heterozygotes with Tyr395Cys/Ex7del [303]. Clinical severity and early age of onset appear to correlate reasonably well with the amount of active protective protein available. Thus, clinical heterogeneity relates partially to heterogeneity in molecular pathology, but both appear to be largely surpassed by genotypic heterogeneity.

PYKNODYSOSTOSIS; CATHEPSIN K DEFICIENCY (MIM 265800)

Named and first described by Maroteaux and Lamy in 1962 [328], pyknodysostosis is an osteochondrodystrophy clinically apparent from early childhood, characterized by short-limb type shortness of stature, a disproportionately large calvaria with frontal and occipital bossing and late or never closing fontanelles, a small nose, and receding chin. In addition, patients have various dental anomalies, short and broad hands, and increased bone fragility.

The radiographic abnormalities are at first mild and hardly typical. They become more complete in later childhood. The cranial sutures and large fontanelle remain wide open. Wormian bones are found. The mandibular angle is obtuse, the facial bones relatively small. Bone density increases gradually. There is some metaphyseal undermodeling of tubular bones, and often coxa valga deformity and partial hypoplasia with irregular osteolytic lesions in the terminal phalanges of the fingers and toes. The acromial ends of

the clavicles are usually hypoplastic. Often signs of old or more recent bone fractures are found in radiographic surveys [2,329].

Pyknodysostosis is inherited as an autosomal recessive trait. That the condition is rare, is reflected by the high degree of parental consanguinity encountered in reported series [329–331].

Recent progress in identifying and characterizing the pyknodysostosis gene is the result of positional cloning based on homozygosity mapping and linkage analysis which showed it to be located on 1q21 [332–334]. By the candidate gene approach, some genes known to be localized in the same chromosomal region, such as the interleukin-6 receptor gene and the cathepsin S gene, although known to be highly expressed in osteoclasts, were effectively ruled out as candidates for the pyknodysostosis gene [332–334]. On the other hand, the cathepsin K gene (*CTSK*), which maps to the same region and is also highly expressed in osteoclasts, was shown to be defective in pyknodysostosis and to carry an A to G transition at nucleotide 1095, leading to a change of the normal termination codon 330 into one for a tryptophan residue (Stop330Trp) and therefore to the elongation of the C-terminus of cathepsin K by 19 amino acids. This mutation cosegregated with pyknodysostosis in all affected individuals in the pedigree reported by Edelson et al. [329,334]. In addition, nonsense and missense mutations were also discovered in other patients. The human cDNA for cathepsin K has been cloned and sequenced [334,335] and shown to encode a 329 amino acid–containing protein. This work was facilitated by the great homology of human cathepsin K with its rabbit homolog. Its amino acid sequence is about half identical also to human cathepsin S, the gene for which is located in the same vicinity and possibly the accompanying product of a tandem duplication of an ancestral cathepsin. Cathepsin K is a cysteine protease of major importance in bone resorption and remodeling mainly mediated by osteoclasts. It has the highest type I collagenolytic activity among the cysteine proteinases. Osteoclasts viewed by light microscopy appear normal in pyknodysostosis, but their pericellular zone of demineralization is enlarged. Under the electron microscope, these osteoclasts contain large, abnormal cytoplasmic vacuoles containing fibrils, probably of collagen I, the main fibrillar component of the intracellular matrix of bone. Pyknodysostosis has thus been shown to be a lysosomal disorder for which defective tissue-specific expression and pericellular secretion of cathepsin K is the pathogenetic mechanism [332,334]

GAUCHER DISEASE TYPE I; ACID β-GLUCOSIDASE DEFICIENCY (MIM 230800)

Gaucher disease, a cerebroside (glucosylceramide) lipidosis and, as such, a member of the group of sphingolipidoses, is the most prevalent lysosomal storage disorder and may have its clinical onset at any age. Characterization of the compound stored excessively has contributed significantly to the gradual elucidation of the specific enzyme deficiency of glucosylceramide β-glucosidase (EC 3.2.1.45) by several authors [336,337]. Phenotypic heterogeneity is notorious in Gaucher disease, leading to the delineation and conventional classification of three clinical types. The chronic or adult form of Gaucher disease is most frequent (70–80% of all patients). It has been termed Gaucher disease type I, and is the only form in which connective tissue is adversely involved. There is no involvement, however, of the central nervous system in this most frequent type. At least two-thirds of patients are of Ashkenazi Jewish extraction. In some groups the heterozygote frequency is estimated to be about 1 in 16 [338].

Symptoms may arise in early childhood and are usually present by adulthood (Fig. 14). They include splenomegaly, with evidence of hypersplenism and pancytopenia. Splenectomy is often indicated, but is often followed by intensifying bone disease. There is sometimes hepatomegaly. The skeleton is often involved, with bony lesions consisting of either mere expansion of the space normally occupied by the bone marrow (Erlenmeyer flask deformity of the femur), or osteopenia, cortical thinning and osteonecrotic lesions with pathological fractures (Fig. 14c). The latter are often refractory to orthopedic surgical or conserving measures. Painful bone crises lasting several days are common in this stage of Gaucher disease type I. Skeletal surveys and ultrasonographic studies may also detect intrathoracic and/or abdominal lymphadenopathy. The lungs may become affected with, as consequences, progressive dyspnea and sometimes cyanosis, failing gas exchange, and clubbing of fingers and toes. Unexplained febrile episodes are observed. In a few patients, renal failure may become a troublesome component. In addition, an abnormal increase in γ-globulin content is regularly found in Gaucher disease serum. Cardiac involvement, mostly of the calcified constrictive pericarditis type, has been reported in Gaucher disease type I patients. This phenomenon may be associated with a specific missense mutation [339]. Although the central nervous system is not primarily affected in Gaucher disease type I, complications may arise as a consequence of systemic vascular or bone disease [340].

The pathologic hallmark in Gaucher disease is the Gaucher cell, a disease-altered reticuloendothelial (monocyte/macrophage lineage) cell which, under the light microscope, contains rather typical fibrillary cytoplasmic material. This type of cell is observed mainly in the bone marrow, but also in lymph nodes and visceral organs.

As many thousands of patients have been diagnosed and studied worldwide, the phenotypic heterogeneity of Gaucher disease, even within each of the "classic types," continues to expand. Type II Gaucher disease represents but 15% of patients. It is a fulminant disorder of the central nervous system, starting in infancy and ending fatally, usually before 2 years of age. The reader is referred to authoritative reviews elsewhere [338,340,341]. Type III Gaucher disease, encountered mainly but not exclusively in Sweden, has its onset in infancy. Although neuromotor and mental development may continue normally until later childhood, intellectual and neurologic deterioration becomes manifest and progresses inexorably until the fatal outcome before adolescence (see the reviews cited above). In type II and type III Gaucher disease, Gaucher cells are readily demonstrable. They are also found in the perivascular regions. However, in these forms of the disorder, neuronal glucocerebroside storage and necrosis are the prevailing pathologic features.

Glucosylceramide accumulates in Gaucher cells in all types of Gaucher disease, but not in the central nervous system in the type I form under discussion here. The residual activity of glucosylceramide β-glucosidase, also called glucocerebrosidase (EC 3.2.1.45), is higher in type I Gaucher disease — levels of 10–20% of normal may be found–than in the infantile neuronopathic type II, in which it is often less than 1% of normal. The enzyme is usually assayed as acid β-glucosidase. Cross-reacting material is found in the spleens of all three types of patient. However, acid β-glucosidase mRNA

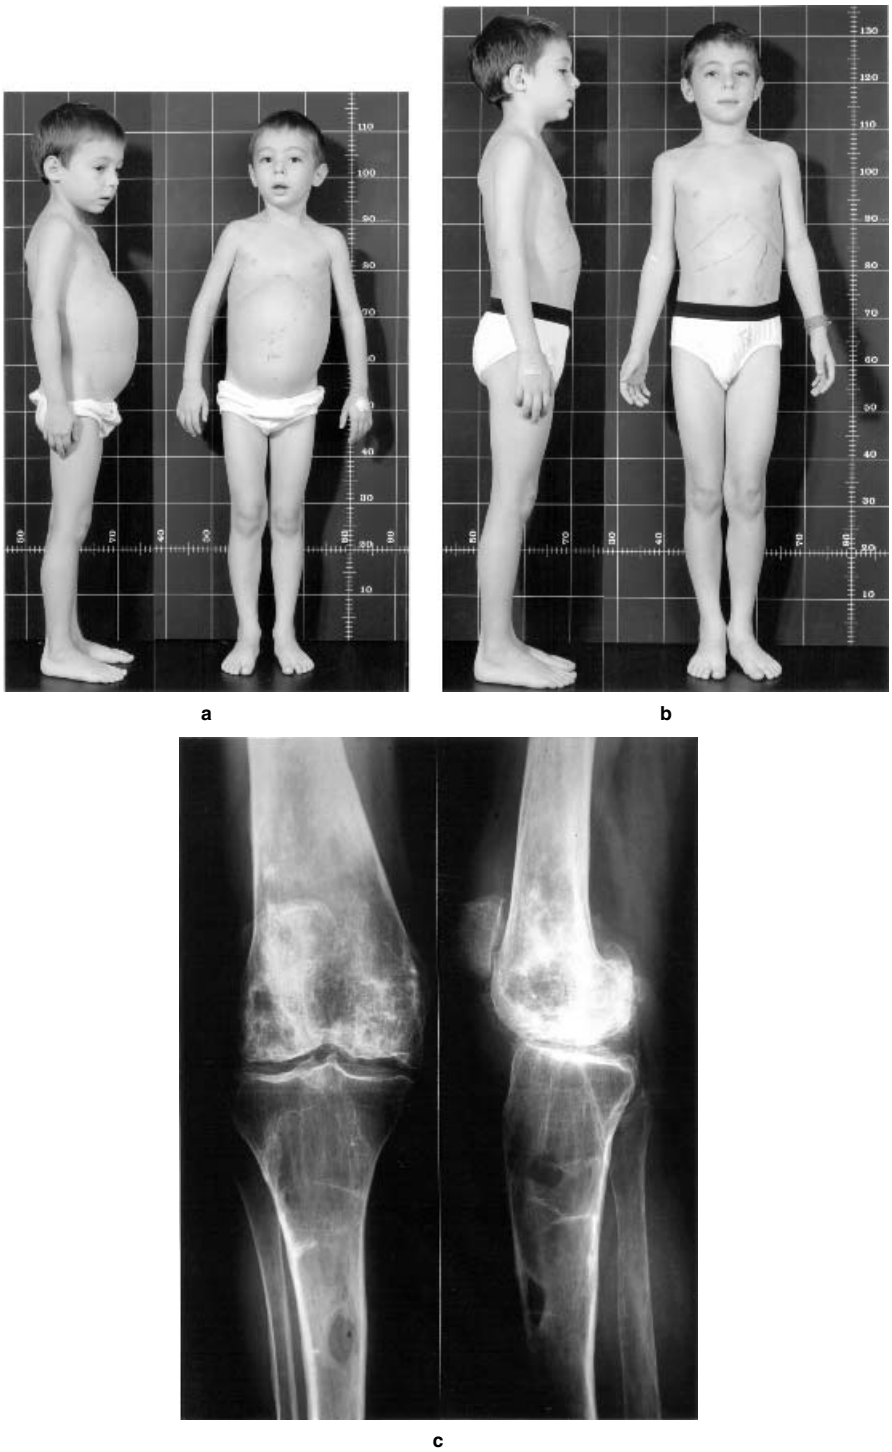


Figure 14. Gaucher disease. (**a**) 6.5-year-old boy (A.S.) with protuberant abdomen and hepatosplenomegaly, short stature (3rd centile), anemia and thrombocytopenia before enzyme replacement therapy and (**b**) 2.2 years later after enzyme replacement therapy: note marked regression of hepatosplenomegaly and catch-up growth (50th centile). The boy is presently 15 years old, his height and weight are on the 50th centiles, his liver and spleen are only mildly enlarged, and his hemoglobin and thrombocyte counts are normal (courtesy of Drs. R. Gitzelmann and A. Superti-Furga, Zürich). (**c**) Radiographs of the right knee of a 53-year-old woman (R.R.) show diffuse osteopenia and osteolytic defects (osteonecrosis) of the distal part of the femur and the proximal parts of the tibia and fibula as well as narrowing of the knee and patellofemoral (right panel) joints. Note the typical Erlenmeyer-like shape of the distal femur due to undertubulation (left panel). Her spleen had been removed at age 4.5 years and at age 53 years the right hip joint had to be replaced (courtesy of Dr. B. Steinmann, Zürich).

is present in normal amounts in fibroblast extracts [342]. The mutant enzyme is most often altered at single amino acid residues, interfering only with catalytic efficiency. *In vitro* complementation between fibroblasts from neuronopathic and non-neuronopathic Gaucher disease patients has not been observed [343], thus providing evidence that all forms of Gaucher disease are allelic. Studying the characteristics of residual acid β-glucosidase activity had previously led to the conclusion of biochemical heterogeneity even among type I patients [344,345].

The gene encoding acid β-glucosidase has been located at 1q21 [338,346,347]. It contains 11 exons and spans 8 kb. A pseudogene (*psGBA*) transcribable into mRNA but not producing any active enzyme, is located 16 kb downstream [348]. Cloning and characterization of the *GBA* gene has allowed the identification of an increasing number of mainly point mutations and gene alterations, showing once again that genotypic heterogeneity still largely surpasses the heterogeneity of Gaucher disease phenotypes. In Ashkenazi Jewish patients with type I Gaucher disease, more than 95% carry one of four so-called frequent or common mutations. These are Asn330Ser, 84insG, Leu444Pro, and IVS 2-G[+1]A, mostly in the compound heterozygous state. Among non-Jewish type I patients, allelic heterogeneity is considerably greater, many mutations being found only in a single patient or family [349]. Fluorescence-assisted methodology has allowed the discovery of further novel mutations in a large French sample of Gaucher disease type I patients [350]. Many patients are compound heterozygotes for two different *GBA* mutations, often carrying one common and one "personal" allele. The Asn370Ser mutation predicts a mild phenotype, while the Leu444Pro allele predicts the more severe type III phenotype. However, even identical compound heterozygotes and sib patients may turn out to have strikingly different degrees of severity of disease. Such clinical differences are difficult to explain, and must be due to environmental factors. In non-sib genotypically identical patients a multifactorial explanation may be offered. Such observations must induce caution with regard to the predictive value of the mutations identified, not only in genetic counseling but also in terms of forecasting success in substitution therapy. Over one third of all mutations known today in the *GBA* gene have been listed as allelic variants and their clinical effects summarized. The mutation Asp409His, MIM allelic variant 230800.0006, is apparently associated with hemorrhagic pericarditis [20].

ANIMAL MODELS

The successful delineation of human lysosomal storage disorders by objective enzyme assays more than two decades ago, created a scientific climate favorable to the discovery of the first models of these disorders, such as α-mannosidosis in Angus cattle [351], and arylsulfatase B and iduronidase deficiency in cats [352,353]. Although, over subsequent years, the number of natural animal models of lysosomal diseases has increased considerably, their rarity, in both nonprimates and humans, is an indication of higher order levels of genomic homology among the species involved. This homology not only concerns structural but also critical regulatory genes. The animal models in the following paragraphs are highly valuable because they contribute to understanding the correlation between the one-dimensionally complex genotype and the resulting multidimensionally complex phenotypes of the lysosomal disorders. Because of the extensive homology of contiguous linkage groups, the localization of animal genes encoding lysosomal enzymes has facilitated considerably the precise mapping of the homologous human genes. One well-known example is the conserved close synteny of the Huntington gene and the *IDUA* gene in mouse and man [354]. In addition to disease models arising in nature, animal models have also been created by targeted gene disruption techniques, such as the iduronidase knockout mouse [355]. As well as their value in the assessment of the main and side effects of any type of treatment, animal models are particularly useful in studying clinical aspects of the natural course of a disease, its pathogenesis and chemo- and anatomopathology, e.g., murine Hurler disease [356].

MPS VI and MPS VII

MPS VI and MPS VII also stand out with respect to the number of animal models detected and studied. The former is known in both cats and mice. The cat model has been used for both the evaluation of strategies of enzyme replacement therapy and genotype-phenotype correlation studies [357]. A mouse model of MPS VI has also been produced by targeted gene disruption [358]. A mutant mouse with β-glucuronidase deficiency (MPS VII) has also been described. Its encoding gene has been mapped and the mutation characterized as a single base-pair deletion [359]. This mutant model has been used in the demonstration of long-term, low-level *in vitro* expression of β-glucuronidase activity in mutant cells following retroviral vector-mediated *gusb* gene transfer [360]. The treatment of newborn MPS VII mice with recombinant mouse β-glucuronidase has been shown to be more effective the earlier it is administered. Early enzyme replacement by itself or followed by syngeneic bone marrow transplantation has long-term therapeutic effects in murine MPS VII, and such early treatment is significantly more effective than therapy initiated at an adult age [361]. Several other strategies of β-glucuronidase substitution in mutant mice have been more or less successfully tried and adequately documented [361,362]. The more recent availability of recombinant products, which may be administered intravenously to the newborn, has renewed interest in enzyme replacement therapy and met with some success [362]. The mutation in the β-glucuronidase-deficient dog has been found by sequencing *GUSB* cDNA to be a single base pair substitution leading to an arginine to histidine substitution [363].

β-D-Galactosidase Deficiency

β-D-galactosidase deficiency has been documented in sheep [364]. It has also been generated in the mouse using embryonic stem cell technology and gene targeting involving homologous recombination between the normal gene and a mutant homologue carried within introduced vector DNA. Although considerable accumulation of G_{M1}-gangliosides occurred in the brain, neurologic abnormalities were not observed before the age of 5 months in the mutant animals, raising a note of caution about ignoring pathogenetic differences between species and possibly overemphasizing the similarities [365].

Mannosidosis

In addition to the observation of α-mannosidosis in cattle [351], the equivalent of this human disease has also been found in cats. These animals treated by bone marrow transplantation showed no disease progression, measurable amounts of α-mannosidase activity in brain tissue, and an absence of storage in neurons [366]. Thus, bone marrow

transplantation can contribute significantly to substituting the missing enzyme in the central nervous system and preventing the effects of the disorder. Both the feline enzyme and the bovine show greater than 80% identity with human α-mannosidase [367,368].

Species differences in the clinical effects of "homologous" gene mutations exist between caprine and human β-mannosidosis. In goats, this disorder severely affects the central nervous system, whereas in man it is milder and more slowly evolving [171]. The disease has also been observed in cattle [369]. Complete cDNA sequencing demonstrated greater than 95% amino acid identity between the caprine and bovine genes. In the former species, the mutation is a single base-pair deletion that results in a frameshift and generation of a premature stop-codon [180].

Other Oligosaccharidoses

Fucosidosis encountered in rat and dog has so far not been an important animal model, but the mutations affect homologous genes with a high degree of structural identity [370]. There is, as yet, no demonstration of an animal model of the human combined deficiency of β-D-galactosidase and glycoprotein sialidase involving the lysosomal protective protein. Observations in sheep suggest a primary mutation of the acid β-galactosidase gene. The first example of "I-cell" disease in a cat has been reported [371]. For more general information on genetic homology between mouse and man the reader may consult the review by Searle et al. [372].

PREVENTION AND TREATMENT

Genetic Counseling and Prenatal Diagnosis

With causal therapy not yet available or unequivocally effective in most of the lysosomal disorders of connective tissue, in general, their conceptual and strategic management remains the goal of preventive medicine. Paradoxically, prevention finds its retrospective foundation in early diagnosis in the proband and its practical strategies in genetic counseling, prenatal diagnosis or, perhaps in the future, preimplantation diagnosis. Fetal monitoring either by assay of the relevant lysosomal hydrolases or confirmation or exclusion of a gene mutation in chorionic villi or cultured amniotic fluid cells is available. Elective termination of pregnancy remains an option for parents. However, prospective preventive measures like mass population screening continue to be unrealistic, although molecular genotyping in probable heterozygotes is becoming increasingly effective as responsible gene mutations become known in more affected individuals. Such tests are much more reliable, even in autosomal recessive disorders, than laborious attempts to demonstrate intermediate lysosomal enzyme activity, because of the overlap usually found between normal individuals and heterozygous carriers.

Supportive and Symptomatic Management

If cure is, as yet, unrealistic for many lysosomal disorders, providing comfort and care can and must be the physician's primary goal. This includes supportive and symptomatic management. This type of "treatment" has been spelled out in detail for patients with the various mucopolysaccharidoses [48,373], but can, however, be called comprehensive only if guidance to a patients' parents and healthy sibs is included. In addition, it should provide information and training to all concerned with the educational and social needs and basic right to human happiness of children and adults with one or other of the slowly progressive multisystemic disorders.

Enzyme Replacement

Infusion Therapy

Methods of enzyme replacement therapy deserve renewed attention, even if only because of recent success in treating type I Gaucher disease patients by administration of alglucerase, a glucocerebrosidase purified from placenta and modified in its carbohydrate side-chains to enhance its uptake by enzyme-deficient macrophages [374] (Fig. 14b). A recombinant acid β-glucosidase, called imiglucerase, is currently under large-scale production and available for treatment [375]. Unfortunately, the success story does not include the neuronopathic type II Gaucher disease.

Attention must also be given to the carefully controlled enzyme replacement therapy performed in the canine model of MPS I using recombinant, properly processed, purified α-iduronidase, following its overexpression in a recombinant Chinese hamster ovary (CHO) cell line, the results of which were impressive [376,377]. Similar treatment protocols in which human α-iduronidase is administered to patients have commenced [378].

Bone Marrow Transplantation

As the lysosomal disorders are systemic in nature, substitutive transplantation of the most affected organ is not a realistic therapeutic option for the provision of functional enzyme. Bone marrow transplantation and thus stem cell donation from the hematopoietic system of a suitable donor to a young patient has proved to be a clinically effective way of treating patients with Hurler disease and some other lysosomal disorders, provided engraftment is obtained. Results have been multisystemic in nature and clinically impressive. They provide a considerably improved quality of life for patients and their families, but are not curative. Remarkably, the central nervous system may benefit from bone marrow transplantation as iduronidase apparently penetrates the blood-brain barrier because some stem cells populate the brain as microglial secretory elements. Dysostosis multiplex and other connective tissue abnormalities do not consistently improve or worsen. In proposing this treatment to parents, its immunosuppressive and myeloablative components and the limits to its success must be explained, in addition to its benefits [379–381].

Gene Therapy

In principle, the lysosomal disorders are among the more suitable candidates for somatic cell gene therapy. Their cause is monogenic and, in nearly all instances, the responsible genes have been isolated and the corresponding specific mutations fully characterized. The underlying pathogenesis has become better understood as has the processing and intra- and intercellular routing of the hydrolases involved. The roles and functions of the plasma membrane receptors are more fully appreciated, and so are the modifications of oligosaccharides in the glycoprotein hydrolases. The chemical modification of exogenous β-glucosidase in the treatment of type I Gaucher disease patients, mentioned above, is an example. Obligate heterozygotes are clinically normal, their sometimes low hydrolase specific activity notwithstanding, which indicates that only a small fraction of normal enzyme activity may be sufficient to prevent lysosomal disease.

However, curative treatment of most lysosomal disorders of connective tissue is not soon expected to be available. Levels of potential therapeutic intervention are, first, the

gene mutation itself; second, the ensuing enzyme deficiency; third, the macromolecular substrates accumulated. Unlike the more or less effective dietary measures that may be adopted to minimize small central nervous system–intoxicating molecules in the newborn with either phenylketonuria or galactosemia, direct means for reduction of macromolecular storage and accompanying tissue damage are unknown. While it is hoped that gene therapy will become of major importance in the future, it is by no means a component of the clinician's armamentarium at present, the main challenge currently being to achieve efficacy. Gene therapy should not require a more rigorous preclinical evaluation than any other novel medical treatment, except for unprecedented applications or in respect of issues such as new viral vectors, gene therapy in fetuses, or approaches involving germ line alteration [382]. The presently known vectors for gene delivery are at best of an experimental nature, their defects and residual biological properties being mostly assets to safety but flaws to long-term effectiveness. An essential prerequisite is the ability to control expression of a newly introduced gene in animal models, because in addition to adequate expression, examples of overexpression of transduced human corrector genes have been demonstrated in autologous cultured cells. *Ex vivo* expression of the wild-type iduronate 2-sulfatase gene transduced within a retroviral vector has been shown to be significantly greater than normal in lymphoblasts of Hunter disease patients [383]. The natural murine MPS VII model has been used for the *in vivo* functional evaluation of implants of genetically modified cutaneous fibroblasts, bone marrow cells, and myoblasts. β-Glucuronidase was secreted by the "organoid" implants for almost 6 months and demonstrated in several organs, with subsequently declining lysosomal storage [384,385].

Application of practical gene therapy for human lysosomal diseases of connective tissue, however, must still await the clarification of several fundamental problems, such as improving the extent of initial transfection, maintaining stable expression of the transgene, and avoiding rejection by the recipient's immunodefense system [360–362].

RECENT DEVELOPMENTS

Mucopolysaccharidoses

Hurler Disease; MPS 1H

This reference mucopolysaccharidosis must now also be ranked among the group of secondary elastic fiber disorders as it has been demonstrated that the accumulation of at least one of the galactose-containing GAGs, dermatan sulfate, results in the functional inactivation of elastin-binding protein (EBP), and hence prevents the normal assembly of elastic fibers by mutant fibroblasts [386] (see also Morquio Disease Type B, below). The defective elastogenesis helps to explain the progressive cardiac valve hardening and subsequent dysfunction characteristic of Hurler disease. Moreover, it helps to understand the obstructive coronary arteriopathy that occurs in some Hurler disease patients. This has been shown to be similar to the elastin arteriopathy in patients with supravalvular aortic stenosis, an example of a primary disorder of elastin fiber synthesis (see Chapter 10, this volume). This secondarily inflicted tissue damage is partially refractory to iduronidase replacement therapy, irrespective of the route of administration. It is likely that other MPS entities also belong to the category of secondary elastic-fiber disorders.

Hunter Disease; MPS II

The number of different mutations discovered within the *IDS* gene now stands at well over 200. Studies in patients from different geographic and/or ethnic backgrounds confirm that most missense mutations result in intermediate or severe phenotypes. About 75% of MPS II patients have severe clinical expression. Small mutations consistently outnumber large deletions and major rearrangements involving the gene by a margin of 4 to 1 [387–390]. A fusion transcript comprising sequences of both the contiguous gene *W* and the *IDS* gene has been identified [391]. Direct dye primer sequencing of PCR products is of great value in carrier testing, even in families without a surviving patient, as shown by the finding of mixed nucleotides in an obligate heterozygote [392].

Morquio Disease Type A; MPS IV A

The observation of a two generation family with intermediate Morquio disease in the younger generation (compound heterozygosity for Arg94Gly/Arg259Gln) and mild disease in the older generation (homozygosity for the Arg259Gln substitution) of the pedigree [393], indicates that compound heterozygotes may be more severely affected than patients homozygous for Arg259Gln. In a patient with both Morquio disease type A and deficiency of adenine phosphoribosyltransferase (APRT), with the expected concomitant urolithiasis, a 16q24.3 deletion apparently involving both contiguous genes has been found [394]. Such a combined enzyme deficiency may be more common in Morquio disease type A patients than statistically anticipated as APRT deficiency may go unnoticed. A structural model of human GalNAc-6-sulfate sulfatase has been proposed based on the total lack of transient *in vitro* expression in "severe" mutants and the considerable residual activity in cells from patients with mild Morquio disease type A phenotypes [395].

Morquio Disease Type B; MPS IV B

This entity is rather frequently associated with the missense mutation Trp273Leu in the *GLB1* (β-galactosidase) gene in both the homozygous and the compound heterozygous genotype [396]. The significant skeletal deformities and connective tissue abnormalities in patients with this terminal β-galactose oligosaccharide storage disorder occur not only as a result of the impaired breakdown of glycoproteins and complex galactose-containing GAGs by the defective β-galactosidase. In addition, the progressive physical handicap is also related to the defective formation of mature elastic fibers. Under normal circumstances, the early stages of elastogenesis are controlled by the 67 kDa EBP which has a galactolectin domain that can bind galactose-bearing moieties (references in [397]). EBP, a cycling molecular chaperone, protects the highly hydrophobic tropoelastin molecules and facilitates their orderly assembly upon the microfibrillar scaffold of growing elastic fibers. The pericellular accumulation of galactosugar-binding molecules can disrupt elastogenesis. EBP has turned out to be a catalytically inactive variant form of acid β-galactosidase encoded by the minor 2 kb transcript of the *GLB1* gene. This protein, a major component in the non-integrin cell surface receptor complex, lacks β-galactosidase activity. It is also called S-gal, and arises following alternative splicing of pre-mRNA which results in the deletion of exons 3, 4 and 6 and the addition of 32 amino acids encoded according to a different reading frame by exon 5. Unlike the regular lysosomal glycoproteins, it is not almost exclusively sorted

into the endosomal compartment. Fibroblasts from patients with infantile G_{M1}-gangliosidosis due to nonsense mutations in the *GLB1* gene and those from patients with Morquio disease type B, in both of which the different molecular forms of β-galactosidase are deficient, are unable to assemble elastic fibers. In contrast, G_{M1}-gangliosidosis fibroblasts with missense mutations that result in the inactivation only of acid β-galactosidase, are able to assemble elastic fibers. The skeletal and connective tissue abnormalities in severe G_{M1}-gangliosidosis are also most probably related to EBP dysfunction [397]. The cardiac involvement recently highlighted in these patients may have a similar molecular basis [398].

Oligosaccharidoses

Sialidosis

Since the cloning of *NEU1*, encoding glycoprotein sialidase [126,127], more than a dozen mutations have been characterized in patients with various clinical types of sialidosis. Among them, the missense mutations Phe260Tyr, Leu270Phe and Ala298Val, clustered in the same region on the surface of the sialidase macromolecule, have been shown to dramatically reduce catalytic activity and cause rapid intralysosomal degradation of the expressed protein, as determined by transgenic *in vitro* expression in cultured mutant cells. Although correctly processed and sorted in patient fibroblasts, the mutant protein was shown not to associate with the multienzyme complex [399,400], the formation of which is required for the proper functioning of glycoprotein sialidase, β-galactosidase, and cathepsin A [124,125,401]. Based on these and similar observations, molecular models of acid sialidase have been proposed [399–401]. In addition, acid sialidase has turned out to be an important signaling factor required for the production of the cytokine interleukin-4 by activated T lymphocytes, on the surface of which catalytic activity is increased. The mechanism of sorting sialidase activity to the plasma membrane must be related to the internalization signal, consisting of the C-terminal tetrapeptide 412TyrGlyThrLeu415, found in lysosomal membrane proteins targeted to endosomes via clathrin-coated pits. Redistribution of sialidase from lysosomes to the activated T lymphocyte surface is accompanied by increased reactivity of the enzyme with anti-phosphotyrosine antibodies. This may indicate that phosphorylation of Tyr 412 inhibits sialidase internalization upon activation of the lymphocytes. Meanwhile, these data indicate that the intracellular distribution of lysosomal sialidase is controlled by the internalization signal in its cytoplasmic tail [402].

G_{M1}-Gangliosidosis

New data about β-galactosidase processing indicate that the C-terminal precursor fragment is an essential domain of the enzyme. During the molecular maturation process it remains associated with the 65 kDa moiety previously thought of as the mature enzyme, instead of being degraded. Thus, β-galactosidase is now recognized as a two-subunit protein in which the C terminal domain is essential for catalytic activity [403].

α-Mannosidosis

Six patients between the ages of 7 and 26 years, including two sets of siblings, have been shown to have an immunodeficiency at both the humoral and the cellular level in a matched case-control study, with sex and age as matching variables [404].

Aspartylglucosaminuria

Knowledge of the molecular pathogenesis of aspartylglucosaminuria is increasing steadily as the effects on the maturation, transport, sorting, stability, and catalytic activity of aspartyl-β-glucosaminidase of 18 different mutations, including the Finnish founder mutation (AGU_{Fin}), Cys163Ser, and six novel mutations, have been better "dissected", making use of the three-dimensional model structure of the enzyme. Mutations at the dimer interface interfere unfavorably with αβ dimerization in the endoplasmic reticulum or prevent it altogether. Active site mutations not only destroy catalytic activity but also interfere with precursor maturation. According to their molecular effects, mutations may be subdivided into groups designated mild, average (includes AGU_{Fin}) and severe [405]. However, detailed clinical follow-up will be required to discern specific genotypes within the aspartylglucosaminuria phenotype which has, until now, been considered rather uniform.

Pyknodysostosis

Recent studies have indicated an expanding role for cathepsin K and its regulatory factors. Dysfunctional osteoclasts resulting in osteosclerosis are found not only in human pyknodysostosis, but also in mice with osteopetrosis with either a dominant or a recessive mode of transmission. Recessively inherited osteopetrosis in mice is associated with homozygous or compound heterozygous genotypes with mutations in the gene for cathepsin K. The phenotype resulting from dominant inheritance, more syndromic in nature, includes microphthalmia, an absence of neural crest-derived pigment cells, and mast cell defects, and is apparently due to heterozygous mutations in the gene encoding Mitf, a member of a helix-loop-helix transcription factor subfamily which also contains TFE3, one of several potential dimerization factors. Mitf also modulates age-dependent changes in osteoclast function. Cathepsin K has been identified as a transcriptional target of Mitf and TFE3 via three consensus elements in its promoter. Cathepsin K mRNA and protein are deficient in osteoclasts with mutant Mitf. Overexpression of wild-type Mitf significantly up-regulates endogenous cathepsin K expression in cultured human osteoclasts [406]. It should be noted that cathepsin K expression has been discovered also in a significant proportion of human breast cancers (references in [406]) and could play a role in breast cancer invasiveness. The enzyme has become of interest in relation to the treatment of osteoporosis and its inhibitors may be explored as potential therapeutic agents [406].

Animal Models

MPS VII

MPS VII missense mutant models produced in the mouse with phenotypes of varying severity include the active site nucleophile replacement Leu76Phe, the commonest human mutation, Glu540Ala, and Glu540Gln. The Glu540Ala mouse has a severe phenotype and no β-glucuronidase activity at all. Following the introduction of both the human *GUSB* Glu540Ala cDNA transgene into intron 9 and the active site Glu540Ala mutation into the endogenous *Gusb* gene, the resulting MPS VII mice display ubiquitous expression of inactive human β-glucuronidase and tolerance to immune challenge with the human enzyme. This observation may serve as a model for studying the immunologic consequences of either long-term enzyme therapy with human β-D-glucuronidase or future gene therapy with vectors expressing the enzyme [407].

Mannosidosis

A natural α-mannosidosis model in the guinea pig which closely resembles the human disease has been described [408]. It will be convenient for investigating the effect of future therapeutic strategies for α-mannosidosis, in particular, and probably neuronal storage diseases in general. It is particularly relevant because the purification and molecular characterization of recombinant human lysosomal α-mannosidase has now been achieved [409].

Treatment

MPS-I

In view of the favorable assessment of recombinant α-iduronidase replacement in the canine model of MPS I [376,377] and the improved availability of the recombinant enzyme [410], a 52-week enzyme replacement study has been carried out in 10 patients (9 with MPS IHS and 1 with MPS IS). In the prepubertal children growth rate increased, as did the range of motion in the shoulder and elbow joints, in all patients. Hepatosplenomegaly decreased significantly. After only two weeks of weekly intravenous enzyme administration the urinary excretion of GAGs decreased. Episodes of sleep hypopnea were less frequent and cardiac functional scores improved, although changes in heart valve function were inconsistent. In general, the ability to perform daily activities and endurance became steadily better. Hypersensitivity reactions and IgG-mediated immune responses to the enzyme infusions were moderate and manageable with premedication and adjustments of the infusion rate. However, null genotype MPS IH patients may be expected to have a greater immune response [378,411]. None of the patients in this trial had Hurler disease (MPS IH) and were thus not mentally handicapped. The recombinant enzyme is not expected to cross the blood-brain barrier and prevent progression of neuronal damage. At present, a second multicenter clinical trial, designed to last two years and to involve more patients with moderate or mild disease, is nearing completion. Preliminary indications are that this type of enzyme replacement therapy is not likely to benefit the most common and most severely affected MPS IH patients.

MPS VI

Based on the observation that enzyme replacement therapy with recombinant human N-acetylgalactosamine 4-sulfate sulfatase (rhASB) was effective in an MPS VI model and had few side effects, a randomized, two dose, blinded study of weekly intravenous treatment with rhASB is currently under way. Following at least 12 weeks of therapy, neither allergy nor serious adverse reactions have been noted [412]. The final report on the efficacy of the treatment in these patients without mental retardation is eagerly awaited.

Aspartylglucosaminuria

Although previous reports may have brought a more optimistic message, bone marrow transplantation cannot now be encouraged for the treatment of aspartylglucosaminuria patients after infancy. In a report on bone marrow transplantation in five patients of between 1 and 10 years of age with the disorder, severe subsequent complications included autoimmune hemolytic anemia. No neurological or mental improvement was observed, although long-term further physical health has been judged good [413]. The ever increasing molecular knowledge of the various *AGA* mutations has not yet led to favorable therapeutic intervention in the disease, which is often not diagnosed before early childhood, especially outside Finland.

Gaucher Disease

The clinical successes of enzyme replacement therapy are being confirmed in an ever growing number of Gaucher disease type I patients. However, the generalized osteopenia that exists in most treated adults is often refractory. A double blind, two arm, placebo-controlled trial of bisphosphonate (alendronate) disodium treatment in adults who had received enzyme replacement therapy for at least 24 months showed a significant increase in bone mineral density and indicates that anti-resorptive therapy is a useful adjunctive measure for Gaucher disease-related osteopenia in adults [414].

Chapter 23, Part I

Chondrodysplasias: General Concepts and Diagnostic and Management Considerations

William A. Horton and Jacqueline T. Hecht

Research Center, Shriners Hospital, Department of Molecular and Medical Genetics, Oregon Health Sciences University, Portland, Oregon (W.A.H.); Division of Medical Genetics, Department of Pediatrics, University of Texas Health Sciences Center, Houston, Texas (J.T.H)

INTRODUCTION

The chondrodysplasias are rare, inherited disorders of skeletal development and linear growth. By definition, they involve disturbances of the cartilage components of the growing skeleton; however, other tissues are often also affected. They occur in all vertebrates, and well over 100 distinct disorders, or, more accurately, clinical phenotypes have been described in man. Their prevalence is estimated at about 1 in 4,000 births. They are characterized clinically by skeletal deformities and varying degrees of dwarfism, typically with disproportion between the lengths of the trunk and the limbs. Some chondrodysplasias are apparent at or before birth, whereas others do not become evident for several years. Their severity ranges from those incompatible with postnatal life to those that are so mild that they are difficult to detect. Thus, the chondrodysplasias are an extremely heterogeneous group of connective tissue disorders.

HISTORICAL PERSPECTIVE

Short persons with abnormal body proportions can be identified in European and American art from ancient times [1]. However, it was not until 1878 that Parrot coined the term "achondroplasia" to distinguish these individuals from short persons with normal body proportions. Fifty years later, Morquio in France and Brailsford in England separated them into two groups, those with predominantly short trunks and those with predominantly short limbs [1]. While the term achondroplasia was retained for the latter group, Morquio-Brailsford syndrome, or simply Morquio syndrome, was applied to the former group. By the middle of the 20th century, it had become evident that considerable heterogeneity existed, and the 1950s through the 1970s saw the identification of many "new" chondrodysplasias, bringing the number to over 100 [2–9]. Delineating the diagnostic features (clinical manifestations, radiographic findings, inheritance patterns, morphology of the growth plate, etc.) received the greatest attention during this period. However, as this was accomplished, a gradual change occurred, bringing the focus of the 1980s to defining the natural history and variability of the disorders [10–15] and that of the 1990s to elucidating the responsible mutations and characterizing the pathogenetic mechanisms by which they disrupt bone growth [16–22].

NOMENCLATURE, CLASSIFICATION, AND ETIOLOGY

The nomenclature of the chondrodysplasias is confusing. They have often been called chondrodystrophies, as well as skeletal and bone dysplasias. Chondrodysplasia is the most appropriate term, because it implies abnormal development or growth (dysplasia) and distinguishes the conditions from the osteodysplasias, such as osteogenesis imperfecta (see Chapter 8, this volume), which involve bone abnormalities. The term "osteochondrodysplasias" refers to both groups and is synonymous with the designations bone and skeletal dysplasias.

Many different schemes have been employed to name individual chondrodysplasias [23,24]. Greek terms have been used, e.g., thanatophoric (death bringing), diastrophic (twisted), and metatropic (changing) dysplasias. Eponyms have been commonly utilized, such as Kniest or Ellis-van Creveld dysplasia. Many conditions have been named after the part of the skeleton or particular bone most affected, e.g., epiphyseal and metaphyseal dysplasias. Even the histologic appearance of growth plate cartilage has been employed on occasion, e.g., fibrochondrogenesis. A common phenomenon has been the "splitting" of what was originally thought to be one condition into two or more. Modifier terms, such as congenita, tarda, dominant, recessive, X-linked, and pseudo-, have been employed to distinguish such disorders as well as to connote particular features. Finally, most disorders are called dysplasias, but some are referred to as syndromes.

Many schemes have also been used to classify the chondrodysplasias. One of the earliest was based on whether it was the limbs or the trunk that was predominantly affected. Conditions were designated short-limbed or short-trunked chondrodysplasias. Other schemes have relied on the age at which the manifestations become apparent, i.e., neonatal versus late-onset chondrodysplasias. In 1964, Rubin published

Connective Tissue and Its Heritable Disorders, pages 901–908

a book entitled *Dynamic Classification of Bone Dysplasias*, in which the location of radiographic changes provided the basis for classification [25]. There were epiphyseal dysplasias, metaphyseal dysplasias, spondyloepiphyseal dysplasias, and so on. Although this provided a convenient way to divide the chondrodysplasias into general categories, it was an oversimplification, and many disorders had to be "forced" into one category or another. Nevertheless, this approach has been the most widely used system until recently, and international conferences were held in the 1970s through the 1990s to refine it for both naming and classifying chondrodysplasias [26].

The concept of chondrodysplasia phenotype families grew out of the need to develop a more manageable scheme to name and classify the chondrodysplasias. As advanced by Spranger in the late 1980s and early 1990s, it grouped disorders with similar quantitative manifestations into chondrodysplasia families [27–29]. The concept implied that common phenotypes arise from common pathogenetic mechanisms. Accordingly, members of a chondrodysplasia phenotype family were predicted to result from a common pathogenesis and potentially from mutations of the same gene. This concept was proven correct to a large extent as the genes harboring chondrodysplasia mutations were identified (Table 1). In fact, by the end of the 1990s, it had become apparent that a large proportion of disorders result from mutations in a relatively small number of genes, the chondrodysplasia genes [20,29,30].

An International Working Group on Bone Dysplasias was convened in 1997 to address the impact of molecular genetics on nomenclature and classification. The group constructed a hybrid scheme using genetic etiology, i.e., gene locus, as the primary basis for classification [31]. This resulted in many changes from earlier classifications since, in several instances, disorders previously thought to be different were grouped together and disorders previously thought to be related were separated. If genetic etiology is unknown, similarities in clinical and radiographic manifestations are employed. A caveat of the scheme is that it is dynamic. As the genetic etiology for a condition is identified, the basis for classification switches from phenotype to genotype. Another consequence of this dynamic, gene-based classification is that it directly interfaces with Online Mendelian Inheritance in Man (OMIM), which provides extensive references for disorders listed in the classification as well as links to a wide range of informational services [32].

The recent delineation of chondrodysplasia genes and their mutations has provided important insights not previously appreciated regarding the etiology of the chondrodysplasias. Allelism is common, and graded series of disorders that range from very severe to very mild are found in the better defined groups, such as those due to mutations of *COL2A1* (type II collagen), *FGFR3* (fibroblast growth factor receptor 3), and *DTDST* (diastrophic dysplasia sulfate transporter) [19,20,33]. This may well turn out to be the case for most of the groups as more mutations are found and the full spectrum of clinical phenotypes associated with mutations of a given gene is defined. These observations have changed the way these disorders are viewed. Previously, they were considered distinct entities with unique clinical, radiographic, and genetic features. The emerging view is that they are clinical phenotypes distributed along spectra of phenotypic abnormalities associated with mutations in particular genes. For mutations in some genes, such as *COL2A1*, the distribution is fairly continuous, with clinical phenotypes merging into one another across a broad range. There is much less clinical overlap for mutations of some other genes, such as *FGFR3*, in which the distribution is discontinuous.

MOLECULAR GENETICS

A number of genes that harbor mutations causing chondrodysplasias were identified in the 1990s (Table 1). Links to references for specific disorders are given in OMIM [32]. These genes encode several categories of proteins including cartilage matrix proteins, transmembrane receptors, ion transporters, and transcription factors. The number of gene loci identified to date is much smaller than had been anticipated from the number of clinical phenotypes delineated earlier. Indeed, the vast majority of patients have disorders that map to fewer than 10 loci, and mutations at two loci (*COL2A1* and *FGFR3*) account for well over half of all patients [19]. This implies that there is a limited number of genes whose function is critical to skeletal development, especially linear bone growth, and that mutations in these genes give rise to a wide range of chondrodysplasia clinical phenotypes.

Mutations at the *COL2A1* and *FGFR3* loci demonstrate quite different genetic characteristics. *COL2A1* mutations are distributed throughout the gene with very few instances of recurrence in unrelated persons [22]. In contrast, *FGFR3* mutations are restricted to a few locations within the gene and the occurrence of new mutations at these sites in unrelated individuals is the rule [34]. There is a strong correlation between clinical phenotype and mutation site for *FGFR3*, but not for *COL2A1* mutations (see also this Chapter, Parts II and IV).

PATHOGENESIS

The pathogenesis of the chondrodysplasias must be considered at at least two levels: disturbances in the behavior of a gene product resulting from a mutation and the consequences of such disturbances to skeletal development and growth. The pathogenesis of specific chondrodysplasias, or groups of chondrodysplasias, is covered in much more depth in subsequent parts of this chapter. This discussion is intended to provide a brief overview.

Molecular Disturbances

Chondrodysplasia mutations act through different mechanisms. For example, most mutations involving cartilage matrix proteins cause disease when only one of the two alleles of the relevant gene is mutated, i.e., in the heterozygous state [22,35]. They typically act through a dominant negative mechanism in which the protein products of the mutant allele interfere with the assembly and function of multimeric molecules that contain the protein products of both the normal and mutant alleles. Mutations of type II collagen illustrate this phenomenon [16,17,36]. The type II collagen molecule is a triple helical entity comprised of three collagen α chains, each of which is the product of the type II collagen gene, *COL2A1*. When α chains from both normal and mutant alleles are combined to form triple helices, most molecules contain at least one mutant α chain. In fact, seven of the eight possible combinations contain at least one mutant α chain. It is not known how many mutant chains are required to produce a dysfunctional molecule, but, depending on the mutation, it could theoretically be as few as one.

Heterozygous mutations involving type X collagen act, at least in part, differently from the model just described [37]. Those known to date map to the region of the α chain that

TABLE 1. Chondrodysplasia Genes and Their Products

Gene Locus	Chromosomal Location	Gene Product	Protein Function	Clinical Phenotype	MIM No.	Inheritance	Mechanism
COL2A1	12q13.1–q13.3	Type II collagen α1 chain	Cartilage matrix protein	Achondrogenesis II	200610	AD	Dominant negative
				Hypochondrogenesis	120140.0002	AD	Dominant negative
				SED congenita	183900	AD	Dominant negative
				Kniest dysplasia	156550	AD	Dominant negative
				Late onset SED		AD	Dominant negative
				Stickler dysplasia	108300	AD	Haploinsufficiency
COL9A2	1p32.2–p33	Type IX collagen α2 chain	Cartilage matrix protein	MED	600969	AD	Dominant negative
COL9A3	20q13.3	Type IX collagen α3 chain	Cartilage matrix protein	MED	600969	AD	Dominant negative
COL10A1	6q21–q22.3	Type X collagen α1 chain	Hypertrophic cartilage matrix protein	Schmid metaphyseal chondrodysplasia	156500	AD	Haploinsufficiency
COL11A1	1p21	Type XI collagen α1 chain	Cartilage matrix protein	Stickler-like dysplasia	184840	AD	Dominant negative
COL11A2	6p21.3	Type XI collagen α2 chain	Cartilage matrix protein	Stickler-like dysplasia	215150	AR	Loss of function
COMP	19p12–p13.1	Cartilage oligomeric matrix protein	Cartilage matrix protein	Pseudoachondroplasia	177170	AD	Dominant negative
				MED	600969	AD	Dominant negative
DTDST	5q32–q33	DTD sulfate transporter	Transmembrane sulfate transporter	Diastrophic dysplasia	222600	AR	Loss of function
				Achondrogenesis 1B	600972	AR	Loss of function
				Atelosteogenesis II	256050	AR	Loss of function
FGFR3	4p16.3	FGF receptor 3	Tyrosine kinase receptor for FGFs	Thanatophoric dysplasia I	187600	AD	Gain of function
				Thanatophoric dysplasia II	187610	AD	Gain of function
				Achondroplasia	100800	AD	Gain of function
				Hypochondroplasia	146000	AD	Gain of function
PTHR	3p21–p22	PTHrP receptor	G protein-coupled receptor for PTH and PTHrP	Jansen metaphyseal chondrodysplasia	156400	AD	Gain of function
SOX9	17q24.3–q25.1	SRY box 9	Transcription factor	Campomelic dysplasia	114290	AD	Haploinsufficiency
CBFA1	6p21	Core binding factor α subunit	Transcription factor	Cleidocranial dysplasia	119600	AD	Haploinsufficiency
LMX1B	9q34.1		Transcription factor	Nail patella dysplasia	161200	AD	Haploinsufficiency
CTSK	1q21	Cathepsin K	Enzyme	Pycnodysostosis	265800	AR	Loss of function

Abbreviations: AD, autosomal dominant; AR, autosomal recessive; SED, spondyloepiphyseal dysplasia; MED, multiple epiphyseal dysplasia; DTD, diastrophic dysplasia; FGF, fibroblast growth factor; PTH, parathyroid hormone; PTHrP, parathyroid hormone-related protein; SRY, sex-determining region of the Y chromosome. (See also ''Recent Developments''.)

is responsible for chain recognition, which is the first step in the assembly of collagen molecules. The mutations disrupt this process resulting in a failure of the mutant α chains to be incorporated into molecules and the loss of function of the products of the mutant allele, in the process referred to as haploinsufficiency. Haploinsufficiency is also thought to be the genetic mechanism in chondrodysplasias involving transcription factors.

Mutations involving ion transport genes, such as the diastrophic dysplasia sulfate transporter, also act through a loss of function of a transporter [33] (see also this Chapter, Part III). However, in this case, the functional loss of one allele does not cause disease; loss of function, or more accurately, a substantial loss of function of the product of both alleles is required. The severity of clinical phenotypes probably reflects the combined level of residual function of the two alleles [38,39].

In contrast, mutations of transmembrane receptors studied to date act through a gain of function; that is, the mutant receptors initiate signals in a constitutive manner independent of their normal ligands [34,40]. As with loss of function mutations, the severity of clinical phenotype is thought to reflect the extent of constitutive receptor activation.

Consequences for Skeletal Development and Growth

Regardless of genetic mechanism, the mutations responsible for the chondrodysplasias disrupt skeletal development. More specifically, they disrupt the growth phase of skeletal development, that is, the phase during which formed elements of the embryonic skeleton grow to reach their final adult size. For the most part, mutations that disturb earlier events in skeletal development are lethal and/or are not recognized as chondrodysplasias. By definition, chondrodysplasia mutations disrupt the function of the skeletal growth plate, which is where postembryonic bone growth occurs.

The reader is referred to Chapter 1, Part II, in this volume, for a discussion of the growth plate. Briefly, it is a dynamic structure that resides near the ends of immature bones. Growth occurs because cartilage template is produced at the leading edge of the structure and converted into bone at its trailing edge. The process is extremely complex and incompletely defined. It is orchestrated largely by differentiating chondrocytes but requires the participation of other cell types including perichondrial cells, vascular and perivascular cells, osteoblasts and osteo(chondro)clasts. Regulatory circuits involving locally synthesized growth factors and their receptors control key cellular events, such as chondrocyte proliferation and terminal differentiation and vascular invasion of the cartilage template, ultimately to govern bone growth. Relevant growth factors identified to date include fibroblast growth factors (FGFs), parathyroid hormone-related protein (PTHrP), bone morphogenetic proteins (BMPs), and Indian hedgehog (Ihh). Matrix proteins also appear substantially to influence cellular events in the growth plate through direct interactions with membrane receptors and through their interactions with growth factors.

A number of mechanisms have been proposed to explain how mutations disturb these phenomena, although most are still at the speculative stage. Mutations involving cartilage matrix proteins such as types II and XI collagen probably act in part by altering the mechanical properties of cartilage as a template [16,19,21]. They may also affect the extent to which growth factors can diffuse through cartilage matrix to reach target cells. Mutations may also alter signals initiated by matrix protein-receptor interactions in the growth plate. Another proposed mechanism involves the toxic effects of accumulated proteins on growth plate cells. In pseudoachondroplasia, chondrocytes are filled with dilated endoplasmic reticulum containing cartilage oligomeric matrix protein (COMP). This may adversely affect the behavior of cells and even their survival [41]. Thus, mutations of matrix genes may potentially disturb growth plate function through many mechanisms ranging from disturbances of the mechanical properties of cartilage matrix to disturbances in the biologic properties and behavior of growth plate cells.

Many of the mechanical properties of cartilage reflect the abundance of the matrix proteoglycan, aggrecan. This molecule is very rich in sulfated glycosaminoglycan side-chains. The consequence of mutations of DTDST (the diastrophic dysplasia sulfate transporter) is that growth plate chondrocytes are unable to synthesize properly sulfated aggrecan, which presumably adversely affects the template functions of cartilage matrix [38,39]. Such disturbance could potentially disrupt the physiologic functions of cartilage matrix as with the collagen mutations.

Mutations that activate transmembrane receptors, such as FGFR3 and PTHR (parathyroid hormone-related protein receptor), exaggerate the physiologic signals normally transduced by these receptors [34,40,42]. Both FGFR3 and PTHR transmit inhibitory signals. FGFR3 appears to inhibit growth plate chondrocyte proliferation and possible terminal differentiation, while PTHR is thought to block terminal chondrocyte differentiation. Constitutive activation of either would be expected to reduce the number of terminally differentiated chondrocytes produced during a given period of time, and thereby to reduce the rate of bone growth.

GENERAL DIAGNOSTIC CONSIDERATIONS

Despite the emphasis in this chapter on dealing with the genetic and biologic aspects of the chondrodysplasias, clinicians must address the clinical aspects of these disorders. A few chondrodysplasias can be diagnosed at first glance, but most require a careful evaluation based on clinical history, physical examination, skeletal radiographs, family history, and laboratory testing. In the end, the process involves recognizing complex patterns characteristic of the different disorders. Specific features of each disorder are listed in subsequent parts of this chapter, and detailed references are also available through OMIM [32].

Clinical Features

The hallmark of the chondrodysplasias is disproportionate short stature [1,23,24,43]. Although this term refers to a disproportion between the limbs and trunk, most disorders exhibit some shortening of both, and subtle degrees of disproportion may be difficult to appreciate. Skeletal disproportion is usually accompanied by short stature, i.e., length/height below the 3rd percentile, but these measurements are occasionally within the low-normal range early in the course of certain conditions. There may also be disproportionate shortening of different segments of the limbs; the particular pattern may provide clues toward specific diagnoses.

With some notable exceptions, there is a strong correlation between the age of onset and the overall clinical severity. Many of the so-called lethal neonatal chondrodysplasias are evident by the time routine ultrasound examinations are

performed at the end of the first trimester of gestation. Gestational standards exist for long bone lengths, and discrepancies are often detected between biparietal diameter of the skull and long bone lengths. Many disorders become apparent around the time of birth, whereas others show up during the first year. A number of disorders become manifest in early childhood, a few in late childhood or later.

Although growth deficiency typically dominates the clinical picture, most patients also have problems unrelated to growth. For example, skeletal deformities such as abnormal joint mobility, angular deformities, etc., are common and usually symmetrical. Sometimes skeletal abnormalities adversely affect nonskeletal tissues, e.g., impaired growth at the base of the skull and of vertebral pedicles reduces the size of the spinal canal in achondroplasia. Short ribs reduce thoracic volume, which may compromise breathing in short trunk chondrodysplasias. Cleft palate is common to many disorders, presumably reflecting defective palatal growth.

In some instances, manifestations are unrelated to the skeleton, and reflect the expression of mutant genes in nonskeletal tissues. Examples include retinal detachment in spondyloepiphyseal dysplasia congenita, sex reversal in campomelic dysplasia, congenital heart malformations in Ellis van Creveld syndrome, immune deficiency in cartilage-hair hypoplasia, and renal dysfunction in asphyxiating thoracic dystrophy. These nonskeletal problems provide valuable clues to specific diagnoses.

Family and Reproductive History

A careful family history is designed to identify relatives with the condition manifested by the patient. Sometimes a Mendelian inheritance pattern can be elicited. However, because the clinical presentation may vary substantially in some disorders, one must search not only for features observed in the patient, but also for features that might be related to those observed in the patient. Special attention should be given to mild degrees of short stature, disproportion, deformities and other manifestations, such as precocious osteoarthritis, that may have been overlooked by the family. Physical examination of relatives may be helpful, as may be review of photographs, X-rays, and medical records of family members.

A reproductive history may be informative in as much as previous stillbirths, fetal losses, and other abnormal pregnancy outcomes may indicate a skeletal dysplasia in the family. Pregnancy complications, such as polyhydramnios or reduced fetal movement, are also common in bone dysplasias, especially neonatal lethal ones.

Even though almost all of the skeletal dysplasias are genetic, it is common for there to be no history of the disorder in a family. New mutations to normal parents are common for autosomal dominant disorders, especially chondrodysplasias that are lethal in the perinatal period, e.g., thanatophoric dysplasia. The majority of achondroplasia cases result from new mutations. Germ cell mosaicism, in which one parent harbors clones of mutant germ cells in their gonads, has been observed in some dominant disorders. A negative family history is common for recessively inherited disorders.

Radiographic Features

X-ray evaluation of a chondrodysplasia should include plain films of the entire skeleton. Efforts should be made to identify which bones and which parts of bones (epiphysis, metaphysis, and diaphysis) are most affected. If possible, films taken at different ages should be examined, because the radiographic changes evolve with time. Films taken before puberty are generally much more informative than those taken afterwards, because "closure" of the epiphyses obliterates many of the signs relied upon for radiographic diagnosis.

Diagnosis

Once it is established that a patient has a probable chondrodysplasia, establishing a diagnosis depends on matching the observed clinical picture with clinical phenotypes of well-documented disorders. There are a number of reference texts to facilitate matching phenotypes [3,6–8,44–50]. The online database OMIM provides frequently updated information about the disorders and comprehensive lists of current references [32].

With a few exceptions, laboratory testing has not been useful for diagnosing chondrodysplasias. However, this may change as molecular genetic testing for chondrodysplasias becomes more feasible and established in the commercial arena. Such testing would be most useful for disorders in which recurrent mutations occur, such as achondroplasia [51]. However, it should be emphasized that the diagnosis of achondroplasia can usually be made clinically. The greatest utility of such testing may be in prenatal diagnosis for couples in which both parents have typical (heterozygous) achondroplasia. They are at 25% risk for transmission of the much more severe homozygous achondroplasia, which can be detected by mutation analysis. Another example is in disorders due to mutations of *DTDST* [38]. These disorders are inherited in an autosomal recessive manner, and a limited number of mutant alleles have been found. If the mutations are identified in a patient, then they should be detectable in the parents and potentially useful for prenatal diagnosis. In contrast to the situation with these disorders, most chondrodysplasia mutations tend to be dispersed throughout host genes. This phenomenon makes their detection more difficult and thereby reduces the usefulness of such testing for diagnostic purposes, at least in the near future.

Many of the chondrodysplasias have distinct histologic changes of the skeletal growth plate [4,9,49,50]. Sometimes such tissue obtained at biopsy or discarded from a surgical procedure is helpful diagnostically. However, it is uncommon to make a diagnosis histologically if not already suspected on clinical grounds. An exception is for the lethal neonatal chondrodysplasias, in which an aborted fetus or newborn is difficult to evaluate clinically and radiographically.

MANAGEMENT

The first step in managing the care of a patient with a chondrodysplasia is to establish the correct diagnosis. This allows prediction of a prognosis and anticipation of the medical and surgical problems associated with a particular disorder. Establishing a diagnosis is especially important when trying to distinguish between what have been called "lethal disorders" and nonlethal disorders in a premature or newborn infant. For example, the poor prognosis for long-term survival would argue against initiating extreme lifesaving measures for thanatophoric dysplasia or achondrogenesis types Ib or II, whereas they may buy time for infants with SED (spondyloepiphyseal dysplasia) congenita or diastrophic dysplasia, which carry a good prognosis if they survive the newborn period.

There is no definitive therapy to normalize bone growth in any of the conditions. Consequently, management is

focused on preventing and correcting skeletal deformities, treating nonskeletal complications, genetic counseling, and helping patients and families cope with the disorders. Each disorder has its own unique set of problems and consequently management must be tailored to each disorder. Nevertheless, there are many problems common to many chondrodysplasias for which general recommendations can be made [4,8,10,11,13,49,52,53]. For instance, children with most chondrodysplasias should avoid contact sports and other activities that cause injury or stress to joints. Good dietary habits should be established in childhood to prevent or minimize obesity in adulthood. Dental care should be started early to minimize crowding and malalignment of teeth. Because of their small pelvis, pregnant women with various of the chondrodysplasias should be followed in high-risk prenatal clinics and have Cesarean section to deliver their babies. Prenatal diagnosis may be possible by ultrasonography if limb bone lengths differ enough from established norms. However, there are many conditions in which the growth deficiency is not sufficient to be distinguished from normal early in the pregnancy. Children and relatives should be given the opportunity to participate in support groups, such as the Little People of America and the Human Growth Foundation [54,55].

Two approaches have been used to date to increase bone length. Both are controversial. Surgical limb lengthening has been employed for a few disorders [56–60]. Its greatest success has been in achondroplasia in which nonskeletal tissues tend to be redundant and easily stretched. The procedure is usually done during the teen years. Injections of human growth hormone in pharmacologic doses comparable to those used to treat Turner syndrome have also been tried in several disorders; the results have been equivocal [61–65].

RECENT DEVELOPMENTS

Several new "chondrodysplasia genes" were incorporated into the International Nosology and Classification of Constitutional Disorders of Bone at a meeting of the International Working Group on Bone Dysplasias held in Oxford, England, in September 2001. The most notable of these are *SEDL*, which encodes a protein named sedlin that is thought to participate in protein secretion, and is mutated in X-linked SED (spondyloepiphyseal dysplasia) tarda [66]; *RMRP*, which encodes a nontranslated RNA component of a mitochondrial RNA-processing endoribonuclease, and is mutated in cartilage-hair hypoplasia [67]; *HSPG2*, which encodes the heparan sulfate-containing pericellular proteoglycan perlecan, and is mutated in dyssegmental dysplasia — Silverman-Handmaker type [68] and Schwartz-Jampel syndrome [69]; and *MATN3*, which encodes the cartilage matrix protein matrilin 3, and is mutated in MED (multiple epiphyseal dysplasia) [70].

Chondrodysplasias: Disorders of Cartilage Matrix Proteins

William A. Horton and Jacqueline T. Hecht

Research Center, Shriners Hospital, Department of Molecular and Medical Genetics, Oregon Health Sciences University, Portland, Oregon (W.A.H.); Division of Medical Genetics, Department of Pediatrics, University of Texas Health Sciences Center, Houston, Texas (J.T.H.)

SUMMARY

- **A major subset of the human chondrodysplasias are due to mutations of genes that encode cartilage matrix proteins, including types II, IX, X, and XI collagens and cartilage oligomeric matrix protein (COMP). The nomenclature and classification of these disorders has undergone substantial revision as clinical phenotypes have been matched to mutations at specific gene loci.**
- **Mutations of the gene for type II collagen, *COL2A1*, produce a broad spectrum of clinical phenotypes that fall under the general designation, spondyloepiphyseal dysplasia (SED). These autosomal dominant disorders range in severity from achondrogenesis type II, which is lethal at or before birth, to late-onset SED, the major feature of which is precocious osteoarthritis. Disorders of intermediate severity include SED congenita, SED Strudwick, and Kniest dysplasia. The mutations are thought to act through a dominant negative mechanism to reduce the number of collagen fibrils in cartilage matrix.**
- **Stickler dysplasia has been divided into three types. Classic Stickler dysplasia (type I), which involves eyes, ears, and the skeleton, results from a subset of mutations of *COL2A1* that lead to haploinsufficiency. The nonocular form of Stickler dysplasia (type II) and Stickler dysplasia type III are due to mutations of *COL11A2* and *COL11A1*, respectively. Mutations of type XI collagen genes have also been found in otospondylomegaepiphyseal dysplasia (OSMED), Weissenbacher-Zweymuller syndrome (WZS) and Marshall syndrome.**
- **Schmid metaphyseal chondrodysplasia, a relatively mild disorder affecting mainly the lower extremities, results from mutations of the gene encoding type X collagen, *COL10A1*. The mutations are heterozygous and cluster in the carboxyl terminal nonhelical NC1 domain of the molecule.**
- **Mutations of the gene for cartilage oligomeric matrix protein (COMP) have been found in patients with pseudoachondroplasia (PSACH) and multiple epiphyseal dysplasia (MED). COMP is a member of the thrombospondin family of proteins. A 3 bp deletion that maps to a highly conserved region of thrombospondins involved in binding calcium accounts for more than 30% of the total COMP mutations. The mechanisms by which COMP mutations act remain unknown.**
- **Mutations of genes for the α2(IX) and α3(IX) collagen chains, *COL9A2* and *COL9A3*, respectively, have been detected in patients with MED.**
- **A number of mouse strains have been genetically engineered to serve as models for human chondrodysplasias due to *COL2A1* and *COL10A1* mutations. The naturally occurring mouse mutants, *Dmm* and *Cho*, which involve mutations of *Col2a1* and *Col11a1*, respectively, have been proposed as models for Stickler dysplasia types I and III, respectively.**

INTRODUCTION

This chapter primarily addresses chondrodysplasias due to mutations of genes that encode cartilage matrix proteins. The disorders fall into three categories, reflecting the distribution and function of the proteins. The first group contains disorders that result from mutations of types II and XI collagen genes. These collagens constitute the major and minor elements, respectively, of collagen fibrils of hyaline cartilage. The second group includes disorders due to mutations of cartilage oligomeric matrix protein (COMP), which resides in the matrices of many connective tissues, and of type IX collagen, which contributes to cartilage collagen fibrils. The third category is comprised of disorders of type X collagen, the distribution of which is restricted to the hypertrophic zone of the growth plate. Several other disorders for which the genetic basis has not been identified are included here because their clinical phenotypes resemble those due to cartilage matrix protein defects.

DISORDERS DUE TO MUTATIONS OF THE GENES FOR TYPES II AND XI COLLAGENS

The disorders in this category exhibit an extremely wide range of severity. Indeed, the clinical phenotypes range from

Connective Tissue and Its Heritable Disorders, pages 909–937

profound dwarfism, lethal *in utero*, to phenotypically normal individuals with precocious osteoarthritis in adulthood. From severe to mild, the disorders include achondrogenesis type II, hypochondrogenesis, spondyloepiphyseal dysplasia congenita (SED congenita) and its variants, SED Strudwick, Kniest dysplasia, late-onset SED, and Stickler dysplasia.

Nomenclature and History

The nomenclature of these conditions has, historically, been confusing. For example, achondrogenesis refers to a lethal chondrodysplasia phenotype with a short trunk and very short extremities. It was initially divided into two types: type I, designated Parenti-Fraccaro (MIM 200600), and type II, termed Langer-Saldino (MIM 200610) [1–4]. Type I was subsequently subdivided into type IA (Houston-Harris) and type IB [5]. During the same period, another condition was reported and named hypochondrogenesis [6]. As infants with severity intermediate between achondrogenesis type II and hypochondrogenesis were ascertained, it was suggested that hypochondrogenesis was simply a mild form of achondrogenesis type II [7]. This was supported by histologic and biochemical evidence showing similar abnormalities in infants with the two conditions [7,8]. Further confusion arose when Whitley and Gorlin proposed the division of achondrogenesis into types I–IV based on radiographic severity [9]. Whitley-Gorlin type I corresponded to the original type I. Whitley-Gorlin type II was the severe form of the original (Langer-Saldino) type II achondrogenesis, whereas Whitley-Gorlin type III corresponded to the typical Langer-Saldino achondrogenesis type II, and Whitley-Gorlin type IV to hypochondrogenesis. It is now clear that achondrogenesis type II (Langer-Saldino) and hypochondrogenesis constitute the severe end of the spectrum of disorders resulting from type II collagen mutations, sometimes called type II collagenopathies. In contrast, achondrogenesis type 1B has turned out to be the most severe form of a series of disorders that result from mutations of the diastrophic dysplasia sulfate transporter gene (see Part III, this chapter).

Spondyloepiphyseal dysplasia, or SED, refers to a clinical phenotype manifesting radiographic abnormalities primarily of the spine and epiphyses. The term is sometimes used generically to refer to chondrodysplasias that exhibit such changes. At other times it is used for specific disorders, such as SED congenita, which is apparent at birth, and SED tarda, the onset of which is in later childhood. Although it was originally thought that these disorders were related because of the similarity of involvement, they are not, as the former phenotype results from type II collagen mutations, whereas the latter is due to mutations of an X-linked gene distinct from the type II collagen gene. The term SED tarda has occasionally been applied to chondrodysplasias due to type II collagen mutations that become manifest in childhood or later. We prefer to employ the term late-onset SED for this clinical phenotype, reserving SED tarda for the X-linked disorder.

Clinically distinct phenotypes have been defined that overlap SED congenita. They are due to mutations of type II collagen and thus fall within the type II collagenopathy spectrum, yet they can be distinguished from typical SED congenita. The two most notable conditions in this category are Strudwick dysplasia and Kniest dysplasia.

Stickler dysplasia refers to a clinical phenotype usually dominated by eye abnormalities accompanied by degenerative arthritis, hence the alternative designation, hereditary arthro-ophthalmopathy. Type II collagen mutations are found in some patients, making it a type II collagenopathy. However, mutations of genes encoding type XI collagen chains have been found in other families. Currently, three forms of Stickler dysplasia are recognized according to the mutant gene locus. The term Stickler dysplasia type I is used when mutations involve type II collagen, whereas the terms Stickler dysplasia types II and III are used when the mutations map to genes encoding the α2 and α1 chains of type XI collagen, respectively. As discussed below, patients with the type II variant lack the eye component of Stickler syndrome. From linkage exclusion, it has been suggested that a fourth locus exists for Stickler dysplasia [10].

Originally described as Pierre Robin syndrome with fetal chondrodyplasia, Kelly suggested in 1982 that the Weissenbacher-Zweymuller syndrome (WZS) (MIM 108300) is the neonatal expression of Stickler dysplasia [11,12]. When three infants with manifestations of WZS were found to develop the ocular and auditory findings of Marshall syndrome (MIM 154780), Winter proposed that WZS, Marshall syndrome, and Stickler dysplasia were related [13]. Subsequent studies showed that WZS and Stickler were separate entities, but revealed overlap between WZS and otospondylo-megaepiphyseal dysplasia (OSMED), which has also been called Nance-Insley syndrome (MIM 215150) and Nance-Sweeney chondrodysplasia [14–17]. OSMED occurs in both heterozygous and homozygous forms [18]. The confusion has now been largely resolved by the finding of *COL11A2* mutations in patients with WZS and OSMED as well as with Stickler dysplasia type II. Thus, the three conditions are allelic. Marshall syndrome has subsequently been linked to mutation of the *COL11A1* locus [19]. Controversy exists over whether Marshall syndrome is part of the Stickler dysplasia spectrum or a separate nosologic entity [16,19–21]. Spranger has suggested that the term Stickler dysplasia type III be used for all phenotypes resulting from *COL11A1* mutations [22].

The clinical manifestations of Wagner syndrome (MIM 143200) are dominated by degenerative changes of the vitreous and retina similar to those seen in Stickler dysplasia. Even though patients lack the arthropathy typical of Stickler dysplasia, there has been debate over whether Wagner syndrome is nosologically distinct from Stickler syndrome. It now appears that there are two forms of Wagner syndrome. One can result from mutations of *COL2A1* [23], while linkage to *COL2A1* is excluded in the second form, which maps to chromosome 5q13-14 [24].

Mutations

COL2A1

A mutation of the type II collagen gene (*COL2A1*) was first reported in 1989 by Lee et al. in affected members of a family with SED congenita [25]. The number of *COL2A1* mutations associated with SED and SED-like phenotypes has subsequently grown to over 40, as compiled by Kuivaniemi et al. in 1997 [26]. Table 1 lists mutations reported to date, including references. All have been heterozygous mutations and most map to the triple helical domain of the type II collagen α chain, where they are dispersed fairly evenly. The most frequent mutations involve the substitution of a bulky amino acid for glycine, which normally occupies every third position. Glycine to serine substitutions are the most common mutations.

There is a tendency for mutations residing toward the carboxyl terminus of the triple helix to produce more severe manifestations than those that map toward the amino terminus of the helix. This phenotypic gradient resembles

SED, spondyloepiphyseal dysplasia.

that observed for *COL1A1* and *COL1A2* mutations in osteogenesis imperfecta (see Chapter 8, this volume). However, as with *COL1A1* and *COL1A2* mutations, there are many exceptions. For instance, SED congenita mutations are distributed along the entire length of the triple helix, overlapping with mutations responsible for Kniest dysplasia and achondrogenesis type II. Thus, there is not a high correlation between the region to which a mutation maps and the specific phenotype that is produced. However, in the few instances in which specific mutations have recurred in different families, the resulting phenotype is similar.

Identical mutations do not generally recur in *COL2A1*. One notable exception is the Arg519Cys mutation found in five unrelated families with late-onset SED with precocious osteoarthritis [27–29]. Studying the genetic background from which this mutation arose in these families, Bleasel et al. identified three distinct haplotypes and concluded that the Arg519 codon may constitute a hot spot for mutations in *COL2A1* [29]. Recurrences have also been observed for Arg75Cys, Arg789Cys, and Gly997Ser mutations [28,30–34].

Most *COL2A1* mutations are missense mutations in exons that lead to amino acid substitutions, most often of glycine in the type II collagen α1 chain. In-frame duplications and deletions have been observed in SED congenita. Mutations that disrupt splicing, producing small in-frame deletions have also been found, especially in Kniest dysplasia. In contrast, splice mutations and deletions that shift the reading frame, leading to premature termination of translation, are characteristic of Stickler dysplasia type I, as are missense mutations that create premature stop codons.

COL11A1 and COL11A2

Mutations at these loci (Table 2) are less common than those of *COL2A1*, and they tend to be heterogeneous. For instance, *COL11A2* mutations associated with nonocular Stickler dysplasia type II include a 27 bp deletion, a splicing mutation that leads to an 18 amino acid deletion and a glycine to arginine missense mutation [35,36]. The patients were heterozygous for the first two mutations and homozygous for the mutation in the third instance. Heterozygosity for a glycine to glutamate (Gly955Glu) mutation has been found in WZS [37], while homozygosity for a missense mutation has been detected in OSMED [18].

A splicing mutation predicted to delete 18 amino acid residues from the triple helical region of the α1(XI) chain has been reported in a large family with Marshall syndrome [19]. Mutation analysis of 30 patients suspected of having Marshall syndrome or Stickler dysplasia revealed 15 novel mutations of *COL11A1* [38]. The majority of the mutations disrupted splice consensus sequences for 54 bp exons that mapped to the carboxyl terminal half of α1(XI). These patients exhibited phenotypes consistent with Marshall syndrome, i.e., moderate to severe hearing defect and less severe ocular findings.

Animal Models

There are a number of mouse strains that harbor mutations of genes encoding cartilage collagen chains. Most involve the *Col2a1* gene and most have been generated by transgenesis. The lower case *Col2a1* refers to the murine homolog of the human *COL2A1*. Despite the diversity of mutations, the resulting phenotypes are similar.

Col2a1

The semidominant, disproportionate micromelia (*Dmm*) mouse was detected in offspring of a male mouse whose

OSMED, otospondylo-megaepiphyseal dysplasia; WZS, Weissenbacher-Zweymuller syndrome.

sperm were irradiated [39]. Heterozygotes exhibit short extremities and a blunt head. Homozygotes die at birth; they show severe dwarfism involving primarily the limbs. The growth plate is disorganized; the chondrocytes contain a distended rough endoplasmic reticulum and the matrix displays a paucity of collagen fibrils [40]. The mutation in *Dmm* is a 3 bp deletion that alters two codons, leading to the substitution of an asparagine residue for lysine and threonine residues, in a highly conserved region in the C-propeptide of type II collagen [41]. This is believed to disrupt the formation of intrachain disulfide bonds, which disturbs the association of chains and assembly of type II collagen molecules. *Dmm* has been proposed as a model for Stickler dysplasia type I, in which similar mutations have been found.

Several *Col2a1* mutations predicted to act in a dominant negative fashion have been targeted to cartilage in transgenic mice. Vanderberg et al. deleted exons 16–27 to produce a minigene designed to promote "protein suicide," a term used to describe the accelerated degradation of abnormally folded proteins [42]. The resulting phenotype was dominated by short tubular bones and included cleft palate, a short snout, delayed skeletal development, and a short spine. The growth plate was disorganized and cartilage matrix contained fewer than normal collagen fibrils. Taking into account some variability in severity, similar phenotypes have been produced in transgenic mice harboring Gly85Cys [43] and Gly574Ser [44,45] mutations, and a deletion of exon 7 [46]. Mice null for *Col2a1* exhibit a similar but more severe phenotype; cartilage collagen fibrils are markedly reduced and displayed an abnormal structure [47,48]. The common phenotype observed in these mice probably reflects the consequences of a reduced abundance of cartilage collagen fibrils on the formation and function of cartilage matrix as a template for skeletal growth. The mice serve as models for the SED group of human chondrodysplasias and may be useful for studying the non-growth-related manifestations of these disorders. For instance, evidence of osteoarthritis is found in older mice with the minigene [49], otic capsule abnormalities are detected in mice transgenic for the Gly574Ser mutation [50], and ocular abnormalities are observed in several transgenic strains [51]. Osteoarthritis and hearing and visual problems occur in patients with SEDs.

Col11a1

The recessively inherited chondrodysplasia (*cho*) mouse is characterized by short limbs and spine, a short snout, and cleft palate [52]. The growth plate architecture is disturbed and cartilage collagen fibrils are unusually thick [53]. A single base deletion that introduces a premature stop codon about 570 bp downstream of the translation initiation codon of *Col11a1* has been found in the *cho* mouse [54]. This would produce the equivalent of a *Col11a1* knockout. It is proposed that the absence of the α1(XI) collagen chain in homozygous mice interferes with the normal function of type XI collagen in regulating the size of cartilage collagen fibrils. This would account for the thick fibrils, but how abnormal fibrillogenesis disturbs cartilage development and growth is not well understood. The *cho* mouse is potentially a model for Stickler dysplasia type III.

Pathogenesis

In most instances, mutations of *COL2A1* cause disease in the heterozygous state. This presumably reflects the vulnerability of the homotrimeric type II collagen molecule to the dominant negative effects of mutant α chains from a single mutant allele [55,56]. Of the eight possible ways chains from mutant and wild-type alleles can combine, seven contain at least one mutant chain. It is not known how many mutant chains are required to produce a dysfunctional molecule, but it could theoretically be as few as one, although this probably varies according to mutation. Current dogma holds that the assembly of type II collagen molecules begins with the association of α chain carboxyl propeptides and is

completed after the α chains have wound around each other in a carboxyl to amino direction to form the triple helix. Accordingly, alterations in mutant α chains, such as deletions or insertions of amino acids or substitutions of bulky for compact residues or charged for uncharged residues, or vice versa, may disturb and delay or prevent proper folding of the molecule. Delayed folding may allow for excessive post-translational modification, i.e., overmodification, of certain lysyl and hydroxylysyl residues in the unfolded chains. Abnormally folded molecules may be degraded, poorly secreted, and/or accumulate in the rough endoplasmic reticulum. Alternatively, they may be secreted but not incorporated into fibrils, or their incorporation may produce dysfunctional fibrils. Collagen molecules containing mutant α chains may also be abnormally susceptible to degradation by enzymes that reside in the matrix outside cells. The molecular consequences of abnormal collagen biosynthesis is discussed further elsewhere in this volume (Chapters 8, 9, and 15). The net effect in many, if not most, instances is to reduce the number of collagen fibrils in cartilage matrix. In fact, there appears to be a correlation between the extent of fibril reduction and severity of phenotype, regardless of the specific mutation.

Most mutations associated with Kniest dysplasia disrupt mRNA splicing and lead to skipping of exons and short in-frame deletions in the type II collagen molecule [57]. It is not clear why such deletions produce the Kniest dysplasia phenotype, because they predict disruption of helix assembly in the same manner as other dominant negatively acting mutations.

In contrast to the dominant negative effects of mutations that disturb the folding of type II collagen, many mutations associated with Stickler dysplasia type I are believed to act through haploinsufficiency [58]. Most of these mutations create premature translation stop signals, either because an in-frame stop codon is produced or, more commonly, because the translation reading frame is shifted so that an out-of-frame stop codon becomes in-frame. In either case, the predicted collagen chains are shorter than normal and lack all or part of the noncollagenous carboxyl propeptide necessary for them to be incorporated into triple helical molecules. In principle, haploinsufficiency would reduce the number of collagen fibrils by half.

There are many potential mechanisms by which a reduction in type II collagen molecules or, probably more accurately, in cartilage collagen fibrils, could interfere with skeletal development and growth. They are all speculative in nature and not mutually exclusive. A reduction in the number of collagen fibrils would be expected to alter the mechanical properties of cartilage as a template for endochondral ossification. Given their role in providing structural integrity to tissues, cartilage containing fewer than normal fibrils would likely be less resistant to compressive and other forces exerted on the growth plate as a bone elongates. This could be a direct effect of the reduction in the number of fibrils and/or secondary to loss of proteoglycans, which normally occupy space within the fibrillar network. Proteoglycans attract and hold water within the fibrillar network, which gives cartilage its resilience to deformation.

The cellular events that normally occur in the growth plate could be disturbed by alterations of cartilage collagen fibrils. For example, there is evidence that collagens bind to receptors on chondrocyte surfaces. These interactions could be disrupted by changes in number, composition, or structure of collagen fibrils. Similarly, such changes could interfere with the diffusion, sequestration, and presentation of growth factors to chondrocytes in the growth plate and other cartilaginous tissues.

Relatively little is known about why mutations that produce haploinsufficiency for type II collagen, or disturb the biosynthesis of type XI collagen, produce the Stickler dysplasia phenotype. It is of interest, however, that ocular manifestations are not associated with mutations of *COL11A2*. This is consistent with observations that the α2 chain of type XI collagen in tissues such as cartilage and inner ear, is not expressed and is replaced by the α2 chain of type V collagen in the eye [59] (See Chapter 1, Part V, in this volume).

Clinical Phenotypes

Achondrogenesis Type II (MIM 200610) and Hypochondrogenesis (MIM 120140.0002)

Achondrogenesis type II and hypochondrogenesis represent the severe end of the spectrum of SEDs, or the alternatively designated type II collagenopathies. They are discussed together because the phenotypes blend from the more severe achondrogenesis type II to the slightly less severe hypochondrogenesis [7]. Both are frequently associated with prematurity and hydrops fetalis, and affected infants are either stillborn or die relatively soon after birth.

Affected fetuses and infants exhibit a large head, soft cranium, and flat face. The neck is very short, and the trunk is barrel-shaped. Radiographically, the ribs are short, the iliac wings are hypoplastic, and the acetabular roofs flat (Fig. 1). Rib fractures are common. The long bones are typified by the femora, which are short and broad with irregular cupped metaphyses. The vertebral pedicles are ossified, but the extent of ossification of the vertebral bodies varies. Severely affected infants show lack of ossification of the entire spine and sacrum, whereas milder cases (hypochondrogenesis) have defective ossification of only the cervical vertebrae and the sacrum (Fig. 2). The severity of vertebral ossification defects correlates well with that of long bone changes.

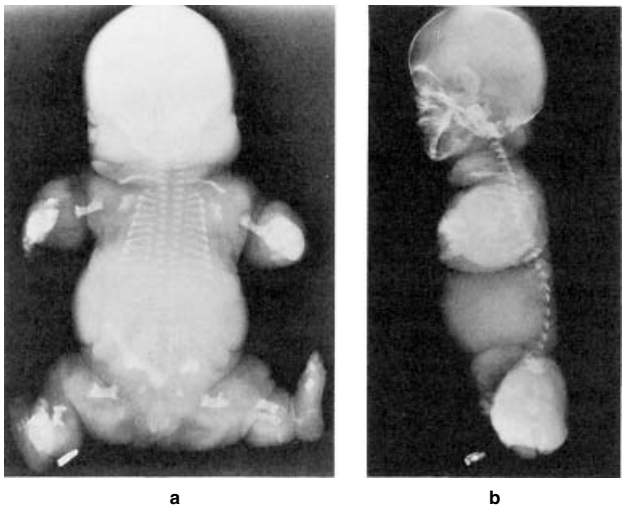

Figure 1. Radiographs of an infant with achondrogenesis type II (**a, b**), showing markedly short ribs, hypoplastic ilia, and flat acetabular roofs. The long bones are extremely short and broad with irregular, cupped metaphyses. The vertebral pedicles are ossified but the bodies are not.

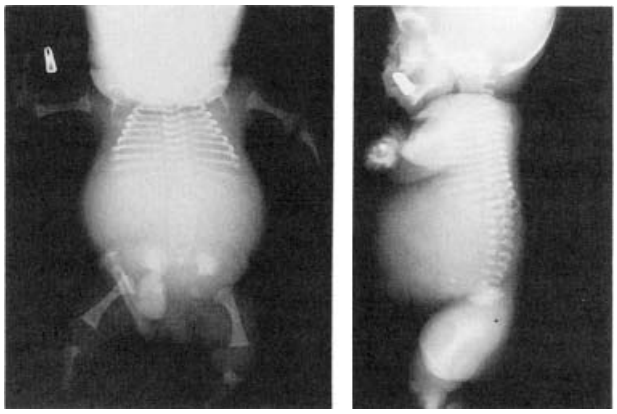

a b

Figure 2. Radiographs of an infant with hypochondrogenesis (**a, b**), showing similar but less severe findings than in achondrogenesis type II. Note ossification of the vertebral bodies.

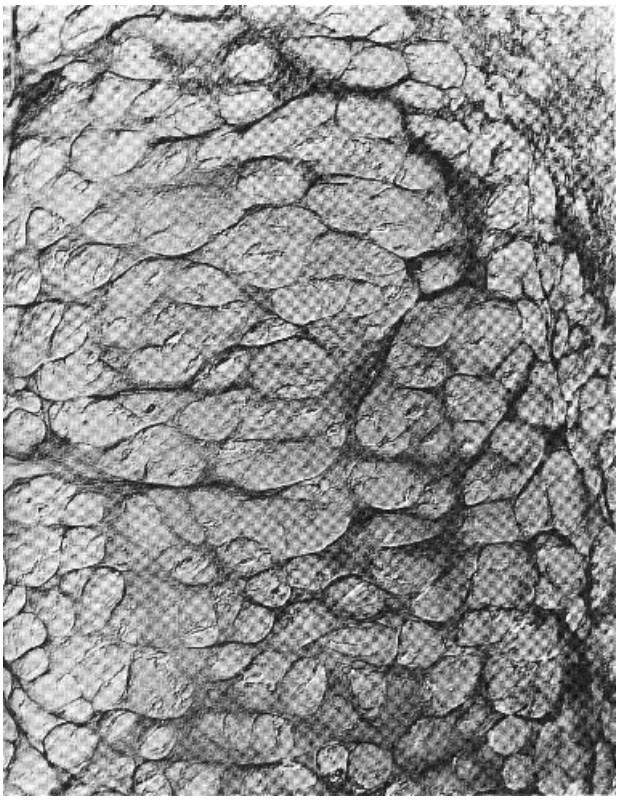

Figure 3. Photomicrograph of epiphyseal cartilage in achondrogenesis type II. Note the large chondrocyte lacunae and scant matrix. Interstitial connective tissue associated with a vascular canal is seen at top right. Toluidine blue stain. ×200.

Histologic examination of epiphyseal cartilage reveals hypercellularity, with reduced matrix and a poorly organized to absent growth plate (Fig. 3) [7]. The relative amount of matrix varies within any one specimen, but that in cartilage from milder cases tends to be more abundant. Cartilage canals are greatly increased in number and in the amount of interstitial connective tissue associated with the structures. The chondrocytes tend to be larger than normal, and electron microscopy reveals many of them to contain dilated rough endoplasmic reticulum, as well as thickening and irregularity of collagen fibrils in the matrix.

Cartilage collagen has been analyzed in several cases of achondrogenesis type II-hypochondrogenesis [8,9,60–65]. The most dramatic finding has been the presence of large amounts of type I collagen in the cartilage, which immunostaining has shown to be associated mainly with the cartilage canals, although small amounts are detectable in the matrix. In some instances, type I collagen has been the only type of collagen detected, while substantial amounts of type II collagen have been identified in other cases. Abnormal type II collagen peptides indicative of overmodification of the type II collagen have been observed [62,65]. The presence of types I and III collagen in cartilage has also been noted in mice null for *Col2a1* [48]. Diminished amounts of type II collagen have further been observed in cartilages from the bulldog calf, which has been considered a bovine model of achondrogenesis type II-hypochondrogenesis [67].

Although achondrogenesis type II was originally considered to be an autosomal recessive disorder [68], it is now clear that it, as well as hypochondrogenesis, results from *de novo*, heterozygous mutations of *COL2A1*. Consequently, the recurrence risk is very low for both conditions. The possibility of germ line mosaicism must be kept in mind during genetic counseling.

SED Congenita (MIM 183900)

SED congenita presents at birth with shortening of the trunk and, to a lesser extent, of the extremities [69–72]. Clubfoot and cleft palate are sometimes present, and the head and facies are usually considered normal. The neck is short, and the chest is barrel-shaped with accompanying kyphosis and exaggerated lumbar lordosis. The limb shortening is most prominent proximally, with the hands and feet appearing relatively normal. These features become more prominent with time. Infants with SED congenita may be hypotonic. Severe axial myopia is common, and retinal detachment may occur. There is considerable variation in severity in SED congenita, and adult patients typically vary in height from 95 to 128 cm [73].

Radiographic changes primarily involve the spine and proximal extremities. The vertebral bodies in the newborn are ovoid in the lateral view, but become markedly flattened with irregular endplates during childhood (Fig. 4). The odontoid process is often hypoplastic and in some cases may be aplastic. The iliac bones are short and square, and the pubic symphysis is poorly ossified at birth. The tubular bones are moderately short with mild metaphyseal irregularity. The epiphyses may be fragmented and show delayed ossification. Epiphyseal changes are most marked in the proximal femora, with a coxa vara deformity occurring commonly.

Patients with SED congenita usually survive infancy and have normal developmental milestones. Typically, a waddling, widebased gait develops in early childhood. Kyphosis and sometimes kyphoscoliosis arises and progresses in childhood; it may compromise respiratory function. Odontoid hypoplasia may predispose to cervico-medullary instability and spinal cord compression, but sudden death is not known to be increased. However, when the diagnosis of SED congenita is made, flexion and extension films of the upper cervical spine should be taken. Delayed ossification in this area can complicate interpretation of

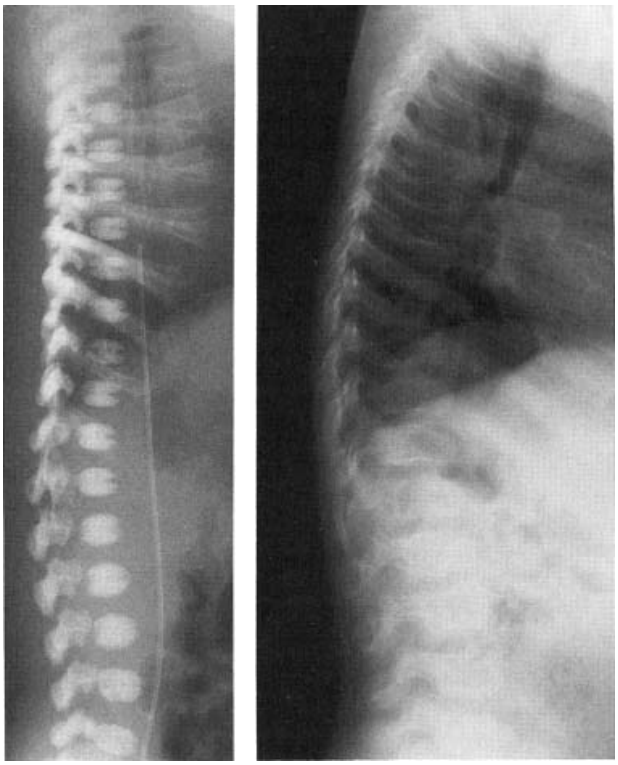

Figure 4. Radiographs of the spine in spondyloepiphyseal dysplasia congenita. **a**: Lateral projection showing ovoid vertebral bodies in a newborn. **b**: Lateral projection showing flattening of vertebral bodies in a 10-year-old child. The vertebral end plates are irregular.

such a study. If cervical instability is detected, other studies such as magnetic resonance imaging or electrophysiologic investigations should be done to search for evidence of spinal cord compression. Careful ophthalmologic evaluation and follow-up are indicated to identify and treat small retinal tears, prior to complete detachment with loss of vision. SED congenita is inherited as an autosomal dominant trait.

Histologically, the growth plate exhibits shorter chondrocyte columns and wider matrix septa than normal [74]. Epiphyseal chondrocytes contain cytoplasmic inclusions by light microscopy. Electron microscopy shows these to be dilated cisternae of rough endoplasmic reticulum, and reveals irregularities of collagen fibrils in the extracellular matrix. Chromatographic and electrophoretic abnormalities of type II collagen have been reported in several cases [32,75–78].

SED Strudwick (MIM 271670)

SED Strudwick is an SED clinical variant [79,80]. Clinically and radiographically indistinguishable from SED congenita during infancy, SED Strudwick type differs in childhood by having greater metaphyseal involvement. It is sometimes referred to as spondylometepiphyseal dysplasia. Skeletal radiographs show a mottled appearance of the metaphyses. Histology shows mild nonspecific changes in organization of the growth plate and dilated rough endoplasmic reticulum of epiphyseal chondrocytes, similar to that seen in SED congenita. A report of affected sibs born to unaffected parents initially suggested autosomal recessive inheritance [80]. However, it is now evident that it is an autosomal dominant condition due to heterozygous mutations of *COL2A1* [81].

Kniest Dysplasia (MIM 156550)

Kniest dysplasia is an autosomal dominant generalized disorder of skeletal tissues that presents at birth with shortening of the trunk and limbs [82–85]. The face is round and flat, the nasal bridge is depressed, and the eyes are prominent. Associated findings may include cleft palate, clubfoot, and inguinal herniae. Joints are often large at birth and continue to enlarge during childhood. The fingers appear long and knobby. Motor milestones are often delayed because of the joint deformities. Axial myopia and hearing loss of both conductive and sensorineural types commonly develop in childhood, and retinal detachment may occur. Intelligence is usually normal.

There is flattening and anterior wedging of the vertebral bodies on radiographs (Fig. 5). Coronal clefts of lumbar vertebral bodies may be seen in infants. The iliac bones are small with irregular acetabular angles. The long bones are short and expanded at the metaphyses, giving rise to a dumbbell appearance. Epiphyses are irregular and fragmented and develop a sclerotic, stippled appearance with age. The femoral necks are short and broad. The capital femoral epiphyses are late to ossify, eventually becoming flat and associated with a coxa vara deformity (Fig. 6). The tubular bones in the hands have flattened and squared-off epiphyses, with narrowing of the joint spaces. There is generalized osteopenia affecting the ends of the long bones.

The major problems result from progressive and painful joint enlargement accompanied by flexion contractures. Muscle atrophy may result from disuse. The combination produces varying degrees of incapacitation and may be complicated by degenerative arthropathy. Symptomatic

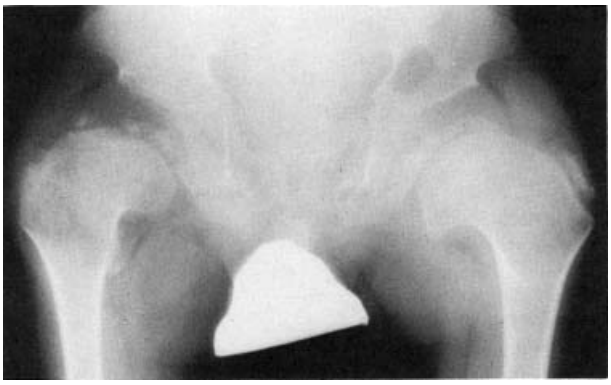

Figure 6. Radiograph of the hips and pelvis of a 12-year-old child with Kniest dysplasia. The capital femoral epiphyses are flat and fragmented. The femoral necks are wide and dysplastic. There is a coxa vara deformity of the hips.

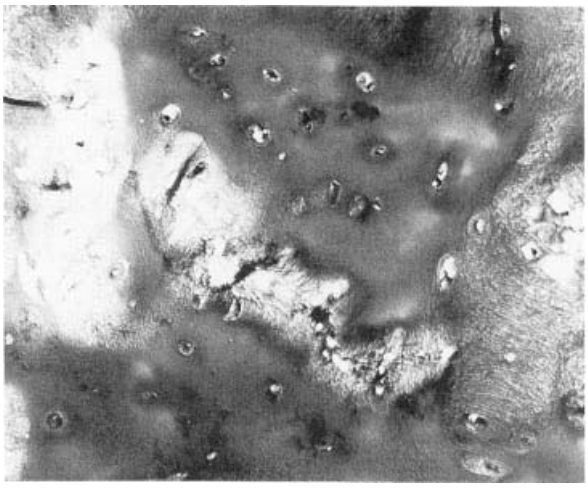

Figure 7. Photomicrograph of epiphyseal cartilage in Kniest dysplasia. Note the extensive fibrous lesions of the matrix, which in some areas form large ''holes.'' Toluidine blue stain. ×200, original magnification.

treatment is indicated for the hearing loss and myopia. Retinal detachment requires ophthalmologic care.

Cartilage is soft, and the most distinctive histologic feature of both epiphyseal and growth plate cartilage is the vacuolar degeneration of both chondrocytes and matrix (Fig. 7). Large cystic lesions are found in paraffin sections, which resemble the holes found in Swiss cheese [74,85]. Cytoplasmic inclusions have been observed in epiphyseal chondrocytes [86]. The inclusions correspond to dilated rough endoplasmic reticulum on electron microscopy, which also shows the collagen fibrils to be abnormally thin and to stain poorly [87,88]. Electrophoretic abnormalities of type II collagen have been observed in at least one instance [89,90]. Most mutations reported to date cause skipping of exons, which leads to small in-frame deletions in the type II collagen triple helix (Table 1).

Stickler Dysplasia (MIM 108300,120290)

Stickler dysplasia type I, which is inherited in an autosomal dominant fashion, classically affects the eyes, the ears, and the skeleton [91–94]. The diagnosis can be made at birth if cleft palate and micrognathia (Pierre-Robin anomaly) are present. Severe axial myopia is typical and retinal detachment sometimes occurs in childhood. Choroidoretinal and vitreous degeneration may occur, as may cataracts. Sensorineural hearing loss may develop in adolescence. Degenerative arthritis, manifested by painful joints and stiffness in the morning and after exercise, usually develops in the second or third decade. Some patients exhibit a Marfanoid habitus and ligamentous laxity, and mitral valve prolapse occurs in around 50% of cases. Short stature is not a feature of this condition.

Spranger et al. reported a child with Kniest dysplasia associated with a heterozygous *COL2A1* mutation. The child's mother, who was mosaic for the mutation, exhibited the clinical phenotype of Stickler dysplasia [95].

Irregular ossification of epiphyses can be seen on radiographs during childhood, and degenerative joint changes are usually evident by adolescence. The tubular bones have narrow shafts with thin cortices. Mild irregularities of the vertebral end plates may be observed. Management depends on the extent of involvement. The cleft palate requires surgical correction, and ophthalmologic care is essential to minimize visual impairment. Surgical replacement of major joints may be required for the arthropathy.

The skeletal and otologic manifestations of Stickler dysplasia type I are found in the nonocular, Stickler dysplasia type II phenotype, but such patients lack the ocular findings [35,36]. OSMED (otospondylo-megaepiphyseal dysplasia), which is recessively inherited, shows similar but more severe changes [18]. Vitreoretinal findings are prominent in Stickler dysplasia type III [96] and Marshall syndrome [19], both of which are due to *COL11A1* mutations.

Disorders of Less Well-Defined Etiology with Similar Clinical Phenotypes

SED Tarda (MIM 313400)

SED Tarda is an X-linked disorder distinct from the other COL2A1-related SEDs. It commonly presents in boys between the ages of 10–14 years with short stature, primarily affecting the trunk [68,97,98]. Vague back pain may occur during adolescence, and precocious osteoarthritis is typical in young adulthood. Average adult height is 145 cm.

Skeletal X-rays show vertebral flattening with a distinctive hump-shaped build-up of bone in the central and posterior portions of the upper and lower end-plates (Fig. 8) [68,99]. This is thought to reflect defective ossification of vertebral ring apophyses. Mild epiphyseal dysplasia is seen in large joints, especially the hips and shoulders, where degenerative changes arise in early adulthood. Eventually, there is degeneration of intervertebral discs with destruction of spinal facet joints [98]. Obligate heterozygote females often show similar, but milder X-ray changes; they often exhibit arthralgia by mid-adulthood.

SED tarda maps to chromosome Xp22.2-22.1 [98,100,101]. Mutations in this region have recently been identified in a gene, *SEDL*, the product of which is proposed to facilitate the secretion of proteins in many cell types [102]. Those identified to date are predominantly frameshifts and premature terminations suggesting that haploinsufficiency for the gene product accounts for the findings.

Metatropic Dysplasia (MIM 250600)

Metatropic dysplasia is an autosomal recessive chondrodysplasia, recognizable at birth by the presence of a long, narrow trunk and mild shortening of the limbs [85,103,104].

Figure 8. Radiograph of the thoracolumbar spine of an adolescent boy with spondyloepiphyseal dysplasia tarda. A characteristic hump-shaped accumulation of bone (arrowhead) can be seen in the central and posterior portions of the superior and inferior endplates of the vertebral bodies.

A ''tail-like ''appendage is occasionally found at the base of the sacrum. Kyphoscoliosis develops in late infancy and progresses throughout childhood to produce severe short-trunk dwarfism. The name metatropic dysplasia derives from this tendency of the dwarfism to change from the short-limbed to the short-trunk type over time. The joints are enlarged, and their mobility is restricted, except for those of the fingers, which tend to be hyperextensible. Contractures of the hips and knees develop in childhood. Odontoid hypoplasia occurs commonly. The head and face are normal. Developmental milestones are attained at appropriate times, and intelligence is normal. Adult height ranges from 110 to 120 cm [68].

On radiographic examination, the vertebral bodies are thin and either flat or slightly diamond-shaped. The vertebral bodies widen, and the central region of the upper lumbar vertebrae becomes thickened with age. The intervertebral spaces are wide. Lateral projection shows marked platyspondyly (Fig. 9). The iliac bones are short and flared. The combination of a narrow sacrosciatic notch and a lateral notch just above the outer rim of the acetabulum gives the ilium a halberd appearance. The tubular bones are short with markedly expanded, irregular, and deformed metaphyses, producing a dumbbell appearance (Fig. 10).

The major complication relates to the progressive kyphoscoliosis, which is resistant to treatment and which may compromise cardiopulmonary function. Cervical instability from the odontoid hypoplasia may require surgical fusion. The progressive joint contractures may lead to considerable disability.

The growth plate histologic findings are relatively nonspecific [68,74]. The cartilage-bone interface is irregular due to uneven metaphyseal vascular invasion, and foci of dysplastic, unmineralized cartilage may extend into the subchondral bone. Metachromatic inclusions have been observed in epiphyseal chondrocytes, which may be excessively vacuolated.

Figure 9. Lateral radiograph of the spine of a 4-year-old child with metatropic dysplasia showing severe platyspondyly.

Dominant Metatropic-like Spondylo-Epi-Metaphyseal Dysplasia

Dominant metatropic-like spondylo-epi-metaphyseal dysplasia (see MIM 250600), described by Beck et al. [105], is clinically and radiologically distinct from metatropic dysplasia. We have observed several children with the disorder. Newborns are generally proportionate at birth. Longitudinal growth begins to fall off between the first and second years. Physical findings include an attractive facies without midface hypoplasia, a short neck, and a barrel-shaped chest. The extremities and the hands are short and the joints wide. A characteristic waddling gait is seen in early childhood, when hip and knee flexion contractures develop, giving rise to a crouched appearance. Other joints exhibit ligamentous laxity. Kyphoscoliosis arises in late childhood and is usually mild. Genu valgum is also a common finding that may require surgical intervention. Ligamentous laxity is exaggerated, particularly in childhood. Other problems include pain in the major joints of the lower extremities that contributes to the decreased mobility and atlantoaxial instability from odontoid hypoplasia, which may require surgical intervention. Adult heights vary from 116 to 123 cm.

Radiographic findings are present at birth, but become more pronounced with time. The spine shows marked

Figure 10. Radiograph of the lower lumbar spine, pelvis, and lower extremities of a newborn with metatropic dysplasia. The vertebral bodies are thin and flat. The iliac bones are short and flared, and the sacrosciatic notches are narrow. The tubular bones are short with markedly expanded, irregular, and deformed metaphyses producing a characteristic dumbbell appearance.

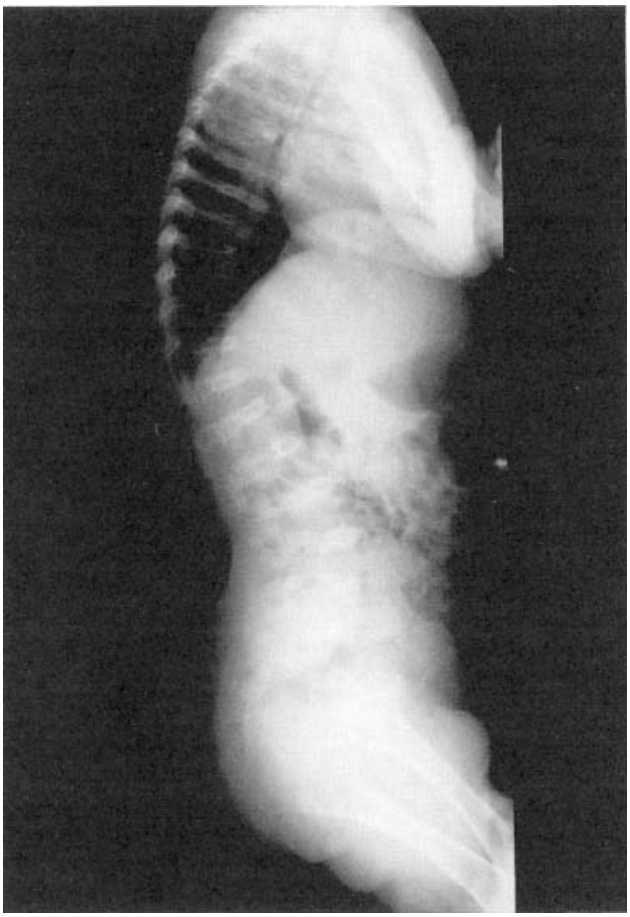

Figure 11. Radiograph of a newborn with dominant metatropic-like spondylo-epi-metaphyseal dysplasia showing marked platyspondyly.

platyspondyly, and mild to severe odontoid hypoplasia is a constant finding. The metaphyses are flared and irregular, while the epiphyses are small and fragmented. The capital femoral epiphyses are dysplastic and have a coxa vara deformity (Fig. 11). Extra ossification centers seen around the knee in late childhood give a bulbous appearance to the knees.

Autosomal dominant inheritance has been observed, and gonadal mosaicism was suspected in one family (unpublished observation). The growth plate has not been examined, and the basic defect is not known.

Brachyolmia

Brachyolmia refers to at least three conditions that present in early to mid-childhood with mild short stature that mainly affects the trunk [106–108]. The Hobaek type (MIM 271530) is an autosomal recessive form. Poorly defined back and hip pain arise typically during adolescence, and back stiffness and pain commonly occur in adulthood. Some patients may exhibit scoliosis.

Skeletal radiographs show generalized platyspondyly, which is most marked in the thoracic region. The lateral margins of the vertebral bodies extend well beyond the vertebral pedicles on the anteroposterior projection, and there is mild irregularity of the vertebral end plates. The iliac bones are short. The femoral necks are short and broad, and linear densities may extend from the physeal region into the femoral neck.

Microscopic examination shows that the epiphyseal chondrocytes are unevenly distributed, often in groups, and many are large, exhibiting a degenerative appearance [107]. They occupy large lacunae that are encircled by a broad band of interconnected dense fibrils that immunostain as type II collagen [109]. The band area stains poorly for proteoglycans. The growth plate contains fewer proliferative and hypertrophic cells than normal, and these tend to be organized into round clusters.

Two other forms of brachyolmia have been described. The Maroteaux type is inherited in an autosomal recessive manner, whereas the other (MIM 113500) is an autosomal dominant trait. The latter is sometimes called brachyrachia. Both have similar clinical features to the Hobaek type. In the Maroteaux type, radiographs are similar to those of the Hobaek type, but show rounding of the anterior and posterior vertebral borders with less extension of the lateral borders [108]. The vertebral changes are more severe in general and patients have scoliosis in the autosomal dominant type [108].

Dyssegmental Dysplasia

Two autosomal recessive disorders have been designated as dyssegmental dysplasias because of segmentation defects of the spine [110–114]. Apparent at birth, both are characterized clinically by very short extremities, an unusual facies, a short neck, and a narrow thorax. There may be a cleft palate, and joint mobility may be restricted. Infants with the milder form, the Rolland-Desbuquois type (MIM 224400), may survive beyond the neonatal period, whereas infants with the severe Silverman-Handmaker type (MIM 224410) usually die at or before birth. Other anomalies may occur, especially encephaloceles.

The two types can be distinguished radiographically [114]. The changes in the Rolland-Desbuquois type resemble those seen in Kniest dysplasia. The limb bones are short and thick. The vertebral bodies have coronal clefts and vary in size and shape on lateral view. The pelvis and scapulae are unremarkable. In the Silverman-Handmaker type, the long bone changes are greater, and there may be midshaft angulation. Segmentation defects of the vertebral bodies are severe and widespread. The ilia and scapulae are hypoplastic and exhibit a dense, amorphous pattern of ossification.

Histologic examination of the mild type shows disorganization of the growth plate and patches of thickened collagen fibrils and excessively vacuolated chondrocytes in epiphyseal cartilage. Areas of mucoid degeneration can be seen in epiphyseal cartilage in the Silverman-Handmaker type. In addition, this type shows abnormal mineralization in the lower growth plate and subchondral bone; large, unfused calcospherites have been observed by scanning electron microscopy [114].

DISORDERS DUE TO MUTATIONS OF THE GENE FOR TYPE X COLLAGEN

Mutations of type X collagen are found in Schmid metaphyseal chondrodysplasia. The condition was originally named Schmid metaphyseal dysostosis. This was a misnomer because it is not a dysostosis (a defect in bone formation) nor is the primary defect in the metaphysis. It was grouped with other disorders whose radiographic pictures were dominated by metaphyseal changes, i.e., Jansen metaphyseal chondrodysplasia (MIM 156400) and McKusick metaphyseal chondrodysplasia (cartilage-hair hypoplasia), until the mid-1990s, when mutations in the gene encoding type X collagen were found exclusively in Schmid metaphyseal chondrodysplasia [115–117].

Mutations

Over 25 mutations of *COL10A1* have been reported to date (Table 3). They are all heterozygous and cluster in the carboxyl terminal nonhelical NC1 domain of the molecule. About half lead to truncation of translated products because a premature stop codon is created by a missense mutation or encountered because a deletion shifts the reading frame. Most of the others are missense mutations that change conserved residues in the NC1 domain [115–119]. Mutations have occurred more than once at two codons, i.e., Tyr597 and Trp651.

Animal Models

Potential mouse models have been generated using both transgenic and gene targeting technologies. Jacenko et al. produced transgenic mice harboring an in-frame deletion in the helical domain of type X collagen [120]. The mice exhibited skeletal deformities, most notably kyphoscoliosis, shortening of long bones and craniofacial changes associated with structural abnormalities of the growth plate, especially compression of the hypertrophic zone [120,121]. It was suggested that the mutant type X collagen chains disrupted the assembly of type X collagen molecules in a dominant negative manner. These transgenic mice also displayed evidence of dysfunction of bone marrow, spleen, and thymus. Jacenko et al. proposed that they model spondylometaphyseal and metaphyseal chondrodysplasias.

The *Col10a1* gene in mice has been knocked out by two groups. Those knockout mice generated by Rosati et al. had essentially no abnormal phenotype [122], whereas those reported by Kwan et al. displayed coxa vara, reduced thickness of growth plate and articular cartilage, and an abnormal distribution of matrix proteins in the growth plate [123]. The latter observations suggest that type X collagen influences the distribution of matrix vesicles and proteoglycans in the growth plate and helps to provide support for endochondral ossification.

Pathogenesis

Three mechanisms have been proposed to explain how *COL10A1* mutations associated with Schmid metaphyseal chondrodysplasia act. In the first case, haploinsufficiency may result from an inability of type X collagen chains harboring mutations of essential residues or truncations in the NC1 domain to associate with normal type X collagen chains and be incorporated into triple helical molecules [116,118,124]. *In vitro* studies showing that type X collagen chains containing several Schmid mutations neither assemble into collagen molecules nor associate with normal type X collagen chains support the likelihood of this mechanism [125,126]. The second potential mechanism involves haploinsufficiency through premature decay of mutant *COL10A1* mRNA

transcripts [127]. Nonsense-mediated mRNA decay occurs commonly in transcripts harboring premature termination mutations. There is also evidence that some mutations act in a dominant negative fashion to interfere with assembly of the triple helix [120,128].

Clinical Phenotype

Schmid Metaphyseal Chondrodysplasia (MIM 156500)

This autosomal dominant disorder usually presents after the age of 2–3 years with mild short stature, bowing of the lower extremities, and a waddling gait. Hip pain may be present. Enlargement of the wrists, inability to extend completely the fingers, and flaring of the lower rib cage are associated findings [129–134].

Radiographically, the metaphyseal changes are relatively mild. The tubular bones are moderately short and metaphyses are flared, cupped, and irregularly mineralized (Fig. 12). The physeal space is widened. Changes are most marked at the hips, shoulders, knees, ankles, and wrist. The capital femoral epiphysis is enlarged in early childhood, and severe coxa vara is usually present. The distal metaphyses of the skeleton are only mildly affected. The spine is usually normal, but may show mild irregularities. Histologic changes in the growth plate are not specific.

Disorders of Unknown Etiology with Similar Clinical Phenotypes

Metaphyseal Chondrodysplasia, McKusick Type (MIM 250250)

Metaphyseal chondrodysplasia, McKusick type, is also called cartilage-hair hypoplasia [135–141]. Although growth deficiency usually does not become evident before the second to third year, dwarfism is marked in adults. Children have short extremities, bowed legs, and flaring of the lower rib cage with a prominent sternum. Hands and feet are short and broad. The fingers are short and stubby and exhibit extreme ligamentous laxity. The hair tends to be blond and thin, and the skin is lightly pigmented. Cellular immune deficiency, anemia, Hirschsprung disease, and gastrointestinal malabsorption have been observed. The disorder was first recognized and described in the Amish population, but has since been noted in other ethnic groups.

Short tubular bones with flared, irregularly mineralized, and cupped metaphyses can be seen on radiographs (Fig. 13). The knees are most severely affected. The proximal femora exhibit relatively mild involvement without coxa vara. The distal fibula is disproportionately longer than the tibia. The metacarpals and phalanges are short and broad with metaphyseal changes, and cone-shaped epiphyses may be present. Vertebral end plates may show mild irregularities.

This disorder is associated with several nonskeletal complications. Although not fully defined, affected children may have a variable immune deficiency, with particular problems with varicella infections and possibly vaccinia [142,143]. The problem with varicella infection may be limited to the Amish population, but immune function should be evaluated in all children with this disorder. Chickenpox exposure should be avoided, and the use of attenuated live-virus vaccines may pose risks of serious disease for

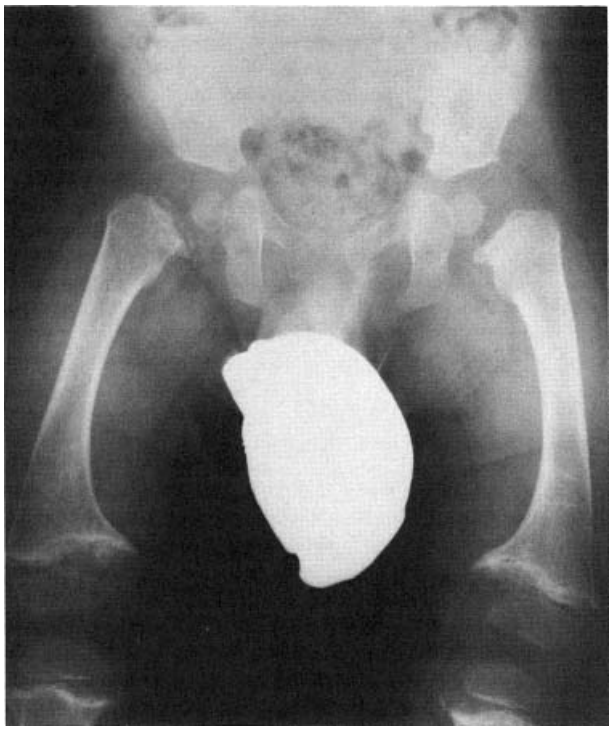

Figure 12. Radiograph of the pelvis and lower extremities of a 5-year-old child with metaphyseal chondrodysplasia, Schmid type. The tubular bones are moderately short and the metaphyses are flared, cupped, and irregularly mineralized.

Figure 13. Radiograph of the pelvis and lower extremities of a 3-year-old child with metaphyseal chondrodysplasia, McKusick type. The tubular bones are short with flared, irregular metaphyses. The knees are most severely affected. The proximal femora exhibit relatively mild involvement without coxa vara. The distal fibula is disproportionately longer than the tibia.

children with the disorder. Malignancies of the skin and lymphoid tissue have been observed in adults in the Amish and Finnish populations [144,145]. In a large cohort of Finnish patients, the greatest cancer risk was for non-Hodgkins lymphoma and to a lesser extent for basal cell carcinoma [145].

Metaphyseal chondrodysplasia, McKusick type, is an autosomal recessive disorder. It is especially common in the Amish population, where the founder effect has increased the incidence. Uniparental disomy has been observed [146]. The disease locus has been mapped to chromosome 9p13 [147–149], but its identity is still unknown.

Other Metaphyseal Dysplasias

Growth deficiency associated with metaphyseal irregularities on radiographic examination and immune deficiency is found in three other autosomal recessive conditions [68,150–152]. The skeletal changes occur with pancreatic exocrine insufficiency, cyclic neutropenia, and other hematologic abnormalities in the Shwachman syndrome (MIM 260400) [153–156]. The second disorder is so-called metaphyseal chondrodysplasia with thymolymphopenia, and the third is adenosine deaminase deficiency [157] (see MIM 102700). The biological connection between immune deficiency and metaphyseal chondrodysplasia is not known: however, it has been suggested that cellular proliferation and differentiation, which are common to both, are defective. Moreover, transgenic mice expressing a dominant negative *COL10A1* mutation display immune-related defects [120].

Spondylometaphyseal Dysplasia

There are several disorders in which the radiographic abnormalities are primarily of the spine and the metaphyses of long bones. The best delineated is the Kozlowski type of spondylometaphyseal dysplasia (MIM 271660), which is inherited as an autosomal dominant trait [68,158,159]. It usually presents during early childhood, with a waddling gait and mild short stature mostly affecting the trunk. The hands and feet are short and stubby, and hip mobility may be mildly limited. Scoliosis may develop during adolescence. The head and face are normal. Adult heights range from 130 to 150 cm [68].

Generalized flattening of the vertebral bodies is seen on skeletal radiographs (Fig. 14). They extend laterally beyond the vertebral pedicles as seen on anteroposterior view. The iliac bones are short and flared, and the acetabular roofs are horizontal. Tubular bones exhibit flaring and irregular mineralization of the metaphyses. The latter is greatest in the femora where coxa vara is common.

Histologic abnormalities have been detected in the growth plate, but they are not specific. They include poor organization, irregular vascular invasion, and fewer proliferative chondrocytes than normal [74]. Granular inclusions have been detected in epiphyseal chondrocytes by electron microscopy [87]. Gel electrophoresis of proteoglycan extracts revealed a rapidly moving band not seen in controls, although its significance has not yet been determined [87]. Analysis of cyanogen bromide-derived peptides of type II collagen has been normal [87,160].

Ikegawa et al. have reported a mutation in *COL10A1* in a family with spondylometaphyseal dysplasia [161]. They raise the possibility that mutations in this gene may account for some cases of this disorder. However, Lachman suggests the radiographic features are more consistent with Schmid metaphyseal chondrodysplasia with mild changes of the spine [162].

Figure 14. Radiograph of the pelvis of an 11-year-old with spondylometaphyseal dysplasia, Kozlowski type, showing a severe coxa vara deformity of the proximal femora. Note the platyspondyly.

DISORDERS DUE TO MUTATIONS OF GENES FOR CARTILAGE OLIGOMERIC MATRIX PROTEIN (COMP) AND TYPE IX COLLAGEN

The disorders in this group include pseudoachondroplasia (PSACH) and multiple epiphyseal dysplasia (MED). MED is genetically heterogeneous (EDM1, EDM2, EDM3), but EDM1 is allelic with PSACH.

Nomenclature and History

Maroteaux and Lamy first described PSACH in 1959 and many clinical reports delineating the phenotype followed [163]. Fairbanks and Ribbing independently described the clinical and radiographic findings of a condition that involved a generalized epiphyseal dysplasia with skeletal findings similar to, but much milder than PSACH [164,165]. The term multiple epiphyseal dysplasia (MED) was coined to describe this condition. Mutation analysis studies have shown that all cases of PSACH and many of MED, specifically those of EDM1, result from mutations in cartilage oligomeric matrix protein (COMP). Case reports suggesting a recessive form of PSACH [166] are now attributed to germline mosaicism for mutant *COMP* alleles [167,168]. Mutations in *COMP* cause a range of phenotypes from normal to mild short stature with or without hip and knee pain (MED) to severe disproportionate short stature with joint symptoms (PSACH). In contrast, mutations in *COL9A2* (*EDM2*) and *COL9A3* (*EDM3*) genes cause a mild epiphyseal dysplasia [169–171].

COMP Protein and Gene

COMP is a large pentameric glycoprotein found in the extracellular territorial matrix of chondrocytes; it is also abundantly present in tendon and ligament [172–175] (see also Chapter 4, this volume). It is the fifth member of the thrombospondin gene family and has homology to the other family members, particularly thrombospondin-3 and thrombospondin-4 [176]. Although its function has not yet been defined, it may exhibit adhesive properties similar to those of other thrombospondins [177]. It has been demonstrated that both collagen types I and II interact with COMP through their C-terminal globular domains and that

this interaction is promoted by the presence of Zn^{2+} but not other cations [178].

The 2.4 kb COMP cDNA is encoded by 19 exons [176]. COMP has a bouquet appearance upon rotary shadowing, with five identical subunits or chains [179]. Each subunit is composed of a pentamer formation domain (exons 1–3), four epidermal growth factor (EGF)-like domains (exons 4–7), seven calcium-binding domains (exons 8–14), and a globular domain (exons 15–19). An alternative numbering scheme for the exons is based on the thrombospondin nomenclature (Table 4) [177]. All but three of the mutations reported to date have been identified in the calcium-binding domains, which are highly conserved between thrombospondin family members in all species [176], suggesting that this region has an important role in maintaining protein structure (Figure 15).

Mutations

COMP

Fifty-one *COMP* mutations have been reported to date, with the majority resulting in PSACH [167,168,175, 180–189]. Only eleven result in the MED (EDM1) phenotype (Table 4). The most common PSACH mutation, a 3 bp deletion involving amino acids 469–473 (exon 13, exon 17B in the alternative scheme), accounts for more than 30% of the total mutations [180]. Moreover, exon 13 appears to be a hotspot for mutations and should be targeted for mutational analysis (Fig. 15). Twenty-eight of the mutations involve aspartic acid residues that are highly conserved and make up the calcium-binding motif, DXDXDXXXDXXD, that is found in all thrombospondins [177]. Three mutations found outside the calcium-binding domains occur in exon 16 that encodes part of the globular domain. No genotype/phenotype correlations can be made, as mutations affecting the same codon have been found for both PSACH and MED [182] (Fig. 15).

Hall and Dorst [166] first suggested germline/somatic mosaicism in PSACH. Molecular analysis of *COMP* alleles in families with more than one sib affected with PSACH born to parents of average stature, confirmed that mosaicism occurs [167,168]. This suggests that all cases of PSACH are secondary to heterozygous mutations in *COMP*, and that germline mosaicism should be considered when counseling all isolated cases. A recurrence risk of 1–2% is suggested (Hecht, unpublished results) and prenatal diagnosis is possible after the mutation is identified in the affected parent. Targeted ultrasound is not a useful prenatal diagnostic procedure as the skeletal findings are not obvious at birth.

COL9A2 and COL9A3

Mutations in two of the type IX collagen genes produce a phenotype that is similar to mild MED (EDM1) [169–171]. The clinical reports suggest that mutations in these genes specifically affect the articular cartilages of the knee and, to a lesser extent, those of the hip. Overall, adult height does not appear to be reduced. Three mutations have been identified in *COL9A2* [169,171] and one in *COL9A3* [170] and each involves the intron 3 splice site and affects the processing of exon 3. The small number of reported mutations makes it difficult to predict what the spectrum of the mutations will be or to correlate genotype with phenotype.

Animal Models

There are no precise animal models for chondrodysplasias due to *COMP* or for *COL9A2* or *COL9A3* mutations. However, type IX collagen biosynthesis has been disturbed in mice by mutations introduced into *Col9a1* in two instances. In the first, mice expressing a transgene encoding a truncated form of the α1(IX) chain displayed osteoarthritis and a mild chondrodysplasia phenotype [190]. Mice null for *Col9a1* also developed osteoarthritis [191]. Hagg et al. showed that the α1(IX) deficiency prevented assembly of type IX collagen molecules and suggested that absence of these molecules predisposes to osteoarthritis [192].

Pathogenesis

Given the pentameric nature of COMP, mutations in PSACH and MED presumably exert a dominant negative effect on COMP function as 97% of all COMP molecules are predicted to have from one to five mutant subunits or chains under such circumstances [180]. However, it is not known if dysfunction requires a certain number of mutant subunits per molecule, i.e., if there is a threshold, or if mutant molecules behave differently depending on how many mutant chains they contain. Studies of chondrocytes in cartilage from PSACH and MED patients show large lamellar inclusions in rough endoplasmic reticulum that contain COMP, aggrecan and type IX collagen [87,185,188,193,194]. *In vitro* studies of redifferentiated PSACH chondrocytes indicate that the massive retention of these extracellular matrix proteins compromises chondrocyte function and causes chondrocyte death (Fig. 16) [194], suggesting that the decrease in linear growth may be related to the loss of growth plate chondrocytes. Moreover, compared with control chondrocytes, PSACH chondrocytes appear to produce smaller amounts of a matrix that contains diminished amounts of COMP [185,194]. Thus, the growth deficiency associated with COMP mutations may reflect the dysfunction and/or premature loss of chondrocytes that contribute to endochondral bone growth, whereas the precocious osteoarthritis may reflect a structurally abnormal and diminished cartilage matrix that erodes over time. Disturbed secretion of type IX collagen may contribute to the articular manifestations given the observations in mice.

Clinical Phenotypes

Pseudoachondroplasia (MIM 177150)

PSACH is an autosomal dominant disorder characterized by disproportionate short stature, short extremities, and ligamentous laxity [68,163,195]. It is distinguished from achondroplasia by a normal appearance and size at birth, a normal head circumference, and a normal to attractive facial appearance. The diagnosis is usually made between the first and second years of life, when skeletal growth decelerates and a waddling gait appears. Limb shortening becomes accentuated with age. The hands are short and broad and usually show ulnar deviation. The forearms may be bowed. Ligamentous laxity is generalized, but especially marked in the hands and fingers. However, mobility at the elbows may be restricted and flexion contractures may develop at the hips. Genu varum, genu valgum, and "windswept" deformities of the knees, in which both knees deviate in the same direction, develop in childhood. They respond to surgical correction but tend to recur. Odontoid hypoplasia occurs occasionally and, with ligamentous laxity, can cause cervical instability [196,197]. Precocious osteoarthritis of the hips and knees is typical, and surgical replacement is often required. In a natural history study, 33% of patients greater than age 19 years reported having hip replacement [198]. Developmental milestones are attained

[1]Alternative exon naming scheme used by some authors. PSACH refers to pseudoachondroplasia, MED to multiple epiphyseal dysplasia.

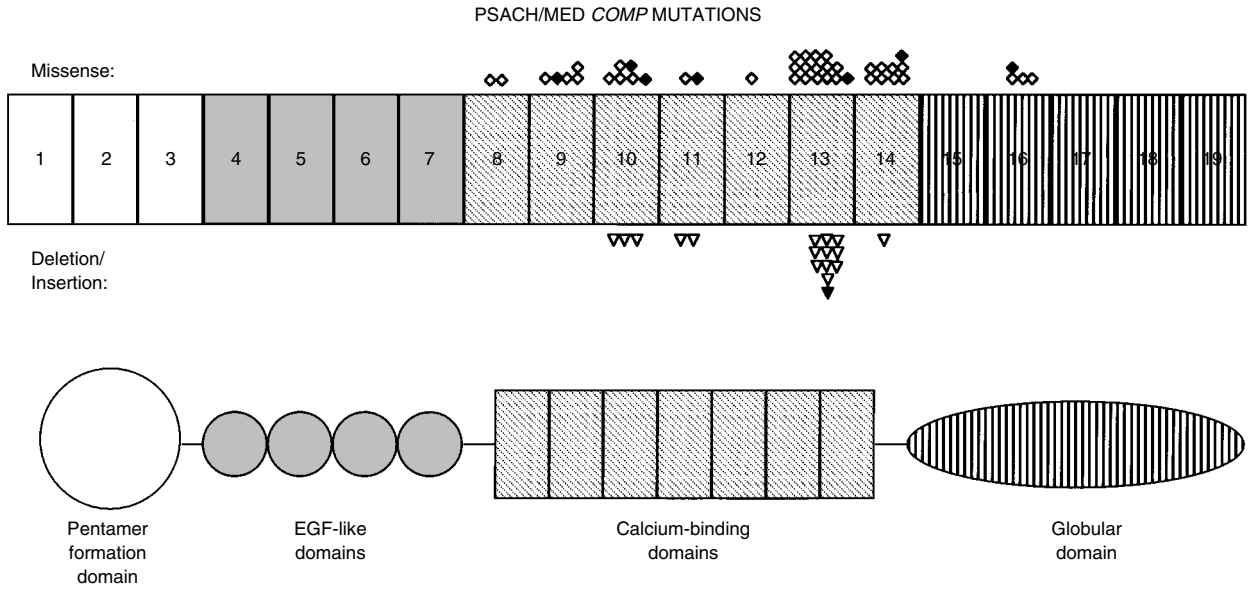

Figure 15. Genomic and protein structures of cartilage oligomeric matrix protein (COMP) are shown, corresponding exons and protein domains have similar patterns. Missense mutations are denoted by diamonds (♦) and deletion and insertion mutations by triangles (▼). The figures are open for pseudoachondroplasia (PSACH) mutations and closed for multiple epiphyseal dysplasia (MED) mutations.

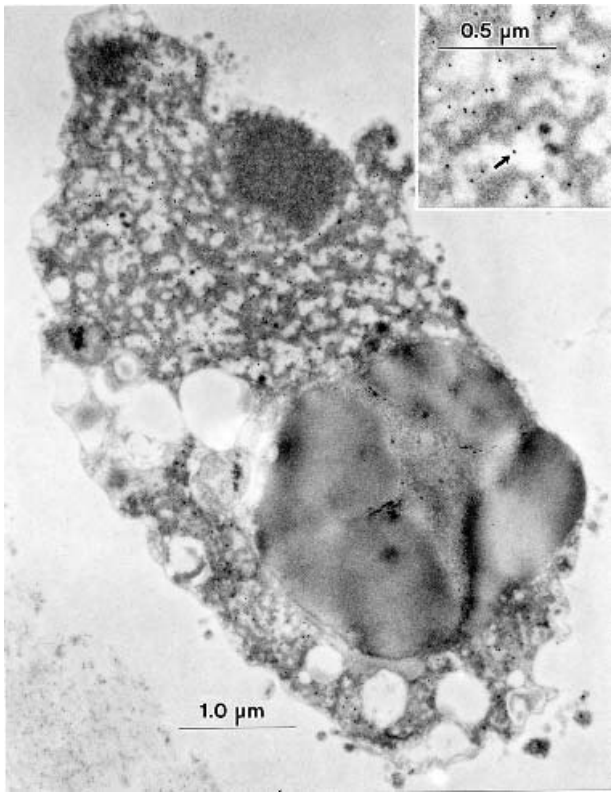

Figure 16. Transmission electron micrograph demonstrating a dead pseudoachondroplasia (PSACH) chondrocyte with large cisternae of rough endoplasmic reticulum. The presence of relatively large amounts of cartilage oligomeric matrix protein (COMP) within the cisternae is visualized by immunogold staining with anti-COMP (inset; arrow).

normally, and intelligence is normal. Adult height ranges from 105 to 128 cm [73,198].

Radiographs show involvement of epiphyses, metaphyses, and the spine [163,199]. The diagnosis can be made at birth by the presence of platyspondyly, even though affected infants are proportionate and have a normal birth length. In early childhood, the vertebral bodies display an ovoid shape and anterior tongue-like projections on the lateral view (Fig. 17). The anterior projection diminishes with age, but irregularities of the end plates persist. The tubular bones are short, with markedly irregular and flared metaphyses (Fig. 18) and the epiphyses are small and poorly formed.

Multiple Epiphyseal Dysplasia (MIM 132400)

Individuals with MED (EDM1) present in mid-childhood with an abnormal gait, hip pain, and Legg-Perthes disease (avascular necrosis of the capital femoral epiphysis) [164,165]. Stature may be slightly reduced but is most often within the normal range. Fingers are short, and genu varum and valgum may occur in childhood. The diagnosis of MED is often made in a child presenting with bilateral Legg-Perthes disease. The treatment for this complication is similar to that provided to normal children with isolated Legg-Perthes disease. Joint erosion occurs in early adulthood and hip replacement becomes necessary because of debilitating hip pain. Restriction of activities that stress the joints is strongly recommended for both PSACH and MED.

Radiographic findings in MED (EDM1) are similar to, but much milder than those seen in PSACH [199] (Fig. 19). All of the epiphyseal centers are small and underossified, especially in the hips. There is less metaphyseal and vertebral involvement compared to PSACH, although platyspondyly has been reported in MED.

In three families with mutations in *COL9A2* (*EDM2*) and in one family with a *COL9A3* (*EDM3*) mutation (Table 5), the presenting complaint was waddling gait, mild short stature, genu valgum and hip pain [169–171]. Epiphyseal

TABLE 5. Reported Mutations of *COL9A2* and *COL9A3*

Locus	Phenotype	Type	Mutation	Reference
COL9A2	MED (EDM2)	Splice	IVS3 +2 T>C skip exon 3	[169]
		Splice	EXN3 −1 G>A skip exon 3	[171]
		Splice	IVS3 +5 G>C skip exon 3	[171]
COL9A3	MED (EDM3)	Splice	IVS2 −2 A>T skip exon 3	[170]

MED refers to multiple epiphyseal dysplasia, EDM2 and EDM3 to multiple epiphyseal loci 2 and 3.

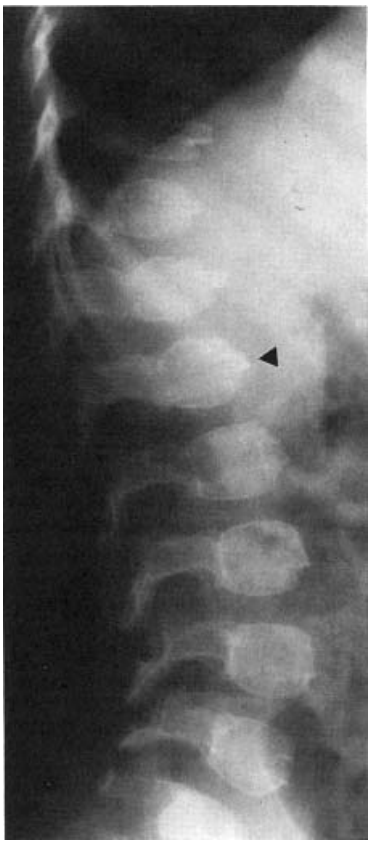

Figure 17. Lateral radiograph of the spine of a 3-year-old with pseudoachondroplasia (PSACH), showing the ovoid shape of the vertebral bodies with anterior tongue-like projections (arrowhead).

Figure 18. Radiograph of the hand of a 3-year-old with pseudoachondroplasia (PSACH). All tubular bones are short and show markedly irregular and flared metaphyses.

dysplasia appears to be limited to the large joints of the lower limbs. Hip replacement occurring after the sixth decade has been observed in a few individuals.

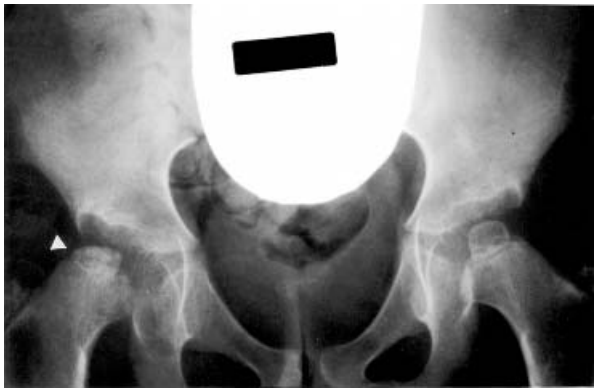
MISCELLANEOUS DISORDERS

Fibrochondrogenesis (MIM 228520)

Fibrochondrogenesis is an autosomal recessive chondrodysplasia characterized by moderate shortening of the limbs, enlargement of the joints, a proportionate head and trunk, a narrow chest, and a round flat face with prominent eyes. Cleft palate is a frequent associated finding. Death occurs soon after birth from respiratory insufficiency [200–204].

The vertebral bodies are flattened and project a pyriform silhouette on lateral radiographic examination. The iliac and pubic bones are short and broad. The tubular bones are also short and broad, with irregular metaphyses. The bones of the skull, hands, and feet are normal.

The epiphyseal cartilage is hypercellular, and the cells are elongated on microscopic examination (Fig. 20). The matrix is very fibrous, forming interwoven septa through the cartilage [87]. These septa extend into and disrupt the normal architecture of the growth plate, where relatively few proliferative and hypertrophic chondrocytes are seen. Although the epiphyseal cartilage resembles fibrocartilage morphologically, cyanogen bromide-derived peptide mapping of the cartilage collagen shows only type II collagen, and the absence of type I collagen has been confirmed by immunostaining [87]. The significance of these morphological changes is unknown.



a

b

Figure 19. Radiographs of pelvis (**a**) and hand (**b**) from a patient with multiple epiphyseal dysplasia (MED) with a cartilage oligomeric matrix protein (COMP) mutation. The capital femoral epiphyses are small and the one on the patient's right shows early changes of Legg-Perthes disease (arrowhead).

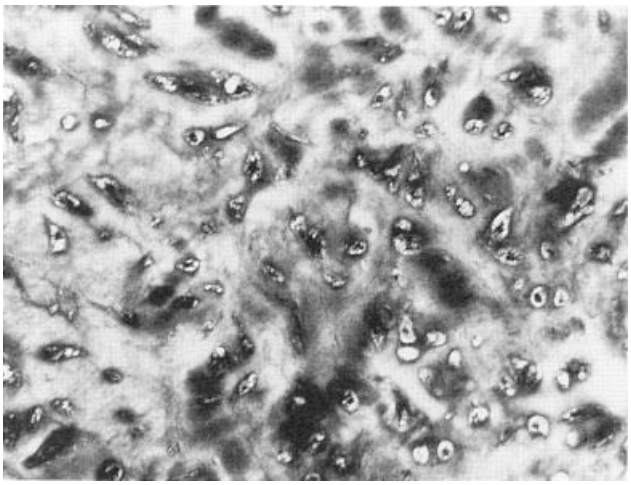


Figure 20. Photomicrograph of epiphyseal cartilage in fibrochondrogenesis. The cartilage is hypercellular and many of the cells display an elongated shape. The matrix stains unevenly and appears more fibrous than normal. Toluidine blue stain. ×200, original magnification.

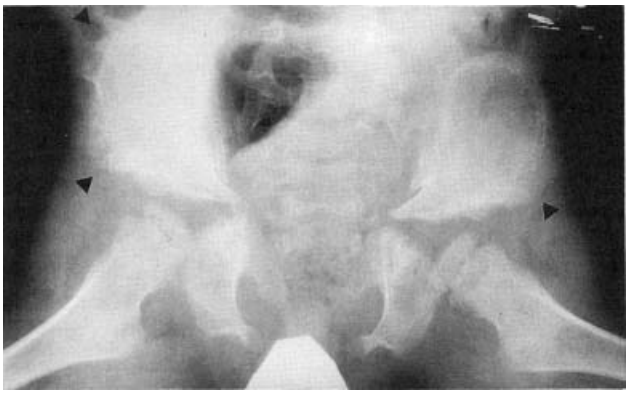

Figure 21. Radiograph of the pelvis of a 7-year-old child with Dyggve-Melchior-Clausen dysplasia. The short iliac bones have a distinctive lace-like mineralization along the iliac crests (arrowheads).

Dyggve-Melchior-Clausen Dysplasia

Dyggve-Melchior-Clausen dysplasia is a rare disorder, characterized by short-trunk dwarfism [205–208]. Growth deficiency usually becomes evident in late infancy or early childhood. The sternum becomes prominent and the lumbar lordosis exaggerated. The hands and feet are small, and the fingers have a clawed appearance. Mental retardation is a common but inconstant feature. The condition exhibits autosomal recessive inheritance in most families (MIM 223800); however, an X-linked pattern (MIM 304950) was observed in one large family [209].

Skeletal radiographs in Dyggve-Melchior-Clausen dysplasia show generalized flattening of the vertebral bodies, with irregular notches of the end plates. The iliac bones are short and broad, and there is a distinctive lace-like mineralization of the iliac crests (Fig. 21). A spur can be seen in childhood projecting medially from the femoral neck, which tends to be horizontally oriented. The capital femoral epiphysis is late to ossify. The tubular bones are short, with irregular ossification of the epiphyses and metaphyses.

The epiphyseal and growth plate cartilages exhibit heterogeneity in their morphologic appearance [210]. The matrix is extremely fibrous in some areas. Dense bundles

of fibers traverse both cartilages, disrupting the normal architecture and giving an appearance similar to that of fibrocartilage. Immunostaining, however, reveals that the fibers are comprised of type II collagen, rather than type I collagen as in fibrocartilage. In other areas of both epiphyseal and growth plate cartilage, the matrix is much less fibrous. Epiphyseal chondrocytes in these areas are found in clusters containing as many as 10 cells. The clusters stain intensely for proteoglycan, and many of the cells contain cytoplasmic inclusions. The clusters may also be found in the growth plate; those near the cartilage-bone interface are associated with deposits of mineral, which are much larger than normal.

Patients with features of Dyggve-Melchior-Clausen dysplasia who lack mental retardation are sometimes referred to as having Smith-McCort dysplasia [211]. Nakamura et al. observed dilated cisternae of the rough endoplasmic reticulum in iliac crest chondrocytes from two patients with this condition [212].

Craniometaphyseal Dysplasia

This disorder is characterized by craniofacial hyperostosis accompanied by metaphyseal widening and diaphyseal sclerosis of tubular bones [213–216]. It is usually evident during infancy from the excess of bone over the bridge of the nose, the prominent forehead, and ocular hypertelorism. Hyperostosis of bones at the base of the skull may encroach upon cranial foramina leading to hearing loss, optic atrophy and facial paralysis. Intelligence is normal. Diaphyseal sclerosis dominates long bone radiographs of affected infants, while club-shaped metaphyseal widening of these bones is typical in children and adults. Life expectancy and adult height are usually normal.

Craniometaphyseal dysplasia must be distinguished from Pyle disease, which has less skull and more metaphyseal involvement radiographically, and craniodiaphyseal dysplasia, which exhibits more severe sclerosis of the skull and long bone abnormalities that involve diaphyses more than metaphyses [99]. Both autosomal dominant and recessive forms of craniometaphyseal dysplasia have been delineated. The recessive form is more severe. The dominant form has been mapped to chromosome 5p15.2–p14.1 [217].

Acromelic Dysplasias

The acromelic dysplasias are a heterogeneous group of disorders in which the skeletal abnormalities mainly affect the distal extremities [68,218]. They all show some degree of growth deficiency, indicating involvement of bones that contribute to height as well. In autosomal dominant peripheral dysostosis (MIM 170700), affected persons usually present during adolescence with swelling and reduced mobility of finger joints [219–221]. The hands and feet are short. Radiographs show shortening of metacarpals, metatarsals, and phalanges, with mild metaphyseal abnormalities and cone-shaped epiphyses of these bones.

Acrodysostosis

Acrodysostosis (MIM 101800) is a sporadic disorder, characterized by extremely short hands and feet and an abnormal facies, consisting of a low nasal bridge, short nose, and anteverted nostrils [222,223]. Patients are usually short from birth and often exhibit obesity and mental retardation later. Radiographs show short and wide metacarpals, metatarsals, and phalanges, with cone-shaped epiphyses. Brachycephaly and nasal hypoplasia are seen on skull films, and there may be mild irregularity of the vertebral end plates.

Tricho-Rhino-Phalangeal Syndrome

The tricho-rhino-phalangeal syndrome type I (TRPS I) (MIM 109350) is an autosonal dominant condition [224]. Patients exhibit thin, sparse hair, a pear-shaped nose, mild short stature, and hands and feet that are short and broad. Short metacarpals, metatarsals, and phalanges with cone-shaped epiphyses are observed on radiographs. These features are combined with prominent ears, microcephaly, micrognathia, mental retardation, and multiple cartilaginous exostoses in TRPS type II or the Langer-Giedion syndrome (MIM 150230). TRPS type II occurs sporadically and is associated with deletions of chromosome 8q24.1 [225]. TRPS II is considered a contiguous gene deletion syndrome as the *TRPS I* and *EXT1* genes are deleted. Mutations in the *EXT1* gene give rise to hereditary multiple exostosis syndrome (MIM 133700), an autosomal dominant condition associated with inappropriate bone growth (exostoses) at the ends of the long bones [226]. Deletion of one copy of the *EXT1* gene in TRPS II is also associated with unregulated bone growth that is identical to that observed in hereditary multiple exostosis syndrome. The *TRPS 1* gene is a novel zinc finger gene with significant homology to GATA-binding transcription factors. Four mutations in TRPS I patients have been identified [227].

Larsen Syndrome

Larsen syndrome is characterized by multiple congenital joint dislocations, an unusually flat face with a prominent forehead, depressed nasal bridge and widely spaced eyes, and abnormal hands with relatively short metacarpals and cylindrical fingers [99,228–230]. Around 50% of affected infants have a cleft palate or uvula. The dislocations usually involve the hips, knees, and elbows, and laxity of the costochondral cartilage has been described. Other manifestations include short fingernails, equinovarus deformity of the foot, delayed dental development, and other dental abnormalities. Cardiovascular lesions, including congenital septal defects and acquired lesions similar to those found in the Marfan syndrome, i.e., mitral prolapse, aortic dilatation, have been reported [231]. Motor developmental delay is common due to the orthopedic deformities, and spinal cord compression may result from excessive mobility of vertebral bodies. Osteoarthritis secondary to the joint deformities is a common complication in adulthood.

The dislocations are evident radiographically and secondary epiphyseal deformities may be detected. Abnormal curvature of the spine may be seen, especially in the cervical region [232]. Radiographs of the hands often show extra carpal bones, as well as irregularities of the metacarpals and phalanges. An extra calcaneal ossification center is characteristic of Larsen syndrome. It usually appears during late infancy and fuses with the main calcaneal ossification center during childhood.

Most cases of Larsen syndrome are sporadic. However, dominant inheritance has been seen (MIM 150250), as has the occurrence of the condition in sibs of unaffected parents suggesting autosomal recessive inheritance (MIM 245600). However, in at least one instance, evidence of germ line mosaicism has been detected in a family in whom recessive inheritance was suspected [233]. A Larsen syndrome locus, *LAR1*, has been mapped to chromosome 3p in the region of, but distinct from, the *COL7A1* locus [234].

RECENT DEVELOPMENTS

X-Linked Spondyloepiphyseal Dysplasia Tarda

The spectrum of *SEDL* mutations associated with X-linked SED tarda has been defined in different ethnic populations. Gedeon et al. found 21 different mutations in 30 unrelated cases [269]. These included missense and nonsense mutations, and insertions, deletions, and putative splicing mutations, all predicted to change the reading frame, leading to a premature stop codon. Deletions accounted for more than half of the mutations. Several recurrent mutations were detected. In one case, RNA analysis indicated that *SEDL* had escaped X-inactivation [270]. A comparison of *SEDL* with homologs in other species suggests that the gene product, sedlin, normally promotes vesicular transport from the endoplasmic reticulum to the Golgi apparatus, leading to speculation that the secretion of cartilage matrix proteins is disturbed in SED tarda [270].

Dyssegmental Dysplasia and Schwartz-Jampel Syndrome

Mutations of *HSPG2*, the gene encoding perlecan, have been discovered in both dyssegmental dysplasia [271] and Schwartz-Jampel syndrome [272]. Perlecan is a large proteoglycan typically found in basement membranes and in other tissues such as cartilage. Similarities in growth plate morphology and ultrastructure between mice null for *Hspg2* and humans with dyssegmental dysplasia led to the identification of mutations in the latter condition. Cultured fibroblasts from a patient with dyssegmental dysplasia displayed cytoplasmic inclusion bodies that stained for perlecan, and they failed to secrete perlecan into the medium [271].

Cartilage-Hair Hypoplasia

Mutations of a gene coding for a large untranslated RNA component of an enzyme complex involved in processing mitochondrial RNA have been found in cartilage-hair hypoplasia (CHH; metaphyseal chondrodysplasia, McKusick type) [273]. The gene is designated *RMRP*. The enzyme, mitochondrial RNA-processing endoribonuclease (RNAase MRP) can cleave the "primer" RNA needed to copy mitochondrial DNA [274]. In yeast, however, most RNAase MRP resides in the nucleolus, where it is involved in processing 5.8 S ribosomal RNA which has been implicated in the translation of proteins and the control of mitosis. Ridanpää et al. attempted to measure RNAase-MRP activity in CHH cells and found no abnormality. However, it is not known if the assay, which was developed for yeast, was sensitive enough for human cells. Thus, it is not clear if the dysfunctions in CHH cells reflect disturbances in mitochondrial DNA replication or in other functions, including the processing of ribosomal 5.8 S RNA and as yet undiscovered functions of RNAase-MRP.

Two classes of *RMRP* mutations were found [273]. The first class includes insertions or deletions in the promoter region. The second class consists of single nucleotide substitutions or other changes involving no more than two nucleotides in regions of the gene that are transcribed. The "ancestral" Finnish mutation (A to G substitution at position 70) falls into the second class. Among 70 CHH patients studied, mutations were detected in both alleles of 55 cases.

Multiple Epiphyseal Dysplasia

Three loci in addition to *COMP* (*EDM1*), *COL9A2* (*EDM2*) and *COL9A3* (*EDM3*) have been implicated in multiple epiphyseal dysplasia (MED). *EDM4* corresponds to the *DTDST* or alternatively named *SLC26A2* (solute carrier family 26, member 2) locus. Patients with recessively inherited MED (rMED) accompanied by club foot and double-layered patellae have been reported to be homozygous for an Arg279Trp mutation at this locus [275]. Of note, is that homozygosity for this mutation was also detected in two sibships with apparently isolated club foot [276].

EDM5 corresponds to the *MATN3* (matrilin-3) locus. Matrilin-3 is an oligomeric protein present in cartilage matrix. Chapman et al. have identified two different missense mutations in the exon encoding the von Willebrand factor A (vWFA) domain of matrilin-3 in two unrelated families with MED [277]. The sixth MED locus, which may end up designated *EDM6*, is the *COL9A1* locus. A splicing mutation in *COL9A1* has been detected in one family with dominant MED [278].

Chapter 23, Part III

Skeletal Dysplasias Related to Defects in Sulfate Metabolism

Andrea Superti-Furga

Division of Metabolism and Molecular Pediatrics, Department of Pediatrics, University of Zurich, Zurich, Switzerland

SUMMARY

- **Sulfated proteoglycans are abundant components of skeletal and connective tissues and particularly of cartilage. Genetic defects in the metabolism of sulfate may affect the biosynthesis or the degradation of sulfated proteoglycans and thus perturb the homeostasis of the extracellular matrix.**
- **Impaired degradation of sulfated proteoglycans, caused by deficiency of one of various lysosomal sulfatases, is found in the lysosomal storage disorders (see Chapter 22, this volume).**
- **Defective synthesis of sulfated proteoglycans has been observed more recently: mutations in two genes involved in sulfate metabolism, *DTDST* (for diastrophic dysplasia sulfate transporter, a sulfate/chloride exchanger of the cell membrane) and *PAPSS2* (phosphoadenosine-phosphosulfate synthase 2, an isoform of a bifunctional enzyme responsible for the metabolic activation of inorganic sulfate to the high-energy sulfate donor, PAPS) may impair the sulfation of newly synthesized proteoglycans and produce a clinical phenotype of skeletal dysplasia.**
- **Mutations in the *DTDST* gene may produce a spectrum of disorders that ranges from lethal, generalized skeletal hypodysplasia (achondrogenesis 1B, atelosteogenesis 2) through a non lethal, short-stature dysplasia (diastrophic dysplasia), to a relatively mild dysplasia with normal stature (recessive multiple epiphyseal dysplasia). The pathogenesis involves sulfate depletion in cells with high sulfate requirement, such as chondrocytes, leading to insufficient sulfation of cartilage chondroitin sulfate proteoglycans, the severity of the phenotype being determined by the nature of the *DTDST* mutations and the residual activity they allow for.**
- **Homozygosity for a stop codon mutation in the *PAPSS2* gene has been observed in members of a family affected by moderately severe spondylo-epi-metaphyseal dysplasia and short stature.**
- **The consequences of phosphoadenosine-phosphosulfate synthase deficiency have been extensively studied in the mouse model *brachymorphic*, which has a phenotype of skeletal dysplasia with short limbs and is caused by a mutation in the orthologous gene *PAPSS2*.**

SULFATE AND THE EXTRACELLULAR MATRIX

Proteoglycans comprise a broad category of macromolecules consisting of core proteins to which from one to several hundred glycosaminoglycan side chains are attached [1,2]. The glycosaminoglycan side chains are composed of repeated disaccharide-sulfate units. Proteoglycans are present in the cell nucleus, the cytoplasm, and the cell membrane, but they are particularly abundant in the extracellular matrix of connective tissues [1,2] (see also Chapter 4, this volume). Proteoglycans are highly sulfated. While sulfation of certain amino acid residues of the core protein has been observed, the bulk of proteoglycan sulfation is directed toward the amino group of N-acetyl-glucosamine and N-acetyl-galactosamine sugars in the glycosaminoglycan side chains of the proteoglycans. Here, up to 80–90% of susceptible sugar residues may be sulfated. Because sulfate groups are dissociated at physiological pH values, sulfated proteoglycans exist as polyanions. There is little direct experimental evidence highlighting the role of sulfate groups in proteoglycans, but some insight has been gained by the observation of the phenotypic consequences of disturbances in proteoglycan sulfation, both in the human and the experimental animal.

THE CELLULAR METABOLISM OF SULFATE

Biological sulfation involves such diverse molecules as proteoglycans, membrane lipids, plasma proteins, and xenobiotics detoxified in the liver [3]. Early studies on the sulfation of phenol in liver extracts showed that ATP could significantly accelerate the sulfation reaction (reviewed in [4]). This observation led to the hypothesis that, by analogy to the phosphate donor, ATP, there be a''universal'' sulfate donor that could serve for different substrate-specific sulfotransferases [4]. Studies in yeast, liver tissue, and cartilage tissue have confirmed this hypothesis by showing that the postulated universal high-energy sulfate donor for sulfotransferase reactions exists in the form of phosphoadenosine phospho-sulfate (PAPS). Investigations into the biosynthesis of the high-energy sulfate donor, PAPS, led to the

Connective Tissue and Its Heritable Disorders, pages 939–960

recognition of the metabolic pathway called the''metabolic activation of sulfate'' [3,4](Fig. 1). Inorganic sulfate anions in the cytoplasm may either be derived from extracellular fluid, or formed in the cytoplasm by catabolism of sulfur-containing amino acids and other thiol compounds with the production of sulfite which is oxidized to sulfate. The transit of sulfate ions across cell membranes and epithelial tissues is mediated by carrier proteins. Sulfate transport mechanisms have been identified in the intestinal epithelium [5], renal tubular epithelium (NaSi) [6,7], the basolateral and apical membranes of liver cells [8–10], endothelial cells (SUT-1) [11], fibroblasts [12], smooth muscle cells, and Chinese hamster ovary (CHO) cells [13]. Sulfate transporters function either as sulfate-chloride exchangers (or more generally anion exchangers, as other anions may be transported by some of them) or as sodium-sulfate cotransporters. A coordinated model of the role and importance of each of these transport systems in whole-body sulfate homeostasis in man has not yet emerged [14]. Plasma sulfate concentrations in humans span a broad range (approximately 200–450 μM; higher values may be seen during pregnancy [15]), and the mechanisms by which plasma sulfate is regulated are still not clear.

Cytoplasmic Sulfate and Proteoglycan Synthesis

Studies on the synthesis and sulfation of proteoglycans in various types of cultured cells have shown that sulfate groups on proteoglycans may be derived both from the intracellular catabolism of cysteine and other thiols, and from the extracellular fluid. The relative contribution of the two pathways to the pool of intracellular sulfate apparently varies from one cell type to another. Ion uptake and inhibition studies have indicated that in fibroblasts and chondrocytes, sulfate ions are taken up by an anion exchange mechanism driven by the chloride gradient: intracellular chloride ions are released while sulfate ions are taken up by the cell [12,16]. The molecule responsible for this exchange appears to be the chloride-sulfate exchanger designated diastrophic dysplasia sulfate transporter (DTDST; see below). The availability of extracellular sulfate to cultured cells can be curtailed by reducing its concentration in the culture medium, by competing with chlorate, or by inhibiting its uptake with 4,4′-diisothiocyanostilbene-2,2′-disulfonic acid [16,17]. Under these conditions, some cell types synthesize proteoglycans that are undersulfated [16–23]. Chondrocytes appear to be mostly dependent on extracellular sulfate for proteoglycan sulfation [17,20], whereas CHO cells appear to make more extensive use of cysteine-derived sulfate [13], and in fibroblasts both pathways are utilized [13,16,23]. Thus, a high rate of synthesis of proteoglycans seems to correlate with dependence on the uptake of extracellular sulfate for their sulfation [13]. These indirect conclusions have been confirmed by studies in cells from patients with *DTDST* mutations [24] (see below).

The Metabolic Activation of Sulfate

Cytoplasmic sulfate is activated in two steps; these are catalyzed by two distinct enzymes in lower organisms and plants [3,25] (Fig. 1). ATP sulfurylase (sulfate adenylyltransferase; EC 2.7.7.4) catalyzes the synthesis of adenosine-phosphosulfate (APS) from sulfate and ATP, and APS kinase (adenylylsulfate kinase; EC 2.7.1.25) catalyzes the synthesis of PAPS from APS and ATP [3]. In the marine worm *Urechis caupo* [26], *Drosophila* [27], mouse, rat, and man, a single bifunctional enzyme exists with both activities, ATP sulfurylase and APS kinase (formerly ''ATP sulfurylase-kinase'',

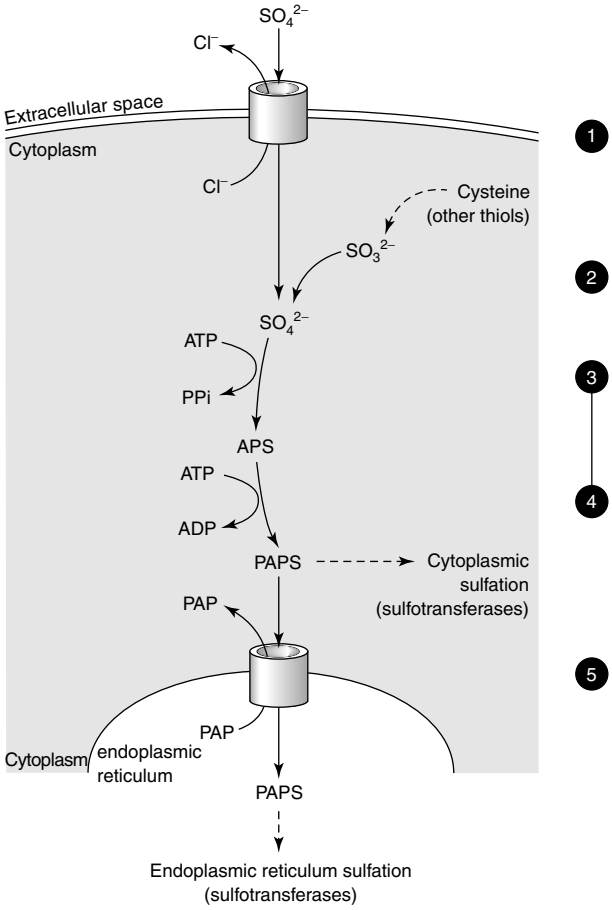

Figure 1. Simplified representation of the cellular metabolism of sulfate in higher organisms. The numbers on the right refer to the following steps: (1) Sulfate-chloride exchange by DTDST. The stoichiometry has not been determined directly, but since the transporter is not ATP-dependent or electrogenic it is assumed to be two chloride ions for one sulfate ion. (2) Sulfite oxidase, catalyzing final oxidation of thiol-derived sulfite to sulfate. (3 and 4) Two-step metabolic activation of inorganic sulfate by the bifunctional enzyme PAPS synthase, of which two genetic isoforms are known, PAPSS1 and PAPSS2. There is evidence to suggest that in some cell types, PAPSS1 (but not PAPSS2) may be localized to the cell nucleus rather than the cytoplasm [41]. (5) Translocation of PAPS into the endoplasmic reticulum by a putative PAPS-PAP antiporter. DTDST, diastrophic dysplasia sulfate transporter; PAPS, phosphoadenosine-phosphosulfate; PAP, phosphoadenosine-phosphate.

ATPSK [28–30]; now ''PAPS synthetase'', PAPSS [31]), contained in the C-terminal and N-terminal segments of the protein, respectively [32,33] (see below). Studies on the bifunctional enzyme of rat chondrosarcoma and mouse cartilage have shown that the substrate of the second reaction is much more likely to come directly from the first active site of the enzyme than from the surrounding fluid, i.e., there is ''channeling'' of substrate from one active site to the other [34,35]. This is consistent with the observation that the equilibrium for the first reaction is shifted toward inorganic sulfate: ''channeling'' of APS toward the second reaction removes product and facilitates the first reaction. Once formed, PAPS is relatively stable. It is the sulfate

donor for sulfation in the cytoplasm. For the sulfation of most membrane-bound and secreted molecules (such as most proteoglycans), PAPS must be transferred to the endoplasmic reticulum and/or the Golgi [36]. Earlier suggestions of a nucleoside sulfate/nucleoside exchange system in Golgi membranes [37] have been partially modified by newer studies that have suggested a PAP/PAPS antiporter activity residing in a 230 kDa protein [38,39]. The role of a further PAPS translocase activity from rat liver Golgi associated with a 70 kDa protein present as a dimer is unclear [40]. Studies on the sulfation of xenobiotics have shown that PAPS availability is the rate-limiting factor in many sulfotransferase reactions [36].

Sulfate activation may not necessarily occur in the cytoplasm in all cell types. Recent evidence suggests a different localization of two PAPSS isoforms (see below): while PAPSS2 is cytoplasmic, PAPSS1 may be associated with the nucleus [41]. The significance of the nuclear localization of PAPSS1 is not yet clear, but may have to do with the abundance of sulfated proteoglycans in the nuclei of certain cell types [42,43].

Deficiencies in specific sulfohydrolases responsible for the lysosomal degradation of sulfated proteoglycans and lipids result in lysosomal storage disorders classified under the mucopolysaccharidoses (see Chapter 22, this volume) or leukodystrophies. Mutations in a neutral arylsulfatase, ARSE, have been implicated in the pathogenesis of one form of chondrodysplasia punctata (see Part II, this chapter), while mutations in, or deletion of, a steroid sulfatase gene are responsible for X-linked ichthyosis [44] (see also Chapter 24, this volume). Defects involving the cellular uptake and the metabolic activation of sulfate, caused by mutations in the *DTDST* and *PAPSS2* genes, have been identified in patients with skeletal dysplasias and are described below.

The Diastrophic Dysplasia Sulfate Transporter (*DTDST*) Gene

The isolation of a human sulfate/chloride exchanger gene was the result of a long-term project aimed at elucidating the molecular basis of diastrophic dysplasia (DTD), a skeletal dysplasia present in most human populations, but particularly frequent in the Finnish population because of a founder effect [45]. The locus responsible for this disorder was initially mapped to chromosome 5 [46]. A more precise mapping to 5q32–q33.1 was obtained using linkage disequilibrium with polymorphic markers on chromosome 5 in the Finnish population [47], as well as with data obtained during the cloning of the Treacher-Collins syndrome gene (MIM 154500). A candidate cDNA encoded by a gene from that region [48] was noted to have homology with *Sat-1*, a rat hepatocyte sulfate transporter [10]. The hypothesis that diastrophic dysplasia was associated with impaired sulfate transport was confirmed by the demonstration of reduced sulfate uptake in cultured fibroblasts from patients with DTD and by the demonstration of mutations in the candidate gene in such individuals [48]. Recognition that the gene responsible for DTD encoded a sulfate transporter was a surprise because there was no prior experimental evidence of abnormal sulfate or proteoglycan metabolism in this disorder.

The coding sequence of *DTDST* (GenBank accession number U14528) is organized in two exons separated by an intron of approximately 1.6 kb, and predicts a protein of 739 amino acids that, by hydrophobicity analysis and analogy with *Sat-1*, was predicted to have 12 transmembrane domains as well as a carboxyl terminal, moderately hydrophobic domain [48]. A further *DTDST* exon has been identified in 5′-position to the two coding exons. This 5′ exon does not contain coding sequence [49].

The DTDST protein (Swiss Prot accession number P50443) belongs to the family of sulfate permeases and has been assigned number 2.A.53.2.1 in the transporter classification system (http://www-biology.ucsd.edu/~msaier/transport/titlepage2.html). Its overall structure, with 12 membrane-spanning domains (Fig. 2), is shared with two other human anion exchangers, PDS (a chloride-iodide transporter involved in Pendred syndrome; MIM 274600 [50]) and CLD (a chloride-bicarbonate exchanger, mutations in which are responsible for congenital chloride diarrhoea, MIM 214700 [51]; CLD was previously known as DRA, for "down-regulated in adenoma"), and there is significant amino acid homology between these three evolutionarily related anion exchangers (see the review by Everett and Green [52]). The function of the carboxyl terminal hydrophobic domain of DTDST is not known, but it has been observed that this domain shows homology to bacterial proteins known as antisigma-factor antagonists, which are kinase antagonists and themselves kinase substrates [53]. A similar cytoplasmic domain is present in CLS and PDS, and the name STAS domain (for sulfate transporter and anti-sigma factor antagonist) has been proposed [53]. If homology between the bacterial anti-sigma antagonists and the carboxyl terminal domain of these three transporters has functional relevance, it may indicate that phosphorylation is involved in regulation of anion exchange.

Northern blot analysis showed that DTDST is expressed in many tissues, but human cartilage was not studied (compare with rat DTDST expression, below). The size of the predominant mRNA species is >8 kb, indicating that there are significant untranslated sequences [48]. Some additional data on DTDST expression in the intestine have been obtained by *in situ* hybridization [54].

Following the characterization of human *DTDST*, rat and mouse homologues have been cloned. The rat gene has five exons with the coding sequence distributed in two exons separated by an intron positioned at the same position as

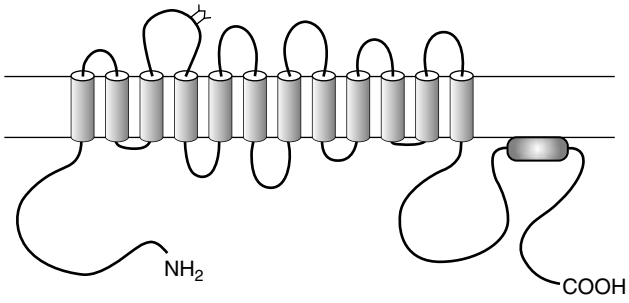

Figure 2. Schematic representation of the DTDST protein as deduced from the primary amino acid sequence (redrawn from [48]). The transporter is predicted to have 12 transmembrane domains and a moderately hydrophobic cytoplasmic domain near the carboxyl-terminus, which has been shown to be homologous to bacterial proteins known as antisigma-factor antagonists, and tentatively called the STAS domain [53] (and see text). This overall structure is shared by the two related anion exchangers, PDS and CLD [52].

in human *DTDST* [55]; the rat protein is composed of 739 amino acids like the human protein. Expression of *Dtdst* in rat is widespread, but highest in cartilage and intestine. Ion uptake and inhibition studies using *Xenopus* oocytes transfected with rat *Dtdst* mRNA confirmed its function as a sulfate/chloride exchanger [55]. A mouse cDNA orthologous to human *DTDST* was cloned during an effort to identify genes induced by bone morphogenetic protein (BMP)-2 and thus associated with osteoblastic differentiation [56,57]. The mouse protein also has 739 amino acids with 81% identity to human DTDST.

The Phosphoadenosine-Phosphosulfate Synthase Genes: *PAPSS1* and *PAPSS2*

Murine and human cDNA and genes coding for phosphoadenosine-phosphosulfate synthase (PAPSS; formerly, ATP sulfurylase-APS kinase) have been characterized by several groups [31–33,58]. Studies on the *Brachymorphic* mouse and on human spondylo-epi-metaphyseal dysplasia (SEMD; see below) have revealed that there are at least two PAPSS genes, *PAPSS1* (MIM 603262; GenBank accession number Y10387) and *PAPSS2* (MIM 603005; GenBank accession number AF091242), present in both mouse and man. *PAPSS1* is on human chromosome 4, while *PAPSS2* is on human chromosome 10 and mouse chromosome 19 [59,60] (to which the brachymorphic locus had earlier been mapped [61]). There are preliminary indications of different expression patterns of the two genes [59,60] (see below). The PAPSS1 protein (Swiss-Prot accession number O43252) and the PAPSS2 protein (Swiss-Prot accession number O95340) are highly homologous; they have two distinct domains, an amino-terminal domain containing the kinase activity, and a carboxyl terminal domain with sulfurylase activity. The mouse proteins (and genes) have a similar arrangement, while each domain has homologs in lower organisms, but the two activities reside on distinct peptides in those species (a detailed list of homologues can be retrieved at http://protein.toulouse.inra.fr/prodom.html). The human PAPSS2 protein has not been extensively characterized so far, unlike the mouse enzyme that has been studied in detail to elucidate the biochemical basis of the *Brachymorphic* mouse mutant (see below).

CLINICAL PHENOTYPES ASSOCIATED WITH DEFECTIVE SULFATION

The Skeletal Dysplasia Family Associated with *DTDST* Mutations

There are currently four distinct phenotypes associated with *DTDST* mutations: achondrogenesis type 1B (ACG1B), atelosteogenesis type 2 (AO2), diastrophic dysplasia (DTD), and recessively inherited multiple epiphyseal dysplasia (rMED). Division into these four categories is useful for differential diagnosis and prognosis but has no biological basis, as the spectrum of disease as judged by both clinical (Fig. 3) and radiological criteria (Fig. 4) is continuous. This phenotypic spectrum ranges from a severe disturbance in embryonic morphogenesis, as seen in achondrogenesis 1B, to such a relatively benign condition as multiple epiphyseal dysplasia. Genotype-phenotype correlations can be drawn, but it appears that the nature of the *DTDST* mutation is not the only factor in determining phenotypic severity. Phenotypic differences have been observed between unrelated and even first degree relatives with the same *DTDST* mutation [62].

Achondrogenesis Type 1B (ACG1B; MIM 600972)

Achondrogenesis is one of the most severe forms of chondrodysplasia in humans, invariably lethal before or shortly after birth. Exact figures of the incidence of achondrogenesis are not available, but it is not exceedingly rare. Reviews with large patient numbers have been published [63,64]. The name *achondrogenesis* (Greek for "not producing cartilage") was given in 1952 by Fraccaro to the condition he observed in a stillborn female with severe micromelia and marked histologic abnormalities of cartilage [65]. The condition described shortly thereafter and also designated achondrogenesis by Grebe [66] is different, although superficially similar to Fraccaro's achondrogenesis because of limb shortening, and has since become known as Grebe chondrodysplasia or Grebe syndrome (MIM 200700). In the 1970s, the heterogeneity of achondrogenesis was recognized. Through a combination of radiological and histologic criteria, achondrogenesis type 1 (ACG1) (then also called Fraccaro-Houston-Harris type or Parenti-Fraccaro type) and type II (ACG2) (called Langer-Saldino type) were distinguished [67,68]. In 1976, it was found that chondrocytes of some (though not all) ACG1 patients contained cytoplasmic inclusions [69]. In the late 1980s, ACG2 was shown to be caused by structural mutations in collagen II and thus represented the severe end of the spectrum of the collagen II chondrodysplasias [70–73] (see also Part II, this chapter). Borochowitz and colleagues [74] and van der Harten and colleagues [75] provided histologic criteria for the subdivision of ACG1 into 1A (with apparently normal cartilage matrix but inclusions in chondrocytes) and 1B (with abnormal cartilage matrix). Using these criteria, some cases from the earlier literature can be unequivocally diagnosed as type 1B, others as type 1A [76]. In 1994, before the *DTDST* gene had been cloned, biochemical evidence of a defect in sulfate metabolism in ACG1B was obtained. Cartilage extracts derived from a newborn with ACG1B were found to stain poorly with toluidine blue after gel electrophoresis, and cultured fibroblasts synthesized proteoglycans that could be marked with radiolabeled glycine or methionine but not with sulfate [77,78]. When pulsed with $^{35}SO_4^{2-}$, fibroblasts from the same patient failed to synthesize both APS and PAPS. The original interpretation as a sulfate activation defect [77,78] analogous to that seen in the *Brachymorphic* mouse (see below) proved to be wrong, as cocultivation studies with DTD fibroblasts, sulfate uptake studies, and, finally, *DTDST* mutation analysis showed that the primary defect in ACG1B was a sulfate uptake defect caused by *DTDST* mutations and, thus, that ACG1B and DTD were allelic disorders [76].

A fetus with ACG1B is frequently in breech position and is immediately perceived as abnormal at birth (Fig. 3A). There is abundant soft tissue relative to the short skeleton giving the infant a fat or hydropic appearance and there is disproportion between the head, which is of normal or near-normal size, and length, which is much shorter than normal. The face is flat, the neck short, and the soft tissue of the neck thickened. The thorax is narrow and the abdomen protuberant. Umbilical or inguinal herniae are frequent. The limbs are severely shortened. The fingers and toes are similarly short and stubby (an important difference from ACG2). The feet and toes are rotated inwardly in a fashion reminiscent of diastrophic dysplasia (see below). ACG1B infants may die before birth, for reasons which are not understood. Even when heart action is present at birth, respiratory insufficiency and death follow shortly.

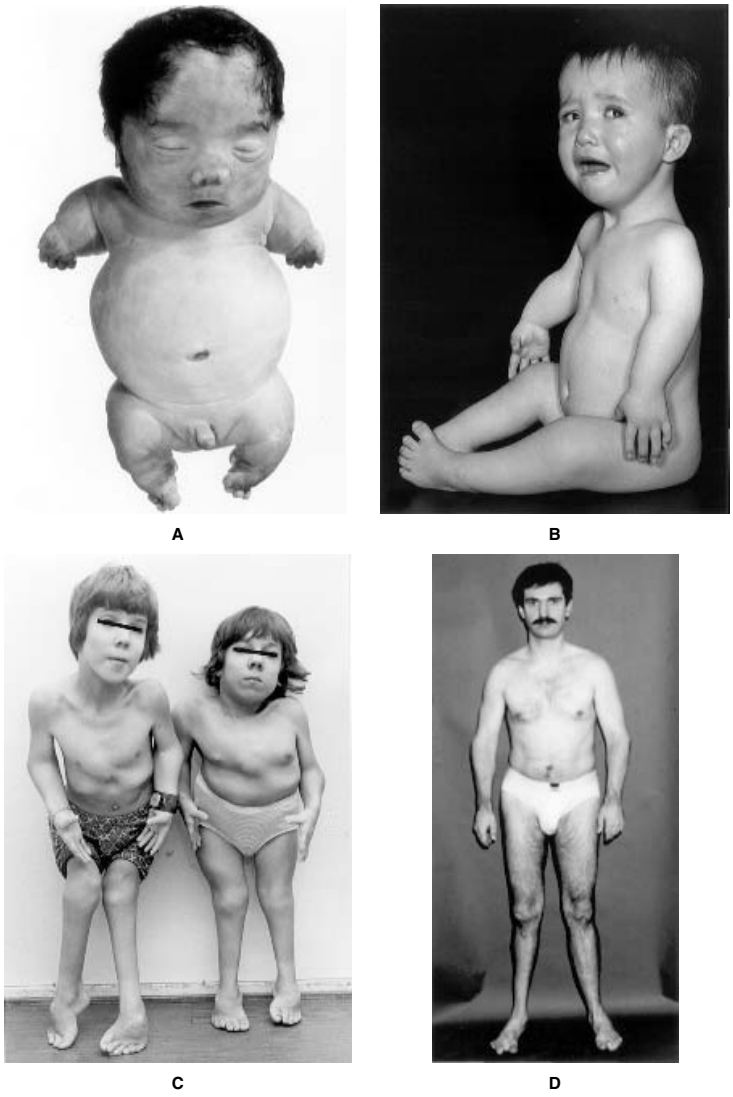

Figure 3. Clinical manifestations of DTDST skeletal dysplasias. **Panel A** shows a newborn with achondrogenesis type 1B, born at week 34, and deceased 25 minutes after birth. Note the flat face, narrow thorax with protuberant abdomen, and severe micromelia with short, stubby fingers and toes. This patient was homozygous for the DTDST *del*V340 mutation (reprinted from [78]) **Panel B** shows a two-and-a-half-year-old girl with diastrophic dysplasia; note the relatively short limbs, the contractures at the knees, and the adducted forefoot. **Panel C** shows a later stage of diastrophic dysplasia in a 14-year-old girl and her 11-year-old brother. Note the short stature and the following characteristic changes: equinovarus-adductus deformity of the feet, muscular hypoplasia of the legs and thighs, flexion contractures of the hips leading to anterior tilting of the pelvis and pronounced lumbar lordosis, limitation of elbow extension, stiff fingers, and the so-called ''hitchhiker'' thumbs. The patients, now adults, are physically handicapped but professionally active at academic level (reprinted from [147]; courtesy of Dr. I. Kaitila, Helsinki, with kind permission of the patients). **Panel D** shows an adult man with recessive MED; he has a tall-normal stature. Foot deformity and muscular hypoplasia are much less pronounced; mild finger deformities are also present (not evident in this photograph) (reprinted from [119]).

Differential diagnosis from other forms of achondrogenesis and other lethal chondrodysplasias requires analysis of radiographic features, histologic study of chondro-osseous tissue, and biochemical and molecular studies (reviewed in ref. [76]; and see below).

Atelosteogenesis Type 2 (AO2; MIM 256050[1]*)*

Sillence et al. [79] first applied this name in 1987 to a group of fetuses or newborns who had previously been considered to have severe DTD, but who had some skeletal features (e.g., a peculiar tapering of the distal humeri) that they considered similar to those seen in another, unrelated disorder, atelosteogenesis 1 (MIM 108720). Nine years later, biochemical studies and mutation analysis showed clearly that AO2 is indeed a severe form of diastrophic dysplasia [80], while AO1 is unrelated to DTDST mutations [81], and, thus, the name AO2 is misleading. It is true, though, that the gap between ACG1B and diastrophic dysplasia is so wide as to justify its occupation by an intermediate entity such as AO2. Newborns or fetuses with AO2 present with short limbs, the adducted feet

[1]The MIM entry is still entitled ''neonatal osseous dysplasia 1'', a confusing and obsolete title, which hopefully will be replaced soon.

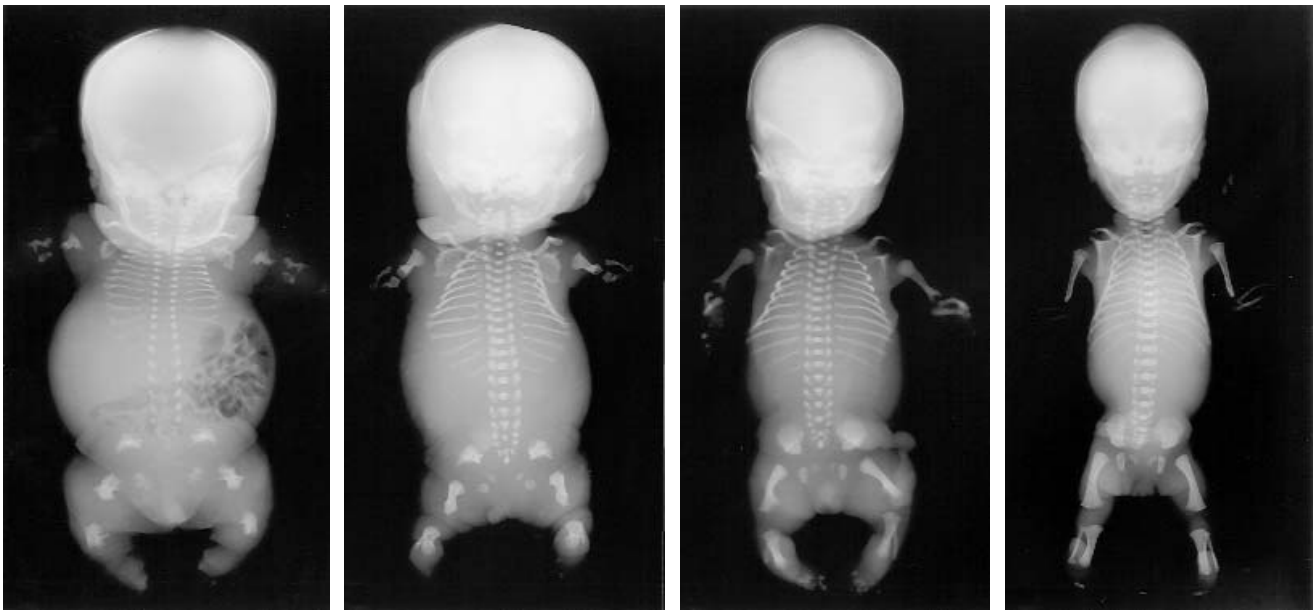

Figure 4. Skeletal morphogenesis is disturbed to different degrees in the DTDST skeletal dysplasia spectrum. The four radiographs of affected fetuses (gestational ages between 20 and 34 weeks) correspond to: achondrogenesis 1B (**panel A**); mild achondrogenesis 1B/severe atelosteogenesis 2 (**panel B**); mild AO2/severe diastrophic dysplasia (**panel C**); and mild diastrophic dysplasia (**panel D**). The gradient in severity can readily be appreciated by comparing the shapes of the femurs, as well as by comparing the lengths of the ribs to that of the spine or the clavicle (which is relatively unaffected because it undergoes desmal, rather than endochondral ossification). The forearms and hands cannot be recognized because of the relative overexposure. Note also narrowing of the interpeduncular space in the lumbar region.

with wide spacing between the hallux and second toe characteristic of ACG1B, and the"hitchhiker thumb" of DTD (see below). The disorder is usually lethal, although survival for several months has been reported. Several cases classified as "severe" or "lethal" DTD prior to 1987 would be diagnosed as AO2 today [82–84]. Radiologic features are similar to those of DTD, with tapering of the distal humerus, as observed with an AP projection radiograph, being more pronounced in AO2 (see Figs. 4B and 4C). Cartilage histology usually shows changes similar to those in DTD [85–87]. A familial, severe skeletal dysplasia known as "de la Chapelle dysplasia", or "neonatal osseous dysplasia 1," may be related to DTD and AO2 but formal proof is still lacking. It seems likely that some patients reported as having de la Chapelle dysplasia had AO2 [85], but the original patients may have had a similar but different disorder [88]. Yet another lethal chondrodysplasia, called McAlister dysplasia [89], appears to be identical to AO2 [90]. These uncertainties show how unreliable radiologic nosology may be without supporting histologic, biochemical and molecular data.

Diastrophic Dysplasia (DTD; MIM 222600)

This condition was one of the first skeletal dysplasias to be delineated clearly. It was described by Lamy and Maroteaux in 1960 as "bone anomalies that simulate achondroplasia during the first years of life but show a quite different evolution" [91]. The name diastrophic dwarfism refers to the "twisted" body shape of affected individuals [91]. DTD is a severe, though usually nonlethal, form of skeletal dysplasia with marked short stature (both the trunk and the limbs are shortened, but the limbs more severely so), bilateral clubfoot, cleft palate, characteristic hand deformities, changes of the ear pinnae, progressive kyphoscoliosis of the spine, and joint stiffness (see Figs. 3 B and C and 5).

The clinical features of DTD have been extensively reviewed [92,93]. The newborn with DTD has a normal-sized head, a slightly shortened trunk, and more markedly shortened extremities. There may be contractures at the hip, elbow, and knee joints. The fingers are short and the thumb is both proximally placed and deviated to the radial side (the so-called hitchhiker thumb). The metatarsals are usually adducted (the great toe stands out as a hitchhiker toe) and there is equinovarus deformity of the feet not dissimilar to that produced by primary neurologic disorders. The hitchhiker thumbs and toes have been observed as early as in the 15th and 16th weeks of pregnancy [94], (and unpublished observations), indicating an early developmental anomaly rather than a deformation. The face may be slightly flattened and the forehead may be broad, but these changes are not consistent in the newborn. Flat hemangiomas on the forehead are common.[2] In more than half of DTD newborns, a peculiar process affects the ear pinnae. Within the first weeks of life, the pinnae develop acute inflammation and swelling with fluctuation or cystic changes on palpation. The inflammation subsides within weeks, leaving thickened and sometimes deformed pinnae, which may eventually calcify [91,93]. When present, these changes are a valuable diagnostic

[2] The reason for this puzzling phenomenon is unknown; it suggests a link between sulfation and angiogenesis.

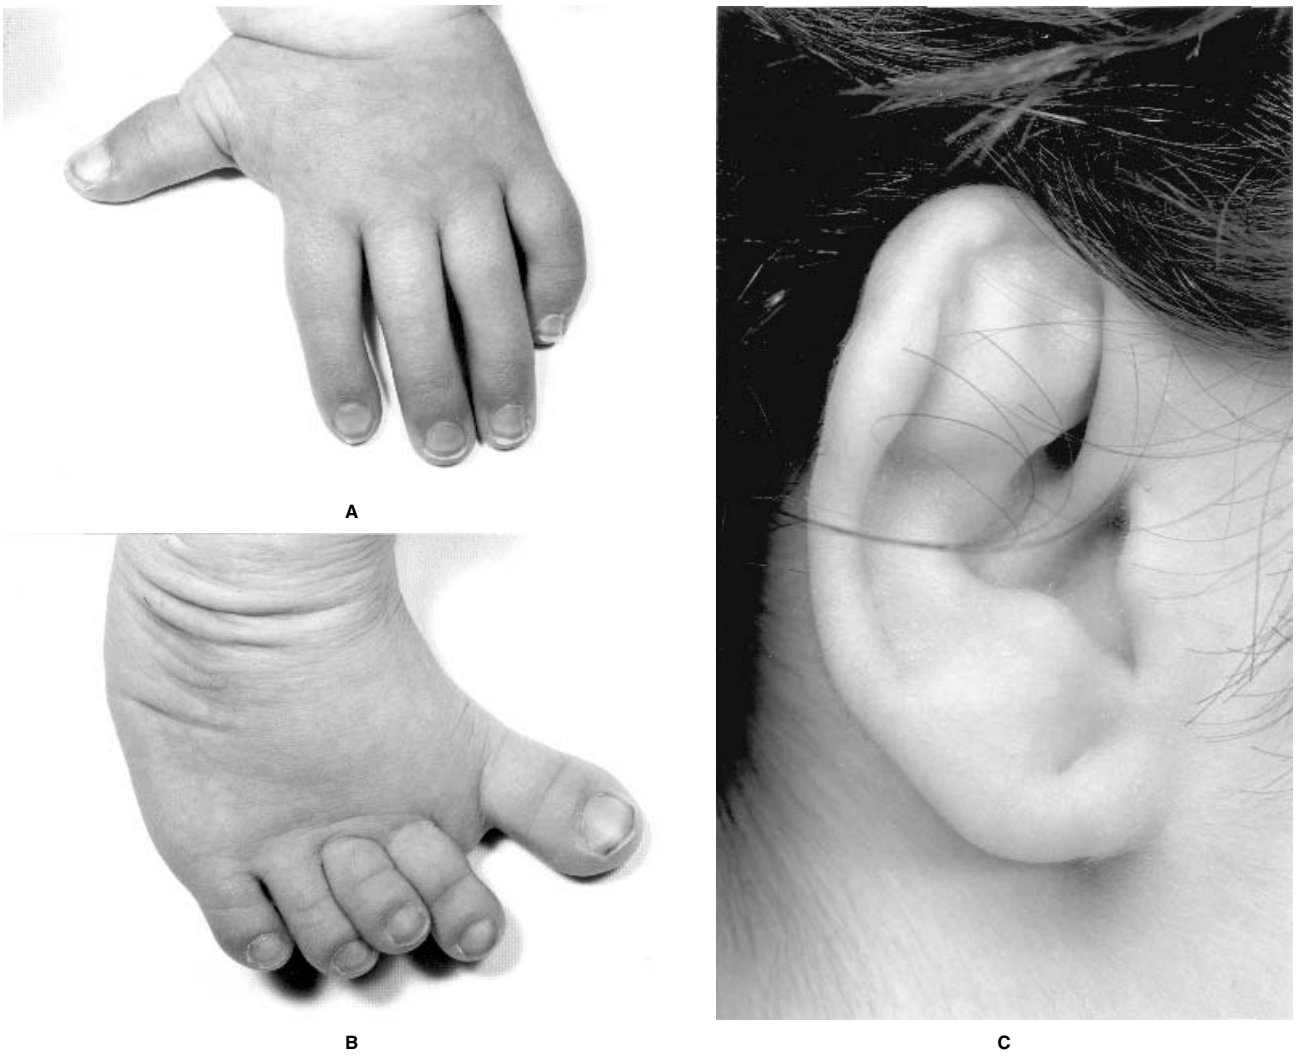

Figure 5. Accessory clinical signs in diastrophic dysplasia. Panels A and B show the hand and foot of the two-and-a-half year-old girl with DTD shown in Figure 3. The hand shows the so-called ''hitchhiker '' thumb deformity, which comprises both proximal insertion and radial deviation of the thumb. The foot shows adduction of the forefoot and wide spacing between the first and second toes; surgical release of the Achilles tendon had already been performed. The pathogenesis of these hand and foot changes, which can be seen as early as the 14th week of pregnancy, is not well understood. Their appearance suggests an increased traction of ligaments and tendons on the ventral aspect of the developing limbs; how this increased traction arises is not clear, but it may have to do with impaired growth (elongation) of tendons or with cell adhesion or proliferation. A pronounced ''hitchhiker'' thumb deformity is not pathognomonic (it can sometimes be seen in the Rubinstein-Taybi syndrome (MIM 180849)), but is highly suggestive of a DTDST skeletal dysplasia. The foot deformity often includes an abnormally short Achilles tendon leading to an *equinus* malposition (see the adolescent patients in Figure 3). The right panel shows the external ear of a 10 year-old girl with DTD. Following acute swelling and tenderness in the neonatal period, indurated nodules have developed. The pathogenesis of this phenomenon, which is pathognomonic for DTD, is not understood; among the possible triggers are changes between pre- and postnatal conditions such as plasma sulfate levels, temperature, and hydration.

clue; their pathogenesis is obscure, but may be related to the absence of an anticalcifying effect of some sulfated proteoglycans; precocious ossification of carpal bones, a double-layered patella, and duplication of sternal ossification centers (see below) may have a similar pathogenesis. Posterior palatal clefting occurs in approximately one-half of cases. Neonatal adaptation may be troubled by respiratory insufficiency because of the small rib cage and tracheal instability and collapsibility, and mechanical ventilation is required in a significant proportion of cases. Mortality in the first months of life is increased, mainly because of respiratory complications such as pneumonia, sometimes aspiration pneumonia [92,95].

The facial appearance of children and young adults with DTD, though not really dysmorphic, has some typical features (Fig. 3B). The forehead is high and broad; the palpebral fissures are relatively small and may be downwardly slanting; the nose is not shortened or stubby as in other chondrodysplasias, but, rather, long and thin because of hypoplastic *alae nasi*; the nares are not anteverted; the facial tissues are tight; the mouth is small, and the mandible normally developed.

Already in the newborn period, and throughout life, the disorder appears to involve not only the skeleton, but also the tendons, ligaments, and joint capsules. These are tighter and shorter than normal, causing restricted joint mobility. The pathogenesis of this ligamentous involvement is not understood; it looks as if growth of the tendons and joint capsules might be impaired[3]. Pretibial dimples may be present, possibly a consequence of reduced intrauterine movements. Because of foot deformities and shortened tendons, many adult individuals with DTD are unable to place their heels on the ground and thus stand solely on their metatarsals and toes. The appearance of an adult individual with classical DTD, who stands on his toes because of severe clubfoot and has marked lumbar lordosis and thoracic kyphoscoliosis (Fig. 3C), is quite typical; this appearance originally prompted the name "diastrophic" for twisted. Based on the characteristic body posture and hand changes, DTD has been diagnosed retrospectively in historical patients [96].

The skeletal changes of DTD are progressive. Degenerative arthrosis of the hip is common in young adults (pain and anterior tilting of the pelvis are the consequences), and the spine may develop excessive lumbar lordosis, thoracolumbar kyphosis, and scoliosis. In the lumbar spine, a decrease of the vertebral interpedicular distance is frequently observed, although it is not as marked as in achondroplasia; related neurological symptoms are only rarely observed (see below). The knee may be unstable in childhood but flexion contractures develop with progressive valgus deformity and lateral positioning of the patella [97]. The patella may be fragmented [97] (see also under recessive MED, below). In addition to brachydactyly, there may be ulnar deviation, phalangeal synostosis, and ankylosis of the finger, with significant disability. In older children and adults, ulnar deviation of the second finger frequently occurs together with radial deviation of the fifth finger (clinodactyly), giving a characteristic "bracket" appearance. Precocious calcification of carpal bones, simulating increased skeletal maturation, is quite common in childhood [98]. A characteristic metacarpophalangeal length pattern has been described [99]. Currarino has pointed to the peculiar double-layered ossification pattern of the sternum in DTD [100], which is reminiscent of the double-layered patella seen in recessive MED (see below). For details of the radiographic features of DTD, see [84,93,101].

In addition to the skeletal abnormalities, a mild degree of muscular hypoplasia of the thighs and legs is common. Neurologic complications may occur, particularly in the cervical region, probably owing to the vulnerability of the cervical spine in DTD and related disorders. Broadening of the cervical spine, with a characteristic "cobra-like" appearance, can often be seen on antero-posterior radiographs, and cervical kyphosis may be seen in lateral radiographs in most newborns; in most cases it ameliorates with age, but in some cases, severe cervical kyphosis may lead to spinal cord compression spontaneously and during intubation procedures [102–106]. Prenatally acquired neuronal degeneration and gliosis of the cervical spinal cord has been observed in a DTD infant with severe cervical kyphosis who died immediately after birth of respiratory insufficiency [82]. Cervical spina bifida occulta has been reported to be very frequent in DTD [102,107]. Newer MRI findings have confirmed that in DTD, the foramen magnum is of normal size but the cervical spinal canal is narrowed; the typical kyphosis may be the consequence of abnormal intervertebral disks [108].

Hearing loss is unusual, and vision defects are seldom observed, although a tendency towards myopia has been reported [109]. The absence of overt corneal changes is remarkable, considering the importance of keratan sulfate in maintaining corneal transparency; a higher affinity of PAPS for keratan-sulfotransferases rather than chondroitin-sulfotransferases may be the explanation. Mental development and intelligence are usually not affected.

Adult stature was found to range between 100 and 140 cm in an early review of American and European patients [93]. A 1982 study reported a mean adult height of 118 cm [110], while a more recent study of Finnish DTD patients (who are genetically homogeneous at the DTDST locus) gave a mean adult height of 136 cm for males and 129 cm for females [111]. Growth curves have been produced that can be used for monitoring of DTD patients [110,111]. The discrepancy in mean height between the older studies and the more recent Finnish study may be due to mutation heterogeneity but may also reflect bias towards more severely affected patients in the older studies.

Based on their experience with Finnish DTD individuals, the Helsinki group has reviewed selected clinical features of DTD such as cleft palate [112], anomalies of dentition [113], and changes in the spine [114], hip joint [115], knee [97], patello-femoral joint [116], and foot [117].

It has long been appreciated that the DTD phenotype may be more variable than in the patients originally described by Lamy and Maroteaux [91]. Affected infants dying in the perinatal period were previously diagnosed as having "severe DTD" but would now be assigned to the AO2 category (see above under AO2). Individuals with milder expression of DTD, particularly those having only mild statural deficit, were previously designated as "DTD variant," but subsequent studies have shown that the differences between classic DTD and so-called diastrophic variant are only quantitative [93] and the "death" of the DTD variant has been decreed [118]. Molecular studies have confirmed this pronouncement. In addition to interfamilial variability, several authors have observed marked differences between affected sibs [62,93,118]. These observations suggest that other genetic or epigenetic factors influence the phenotype.

Recessively Inherited Multiple Epiphyseal Dysplasia (rMED; MIM 226900)

This entity is a recent addition to the DTDST osteochondrodysplasia family. The first reported patient (Fig. 3D) had had clubfoot and hip dysplasia at birth, but no palatal clefting, hitchhiker thumb, or ear swelling, and had grown normally (adult height, 180 cm). He developed hip pain and digital deformations around puberty and was diagnosed as having MED with double-layered patellae [119]. He was shown to be homozygous (and each parent heterozygous) for the Arg279Trp allele (see below), and his fibroblasts exhibited a sulfate incorporation defect similar to that of other DTD patients [119]. The radiologic changes in the hips and the presence of clubfoot are reminiscent of DTD, but the absence of palatal clefting, ear deformity, and hitchhiker thumbs, and — most importantly — the tall-normal stature make the diagnosis of DTD (*nanisme diastrophique*) untenable and justify a separate entity. Patients with a similar form

[3]Perhaps the defective proteoglycan sulfation leads to abnormal packing of collagen fibers or to abnormal adhesiveness of fibroblasts to the extracellular matrix.

of recessively inherited multiple epiphyseal dysplasia have previously been reported [119], and grouped in the McKusick catalog under entry 226900. Following the identification of the patient mentioned above, several other patients who are homozygous or compound heterozygous for the Arg279Trp mutation and who have epiphyseal dysplasia and normal or only mildly short stature have been recognized [120]. In 12 individuals homozygous for DTDST mutation Arg279Trp, a diagnosis of skeletal dysplasia had been made at birth in 2 cases, and in childhood or adolescence in 10 cases. Abnormal findings at birth were present in four cases only (clubfoot in three, cleft palate in one); ear cysts and hitchhiker thumbs were not observed. Leading symptoms and signs were joint pain (8/12 cases), hand and/or foot deformities (4/12), scoliosis or joint contractures (each 1/12). Ten of the 12 cases suffered from chronic joint pain. Stature was below −2 SD for age in 0/2 prepubertal and 4/10 postpubertal patients. A double-layered patella had been observed in four of six patients for whom lateral knee films were available [120].

Diagnosis and Differential Diagnosis of DTDST Skeletal Dysplasias

The differential diagnosis of DTDST-associated chondrodysplasias is usually made within the context of other chondrodysplasias of similar severity and radiographic appearance. ACG1B should be differentiated from other types of achondrogenesis, fibrochondrogenesis, dyssegmental dysplasia, and even thanatophoric dysplasia, lethal osteogenesis imperfecta, and several other less well-defined conditions [76,121]. There are subtle radiographical signs suggesting the correct diagnosis, but cartilage histology and histochemistry can more reliably identify ACG1B, and the final diagnosis should rest on biochemical studies in fibroblast or chondrocyte cultures and on the identification of *DTDST* mutations. As prenatal recognition and pregnancy termination of fetuses affected by skeletal dysplasias (including ACG1B) is increasingly common, a protocol leading to precise diagnosis and thus allowing the provision of accurate genetic counseling is of great importance [76,122]. AO2 should be differentiated from other severe skeletal dysplasias as mentioned for achondrogenesis, and from other forms of atelosteogenesis [85–87,121]; as the disorder is usually lethal, the same considerations noted above for ACG1B apply. Most newborns with AO2 show foot deformities and "hitchhiker" thumbs, as seen in DTD. DTD is usually diagnosed through radiographic abnormalities and the presence of clinical abnormalities including cleft palate, clubfoot,"hitchhiker" thumb and first toes, and the development of painful swelling of the external ear cartilage days to weeks after birth. The latter signs are, however, not always present and their absence does not rule out DTD. Cartilage tissue is not routinely available from DTD patients; diagnostic confirmation can be obtained by analysis of sulfate uptake and incorporation in cultured fibroblasts or by mutation analysis (see below). Mutation analysis proved diagnostic in a DTD patient with unusual radiographic features (severe platyspondyly and broadening of the long bones) suggesting a different disorder [123].

In milder cases, the diagnosis may be difficult [62,119]. The association of clubfoot with skeletal changes suggestive of bone dysplasia, even in the absence of typical hand or ear changes or cleft palate, should alert the physician to the possibility of a DTDST disorder. The rare and still ill-defined condition known as"pseudodiastrophic dysplasia" (MIM 264180) [124] is distinguishable from true DTD by the absence of thumb and ear deformities and by differences in the radiographic changes. There is no DTDST defect in this disorder [125] (and unpublished results); pseudodiastrophic dysplasia may be related to the Desbuquois syndrome (MIM 251450), in which proximal placement and radial deviation of the thumb can be seen; interestingly, advanced bone age can also be seen in this disorder, as in DTD. A distinctive criterion is the presence of joint laxity in Desbuquois syndrome.

The biochemical diagnosis of a DTDST skeletal dysplasia can be made in fibroblast or chondrocyte cultures. When cells from ACG1B, AO2, DTD, or MED patients are incubated in culture medium containing $Na_2{}^{35}SO_4$, they exhibit a characteristic defect in the incorporation of $^{35}SO_4$ into macromolecules. ^{3}H-labeled glycine or glucosamine can be used to provide reference values [78,80,126]. Direct assay of sulfate uptake is technically difficult and thus less suitable for diagnostic purposes [24]. Mutation detection has been efficient, the *DTDST* gene being relatively small [127]. This provides an alternative to biochemical studies in those cases where no cell cultures are available. When the clinical and radiologic features are typical, mutations on both alleles can be found in over 90% of cases (see below); however, the occasional observation of patients with skeletal changes compatible with a DTDST disorder whose fibroblasts show a sulfate uptake defect, but in whom no mutation can be identified, points to the occurrence of pathogenic mutations in the noncoding parts of the *DTDST* gene that have not been explored so far [127].

Prenatal diagnosis of ACG1B, AO2, and DTD is frequently requested by families in which a previous child (or pregnancy) has been affected. When molecular studies are not available, ultrasonography may be used. Achondrogenesis can be recognized as early as weeks 13 to 15 [122,128], and AO2 and DTD a few weeks later [94,129,130]. DTD has been diagnosed (or excluded) by analysis of chromosome 5 markers linked to the disorder [131]. Identification of the mutations segregating in a given family has allowed direct prenatal diagnosis in several families at risk for ACG1B, AO2, and DTD [127]. The possibility of biochemical diagnosis by sulfate incorporation and/or uptake studies in chorionic villus biopsies or cells cultured from such biopsies has not been explored, but the need for such a diagnostic modality is limited when the molecular defects are known.

Approach to Management

The management of DTDST skeletal dysplasias depends on the time of diagnosis and on the severity of the condition itself. A frequent clinical setting is that of unexpected ultrasonographic recognition of severe fetal skeletal dysplasia *in utero*. When quite specific signs are present, such as a clearly recognizable 'hitchhiker' thumb and adducted feet, a mutation screening can be considered but will be time-consuming. Counseling of the parents regarding the probability of survival should be given on the basis of empirical evidence such as measurement of the chest and limbs. If a pregnancy is terminated or if the newborn is unable to survive, it is imperative to obtain materials for proper diagnosis—good X-rays, a source of DNA, a fibroblast culture, and cartilage for histology are minimum requirements.

Intubation may be required for respiratory distress in vital newborns affected by severe skeletal dysplasias such as AO2 and DTD. In some cases, intubation is transitory and may allow survival with reasonably good quality of life. In other cases, it may be impossible to wean the baby from the respirator and troublesome ethical concerns may arise [132].

Therefore, early decisions must be taken cautiously, and consultation with a skeletal dysplasia expert as soon as possible after birth (if not before) is recommended.

No medical treatment being available, the management of individuals with DTD or rMED must take into account orthopedic aspects on the one hand, and psychosocial, educational and professional issues on the other. Cleft palate is similar to that seen in collagen II disorders and can be treated by standard procedures [112], but great care must be taken in intubation procedures because of the potential instability of the cervical spine (see below). Treatment of the orthopedic complications of DTD is a major challenge. Casting for foot deformities is efficacious but burdened by a very high rate of recurrence (''recalcitrant'' clubfoot deformity [101]), so that surgical lengthening of the Achilles tendon and/or arthrodesis is the treatment of choice, to be performed at an appropriate age; casting may help to maintain the surgical results. Contractures at the knees and hips are difficult to treat even surgically; at those sites, physiotherapy may be the only option until painful arthrosis of the hips (caused by both the malposition of the femoral head because of the contractures and the intrinsic cartilage defect) and movement restriction will make hip joint replacement necessary (most commonly in the third or fourth decade [115,133]). Soft tissue release and tenotomies can then be combined with hip joint replacement.

The tendency to contractures makes the treatment of spinal deformity as difficult as that of lower limb deformity. Low-grade cervical kyphosis in newborns and infants is frequent, and in the majority of cases lessens with age without specific treatment [134], although in some cases, myelopathy may occur (see above). Severe thoracic kyphosis requiring surgical treatment is less frequent; combined anterior/posterior vertebral arthrodesis has been successful in one series of patients [135]. Thoracolumbar scoliosis is frequent, affecting at least 50% of DTD individuals. The spine is particularly rigid in DTD, perhaps because of the combination of stiff ligaments with abnormal vertebral disks [108]. The Helsinki team has been conservative, with only two patients operated on because of scoliosis in a series of over 100 DTD individuals [114]. These authors also cite the rare occurrence of lumbar spinal stenosis requiring laminectomy (narrowing of the spinal canal is a frequent finding in DTD; see above).

The psychological and social implications of musculoskeletal dysplasia in DTD are not unlike those seen in other skeletal conditions with short stature. These have been approached by the use of lifestyle questionnaires and health-related quality of life scores [136–143]. Areas where individuals with skeletal dysplasia have significantly lower scores include mobility, usual activities, sexual activity, marital adjustment, and physical discomfort and pain [136–143]. In addition, there are age-specific difficulties, mostly during the time of puberty, which include school and hobbies, friends, and physical appearance [142]. An open and direct approach to these problematic aspects may help the affected individual to develop coping strategies. Interestingly, it appears that unaffected individuals perceive these complications as more severe than affected individuals do; the capacity for adjustment in affected individuals is high.

The Spectrum of DTDST Mutations

Table 1 lists the *DTDST* mutations identified so far in patients and families with DTDST chondrodysplasias, including those reported previously [24,48,49,126,127]; Figure 6 shows their positions along the DTDST protein. Proof of pathogenicity has not been obtained, except for IVS1 + 2T > C and 418delT, which have been shown to cause reduced mRNA levels [49,144], and 1045–1047delGTT, which has been shown to abolish DTDST activity in a *Xenopus* oocyte model [145]. However, assumption of pathogenicity is justified in that some predict a truncated polypeptide chain, and others affect amino acids that are either in transmembrane

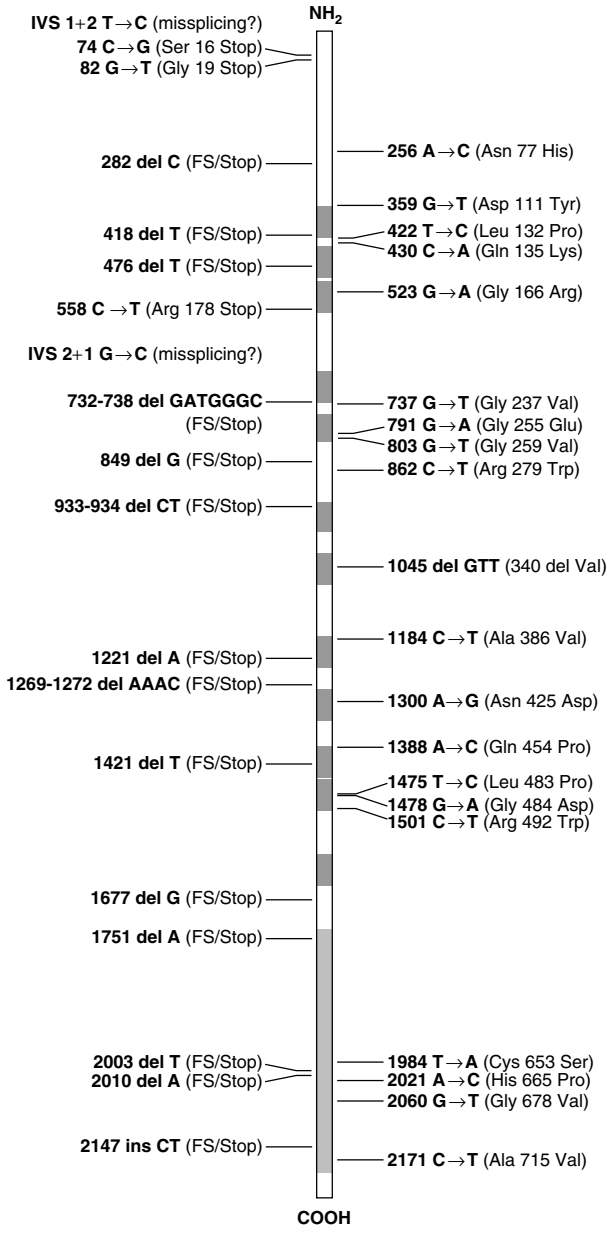

Figure 6. Overview of mutations observed in DTDST skeletal dysplasia patients. The DTDST protein is represented as a vertical bar; the 12 putative transmembrane domains are shaded dark gray; the 3′-cytoplasmic, hydrophobic, putative STAS domain is shaded light gray. Mutations inducing premature stop codons and splice-site mutations are shown on the **left**; on the **right** are mutations leading to amino acid substitutions or deletions of a single amino acid. Of the 20 mutations on the right side, 15 are located within transmembrane domains or the STAS domain (see text).

TABLE 1. Overview of Mutations in the *DTDST* gene

Nucleotide Change	Predicted Change at Protein Level	Associated Phenotype	Remarks	References
IVS1 + 2T > C	Interference with splicing?	DTD, AO2	"Finnish" mutation, giving reduced mRNA levels with intact coding sequence; severity dependent on compounding mutation	[49]
74C > G	S16X	DTD		[127]
82G > T	G19X	DTD		[127]
256A > C	N77H	DTD	Observed in a mild DTD variant; mouse and rat genes have serine at this position	[127]
282delC	FS/stop	DTD		[127]
359G > T	D111Y	DTD		[127]
418delT	FS/stop	AO2		[144]
422T > C	L132P	ACG1B	ACG1B "variant" with proximally pointed femurs	[127]
430C > A	Q135K	DTD		[127]
476delT	FS/stop	ACG1B		[126]
523G > A	G166R	DTD		[127]
558C > T	R178X	ACG1B, DTD	Multiple patients	[126]
IVS2 + 1G > C	Interference with splicing?	DTD	Multiple patients	[48]
732–738delGATGGGC	FS/stop	DTD		[127]
737G > T	G237V	rMED	Compounded with R279W in a rMED patient; not in transmembrane domain, possibly "mild" mutation	Freisinger, Superti-Furga and Bonafé, unpublished
791G > A	G255E	AO2, DTD	Multiple patients	[80]
803G > T	G259V	AO2	Multiple patients; in one case severe AO2, borderline to ACG1B	[127]
849delG	FS/stop	DTD	Compounded with C653S in a DTD patient	[157]
862C > T	R279W	AO2, DTD, rMED	Most frequent mutation outside Finland; probably recurrent; when homozygous, results in rMED	[80,119,144]
933–934del CT	FS/stop	DTD		[127]
1045–1047delGTT	V340del	ACG1B, DTD	Recurrent mutation (see text)	[49,126,145]
1184C > T	A386V	DTD	Homozygous in a patient with classic DTD	[127]
1221delA	FS/stop	ACG1B		[126]
1269–1272delAAAC	FS/stop	DTD		[127]

(*Continued Overleaf*)

TABLE 1. (*Continued*)

Nucleotide Change	Predicted Change at Protein Level	Associated Phenotype	Remarks	References
1300A > G	N425D	ACG1B, AO2	Recurrent mutation	[126]
1388A > C	Q454P	DTD	Nonlethal, severe variant DTD with broad bones	[123]
1421delT	FS/stop	DTD	Severe variant	[127]
1475T > C	L483P	ACG1B		[155]
1478G > A	G484D	DTD		[127]
1501C > T	R492W	DTD	Multiple patients	[127]
1677delG	FS/stop	DTD		[127]
1748C > T	T574I	DTD (?)	Observed as the only mutation in one patient, and in another patient who had two *other* mutations, never in controls –could be rare polymorphism	[127]
1751delA	FS/stop	ACG1B, AO2, DTD	Multiple patients	[48]
1984T > A	C653S	DTD, rMED	Multiple patients; observed in a rMED case, so probably relatively mild mutation	[127]
2003delT	FS/stop	DTD		[127]
2010delA	FS/stop	DTD		[48]
2021A > C	H665P	AO2		[127]
2060G > T	G678V	ACG1B	Rare	[126]
2092A > T	T689S	none	Neutral polymorphism (see text)	[48,145]
2147–2148 ins CT	FS/stop	DTD		[127]
2171C > T	A715V	AO2	Rare	[80]

Note: numbering of nucleotides and amino acids follows reference [48], while the numbering of exons has been revised after the discovery of a 5′ untranslated exon [49].

domains or are conserved in man, mouse, and rat (with the exception of Asn77His, where both mouse and rat have serine).

The 862*C* > T (Arg279Trp) mutation is the most common mutation in Caucasians, accounting for roughly one-third of alleles [127]; it is the second most frequent mutation in Finland, where approximately 90% of DTD alleles carry the so-called Finnish mutation (see below) [49]. The ethnic distribution observed so far for 862*C* > T would be compatible with a Central European origin, but its high frequency could also be explained by independent recurrences as it involves a CpG dinucleotide; indeed, arginine-to-tryptophan substitutions (caused by transition of the cytosine in the first position of the codon to thymine; CGG to TGG) are among the commonest mutations in human genes.

IVS1 + 2T > C, the so-called "Finnish" mutation which may be carried by as many as 1–2% of Finnish individuals, was identified only recently [49]. When it became clear that the Finnish mutation causes reduced mRNA levels [80] but does not reside within the coding sequence of *DTDST*, attention was directed at the flanking sequences. A previously unrecognized 5′ untranslated exon was recognized, and a point mutation at position +2 of the splice donor site was identified. Individuals homozygous for the IVS1 + 2T > C mutation have reduced (though not abolished) levels of mRNA with intact coding sequence [49,80]. Thus, the mutation presumably interferes with splicing and/or with further mRNA processing and transport, although no direct evidence for this has been obtained so far. In accordance with the probable "leakiness" of this mutation, homozygous individuals have diastrophic dysplasia.

The 1045-1047delGTT (del Val340) mutation has been observed in patients of Turkish [126], Hispanic [126], Japanese [145], British, French, and even Finnish [49] origin. This observation, and the occurrence of the mutation at a short direct triplet repeat, suggests it may be a recurrent mutation. This mutation has been shown to abolish DTDST activity in a *Xenopus* oocyte model [145]. Its observation in patients with ACG1B supports the notion that it abolishes transporter activity [126].

Mutation 558*C* > T (Arg178X) has been identified in patients from different ethnic origins and appears to be the fourth most common mutation [126]. Its occurrence at a CpG dinucleotide (again within an arginine codon) would be compatible with independent recurrence. It predicts a truncated protein, and its identification in a patient with ACG1B is again consistent with there being no residual activity of DTDST.

A mutant allele leading to a serine-threonine substitution, 2092*A* > T (Ser689Thr), has been observed [48]. The conservative nature of this substitution, the presence of a serine codon in the corresponding position of the mouse [56] and rat [55] genes, and the observation of the mutation in heterozygous and homozygous states in healthy individuals [49,145] (and J. Hästbacka and A. Superti-Furga, unpublished observations) all suggest it is a neutral polymorphism — the only common one observed so far in this gene.

The results of mutation analysis of affected individuals obtained so far [127] suggest that (i) most mutations are in the coding region and cause structural changes in the transporter, (ii) there is extensive allelic heterogeneity, with only a few common mutations, (iii) there is a paucity of polymorphisms at both genomic and protein levels, implying high selective pressure, and (iv) the high rate of mutation detection implies that there is no second locus producing skeletal dysplasias similar to the DTDST chondrodysplasias; the clinical and radiographic pattern is rather specific for *DTDST* mutations. Correlation of the clinical phenotypes with the underlying mutations suggests the following [119,120,127,146,147]: (i) homozygosity or compound heterozygosity for mutations predicting premature truncation of the protein or amino acid substitutions within transmembrane domains usually results in the more severe phenotype, ACG1B; (ii) amino acid substitutions within extracellular loops or within the N-terminal or C-terminal cytoplasmic domains may have less severe consequences for the transporter protein, and when compounded with a severe mutation can rescue the phenotype from ACG1B to AO2 or DTD; (iii) although originally identified in a patient with AO2 [80], the Arg279Trp allele is associated with non-lethal dysplasias, and produces mild DTD or MED when homozygous [119,120] (and unpublished observations).

Pathogenesis of DTDST Skeletal Dysplasias

Investigations into the pathology and pathogenesis of DTDST chondrodysplasias have focused almost exclusively on the skeletal system. The clinical phenotype points to an involvement of the tendons and joint capsules, but, unfortunately, no data are available yet for these tissues. There are at least two ways by which impairment of DTDST function might result in skeletal dysplasia. The first involves changes in the composition, architecture and mechanical properties of the extracellular matrix in cartilage; the second, still hypothetical, may involve secondary changes in the fibroblast growth factor (FGF) signaling pathway in chondrocytes, which is partly dependent on heparan sulfate proteoglycans.

Chemistry and Pathology of Cartilage. On dissection, ACG1B cartilage is brownish, translucent, and friable, rather than having the white, firm, and elastic nature of normal cartilage. Its consistency is similar to that of a cooked apple, and it can be easily cut through [76]. In this respect, it resembles cartilage from severe collagen II disorders such as ACG2 or Kniest dysplasia (see Part II, this chapter). Light microscopy of cartilage of patients with ACG1B, AO2, and DTD reveals marked changes. In the patient described by Fraccaro, the cartilage looked so different from normal cartilage tissue that the name "achondrogenesis," meant to signify failure of cartilage to differentiate properly, was coined ([65] and M. Fraccaro, personal communication). The changes are generalized in ACG1B, while in AO2 and DTD they may be less pronounced and — more importantly — highly abnormal areas, usually in the interterritorial matrix, may alternate with less severely disturbed areas around clusters of chondrocytes. There is a reduction in the volume of the extracellular matrix with a corresponding increase in cell density. There is a dearth of ground substance in the matrix, corresponding to the deficiency in sulfated proteoglycans, which leads to the"unmasking" of collagen fibers. These become abnormally coarse, and thus visible under the light microscope. In ACG1B, condensation of collagen fibrils around chondrocytes gives a "collagen ring" appearance [74,76,78] (Fig. 7). In DTD, the pericellular area may be spared and the changes confined to the matrix of the interterritorial area [82,148]. Secondarily, there is a disorganization of the growth-plate, the organized transition zone between cartilage and bone tissue where cartilage growth and bone calcification takes place. The coarse

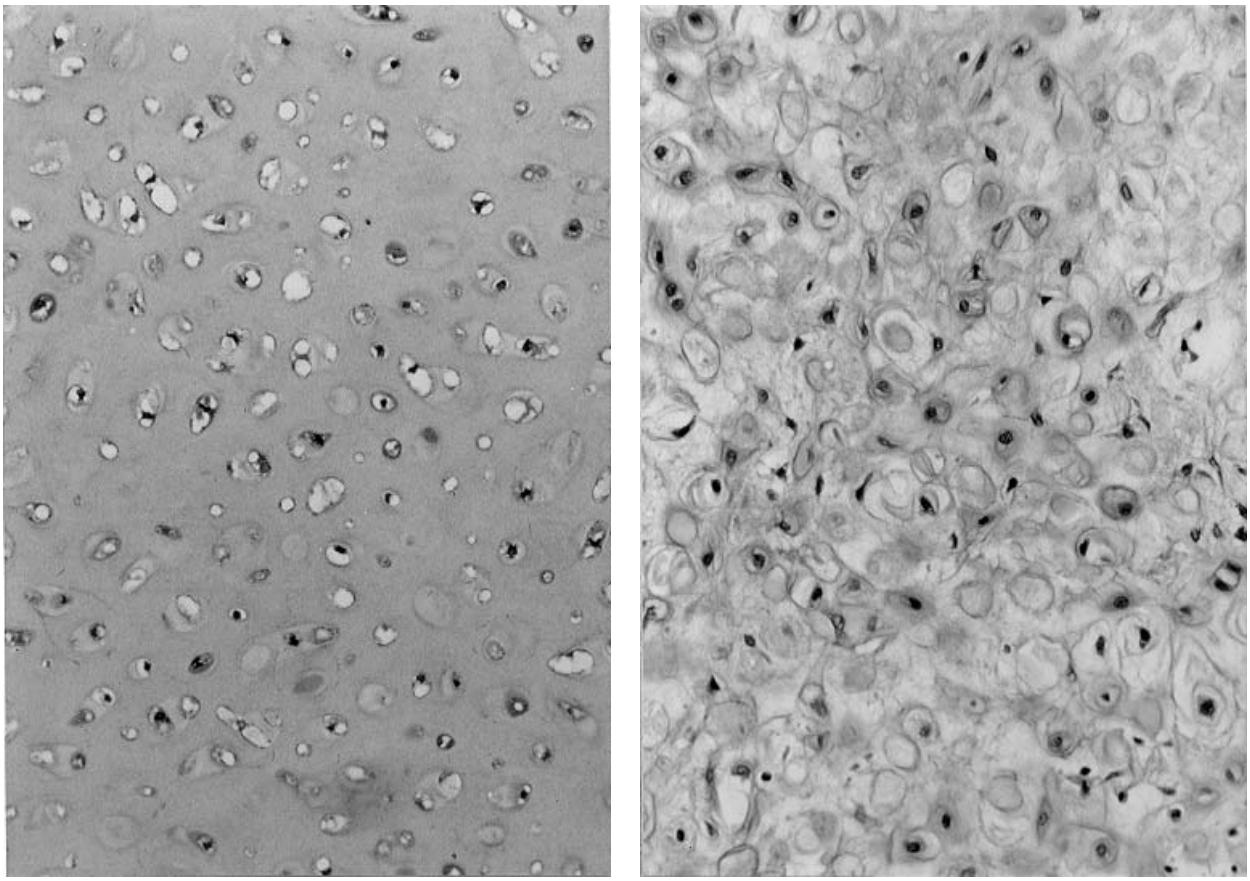

Figure 7. Microscopic appearance of cartilage from a control (**left**) and a newborn with ACG1B (**right**). In the control, the cartilage matrix is homogeneous and individual structures can barely be recognized, corresponding to a ground-glass appearance. In the patient's cartilage, the number of cells is increased. There is a lack of ground substance in the matrix, which leads to unmasking of the collagen fibres which can be accessed directly by the histological stain (visible at higher magnification only); the fibres are also larger than normal and tend to condense particularly around the chondrocytes (collagen ''rings''). [Haematoxylin and eosin staining, magnification approximately 150x] (Reprinted from [76]).

collagen fibers have led investigators on the false track of a collagen defect. An early report on a presumed structural abnormality of collagen II in DTD [149] was disproved by more accurate studies [150] and by exclusion of linkage to the *COL2A1* locus [151]. The observation of a structural anomaly of collagen IX in a DTD patient [152] might be explained by the fact that collagen IX carries a chondroitin sulfate chain and could thus be affected by undersulfation (see below).

Weak or absent metachromasia of cartilage tissue stained with cationic blue dyes such as toluidine or alcian blue is a consequence of the deficiency of sulfated proteoglycans [78]. Rimoin and colleagues, in 1974, studied DTD cartilage histology and suggested an''enzymatic deficiency in chondrocyte mucopolysaccharide metabolism'' [153]; Scheck et al. had reached similar conclusions [154]. Van der Harten studied ACG1B cartilage matrix by semiquantitative histochemical techniques, including pH-dependent staining with alcian blue, and postulated a ''specific defect in the synthesis of sulfated proteoglycans'' [75]. Proteoglycans extracted from ACG1B cartilage migrate more slowly on electrophoresis because of reduced negative charges and are poorly stained by cationic dyes [78,155]. The sulfate content of cartilage hydrolysate is markedly reduced in ACG1B [126] and moderately reduced in AO2 and DTD (A. Superti-Furga and I. Kaitila, unpublished results), while the glycosaminoglycan (GAG) content is only slightly reduced.

The disaccharide composition of cartilage proteoglycans in patients with ACG1B, AO2, and DTD has been studied: while nonsulfated disaccharides account for 2–10 percent of total disaccharides in controls, they range from 11 to 77% in patients (being lowest in DTD and highest in ACG1B) [24]. Chondrocytes from a patient with ACG1B synthesized GAG chains that were of normal length but markedly sulfate-deficient [155]. Thus, it has been proven that functional impairment of DTDST results in deficient sulfation of proteoglycans in cartilage. The mechanism by which the characteristic coarsening of collagen fibers is produced probably involves defective regulation of collagen fibril diameter by undersulfated proteoglycans on the surface of the collagen fibrils themselves [156].

The observation of significantly undersulfated proteoglycans in cartilage of patients with *DTDST* mutations implies that DTDST is a major sulfate transporter in chondrocytes.

The observation of high DTDST mRNA expression in rat cartilage [55] is compatible with this notion. It is not clear yet why cartilage is the only tissue showing overt changes in the presence of *DTDST* mutations, while other proteoglycan-rich tissues (e.g., cornea) do not show overt changes. One possibility is that other sulfate transporters may mediate sulfate uptake in other tissues and cell types; a second possibility is that each of the many cytosolic and endoplasmic sulfotransferases known has a different affinity for PAPS, whereby PAPS deficiency might affect some proteoglycans more than others; a third possibility is outlined below.

A further modulating factor in the phenotypic expression of *DTDST* mutations is sulfate production from the oxidation of cysteine (and perhaps other thiols). We have found that in spite of their defect in the incorporation of exogenous sulfate, patients' fibroblasts synthesize proteoglycans that are sulfated almost to the extent of those from control fibroblasts [24]. In some cell types, such as CHO cells [13] and mouse fibroblasts [23], intracellular sulfate may be derived from cysteine rather than taken up from the extracellular medium. Indeed, cysteine-derived sulfate is incorporated at highly increased rates in DTDST-mutant fibroblasts and chondrocytes *in vitro* [90,157]. Alternative sulfate-producing pathways probably explain the ability of patients' fibroblasts to achieve reasonably good sulfation in spite of the defect in sulfate uptake. It has not yet been shown that this occurs *in vivo* and thus may modulate the tissue-specificity of the phenotype. Chondrocytes, on the other hand, appear not to be able to rescue sulfation through this alternative pathway, perhaps because of a higher requirement, or because of the reduced availability of thiols in cartilage tissue which is largely avascular.

Proteoglycans and Fibroblast Growth Factor (FGF) Signalling. The notions that FGFs require heparan sulfate for efficient signal transmission [158], and that mutations in FGF receptors lead to abnormal skeletal development (Part IV, this chapter) have led to the hypothesis that malfunction of the FGF signaling pathways in chondrocytes may contribute to the development of skeletal dysplasia in the presence of *DTDST* mutations [48,159]. It has not yet been shown that heparan sulfate proteoglycans, which are less abundant than chondroitin sulfate proteoglycans and largely cell-associated rather than in the extracellular matrix, are undersulfated in DTDST dysplasias: the sulfotransferase for heparan has a lower K_M for the sulfate donor, PAPS, than does that for chondroitin, and therefore heparan sulfation may remain normal even when chondroitin sulfation is impaired [21,22]. Moreover, the functions of the various FGF/FGF receptor (FGFR) systems with respect to chondrocyte proliferation and differentiation are still incompletely understood. A mouse model in which the *FGFR3* gene had been disrupted was longer than control mice, rather than dwarfed [160]. Considering these uncertainties, the clinical significance of the recent observation of subnormal proliferative response to FGF stimulation by chondrocytes in which sulfation had been inhibited by treatment with chlorate [55] is uncertain.

Human Spondyloepimetaphyseal Dysplasia Associated with a Mutation in *PAPSS2 (ATPSK2)*

Ahmad et al. have described a large family from Pakistan in which a form of spondyloepimetaphyseal dysplasia (SEMD) segregates as a recessive trait [161]. The clinical phenotype includes short stature, short and bowed lower limbs with enlarged knee joints, kyphoscoliosis, and mild brachydactyly. Radiographs showed platyspondyly, delayed ossification of epiphyses, and osteoarthritic changes. Corneal changes were not reported (although slit-lamp examination was not performed), and intelligence was normal. Ahmad et al. found cosegregation of the disorder with chromosome 10q, in a region which is syntenic with the *Brachymorphic* locus on mouse chromosome 19 [60]. Two pairs of genes coding for ATP sulfurylase/APS kinase (now called PAPS synthetase; PAPSS) were isolated from homologous chromosomal regions in man and mouse, respectively; *ATPSK1 (PAPSS1)* was excluded as the locus for human SEMD and *Brachymorphic*, while a stop codon mutation in human *ATPSK2 (PAPSS2)* cosegregated with human SEMD [60], and a missense mutation in mouse *Atpsk2 (Papss2)*—the same mutation identified shortly earlier by Schwartz and her group [59](see below)—with *brachymorphic*. Why the clinical phenotype of ATPSK2 (PAPSS2) deficiency differs from that of the DTDST disorders is unknown at present.

Spondylar Dysplasia/Brachyolmia: Another Possible Defect in Proteoglycan Sulfation

In 1973, Mourao et al. described sibs with isolated, generalized platyspondyly (a condition also named "brachyolmia," short trunk) and reported that they excreted undersulfated chondroitin sulfate C in their urine [162]. In a later report on the same family, peripheral corneal opacities were noted [163], and in 1981, experiments with patients' serum were reported which suggested a defect in PAPS-chondroitin sulfotransferase [164]. Sewell et al. reported another patient with short stature and brachyolmia. When her urinary glycosaminoglycans were digested with chondroitinase, the resulting disaccharides showed an abnormal mobility on electrophoresis consistent with reduced sulfation [165]. A similar observation was reported (but not shown) in yet another patient [166]. Horton et al. reported three sibs with a recessive condition they designated as"brachyolmia, Hobaek type" which might be the same condition: no biochemical studies were done, but cartilage histology showed glycosaminoglycan deficiency and condensation of collagen fibers, findins that might well fit with a proteoglycan defect [167]. Shohat et al. reported patients with similar abnormalities, again without biochemical studies [168]. In summary, it is possible that one form of generalized platyspondyly exists that is associated with undersulfation of cartilage proteoglycans [169], but its biochemical and molecular basis remains to be characterized.

THE *BRACHYMORPHIC* MOUSE

Brachymorphic (*bm*) is a spontaneously occurring, recessively inherited mouse mutation described by Lane and Dickie in 1968 [170]. The phenotype of homozygous *bm/bm* mice becomes apparent a few days after birth and consists of a dome-shaped skull, and an abnormally short and thick tail. Their growth rate is retarded but adult weight is close to normal. The limb bones are shorter than in the normal mouse. The *bm* mouse has considerably stimulated research into proteoglycan and sulfate metabolism, and for a long time was the only model for abnormal PG synthesis. Orkin and coworkers first observed ultrastructural changes in cartilage suggestive of defective proteoglycan synthesis [171] and showed, by DEAE-cellulose chromatography and cellulose acetate electrophoresis of cartilage glycosaminoglycans, that chondroitin sulfate was undersulfated [172]. Incubating *bm* cartilage with different radiolabeled sulfate compounds, Schwartz and colleagues found that sulfate incorporation was

reduced when inorganic sulfate was provided, but normal when PAPS was used, and suggested that the defect might be impaired PAPS synthesis [173]. Sugahara and Schwartz went on to show that the activities of ATP sulfurylase (EC 2.7.7.4) and APS kinase (EC 2.7.1.25) were moderately and markedly reduced, respectively, in *brachymorphic* cartilage [174]. It was then shown that the biochemical defect was expressed in cartilage and liver but not in skin or brain [175–177]. Copurification of the two enzymatic activities from rat chondrosarcoma and mouse cartilage indicated that they resided in a single protein molecule, and it could be shown that the bifunctional enzyme from *bm* cartilage was defective in "channeling" the product of the first reaction (APS) to the second reaction [35]. The quest for the ATP sulfurylase/APS kinase gene yielded two closely related genes, termed *Atpsk1* and *Atpsk2*: their expression is tissue-specific and a mutation in the kinase domain of *Atpsk2* causes the *brachymorphic* phenotype [59]. Expression of the mutated ATPSK2 in liver (and possibly other tissues) probably explains the abnormalities in hepatic sulfate conjugation and blood clotting seen in *brachymorphic* mice [61,178]. It should be noted that the denominations "ATP sulfurylase" and "APS kinase" used in this paragraph for reasons of historical consistency, have recently been replaced by "PAPS synthase." This makes good sense for those organisms in which the two activities reside in a single polypeptide.

PERSPECTIVES

Insight into the biochemical and molecular basis of skeletal dysplasias associated with impaired sulfation of cartilage proteoglycans has highlighted the importance of proteoglycans in cartilage homeostasis and skeletal growth and development and, at the same time, revealed new aspects of sulfate metabolism. A comprehensive model of whole-body sulfate metabolism and the role of the different organs and tissues is still missing. The observation that fibroblasts of patients with *DTDST* mutations make extensive use of cysteine-derived sulfate would indicate a possible therapeutic avenue, but the task of delivering micro- to millimolar concentrations of thiols to the chondrocyte by the oral route appears impossible at present.

Cloning of the gene responsible for Pendred syndrome (MIM 274600) [179], a form of heritable deafness associated with thyroid gland dysfunction, has revealed homology with *DRA1*, a chloride transporter gene (mutations in which cause congenital chloride diarrhea [51], MIM 214700), and indirectly with DTDST, leading to speculation about its possible role as a sulfate transporter, but later evidence [50,52] suggests that pendredin is a chloride-iodide transporter.

Girard and his coworkers have identified a novel sulfate transporter molecule, called SUT-1, which is a sodium/sulfate cotransporter analogous (but not identical) to NaSi-1 of the renal tubule [11]. Both SUT-1 and DTDST are expressed in high endothelial venules [11]. The physiological role of SUT-1 remains to be determined. The same group has recently discovered that PAPS1 may be located in the cell nucleus under certain conditions [41]; this intriguing finding raises questions about sulfation processes in the nucleus and the role of nuclear glycosaminoglycans.

Genetic defects in one of several sulfotransferase activities [180] can be expected to produce clinical phenotypes, according to substrate specificity and tissue specific expression, including skeletal phenotypes. A genetic deficiency of the core protein of aggrecan, the major chondroitin-sulfate proteoglycan in cartilage, causes severe chondrodysplasia in chickens (*nanomelia*) [30] and mice (*cartilage matrix deficient*) [181]: the human counterpart remains to be identified. A further link between sulfate metabolism and skeletal development may be adduced from the role of sulfated proteoglycans in signalling pathways [182,183]: thus, a defect in heparan 2-sulfotransferase activity leads to a complex renal/ocular/skeletal malformation phenotype in mice [184]. A multitude of substrate-specific sulfotransferases exist, deficiencies of which may potentially have clinical consequences. It appears that the elucidation of sulfation processes and their associated biologic mechanisms and related clinical disorders is only just beginning and may yield more biologically and clinically relevant information.

RECENT DEVELOPMENTS

The Cellular Metabolism of Sulfate

Markovich has provided a masterly review on sulfate transport in mammals [185].

Recessively Inherited Multiple Epiphyseal Dysplasia and Clubfoot

Huber et al. [186] have described four individuals who were diagnosed as having "apparently isolated" clubfoot in infancy or childhood, with clinical and radiographic signs of multiple epiphyseal dysplasia becoming apparent only later. All were found to be homozygous for the *DTDST* Arg279Trp mutation. We had already reported a series of Arg279Trp homozygotes and emphasized that none had received a diagnosis of a skeletal dysplasia until late childhood or later [120]. Bonafé et al. [187] have tested a large population of families with idiopathic clubfoot, mainly of Hispanic origin, for *DTDST* mutations and found just one instance of heterozygosity for Arg279Trp. In summary, it appears that *DTDST* mutations can cause apparently isolated clubfoot but are probably a rare cause of it. Consequently, newborns and children with idiopathic clubfoot should be evaluated or followed up closely for the possibility that the clubfoot may be the presenting sign of recessive multiple epiphyseal dysplasia.

The Spectrum of *DTDST* Mutations and their Consequences

Karniski [188] has established a reporter system in *Xenopus* oocytes to assay the residual sulfate transport activity allowed for by a number of *DTDST* mutations. Though potentially useful to understand genotype-phenotype correlations, the results obtained with this system appear to be at odds with extensive observations with affected human subjects; e.g., the delVal340 mutation results in a high residual sulfate transport activity in the *Xenopus* system but is invariably associated with achondrogenesis 1B when homozygous in humans; four other mutations appeared to have no significant effect on sulfate transport in the *Xenopus* system in spite of their association with skeletal dysplasia in humans. One of the factors responsible for the discrepancy between the observations in the *Xenopus* system and the experience with affected individuals may be the fact that the *in vitro* experiments are performed at temperatures between 16°C and room temperature rather than at 37°C.

Chapter 23, Part IV

Craniosynostosis Syndromes and Skeletal Dysplasias Caused by Mutations in Fibroblast Growth Factor Receptor Genes

Clair A. Francomano and Maximilian Muenke

National Human Genome Research Institute, National Institutes of Health, Bethesda, Maryland 20892-1852

SUMMARY

- **The human skeletal dysplasias and craniosynostosis syndromes are a phenotypically diverse and genetically heterogeneous group of conditions associated with disordered bone growth. Mutations in three of the four known fibroblast growth factor receptor (FGFR) genes cause human disorders involving skeletal dysplasia and/or craniosynostosis.**
- **In this chapter, we consider the craniosynostosis syndromes and skeletal dysplasias caused by FGFR mutations. First, the biology of the FGFRs is presented. Subsequently, the clinical features and molecular etiology of each condition are described. Finally, we discuss the general principles that emerge from an overview of FGFR mutations and the conditions they cause.**
- **Craniosynostosis syndromes caused by FGFR mutations include Pfeiffer syndrome, Crouzon syndrome, Apert syndrome, Jackson-Weiss syndrome, Beare-Stevenson syndrome, Muenke syndrome, and Crouzon syndrome with acanthosis nigricans. The human skeletal dysplasias caused by FGFR mutations are members of the achondroplasia family of skeletal dysplasias. These include achondroplasia, hypochondroplasia, thanatophoric dysplasia, and severe achondroplasia with developmental delay and acanthosis nigricans (SADDAN).**
- **Pfeiffer syndrome is an autosomal dominant condition caused by mutations in *FGFR1* and *FGFR2*. Affected persons exhibit craniosynostosis, and broad thumbs and great toes. Type 1 (classical) has the most favorable prognosis and intelligence is normal. There is a higher risk of neurodevelopmental problems and a decreased life expectancy in types 2 and 3. A cloverleaf skull is seen in type 2, but not type 3.**
- **Crouzon syndrome is an autosomal dominant condition caused by mutations in *FGFR2*. It is characterized by coronal or multiple suture synostoses, shallow orbits, ocular proptosis and a beaked nose.**
- **Apert syndrome is characterized by brachycephaly, midface hypoplasia, broad thumbs and great toes, and symmetric syndactyly of the hands and feet. Two specific *FGFR2* mutations account for 99% of all cases.**
- **Achondroplasia is the most common of the human skeletal dysplasias. Primary skeletal features include rhizomelic short stature, megalencephaly, and spinal stenosis. More than 95% of cases are caused by one of two mutations at *FGFR3* nucleotide G1138, both resulting in Gly380Arg substitutions.**
- **The phenotypic and radiographic features of hypochondroplasia are similar to, but milder than, those of achondroplasia. Two common *FGFR3* mutations result in hypochondroplasia, but these account for less than 90% of cases. Several studies have suggested that hypochondroplasia may exhibit genetic heterogeneity.**
- **Thanatophoric dysplasia is the most common neonatally lethal form of human skeletal dysplasia. Type I is characterized by curved femurs and may or may not include a cloverleaf skull. Type II exhibits cloverleaf skull and straight femurs. A number of different *FGFR3* mutations have been found in type I, but only a single mutation, Lys650Glu, has been seen in type II.**
- **There is overlap between the skeletal dysplasia and craniosynostosis phenotypes. Some craniosynostosis syndromes show involvement of the appendicular skeleton, while some skeletal dysplasias show craniosynostosis. Acanthosis nigricans, a dermatologic condition characterized by hyperpigmentation and thickening of the skin, is consistently seen in SADDAN and Crouzon syndrome with acanthosis nigricans, and occasionally in the other members of the achondroplasia family of skeletal dysplasias.**
- **The pathophysiologic mechanism of action of all known FGFR mutations studied to date is that of gain of function. The mutations render the receptors constitutively active and relatively ligand-independent.**

Connective Tissue and Its Heritable Disorders, pages 961–991

GENERAL BIOLOGY OF THE FIBROBLAST GROWTH FACTOR RECEPTORS

In humans, the fibroblast growth factor receptors (FGFRs) comprise a family of four tyrosine kinase receptors (FGFR1–4) that bind fibroblast growth factors (FGFs) with variable affinity [1]. The FGF family of proteins consists of at least nine structurally related, heparin-binding polypeptides that play a key role in the growth and differentiation of various cells and tissues of mesenchymal and neuroectodermal origin [2–4]. FGFs are also implicated in chemotaxis, angiogenesis, apoptosis, and spatial patterning [5,6]. The prototypical FGF, FGF-2 (also called basic FGF), is a potent angiogenic protein, and stimulates smooth muscle cell growth, wound healing, and tissue repair. FGF-2 is thought to play a role in hematopoiesis and is also implicated in the differentiation and function of the skeleton, eye and nervous system [1,4].

The FGFRs have a highly conserved protein structure. The mature FGFR proteins are membrane-spanning tyrosine kinase receptors with an extracellular ligand-binding domain consisting of three immunoglobulin (Ig)-like domains, a transmembrane domain, and a split intracellular tyrosine kinase domain [1,7]. Between the first and second Ig domains is a stretch of 4 to 8 acidic amino acids, termed the "acid box." Alternative splicing in the FGFR genes results in at least 12 distinct isoforms for each gene [8–10]. Variants include those that lack one or more Ig-like domains, the acid box or the transmembrane domain. Some isoforms have a truncated carboxyl terminus, while others have regions of alternative sequence.

Ligand binding requires dimerization of two monomeric FGFRs and includes a heparin-binding step [5]. Promiscuous dimerization is observed; besides dimerizing with itself, FGFR1 may dimerize with FGFR2, 3, or 4 [7]. Similar dimerization combinations of other FGFR monomers are also possible. Differing combinations of dimers are observed in different tissues and stages of development, and this diversity of dimers probably plays an important role in skeletal differentiation.

The process of FGF binding involves contacts with both the IgII and IgIII domains. It is known that the relative importance of these contacts varies with different FGFs. Autophosphorylation of intracellular tyrosine residues results from binding of ligand to the receptor [11,12] and initiates the intracellular signalling cascade by activating intrinsic protein tyrosine kinase activity. This, in turn, leads to binding by the intracellular domain of proteins containing Src homology 2 (SH2) and phosphotyrosine-binding (PTB) domains [13] and subsequent activation of the RAS/mitogen-activated protein kinase (MAPK) pathway and phosphatidylinositol hydrolysis [14,15].

There is a high degree of homology among the four human genes encoding the FGFR monomers, each of which contains approximately 20 exons [16,17]. Among the human FGFRs, amino acid identity for the extracellular domain is 64–74% and for the kinase domain it is 72–85%. Sequence comparisons demonstrate that FGFR4 is the most highly diverged member of the family.

The *FGFR3* cDNA [18] is 4.4 kb in length and contains an open reading frame (ORF) of 2520 nucleotides encoding an 840 amino acid protein. A 3′-untranslated region of 1800 nucleotides, a consensus polyadenylation signal sequence, and a poly (A) tail follow the ORF. Both human and mouse FGFR3 genes have been characterized [19–21] and span 16.5 kb and 15 kb, respectively. Both genes consist of 19 exons and 18 introns and have translation initiation and termination sites located in exons 2 and 19, respectively. The 5′ flanking regions lack typical TATA and CAAT boxes. However, several Sp1, AP2, Zeste, Krox 24 and IgHC.4 putative *cis*-acting elements are present in the promoter region, which is contained within a CpG island [22]. The promoter regions of the human and mouse *FGFR3* genes are similar, with conservation of several putative transcription factor binding sites, suggesting an important role for these elements and their corresponding transcription factors in the regulation of *FGFR3* expression [21]. It has been shown that the 100 bp of sequence 5′ to the *FGFR3* initiation site is sufficient to confer a 20 to 40-fold increase in transcriptional activity [22]. There is an Sp1 binding enhancer element in intron 1 containing two purine rich elements, between nucleotides +340 and +395. *FGFR3* sequences between −220 and +609 are sufficient to promote tissue-specific expression [22].

At least three polymorphisms have been found within the *FGFR3* gene, in close proximity to the achondroplasia mutation site. These include a G to C transition toward the 5′ end of intron 9 that creates a *Pfl*MI site; a C to T transversion in intron 10 that creates a *Pml*I site, and a single G deletion in a stretch of 11 consecutive guanosine residues in intron 9. In one analysis of the frequency of the *Pfl*MI and *Pml*I polymorphisms in the general population, 10 of 224 chromosomes (4.5%) carried the *Pfl*MI polymorphism and 30 of 288 (10.4%) carried the *Pml*I polymorphism [23].

The FGFR genes are characterized by a complex array of alternative splicing. Alternative patterns of splicing include forms that lack the first Ig-like domain, soluble forms comprising the first one or two Ig-like domains only, and intracellular forms that lack the transmembrane domain [24,25]. One specific FGFR isoform, seen in FGFR1, FGFR2, and FGFR3, but not FGFR4 [9,16] is due to the presence of an alternative splice site found in the third Ig-like domain (closest to the membrane) and typically contains an alternative exon for this domain. The Ig-like domain 3 is encoded by two separate exons: exon IIIa encodes the amino-terminal part of the domain, while the carboxyl-terminal half is encoded by either exon IIIb or IIIc [8,9]. This latter form is of particular importance to the pathophysiology of the craniosynostosis syndromes.

The splice forms differ in their ligand affinity and preferential ligand binding, as well as in their tissue-specific expression. FGFR3 with exon IIIb has a high ligand specificity for acidic FGF/FGF-1 [9], and is expressed in mouse embryo, skin and epidermal keratinocytes [26]. The splice form of FGFR3 containing exon IIIc is detected in developing mouse brain and spinal cord, as well as in developing bone [27].

The developmental expression patterns of the various FGFR splice forms are highly complex [28,29]. In several instances, the expression of different FGFRs or alternative FGFR splice forms appears to be mutually exclusive, suggesting that switching of FGFR expression may play an important role in differentiation. The formation of heterodimers when different FGFRs are expressed simultaneously [7,11,30], as well as the availability of multiple alternative splice forms, compounds the complexity of the signaling pathways. The FGFR signal transduction pathway plays an important role in many different cellular processes, including differentiation, migration, mitogenesis, apoptosis, and pattern formation. Mice homozygous for null mutations of either *Fgfr1* or *Fgfr2* die very early in development, indicating that both FGFR1

and FGFR2 play crucial roles in early embryogenesis. Disruption of fetal development in the *Fgfr1* and *Fgfr2* null mice is attributable, respectively, to defects in mesodermal patterning [31,32] and trophectoderm function [33].

Developmental expression studies of Fgfr3 suggest that this protein plays a significant role in skeletal development. Outside the nervous system, the highest levels of *Fgfr3* expression are observed in cartilage rudiments of developing bone. During endochondral ossification, *Fgfr3* is expressed exclusively in resting cartilage [26]. In the mouse, *Fgfr3* has a unique pattern of expression during organogenesis. It is expressed in the germinal epithelium of the neural tube, and at 1 day post-partum and in the adult mouse and rat brain, is expressed diffusely [26,34].

Homozygosity for *Fgfr3* null mutations is compatible with life, but results in increased length of the long bones and vertebral column, as well as deafness [35,36]. Mice homozygous for *Fgfr4* null mutations are normal [33]. Mice heterozygous for any of the *Fgfr* null mutations are normal.

Analysis of chimeras and targeted insertion of specific mutant alleles by homologous recombination have been used to investigate the functions of *Fgfr1* and *Fgfr2* in later development of the mouse. Chimera analysis has shown that *Fgfr1* plays a role in migration through the primitive streak, with mutant cells demonstrating autonomous behavior [37,38]. Other mutations have revealed an important role for Fgfr1 in limb patterning [38,39] and for Fgfr2 in limb induction [40].

CRANIOSYNOSTOSIS SYNDROMES

Craniosynostosis is the premature fusion of one or several sutures of the calvaria leading to an abnormal shape of the skull. The major sutures of the calvaria include the coronal, lambdoid, and squamosal, all of which are paired (Fig. 1). The sagittal and metopic sutures are single

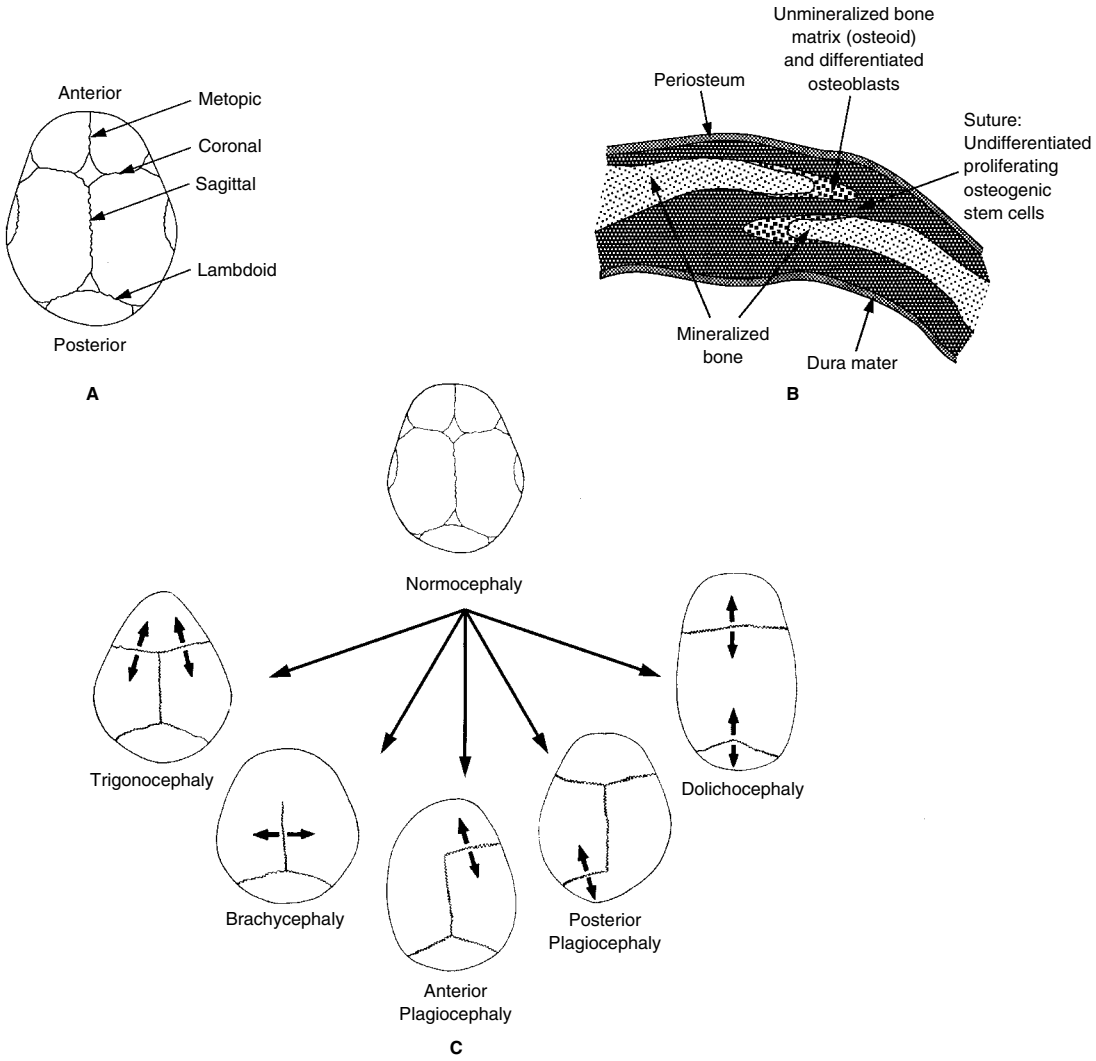

Figure 1. Diagram of the sutures of the skull **A:** Superior view of the normal infant skull. Note that the anterior fontanelle is bordered by the metopic, coronal, and sagittal sutures, the posterior fontanelle by the sagittal and lambdoid sutures. **B:** Cross-section through the coronal suture. The skull bones overlap slightly. In craniosynostosis, the narrow space separating the bones is obliterated. **C:** Premature fusion of the sutures leads to an abnormal head shape. Compensatory expansion (arrows) occurs, particularly at neighboring unfused sutures. (Reprinted from [235], by permission of McGraw-Hill Companies Inc.)

(Fig. 1A). At birth, these sutures are open and the nonmidline sutures overlap slightly (Fig. 1B). Depending on which of the sutures are fused prematurely, the skull can develop a characteristic shape. Simple synostosis of the coronal sutures leads to brachycephaly or short-headedness; variant head shapes include acrocephaly and oxycephaly (pointed head), or turricephaly (tower-shaped head). Unilateral coronal synostosis gives rise to anterior plagiocephaly which is associated with asymmetry of the face and skull (Fig. 1C). Dolichocephaly, or long-headedness, is seen in premature fusion of the sagittal suture. A variant is scaphocephaly (keel-shaped head). Trigonocephaly, or triangular-shaped head, results from premature closure of the metopic suture. Posterior plagiocephaly is due to unilateral fusion of the lambdoid suture. Compound synostosis, i.e., in which two or more sutures are involved, can lead to complex head shapes including cloverleaf (''Kleeblattschädel'') malformation [41].

Classification

Various classifications of craniosynostosis have been applied over the years. One system uses anatomic nomenclature dependent on which suture is involved. This descriptive classification is used in cases of isolated craniosynostosis which do not fit into any of the known craniosynostosis syndromes. A clinical classification based on the craniofacial findings, anomalies in other organ systems, and pedigree information has been used to describe well-known (''classical'') and rare monogenic craniosynostosis syndromes. Over 100 such syndromes are known [42]. The recent identification of mutations, especially in the FGFR genes, has provided new insight into the clinical classification.

Frequency

The most accurate surveys of the frequency of craniosynostosis among live-born infants suggest a prevalence of 1 in 2,100 to 1 in 3,000 [43–47]. The most common craniosynostosis syndromes include Apert (4.5%, of all cases with craniosynostosis), Saethre-Chotzen (4.5%), Crouzon (4.5%), and Muenke (8%) syndromes. Autosomal recessive craniosynostosis syndromes are rare. Craniofrontonasal syndrome is the most common X-linked craniosynostosis syndrome.

CRANIOSYNOSTOSIS SYNDROMES CAUSED BY FGFR MUTATIONS

Pfeiffer Syndrome

Pfeiffer syndrome (MIM 101600) was first described in 1964 [48] in a three-generation family demonstrating autosomal dominant inheritance. It is characterized by craniosynostosis, broad thumbs, and broad great toes. Numerous familial cases have been described since the original report [49,50]. Penetrance is complete; expressivity is variable. In addition to familial occurrence, sporadic cases due to new mutations are well known. These sporadic cases commonly have a more severe phenotype. The birth prevalence of Pfeiffer syndrome is not known; however, it is clearly less common than Apert, Crouzon, Muenke, or Saethre-Chotzen syndromes.

Clinical subtypes of Pfeiffer syndrome were proposed before the underlying etiology was known [49]. Classic Pfeiffer syndrome, or type 1, has the best prognosis and is compatible with a normal life span and normal intelligence in most cases. In contrast, Pfeiffer syndrome types 2 and 3 have a higher risk of neurodevelopmental problems and reduced life expectancy [51–53]. Both types 2 and 3 are almost always sporadic and the clinical findings are more severe, including severe ocular proptosis and elbow ankylosis. Type 2, but not type 3, has a cloverleaf skull. Exceptions with a more favorable outcome have been reported [54].

Linkage studies in families with Pfeiffer syndrome have demonstrated genetic heterogeneity. Loci on chromosomes 8p11.2 [55,56] and 10q25–q26 [57] correspond to mutations in the genes coding for fibroblast growth factor receptors 1 and 2 (*FGFR1*, *FGFR2*), respectively. Pfeiffer syndrome type 1 has been reported with mutations in *FGFR1* and *FGFR2*, whereas patients with types 2 and 3 have mutations in *FGFR2* only. Several large families initially considered to have findings consistent with Pfeiffer

Figure 2. Mild craniofacial and limb anomalies in Pfeiffer syndrome due to *FGFR1* mutation. Brachycephaly with hypertelorism. Partial cutaneous syndactyly of fingers and toes. Note broad, medially deviated great toes. (From Schell et al. [75]. Reprinted by permission of Brazilian Journal of Dysmorphology and Speech-Hearing Disorders.)

syndrome were excluded from either of these two regions but mapped to chromosome 4p16 and were later demonstrated to have Muenke syndrome [58,59].

Craniofacial features in Pfeiffer syndrome are variable and secondary to synostosis mostly involving the coronal sutures [60,61]. Findings include a turribrachycephalic skull, midface hypoplasia with relative mandibular prognathism, a beaked nose, a low nasal bridge, hypertelorism, downslanting palpebral fissures, ocular proptosis, strabismus, a highly arched palate, and crowded teeth (Figs. 2 and 3).

Intelligence is usually normal, although mental deficiency has been observed, particularly in sporadic cases. Rare central nervous system anomalies include large ventricles, hydrocephalus, Arnold-Chiari malformation, and seizures [62].

Anomalies of the hands and feet in Pfeiffer syndrome are distinctive and unique among the craniosynostosis syndromes [63–65]. Characteristically, the thumbs and great toes are broad and deviated away from the other digits (Figs. 2 and 3). However, the thumbs may be of normal width. Brachydactyly is often present, as is partial soft tissue syndactyly of the fingers and toes. Radiographic findings of the hands include malformed and fused phalanges of the thumbs, short middle phalanges (brachymesophalangy) of the second and fifth fingers with complete absence in severe cases, symphalangism (complete osseous fusion of proximal, middle, and distal phalanges which occurs over several years), and occasional fusion of the proximal ends of metacarpals 4 and 5. The distal phalanx of the great toe is broad, and the proximal phalanx is malformed. Broad and short first metatarsals and fusion of carpal and tarsal bones have been described (Figs. 4 and 5).

Additional manifestations may include cloverleaf skull (type 2 Pfeiffer syndrome), fusions of cervical and lumbar

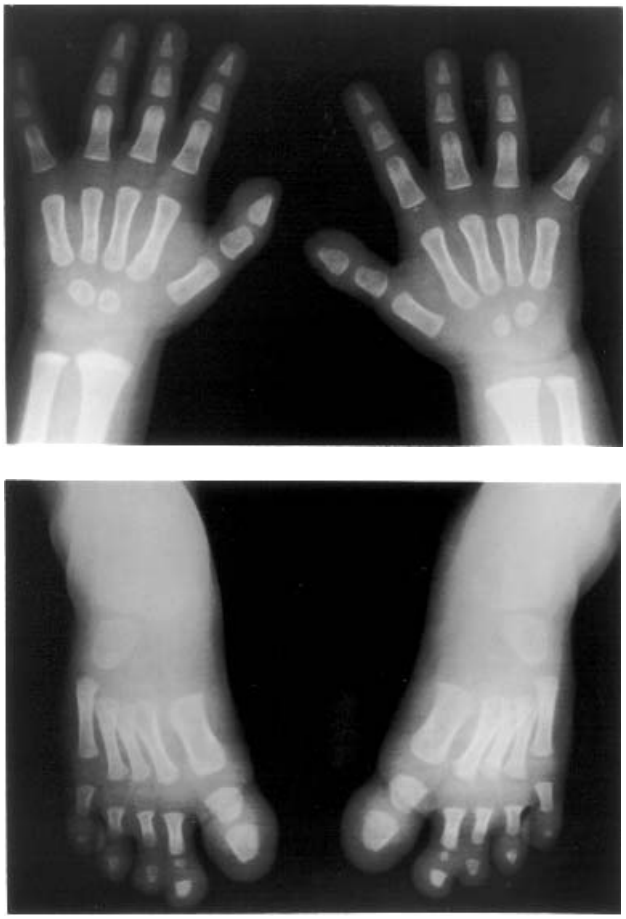

Figure 4. Radiographs of hands and feet in Pfeiffer syndrome with *FGFR1* mutation. Mild brachydactyly and mildly broad thumbs and broad medially deviated great toes. (From Muenke and Wilkie [235]. Reprinted by permission of McGraw-Hill Companies Inc.)

Figure 5. Radiographs of hands, elbow, and feet in sporadic Pfeiffer syndrome with *FGFR2* mutation. Brachydactyly of hands and feet. Abnormally broad proximal phalanges of thumb and great toe. Radioulnar and early humeroulnar fusion of elbow. (From Muenke and Wilkie [235]. Reprinted by permission of McGraw-Hill Companies Inc.)

vertebrae [61,66], cubitus valgus, synostosis of the radio-humeral and ulnar-humeral joints, a shortened humerus, abnormalities of the pelvis, coxa valga, and talipes equinovarus. Abnormalities affecting other organ systems are of low frequency and include hearing loss [67], optic nerve hypoplasia, iris coloboma [68], choanal stenosis/atresia, bifid uvula, tracheal stenosis [69], supernumerary teeth, gingival hypertrophy, widely spaced nipples, intestinal malrotation [70], anal atresia or malpositioned anus [71], pyloric stenosis, umbilical hernia, cryptorchidism, and bifid scrotum [72].

Pfeiffer Syndrome Caused by FGFR1 or FGFR2 Mutations

Prior to the finding that Pfeiffer syndrome is a genetically heterogeneous disorder linked to *FGFR1* on chromosome 8p11.2 and *FGFR2* on chromosome 10q25–q26 [56,57], it was considered one clinical entity. The majority of large families with Pfeiffer syndrome studied by linkage and mutation analysis could be assigned to either *FGFR1* or *FGFR2*. An *FGFR1* Pro252Arg mutation was identified in multiple affected individuals from unrelated families and in sporadic cases [55,57,73–76]. The phenotype in individuals with the *FGFR1* Pro252Arg mutation (Figs. 2 and 4), although somewhat variable even among affected members of the same family, is consistently milder than that of Pfeiffer syndrome due to *FGFR2* mutations.

Clinical findings in Pfeiffer syndrome due to *FGFR2* mutations are consistently more severe (Figs. 3 and 5). The original family [48] and a two-generation family with seven affected members [57] were linked to chromosome 10q25–q26 markers but no mutation was detected when *FGFR2* exons IIIa and IIIc (M. Muenke, unpublished results) were sequenced. These families presumably carry an *FGFR2* mutation outside the IIIa and IIIc exons. Pfeiffer syndrome families with known *FGFR2* exon IIIa and IIIc mutations have been reported [57,75,77–79]. The clinical findings in these families consist of the characteristic craniofacial and limb anomalies in "classic" Pfeiffer syndrome, which are more severe than those resulting from the *FGFR1* Pro252Arg mutation. All sporadic cases of Pfeiffer syndrome reported with severe clinical findings including cloverleaf skull [51,53,57,77,78,80–85] have had *FGFR2* mutations.

Apert Syndrome

Apert syndrome (MIM 101200) was first described in 1906 [86], since when there have been numerous clinical reports (for reviews see [87–92]). It is characterized by brachycephaly, midface hypoplasia, broad thumbs and great toes, and symmetric syndactyly of the hands and feet. The inheritance pattern is autosomal dominant in the few families with parent-to-child transmission. Germline mosaicism was proposed in an unaffected couple who had two children with Apert syndrome [93], although this has not been confirmed at the molecular level. The great majority (~98%) of Apert syndrome cases are sporadic. *De novo* occurrence has been clinically correlated with increased paternal age [94], and the exclusively paternal origin of new mutations has been demonstrated at a molecular level [95]. The birth prevalence of Apert syndrome, estimated as between 1 in 65,000 to 1 in 80,000 newborns, is high among the craniosynostosis syndromes (4.5% of all cases with craniosynostosis) [96,97].

Clinical findings in Apert syndrome tend to be more severe and to affect more organ systems than in many of the other common craniosynostosis syndromes. The skull malformations include turribrachycephaly with a disproportionately high cranium with frontal bossing and occasionally asymmetry. The anterior fontanelle is extremely wide open at birth, extending from the root of the nose to the posterior fontanelle. This midline calvarial defect does not close completely until the third year of life. Other anomalies of the skull include a malformed and often asymmetric cranial base and a very short anterior fossa.

Facial anomalies consist of hypertelorism with downslanting palpebral fissures and ocular proptosis. Strabismus is common, as are myopia, hyperopia, astigmatism, and dissociated eye movements [98]. The midface is hypoplastic with relative mandibular prognathism. The nasal bridge is depressed, the shape of the nose beaked. The palate can be highly arched, often with a median furrow or cleft of the soft palate, and the uvula may be bifid. Dental anomalies (malocclusion, delayed or ectopic eruption of teeth) are common [99]. Significant hearing loss is seen in some.

Central nervous system findings include anomalies of the corpus callosum, septum pellucidum, and limbic structures; hypoplasia of the cerebral white matter and heterotopic gray matter; megalencephaly; and/or ventriculomegaly [87]. Progressive hydrocephalus is present in only a minority of patients with ventriculomegaly [100]. Intelligence is variable and ranges from normal (40–50%) to mild or moderate mental retardation [101].

Hands and feet are syndactylous, characteristic for Apert syndrome, and the pattern differs from that seen in most of the other craniosynostosis syndromes [102–104]. In the hand, the central three digits are always syndactylous, with a broad thumb and part of the fifth finger separate (type 1 according to the classification of Upton [102]). In the "mitten-hand" deformity, the fifth finger is part of the syndactylous mass (type 2), and fusion of all digits ("rosebud") is seen in type 3. Syndactyly of the feet may involve the three lateral digits (type 1), digits 2–5 (type 2), or all digits (type 3). Fusion of digits is associated with fusion of the corresponding nails. Thumbs and great toes are broad and deviate away from the other digits. Incomplete postaxial polydactyly of the hands and preaxial polydactyly of the feet may be present [105,106]. Other limb anomalies include limited mobility at the glenohumeral joint which worsens with growth, moderate shortening of the humerus, and limitation of elbow extension [90]. Progressive synostosis of the bones in the hands, feet, and cervical spine is common. Fusions of the cervical vertebrae are present in 68% of patients with Apert syndrome, C5-C6 fusion being the most common [107].

Skin findings include acneiform eruption in more than 70% of patients. Other cutaneous manifestations are common and include hyperhidrosis, hyperkeratosis, hypopigmentation, nail infections, and skin dimples at the shoulders, elbows, and knuckles [91]. Low-frequency anomalies in the cardiovascular, respiratory, gastrointestinal, and genitourinary systems are reviewed elsewhere [89].

Apert Syndrome Shows Clinical and Allelic Heterogeneity

Two mutations in *FGFR2*, Ser252Trp and Pro253Arg, account for ~99% of Apert syndrome mutations elucidated to date, in a ratio of approximately 2:1 [108,109]. In one study, comparison of patients with the two different mutations showed a higher frequency of cleft palate and a tendency toward more severe craniofacial malformations with the Ser252Trp mutation, but more severe syndactyly with the Pro253Arg mutation [104]. This suggests that distinct molecular mechanisms are responsible for the craniofacial and limb abnormalities of Apert syndrome. Although a different study did not report significant correlations [110], this was based on a smaller sample size and there appeared to be a systematic bias in the classification of syndactyly [104].

Crouzon Syndrome

Crouzon syndrome (MIM 123500) was first described in 1912 [111] and there are numerous reports in the literature (for reviews see [112,113]). It is characterized by coronal or multiple suture synostosis with maxillary hypoplasia, a prominent beaked nose, shallow orbits, and ocular proptosis [100,114]. Crouzon syndrome has an autosomal dominant mode of inheritance, with high penetrance and moderate variability in clinical findings. Approximately half of all cases are familial, while the other half are new mutations with evidence of advanced paternal age. Crouzon syndrome is one of the most common craniosynostosis syndromes, with a birth prevalence of 1 in 65,000 newborns (approximately 4.5% of all craniosynostosis cases) [115].

Clinical findings include brachycephaly, scaphocephaly and trigonocephaly [116]. In one large family, the proband had a cloverleaf skull, several sibs had classic Crouzon syndrome, and several relatives had proptosis and midface hypoplasia without craniosynostosis [117]. Intelligence is usually normal. Seizures are infrequent. Brain anomalies (agenesis of the corpus callosum, for example) are rare, whereas progressive hydrocephalus is not uncommon and may be associated with herniation of the cerebellar tonsils [100,118,119]. Syringomyelia is a rare but important association [100].

Hypertelorism and external strabismus are common. Other ophthalmologic findings may include poor vision, optic atrophy, nystagmus, and exposure conjunctivitis and keratitis [120]. Mild to moderate hearing deficit is present in half of all cases. A hypoplastic maxilla and relative prognathism are common. Cervical spine fusions are also common (30%), mostly involving C2-C3 [121,122]. Calcification of the stylohyoid ligament occurs in 50% of patients [123]. Hands and feet are clinically normal, although minor differences are noted in metacarpophalangeal profile patterns [124–126]. Airway obstruction and visceral anomalies are rare compared with Apert and Pfeiffer syndromes [123,127].

Linkage studies have mapped Crouzon syndrome to chromosome 10q24–q25 [128], and numerous heterozygous mutations have been identified in *FGFR2*.

Crouzon Syndrome with Acanthosis Nigricans

Although Crouzon syndrome was first reported in 1912, Crouzon syndrome with acanthosis nigricans was not mentioned until 1948 [129]. Acanthosis nigricans is a dermatologic condition resulting in thickening of the skin with hyperpigmentation in the flexion creases of the thorax and limbs. With the identification of a consistent heterozygous mutation (Ala391Glu) in *FGFR3* [130–132], it has been recognized as a distinct clinical and molecular entity (MIM 134934.0011). Crouzon syndrome associated with acanthosis nigricans is rare. It is usually reported in females, with an early onset of skin findings including hyperpigmentation, hyperkeratosis, and melanocytic nevi. Verrucous hyperplasia develops predominantly in flexural areas such as the axillae, but also in the neck, face (perioral, periorbital, and nasolabial areas), chest, and abdomen. Craniofacial anomalies are similar to those in Crouzon syndrome itself, and include brachycephaly due to coronal synostosis, hypertelorism, downslanting of the palpebral fissures, and ocular proptosis. Additional anomalies have been described in some patients: choanal atresia, cemental dysplasia of both jaws (cementomas), hydrocephalus, hypoplasia of the foramen magnum, scoliosis, and spinal stenosis with paresthesia of the lower limbs.

Muenke Syndrome

Muenke syndrome (MIM 134934.0014 and 602849; also called Muenke craniosynostosis or *FGFR3*-associated coronal synostosis) was first described in 1996 in sporadic cases and autosomal dominant families with a unique point mutation in *FGFR3* (Pro250Arg) [58,59]. Penetrance is incomplete. The phenotypic spectrum is so variable that patients with this specific mutation had previously been diagnosed variously as having Pfeiffer, Saethre-Chotzen, or Crouzon

Figure 6. Craniofacial and limb anomalies in Muenke syndrome. Note symmetric facial appearance due to bicoronal synostosis (**upper panels**) and plagiocephaly due to unilateral coronal synostosis (**middle panels**). Mild brachydactyly of hands and feet (**lower panels**). (Reprinted from Muenke et al. [59], by permission of American Journal of Human Genetics.)

syndrome [58,59,133–136], as well as Jackson-Weiss syndrome [137] (below), Adelaide-type craniosynostosis (MIM 600593) [138], Ventruto syndrome (MIM 134934) [139], nonsyndromic craniosynostosis [58,59] or brachydactyly-associated craniosynostosis [140,141].

The birth prevalence of Muenke syndrome has not been accurately determined, but a figure of 1 in 30,000 is suggested by one study [141]. The mutation associated with this syndrome is common in sporadic or familial patients with uni- or bicoronal synostosis whose findings do not fit into any of the classic craniosynostosis syndromes. The mutation rate is estimated to be one of the highest in the human genome and comparable to that of achondroplasia (1138G>A in *FGFR3*, see below) and Apert syndrome (755C > G in *FGFR2*) [141].

Clinical findings observed in over 60 patients from more than 20 unrelated families include bi- or unicoronal synostosis (67% of cases), midface hypoplasia (59%),

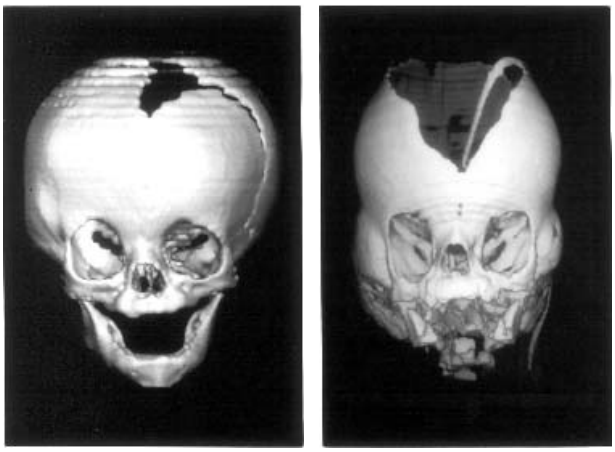

Figure 7. Three-dimensional CT scans in craniosynostosis syndromes. Plagiocephaly with facial asymmetry in a newborn with Muenke syndrome due to right unicoronal and metopic suture fusion (**left**). Severe synostosis of multiple sutures leading to cloverleaf skull and an extremely wide open fontanelle in a newborn with sporadic Pfeiffer syndrome and an *FGFR2* (Ser351Cys) mutation (**right**). (From Muenke and Wilkie [235]. Reprinted by permission of McGraw-Hill Companies Inc.)

downslanting palpebral fissures (50%), and ptosis (27%) (Fig. 6) [59]. In cases with bicoronal synostosis, bulging of the temporal fossae may give a wide-faced appearance [142]. However, it is of note that some mutation carriers do not show any signs of craniosynostosis, having only macrocephaly (6%) or even a normal head size [59,143,144]. In a prospective study, the Pro250Arg *FGFR3* mutation was identified in 4 of 37 individuals with unicoronal synostosis only, some cases of which had previously been attributed to intrauterine constraint [143]. Anterior plagiocephaly has also been described [134,141] (Fig. 7).

Sensorineural hearing loss is seen in 37% of cases, as is developmental delay. Mental retardation was noted in 4 of 9 patients with the Pro250Arg *FGFR3* mutation [134]. The extreme phenotypic variability is emphasized by a five-generation family in which the Pro250Arg mutation in *FGFR3* segregates with moderate congenital bilateral sensorineural deafness and low penetrance of craniosynostosis [145]. A greater severity of phenotype in females than males was suggested [142].

Hand anomalies are found in some, but not all, affected individuals [59] and include brachydactyly (30% of cases) and clinodactyly (42%) with characteristic radiographic findings, such as thimble-like middle phalanges (60%), coned epiphyses (75%), and carpal fusions (13%) (Fig. 8). Some patients (26%) have broad halluces that are not deviated. Radiological findings in the feet include short, broad middle phalanges (13%); coned epiphyses (86%); and calcaneocuboid fusions (35%). Height is normal, in contrast to the FGFR3-associated dwarfism syndromes.

Jackson-Weiss Syndrome

Jackson-Weiss syndrome (MIM 123150) was first reported in 1976 [146] in a large Amish kindred, in which 88 affected individuals were directly examined and another 50 reliably reported to be affected. Inheritance was autosomal dominant with high penetrance and variable expression. The syndrome is characterized by craniosynostosis with midface hypoplasia,

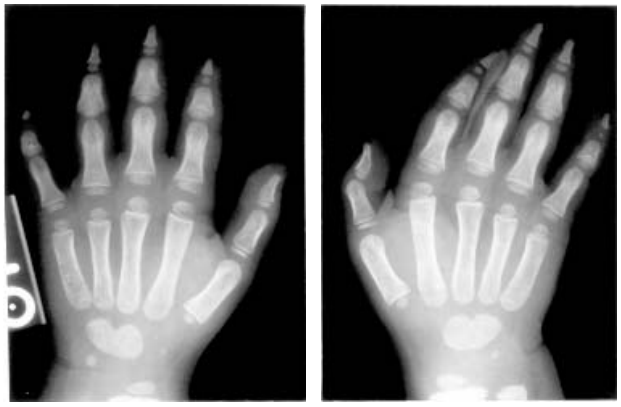

Figure 8. Radiographs of hands in Muenke syndrome. Brachydactyly with short thimble-like middle phalanges of the second through fifth fingers and fusion of the capitate and hamate bones of the wrists. (From Muenke and Wilkie [235]. Reprinted by permission of McGraw-Hill Companies Inc.)

frontal prominence, and foot anomalies with various cutaneous syndactylies and varying degrees of medially deviated and enlarged great toes. Thumbs were normal in all cases except one with fusion of the phalanges, and only one individual was reported with webbing of the fingers. Some affected individuals had no craniofacial anomalies on clinical and radiographic examination. Intelligence was normal. The variability of clinical findings was so marked that, with the exception of Apert syndrome, the entire spectrum of acrocephalosyndactylies was seen in the reported family [146]. Because of the lack of thumb anomalies in Jackson-Weiss syndrome, several families with craniosynostosis and foot anomalies were initially assigned this diagnosis [137,140] but were later found to have mutations in *FGFR1* and *FGFR3*, respectively, and not the *FGFR2* Ala344Gly alteration identified in the original family [147]. There is also overlap between the Jackson-Weiss phenotype and phenotypes associated with different mutations of *FGFR2*, leading to further confusion. In the opinion of the present authors, the diagnosis of Jackson-Weiss syndrome in sporadic cases or small families is likely to cause more confusion than enlightenment. We therefore propose that the designation Jackson-Weiss syndrome be reserved for the original large family, until a new nomenclature for the acrocephalosyndactylies, combining clinical and molecular data, has been agreed upon.

Beare-Stevenson Syndrome

Beare-Stevenson syndrome or the cutis gyrata syndrome of Beare and Stevenson (MIM 123790) was first described in 1969 [148]. It is a rare, lethal, sporadic condition for which there is a total of only 9 published cases [148–154]. Characteristic clinical findings include corrugated skin furrows (cutis gyrata) affecting the scalp, forehead, face, neck, trunk, hands and feet, and acanthosis nigricans. Other skin anomalies include skin tags and an enlarged umbilical stump. Craniosynostosis can be severe, and was present in four of six cases, with cloverleaf skull occurring in three of these [42]. Additional findings in some cases include hypertelorism, a broad nasal bridge, ear defects, cleft palate, hypodontia, choanal atresia, bifid scrotum, anogenital anomalies, and coccygeal eversion.

All reported cases have been sporadic, with an increased paternal age in some. Heterozygous mutations of *FGFR2*, Ser372Cys and Tyr375Cys, have been described, whereas some patients did not have mutations in these regions, suggesting further genetic heterogeneity [153,154].

SKELETAL DYSPLASIAS CAUSED BY *FGFR3* MUTATIONS

All four phenotypes in the achondroplasia family of skeletal dysplasias (achondroplasia, hypochondroplasia, thanatophoric dysplasia and SADDAN) are inherited as autosomal dominant conditions caused by mutations in the *FGFR3* gene on human chromosome 4p16.3. In all of these conditions, penetrance is complete. The majority of cases occur as a result of new mutations.

Achondroplasia

The phenotype of achondroplasia (MIM 100800) may be somewhat subtle in the newborn, but the astute clinician will recognize the relatively short limbs and macrocephaly with frontal bossing and mid-face hypoplasia [155]. The limbs are more notably short in the proximal segment, although the entire limb is short; this is called "rhizomelic" dwarfism. Other features of the limbs include limitation of elbow extension and the so-called "trident hand," in which there is a distinct space between the distal phalanges of the third and fourth digits. Hyperextensibility of the knees and hips is common. A thoracic gibbus may be present at birth and usually resolves spontaneously, coincident with the development of improved muscle tone and the commencement of independent sitting. The expected height for an adult with achondroplasia is 45 to 55 inches (Fig. 9). The growth curves for head circumference (Fig. 10) overlap with those for unaffected children, but true megalencephaly is often present. There is an increased risk of intracranial bleeding during vaginal delivery [156].

The affected newborn is often hypotonic, but muscle tone usually improves during the first and second years of life. One consequence of the low muscle tone during infancy is a delay in the development of motor milestones. Typically, intelligence is normal [157].

Radiographic abnormalities include caudad narrowing of the vertebral interpedicular distance and a notch-like sacroiliac groove in the pelvis. The long bones are short and relatively wide, as are the tarsal and metatarsal bones and all of the phalanges [158,159] (Fig. 11).

The age-specific mortality for achondroplasia is relatively high in the first four years of life, approaching 7.5% in the first year and 2.5% in years 1 to 4 [160]. The mortality curves approach those of unaffected children in later childhood, adolescence and early adulthood, but climb again at the end of the fourth decade [160]. The cause of this increase in age-specific mortality in mid-adulthood is unknown.

Relatively small ear canals often lead to poor drainage and result in frequent episodes of otitis media. These may result in compromised hearing if not recognized and treated appropriately in early childhood.

Neurologic complications may arise from a relatively small foramen magnum present in the newborn period in almost all children with achondroplasia. Compression of the cervico-medullary junction by a small foramen magnum may result in generalized hypotonia, hyperreflexia or clonus, and/or central hypopnea or central apnea [161]. The increased mortality rate in young children is attributable to foramen magnum stenosis. Surgical decompression of

a compromised cervico-medullary junction by a surgeon experienced in the procedure has a high probability of improving neurologic function [162]. Hydrocephalus may result from stenosis of the sigmoid sinus secondary to narrowed jugular foramina [163,164]. Conventional treatment for hydrocephalus in affected patients is the placement of a ventriculo-peritoneal shunt, although venous decompression at the jugular foramen has been proposed as an alternative [165].

In older persons, the narrow spinal canal frequently results in symptomatic thoracic and/or lumbar spinal stenosis. Initial symptoms are usually back pain and pain on walking which are relieved by squatting. These may progress to unremitting pain, leg weakness and bladder and bowel incontinence if untreated. This complication is amenable to surgical correction by spinal laminectomy [166].

Pulmonary compromise may result from any or all of three contributing factors. A relatively small chest may lead to restrictive lung disease. Small upper airways may contribute to the development of obstructive apnea requiring treatment by continuous positive airway pressure (CPAP) or tracheostomy [167–169]. Finally, compression of the cervico-medullary junction may cause central hypopnea or central apnea necessitating, in the most severe instances, surgical decompression of the foramen magnum.

In older patients with achondroplasia, obesity is often a significant problem [170,171]. Up to a height of 75 cm, the mean weight:height curves are comparable for average-statured children and children with achondroplasia, but above 75 cm, the weight:height curves for achondroplasia rise significantly above those for the general population [170]. Obesity contributes to the morbidity associated with lumbar stenosis, and also contributes to nonspecific joint problems and may play a role in the early mortality seen in some adults with achondroplasia.

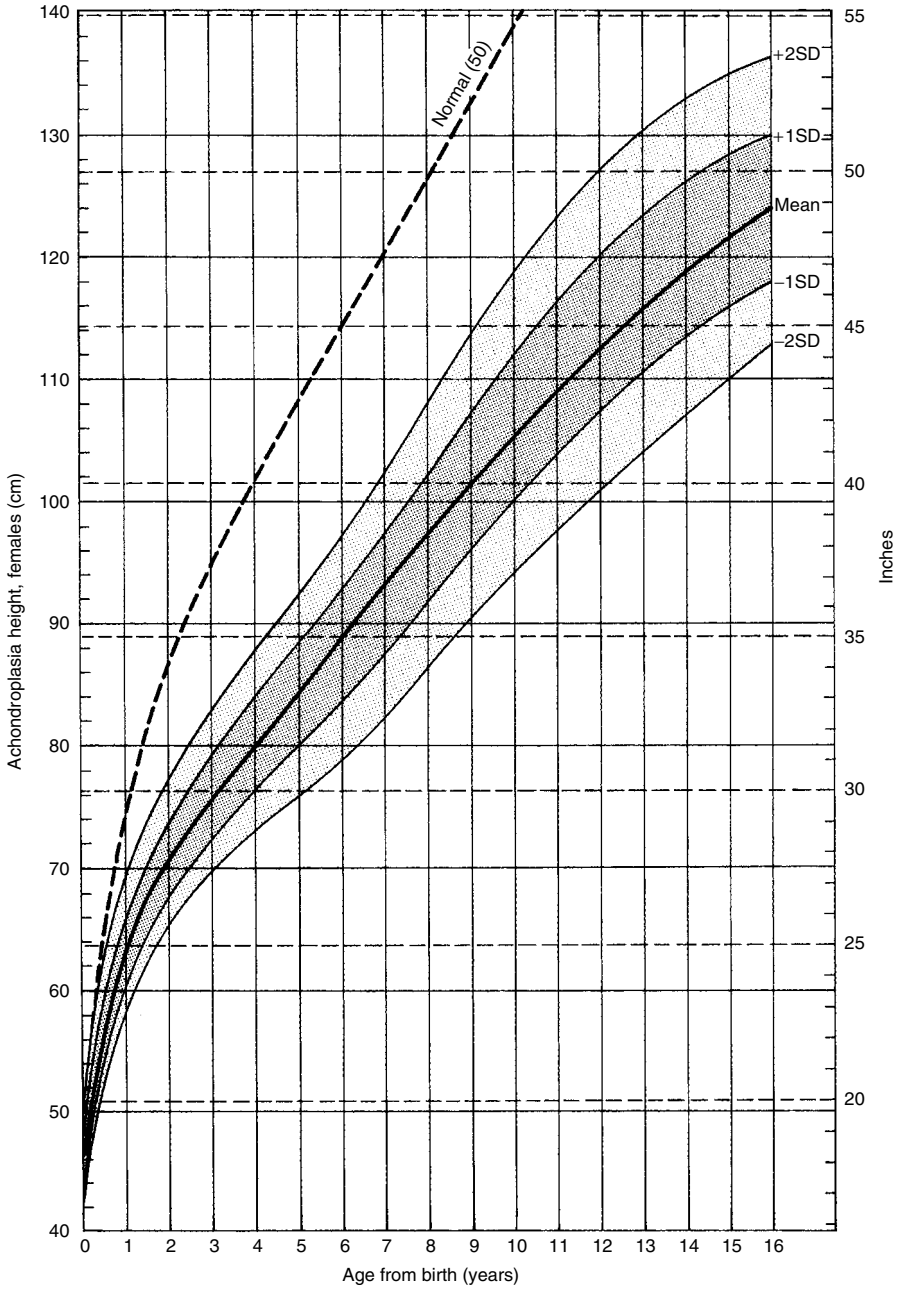

Figure 9. (*Continued*)

Homozygous Achondroplasia

Couples in which both individuals have achondroplasia (Fig. 12) are at 25% risk of having children who inherit two copies of the achondroplasia mutation. These children are said to have homozygous achondroplasia, or, colloquially, "double dominant" achondroplasia [172,173]. This phenotype is almost invariably lethal within the first days to months of life. It may be difficult to distinguish clinically from thanatophoric dysplasia (below), but the family history is the key to this differential diagnosis. Children with homozygous achondroplasia have pronounced rhizomelic dwarfism, marked mid-face hypoplasia, large heads relative to the size of their bodies, and short ribs resulting in a small thorax and restrictive respiratory compromise. A small foramen magnum may also lead to lethal compression at the cervico-medullary junction.

Hypochondroplasia

The phenotype of hypochondroplasia (MIM 146000) (Fig. 13) is very similar to, but generally milder than, that which presents in achondroplasia [174,175]. Affected persons have rhizomelic short-limbed dwarfism, but the short stature is less extreme than in achondroplasia and the growth curve actually overlaps the height ranges of

average children. The craniofacial manifestations are not as pronounced. Head size is usually within the normal range, and there are rarely complications of cervical or lumbar spinal stenosis. A few reports have suggested that learning disabilities may be increased among children affected by hypochondroplasia [176,177].

Thanatophoric Dysplasia

Thanatophoric dysplasia (MIM 187600), a neonatally lethal condition, the name of which means "death bearing," lies at the other end of the severity spectrum from hypochondroplasia. Almost all children with thanatophoric dysplasia die within the neonatal period, although there have been a few reports of survivors into the first decade [178,179]. Children born with this condition have very severe rhizomelic dwarfism, profound midface hypoplasia and extremely short ribs resulting in a small thorax. Death is thought to be due to respiratory failure, as a result of the small thorax and compromised upper airways, or to neurologic impairment, secondary to an extremely small foramen magnum (Fig. 14). Molecular analysis (see below) has enabled the distinction between the two types of thanatophoric dysplasia: thanatophoric dysplasia type I has curved femurs with a cloverleaf skull. Thanatophoric dysplasia type II is associated with straight femurs, with or without cloverleaf skull.

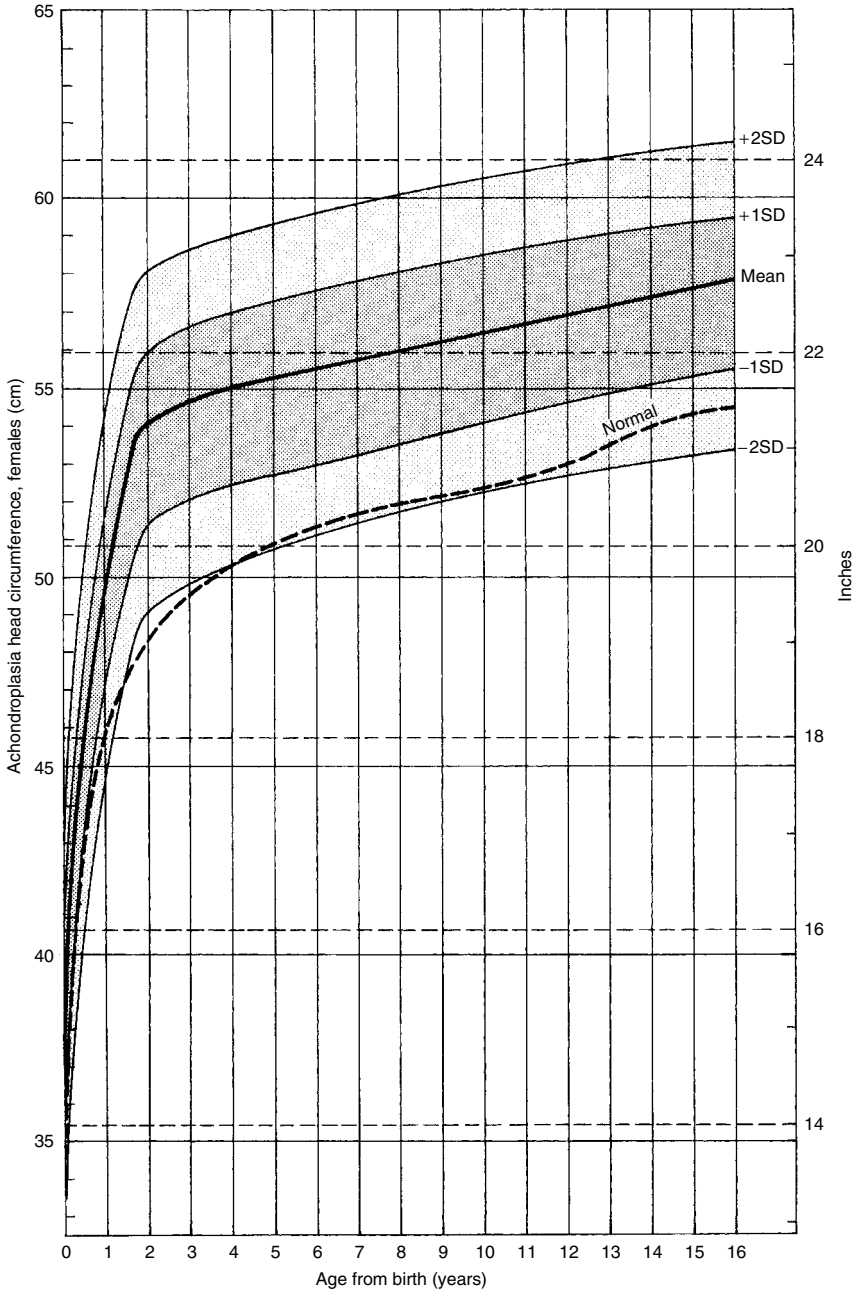

Figure 10. (*Continued*)

Severe Achondroplasia with Developmental Delay and Acanthosis Nigricans (SADDAN)

This phenotype (MIM 134934.0015), first described in 1999, is caused by a single specific mutation in the *FGFR3* gene [180]. Affected persons have profound short stature (one affected 5-year-old child was at the 50th percentile for a 1-year-old with achondroplasia), marked craniofacial characteristics including midface hypoplasia, and severe developmental delay and eventual mental retardation (Fig. 15). They also develop acanthosis nigricans. Medical complications are similar to those seen in achondroplasia, but occur earlier in life and with greater severity. Hydrocephalus and seizures occurred in all three reported children with the SADDAN phenotype [181]. In each case, the disorder resulted from a 1949A>T mutation causing a Lys650Met substitution. This is the same codon in which mutations causing thanatophoric dysplasia type II are found.

COMMON FEATURES OF FGFR DISORDERS

FGFR Mutations in Craniosynostosis Syndromes and Skeletal Dysplasias

Mutations in *FGFR2* were initially identified in Crouzon syndrome in 1994 [147,182]. A candidate gene approach was used after linkage had been established to chromosome 10q

Figure 11. Radiographic features of achondroplasia. Lower limbs in a young child. Note widened metaphyses, ''chevron seat'' epiphyses (arrowed), and short long bones. Radiographically, manifestations can also include lumbar lordosis and mild thoracolumbar kyphosis, with anterior beaking of the first and/or second lumbar vertebrae; small cuboid-shaped vertebral bodies with short pedicles and progressive narrowing of the lumbar interpedicular distance; small iliac wings with narrow greater sciatic notch; short tubular bones; metaphyseal flaring; short trident hand with short proximal midphalanges; and short femoral neck. (Figures courtesy of Dr. Ralph Lachman, Cedars-Sinai Medical Center, Los Angeles.)

in both Crouzon and Jackson-Weiss syndromes [183,184]. Further FGFR mutations were identified in several other craniosynostotic disorders shortly afterwards. To date, heterozygous mutations of *FGFR1*, *−2*, and *−3* have been identified in seven distinct craniosynostosis syndromes. These are: mild Pfeiffer syndrome (*FGFR1*); Apert, Crouzon, mild and severe Pfeiffer, and Beare-Stevenson syndromes (*FGFR2*); Muenke syndrome and Crouzon syndrome with acanthosis nigricans (*FGFR3*). In addition, *FGFR2* mutations have been identified in some other craniosynostosis phenotypes including Jackson-Weiss syndrome.

In 1994, the gene causing achondroplasia was mapped to a region of 2.5 Mb of DNA at the telomeric end of the short arm of chromosome 4, 4p16.3 [185–187]. The candidate region contained the gene encoding FGFR3, which had been cloned in the search for the Huntington disease locus in the same region. Mutations in the *FGFR3* gene were found in the DNA from patients with achondroplasia within 6 months of recognition of the map location [188,189]. Soon thereafter, *FGFR3* mutations causing thanatophoric dysplasia were found [190]. The identification of *FGFR3* mutations that cause hypochondroplasia [191] completed the elucidation of the molecular basis of the achondroplasia family of skeletal dysplasias and confirmed the allelic nature of these disorders.

The paucity of incidences of familial recurrence of achondroplasia speaks against significant levels of germline mosaicism, although there have been a few reports of multiple affected children from families with unaffected parents [192,193]. Germline mosaicism has been demonstrated in families with recurrence of other skeletal dysplasias, including osteogenesis imperfecta type II [194] (see also Chapter 8, this volume) and pseudoachondroplasia [195] (see also this chapter, part II).

Almost all cases of achondroplasia are caused by the same Gly380Arg substitution. Exceptions include three cases with reportedly classical achondroplasia, in which the mutation was 5 codons downstream producing Gly375Cys [196–198]. This mutation also affects the transmembrane domain of FGFR3. One patient with a Gly346Glu mutation has also been reported [199].

Nature of Mutations

The great majority of the mutations seen in the FGFR genes are missense, with a few small insertions, deletions or combined insertion/deletions, all of which remain in-frame.

Figure 12. Typical achondroplasia, in a husband and pregnant wife. Note the disproportionate short stature with rhizomelic (proximal) shortening of the limbs, relative macrocephaly, and midface hypoplasia. Some of the additional manifestations of achondroplasia are lumbar lordosis; mild thoracolumbar kyphosis, with anterior beaking of the first and/or second lumbar vertebrae; short tubular bones; short trident hand; and incomplete elbow extension. The child was found to have heterozygous achondroplasia. (From Vajo et al. [237]. Reproduced by permission of Endocrine Reviews.)

Figure 13. Typical hypochondroplasia. Notice small stature, especially in the bowed lower limbs, and stubby hands and feet. In hypochondroplasia, limbs are usually short, without rhizomelia, mesomelia, or acromelia, but there may be mild metaphyseal flaring. Brachydactyly and mild limitation in elbow extension can be evident. Spinal manifestations may include anteroposterior shortening of lumbar pedicles. The spinal canal may be narrowed or unchanged caudally. Lumbar lordosis may be evident. (From Beals RK [238]. Reproduced with permission of Journal of Bone and Joint Surgery.)

Also found are acceptor and donor splice site mutations of exon IIIc and two *Alu* element insertions.

Mutations in *FGFR1*, *FGFR2*, and *FGFR3*, associated with craniosynostosis are illustrated in Figure 16. Figure 17 illustrates all known *FGFR3* mutations.

The cysteine residues in the IgIII domain of FGFR2 are the sites of highest mutation frequency. The Cys342 residue alone accounts for about 40% of all IgIII mutations. Mutations have been identified which reflect all six amino acid substitutions that can arise by mutating one nucleotide of the TGC codon (Fig. 18). In addition, approximately 35% of mutations at non-cysteine residues within IgIII are substitutions of cysteine. Generation of an odd number of cysteines (1 or 3) in IgIII leads to intermolecular covalent dimerization.

Mutations at the 5′ end of the IIIc exon are thought to result in preferential splicing to the IIIb exon and hence increased expression of the distinct keratinocyte growth factor receptor (KGFR) splice form. This outcome would be expected to confer unique ligand binding characteristics upon the cell and hence represents a potential mechanism for gain-of-function [21] (see below, Biochemical Analysis of Fibroblast Growth Factor Receptor 3 Mutations.)

The first reports of mutations in *FGFR3* causing achondroplasia [188,189] demonstrated that 38 of 39 mutations found were exactly the same, a G to A transition at nucleotide 1138. The remaining mutation was a G to C transversion, also at nucleotide 1138. Both mutations result in the substitution of arginine for the glycine residue at position 380 in the transmembrane domain of the protein (Fig. 19). Most analyses were performed on heterozygous achondroplasia patients but the Gly380Arg mutation was also detected in several cases of homozygous achondroplasia. A larger series reported in 1995 found a Gly380Arg mutation

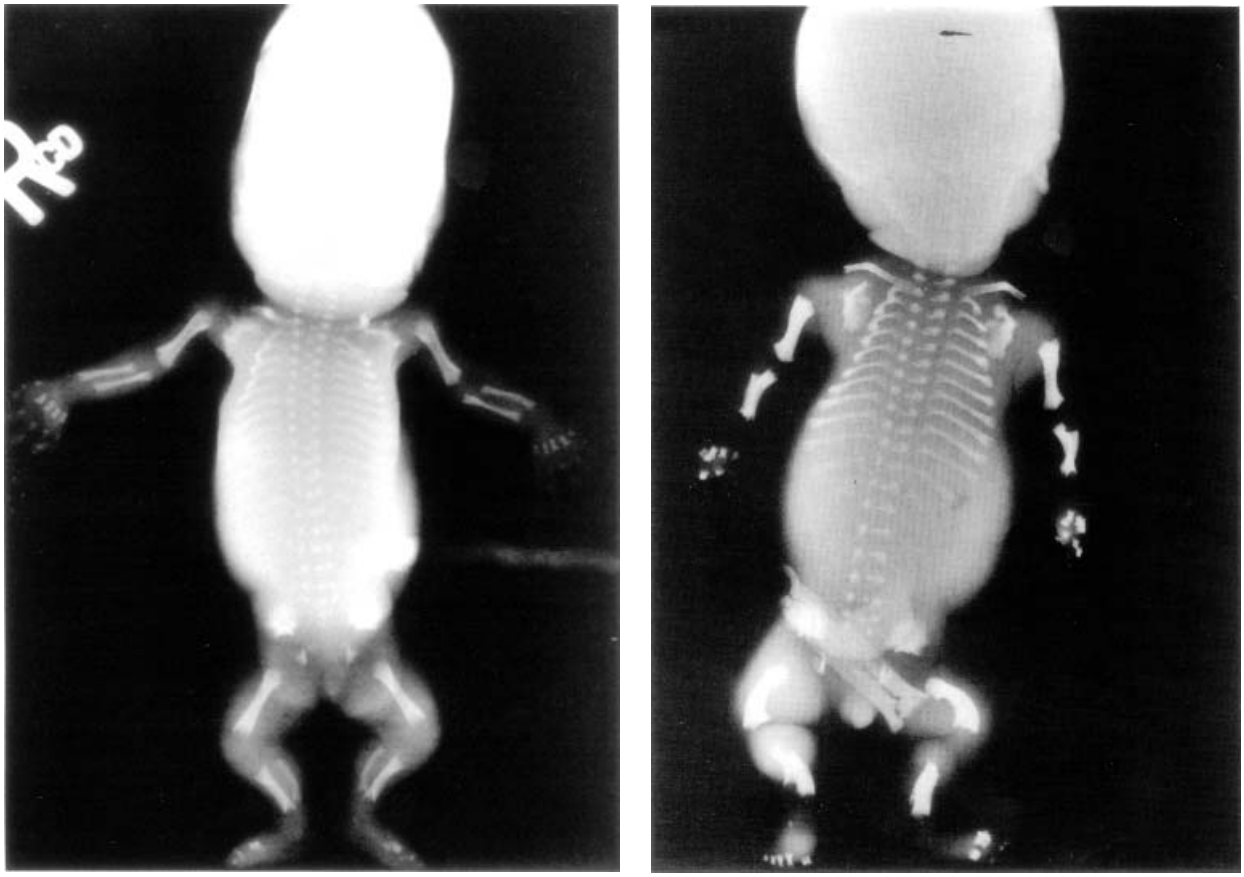

Figure 14. Thanatophoric dysplasia (TD). The features of this condition include micromelic shortening of the limbs, macrocephaly, platyspondyly, and a reduced thoracic cavity with short ribs. **A:** TD type II. Note the straight femurs. Cloverleaf skull may also be a feature of TD II. **B:** TD type I. Note the curved femurs. (Figures courtesy of Dr. Ralph Lachman, Cedars-Sinai Medical Center, Los Angeles.)

on 153 of 154 alleles, confirming the remarkable degree of genetic homogeneity of this disorder [200]. In this later series, the G to A transition accounted for 150 alleles, while the G to C transversion was found in three. (The remaining proband of the 154 patients studied was later recognized as having SADDAN dysplasia.) Stoilov et al. [201] found the Gly380Arg mutations in the DNA from 21 of 23 persons with achondroplasia.

Studies from Sweden, Japan and China have demonstrated Gly380Arg mutations in almost all patients with achondroplasia analyzed [202–204]. A total of 16 Swedish, 10 Chinese, and 20 Japanese patients were studied for the presence of *FGFR3* mutations. All of the Swedish and Chinese patients, and 18/20 of the Japanese patients were heterozygous for the 1138 G>A transition [202–204].

The FGFR mutations vary greatly in frequency, with some being highly recurrent. The C>G nucleotide substitutions encoding the Pro250Arg mutation in *FGFR3* and the Ser252Trp mutation in *FGFR2* represent the most common transversions known in the human genome, with frequencies per haploid genome estimated as 8×10^{-6} [141] and 5×10^{-6} [205] respectively.

Similarly, the estimated mutation rate for *FGFR3* Gly380Arg is between 5.5×10^{-6} and 2.8×10^{-5} per gamete per generation [200]. These rates are based on an estimated frequency of achondroplasia of between 1/15,000 and 1/50,000 live births [206,207].

These observations, taken with the relatively high incidence of achondroplasia, suggest that particular nucleotides in the FGFR genes are among the most mutable nucleotides in the human genome. The altered nucleotide in the common achondroplasia mutation *FGFR3* G1138 occurs in the context of a CpG dinucleotide, which might explain some of the increased incidence at this site. However, the mutation at G1138 is two to three orders of magnitude higher than the rate previously reported for transversions and transitions at CpG dinucleotides [200,208].

The close relationship between specific mutations and specific phenotypes in the FGFR family of genes is unusual. Unlike most human genetic disorders, in which there is a wide range of mutations causing a similar phenotype, in this family of disorders there is a very tight correlation between specific mutations and the phenotypes with which they are associated. In achondroplasia, more than 97% of cases are caused by one of two mutations that substitute arginine for glycine at codon 380 in the transmembrane domain of the protein [202–204]. More than 80% of cases of hypochondroplasia are caused by mutations resulting in the substitution of asparagine for lysine at codon 540 [191].

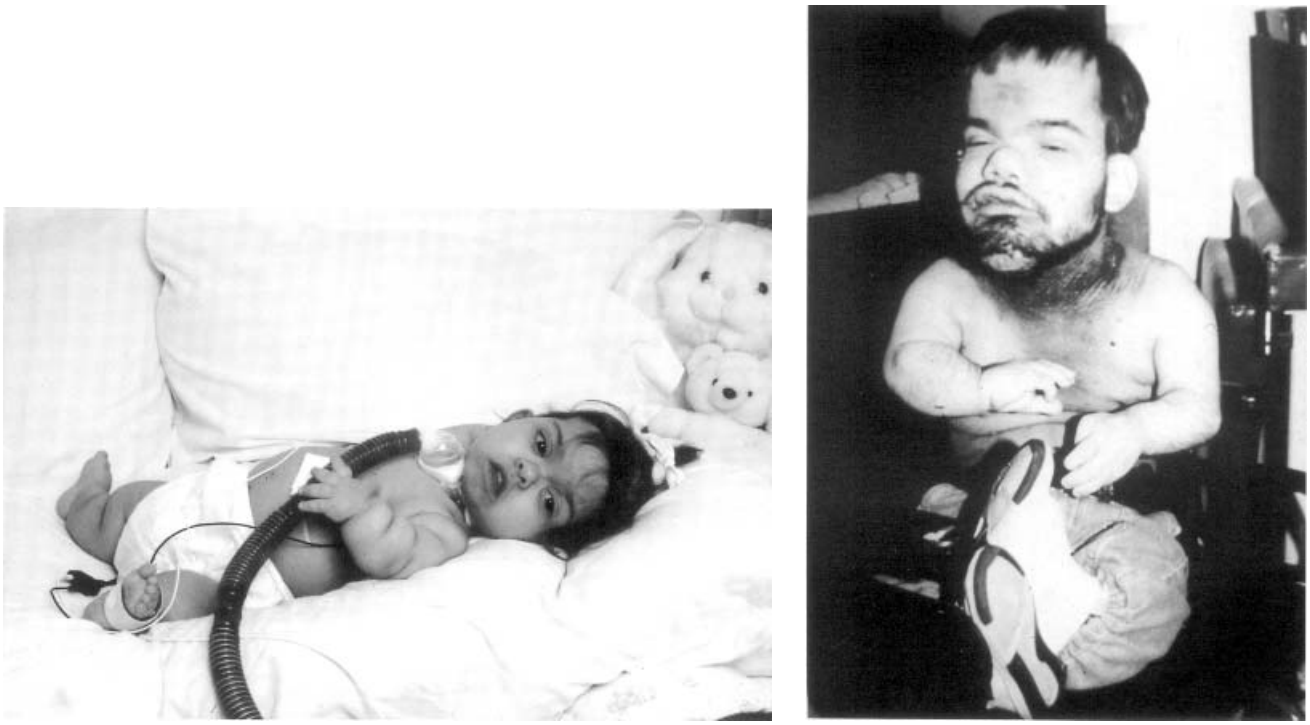

Figure 15. SADDAN dysplasia is characterized by extreme short stature, severe tibial bowing, profound developmental delay, and acanthosis nigricans. **A:** 5-year-old girl. Notice the moderate bowing of the femurs with reverse bowing of the tibia and fibula. **B:** Man in early twenties. Notice the extreme short stature and severe acanthosis nigricans especially around the neck. Individuals with SADDAN dysplasia also have had seizures and hydrocephalus during infancy with severe limitation of motor and intellectual development. (From Bellus et al. [181]. Reprinted with permission of Wiley-Liss, Inc., a subsidiary of John Wiley and Sons, Inc.)

Thanatophoric dysplasia is an interesting case in point; analysis of mutation data allowed clinicians to go back to their patients and sort out two distinct clinical subsets, based on the molecular data. Thanatophoric dysplasia type I is associated with curved femurs and other tubular bones and infrequently a cloverleaf skull, and a variety of mutations in multiple different domains of the FGFR3 molecule. Thanatophoric dysplasia type II, however, presents straight femurs, may or may not show cloverleaf skull, and is invariably caused by mutations resulting in a Lys650Glu substitution in the intracellular tyrosine kinase domain of the FGFR3 molecule [180,209,210].

Mutations at identical positions in FGFR paralogues are observed in several regions of the molecule. The best example of this phenomenon is seen in a Ser-Pro dipeptide in the IgII-IgIII linker, part of a sequence of 16 amino acids conserved between all four human FGFRs. Mutations of proline to arginine in this linker in FGFR1 cause Pfeiffer syndrome [55], in FGFR2, Apert syndrome [108] and in FGFR3, Muenke syndrome [59] (Fig. 20).

The FGFR family of disorders represents several allelic series, i.e., mutations in one gene can cause different phenotypes. Mutations of both *FGFR2* and *FGFR3* have been associated with more than one syndrome. The observation that allelic missense mutations cause distinct dominant phenotypes suggests that different signalling pathways are activated by unique gain-of-function mutations. This point is made particularly apparent by the recognition of distinct *FGFR3* missense mutations in the syndromes of hypochondroplasia, achondroplasia, thanatophoric dysplasia and SADDAN (severe achondroplasia with developmental delay and acanthosis nigricans) syndrome [211]. Craniosynostosis is rare in these latter disorders except in the case of thanatophoric dysplasia.

Paternal Age Effect in Achondroplasia and Apert Syndrome

As has been the case in several different autosomal dominant conditions, studies of families with Apert syndrome have demonstrated that unaffected fathers of affected infants were older, on average, than fathers of unaffected children [97]. Similar observations have been made in families with achondroplasia, and one report demonstrated that the achondroplasia mutation was exclusively present on the paternal allele in a cohort of 40 families [23]. In Apert syndrome, the two common mutations were exclusively paternal in origin in 57/57 cases and exhibited a significant paternal age effect [205]. These observations indicate that these mutations arose during spermatogenesis in the unaffected father.

Pathogenesis of FGFR Disorders

FGF/FGFR Signalling in Cranial Sutures

Several studies have demonstrated expression of FGFs and FGFRs at the mRNA level in mouse cranial sutures [212–214]. Placement of an FGF2-soaked, heparin-coated bead over the coronal suture in mouse embryos

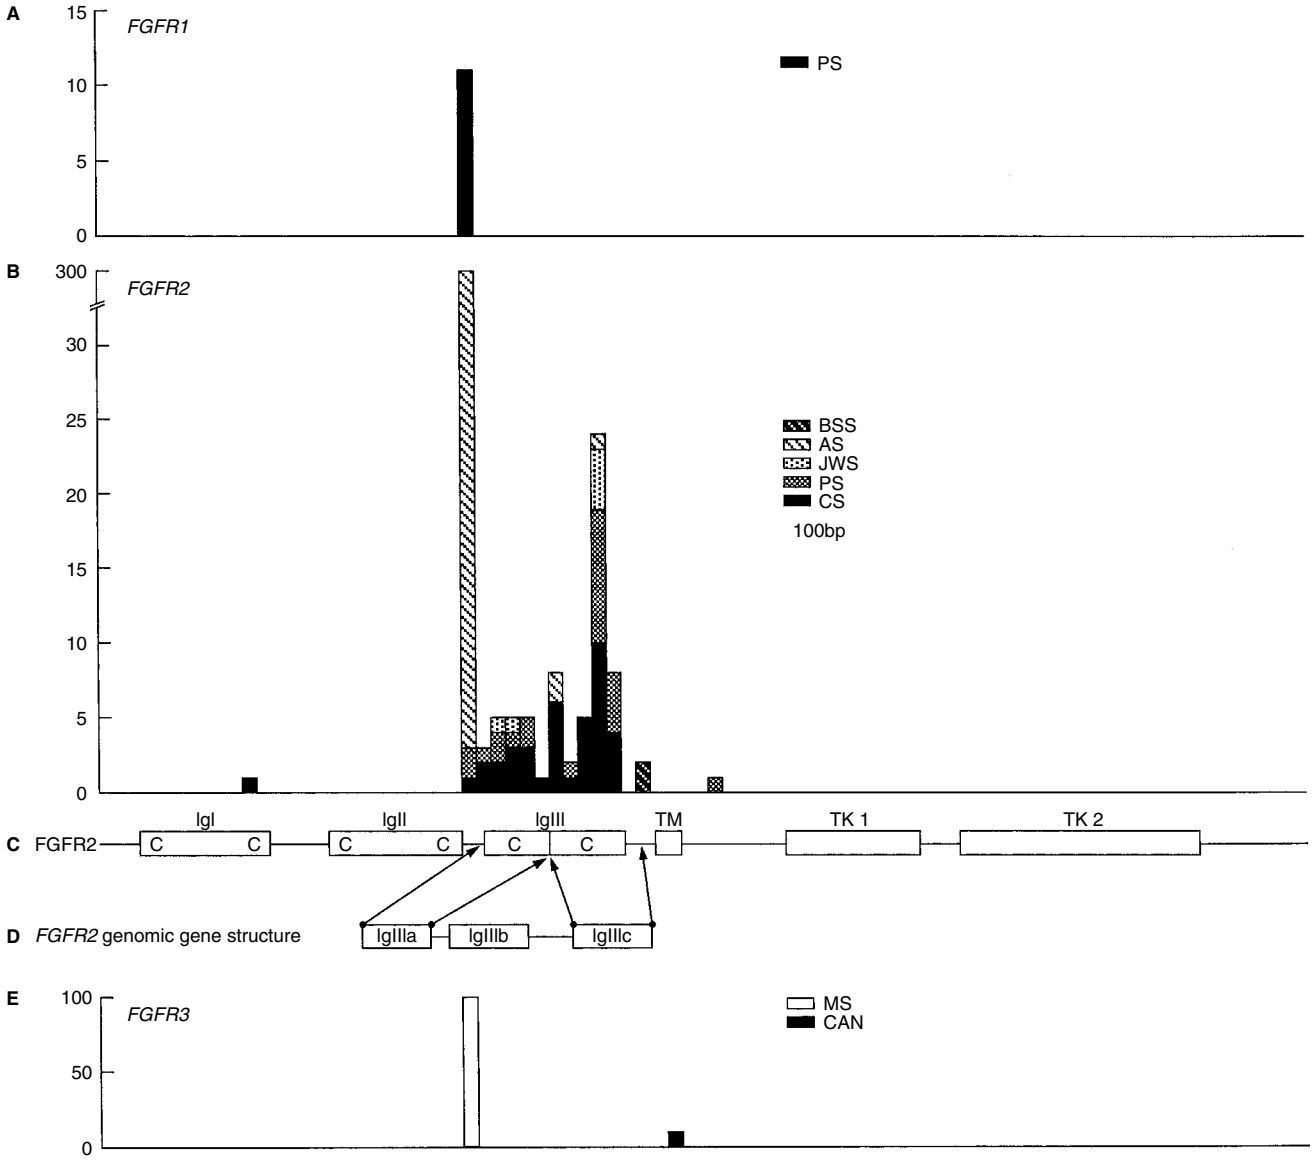

Figure 16. Number and location of the reported mutations in *FGFR1* (**A**), *FGFR2* (**B**), and *FGFR3* (**E**) superimposed on the predicted structure of the *FGFR2* protein with three Ig-like domains in the extracellular region (IgI–IgIII), a transmembrane segment (TM), and a split intracellular tyrosine kinase activity region (TK1 and TK2) (**C**). Genomic structure of the region of *FGFR2* involved in alternative splicing of the IgIII-like domain [108]. (**D**), FGFR mutations have been identified in patients with the different craniosynostosis syndromes: Apert syndrome (AS), Beare-Stevenson syndrome (BSS), Crouzon syndrome (CS), Crouzon syndrome with acanthosis nigricans (CAN), Jackson-Weiss syndrome (JWS), Muenke syndrome (MS), and Pfeiffer syndrome (PS). (From Hehr and Muenke [239]. Reproduced with the permission of Molecular Genetics and Metabolism.)

resulted in differentiation of the sutural tissue underlying the bead, with a new suture-like structure being formed around the bead. Expression of Fgf2 was observed in the rat posterior frontal suture at the time of suture fusion [214]. A mouse model of Crouzon syndrome, Bulgy-eye (Bey), has a retrovirus inserted in the intergenic region between the tandem *Fgf3* and *Fgf4* genes, resulting in significantly higher expression levels of both genes in the cranial sutures of affected mice [215].

Histological examination of 19–28 week human fetuses with Apert syndrome showed increased calcified bone matrix and stronger alkaline phosphatase staining of cells in the subperiosteal area compared to controls, indicating increased maturation of preosteoblast cells. In culture, these cells demonstrated increased bone differentiation markers including alkaline phosphatase and osteocalcin [216].

One seemingly paradoxical result is that immunoassay of FGFR2 protein in the cranial sutures of Apert and Crouzon syndrome patients showed reduced levels [216,217]. However, this is likely to be a consequence of down-regulation of FGFR caused by excessive signalling through the FGF/FGFR pathway, a feedback loop that has been demonstrated in

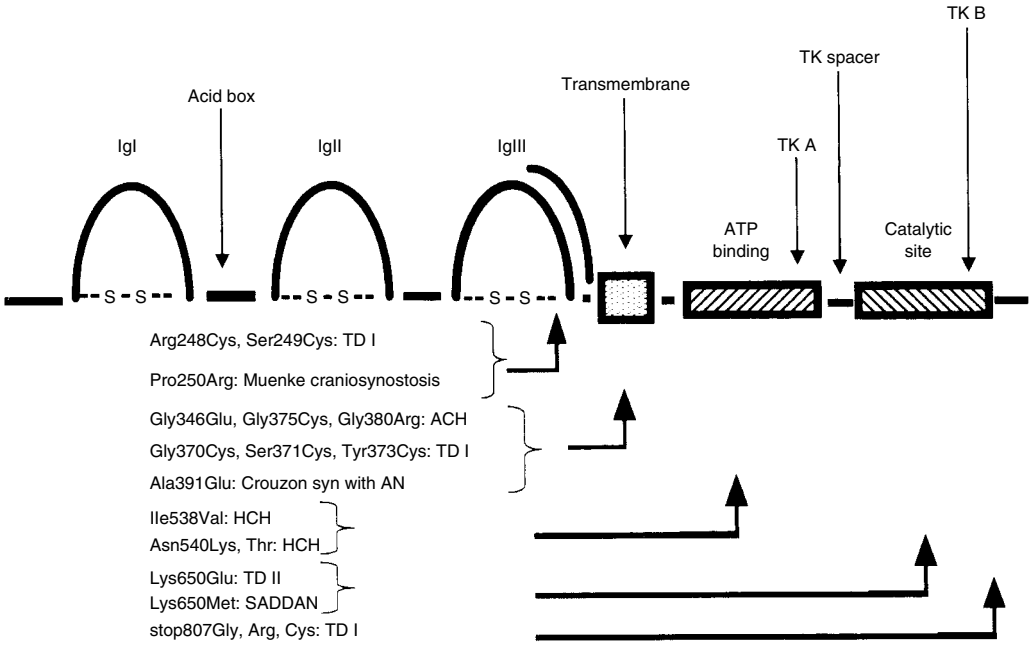

Figure 17. Schematic diagram of a prototypical FGFR protein. Three Ig-like domains (IgI–IgIII) are indicated by loops, closed with disulfide bridges. These Ig-like domains are extracellular and responsible for ligand binding. Alternative splicing in the C-terminal half of the third Ig-like loop is indicated by an extra ''half'' loop. The acid box is a stretch of acidic amino acids found in all FGFRs between IgI and IgII. The tyrosine kinase (TK) domains are found intracellularly. The TK A domain contains the ATP-binding site. The TK B domain contains the catalytic site. Also shown are known *FGFR3* mutations and their approximate corresponding locations within the protein. TD, thanatophoric dysplasia; ACH, achondroplasia; AN, acanthosis nigricans; HCH, hypochondroplasia.

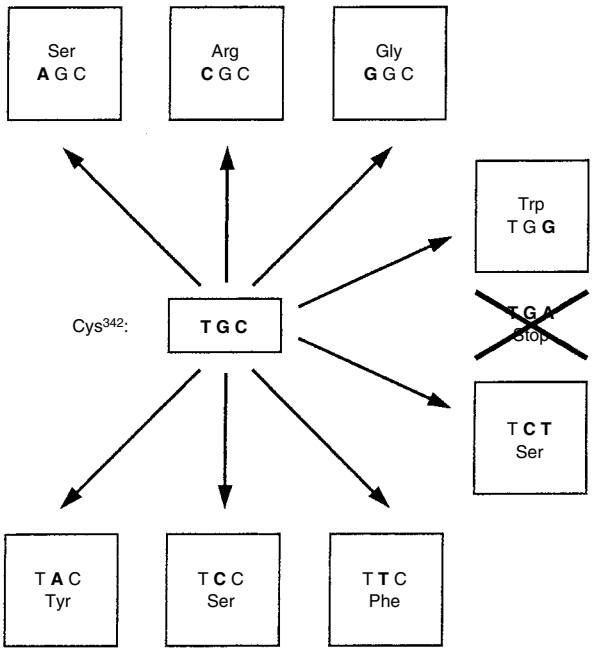

Figure 18. Observed point mutations resulting in the substitution of cysteine at position 342 of *FGFR2*. All possible missense mutations at this position have been identified in patients with craniosynostosis syndromes with one exception, the nonsense mutation TGC > TGA. This further supports the hypothesis of a ''gain-of-function'' effect of the heterozygous FGFR mutations in craniosynostosis. (From Hehr and Muenke [239]. Reproduced by permission of Molecular Genetics and Metabolism.)

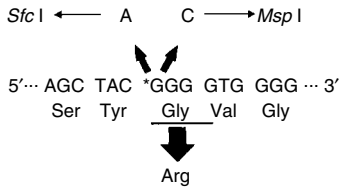

Figure 19. The common *FGFR3* mutations causing achondroplasia both result in Gly380Arg amino acid substitutions. Shown is the *FGFR3* sequence surrounding the site of the common mutation. An 1138 G>A mutation creates a novel *Sfc*I site; an 1138 G>C mutation creates an *Msp*I site. The nucleotide changed in the common mutation (G1138) is depicted by an (*). The regular glycine residue (Gly380) is underlined.

several experimental systems [218,219]. Such studies suggest that signalling through the FGF/FGFR pathway has different consequences at different intensities. Low intensity, tonic signalling stimulates sustained cell proliferation, prevents preosteoblast differentiation, and hence maintains the suture. Higher intensity signalling, consistent with activating mechanisms for FGFR mutations, causes FGFR downregulation and suture differentiation.

Biochemical Analysis of Fibroblast Growth Factor Receptor 3 Mutations

All of the *FGFR3* mutations observed to date result in constitutive activation of the receptor. *In vitro* biochemical studies suggest that the phenotypic differences among the disorders in the achondroplasia family of skeletal dysplasias

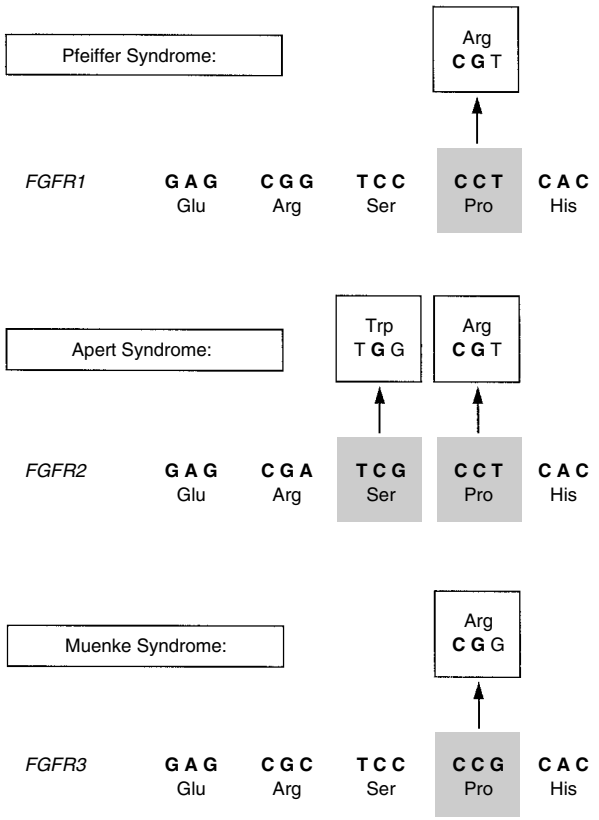

Figure 20. Observed point mutations in patients with Pfeiffer syndrome (PS), Apert syndrome (AS), or Muenke syndrome (MS) at an identical position in all three FGFR paralogues (*FGFR1, FGFR2,* and *FGFR3*) resulting in a substitution of proline to arginine. (From Hehr and Muenke [239]. Reproduced by permission from Molecular Genetics and Metabolism.)

are due, at least in part, to varying degrees of ligand-independent FGFR3 activation.

These considerations predict that loss of *Fgfr3* function will result in a different phenotype. In support of this prediction, mice homozygous for a targeted total disruption of the *Fgfr3* gene exhibit skeletal and inner ear defects. The skeletal manifestations in these mice include kyphosis, scoliosis and kinking of the tail; in addition, the long bones exhibit overgrowth, in direct contradistinction to the shortening of the long bones seen in achondroplasia and related disorders. These observations suggest that the normal function of FGFR3 is the negative regulation of bone growth [35,36]. Thus, *FGFR3* mutations in the achondroplasia family of skeletal dysplasias are thought to be gain-of-function mutations that activate, in a ligand-independent manner, the fundamentally negative growth control exerted by the FGFR3 pathway [35,36,220].

Based on current knowledge of signal transduction by the FGF pathway, activation of FGFRs normally occurs only after ligand binding [221]. Analysis of *Xenopus* receptors has demonstrated that point mutations may activate FGFRs by a number of distinct mechanisms [222].

Additional evidence for the gain-of-function hypothesis was provided by Webster et al. [223]. In an *in vitro* model system, profound constitutive activation of the FGFR3 tyrosine kinase (approximately 100-fold greater than of the wild type) was associated with the Lys650Glu mutation, which causes thanatophoric dysplasia type II (TDII) [223]. Altered kinase activation was dependent on both the position of the altered amino acid, and its charge. The authors speculated that the TD II mutation in the FGFR3 activation loop mimicked the conformational changes that activate the tyrosine kinase domain. Ligand binding and autophosphorylation of the receptor normally initiate this domain. Using immunoprecipitation followed by an *in vitro* kinase assay, Webster and Donoghue [224] also found that the mutation in thanatophoric dysplasia type II increased autophosphorylation of the FGFR3 relative to the wild type or achondroplasia mutation.

Subsequently, similar constitutive FGFR3 activation has been associated with the Gly380Arg mutation causing achondroplasia [224,225]. The downstream events initiated by FGFR3 activation are represented in Figure 21. The thanatophoric dysplasia type II mutation displays a higher level of autophosphorylation than the achondroplasia mutation, suggesting that the severity of the conditions may correlate with the degree of autophosphorylation caused by the receptor mutation [225].

The constitutive tyrosine kinase activity of FGFR3 with the TDII mutation specifically activates the transcription factor Stat1 (signal transducer and activator of transcription) [226]. This mutant receptor also induces nuclear translocation of Stat1 and expression of the cell-cycle inhibitor p21 (WAF/CIP1), resulting in growth arrest of the cell. Stat1 activation and increased p21 (WAF/CIP1) expression were found in chondrocytes from a TDII fetus, but not in those from an unaffected fetus. These observations suggest that in thanatophoric dysplasia, Stat1 may be used as a mediator of bone growth retardation, and that abnormal Stat activation and p21 (WAF/CIP1) expression due to the mutant FGFR3 may be responsible for the phenotype [226].

Thompson et al. [227] constructed a chimeric receptor containing the transmembrane and intracellular domains of FGFR3 with the rare Gly375Cys achondroplasia mutation fused to the extracellular domain of platelet-derived growth factor. PC-12 cells lack this growth factor. Strong neurite outgrowth in cells transfected with these constructs would suggest activation of the receptor. Ligand-dependent autophosphorylation of the chimeric receptor was observed, as well as strong phosphorylation of mitogen-activated protein (MAP) kinase, phospholipase C and Shc. Compared with cells transfected with a chimera with normal *FGFR3* sequences, cells transfected with the *FGFR3*-achondroplasia chimera were more responsive to ligand, with a less sustained MAP kinase activation, indicative of a primed or constitutively "on" condition. This observation is consistent with the hypothesis that these mutations weaken ligand control of the FGFR3 receptor, and may provide a biochemical explanation for the observation that the TD phenotype is more severe than that of achondroplasia [227].

CRANIOSYNOSTOSIS SYNDROMES AND SKELETAL DYSPLASIAS: GENERAL GUIDELINES FOR MANAGEMENT

Genetic Counseling

Almost all of the conditions discussed in this chapter are autosomal dominant disorders. Most cases represent new mutations, in which case the recurrence risk to unaffected parents is low. However, the possibility of

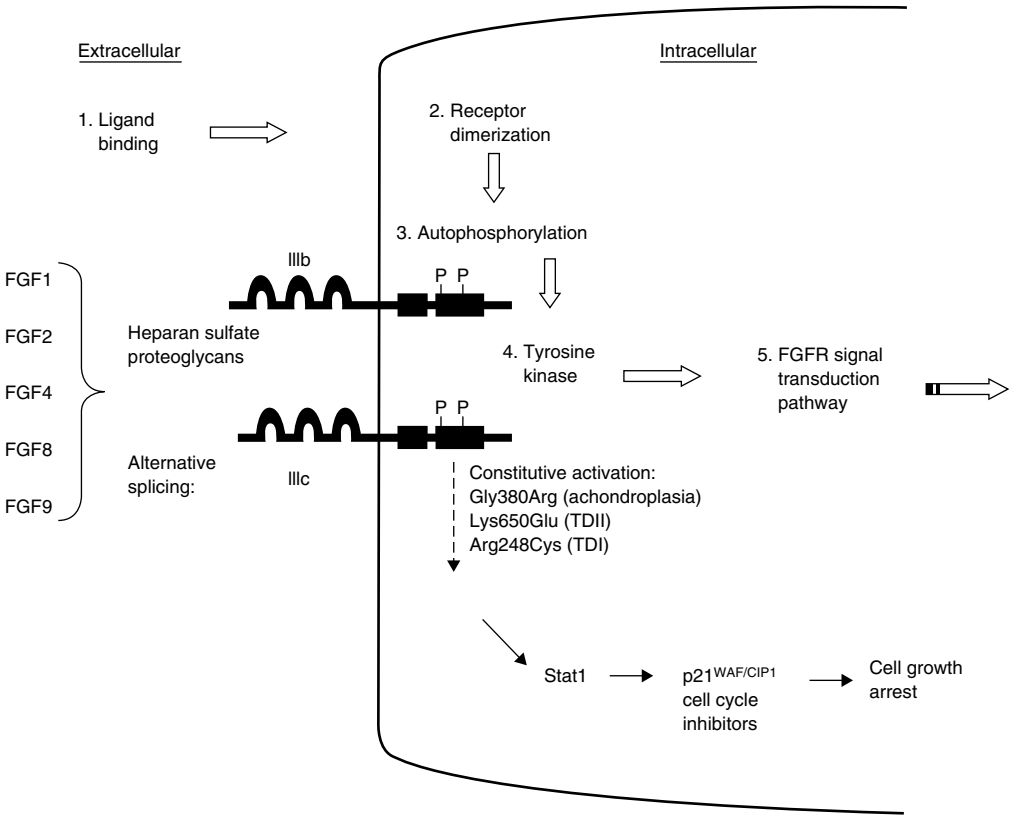

Figure 21. A putative model for FGFR3 signalling. The receptor is shown with both extracellular and intracellular domains. Binding of the ligand (FGF) to the receptor in the presence of heparan sulfate proteoglycans results in receptor dimerization and autophosphorylation of several FGFR3 tyrosine residues in the cytoplasmic domain, which stimulates tyrosine kinase activity. These phosphorylated tyrosine residues provide a means to recruit and phosphorylate other molecules, furthering the FGFR3 signal transduction pathway. It has been shown that mutations in the *FGFR3* gene can allow constitutive, ligand-independent activation of the receptor. For the common achondroplasia and thanatophoric dysplasia mutations, this leads to the activation of Stat1 and cell cycle inhibitors, eventually leading to cell growth arrest.

germline mosaicism in one of the unaffected parents means that the risk is not zero [192,193]. It is recommended that any couple who have had a child with one of these conditions consult a genetic counselor if they are considering further reproductive options.

Prenatal Diagnosis

The relatively small number of mutations and tight correlation between specific mutations and phenotypes makes prenatal diagnosis more accessible for this group of disorders than for many others. However, the high frequency of new mutations makes the application of prenatal testing impractical in most cases. Moreover, known genetic heterogeneity in some conditions, such as hypochondroplasia, may lead to a false negative outcome if not considered.

Therapy

Careful monitoring of the head circumference in infancy is essential in all of these conditions. Deviations from expected growth curves should lead to evaluation for possible hydrocephalus, or neurosurgical intervention for craniosynostosis. Anticipatory monitoring for central and/or obstructive apnea and hearing loss is advised for persons with achondroplasia and many of the craniosynostosis syndromes. Spinal stenosis is common in adults with achondroplasia [166]. The development of paresthesias or weakness in the lower extremities, or loss of bowel or bladder control, should be promptly evaluated.

Growth hormone trials for achondroplasia have not been a resounding success. While growth accelerates during treatment, the ultimate effect on height is still unknown [228,229]. Considering the cost and inconvenience of daily injections, many practitioners and families conclude that the treatment is not worthwhile.

Surgery

Common surgical interventions in achondroplasia include foramen magnum enlargement, placement of a ventriculoperitoneal shunt, placement of pressure-equalizing (PE) tubes in the tympanic membrane, spinal laminectomy, and tibial osteotomy. Limb lengthening is a less commonly performed and controversial approach to increasing height in persons with achondroplasia.

For persons with craniosynostosis syndromes, neurosurgical intervention to release the prematurely closed cranial sutures may be undertaken. In case of increased intracranial pressure, a VP shunt may be placed in these disorders as well. Finally, hand surgery to release the syndactyly associated with the craniosynostosis syndromes, particularly Apert syndrome, is sometimes feasible.

Foramen Magnum Enlargement

Stenosis of the foramen magnum is a common complication of achondroplasia. It is particularly pronounced in infancy, and may compress the cervico-medullary junction, resulting in central apnea and/or severe hypotonia and evidence of neurological compromise. Enlargement of the foramen magnum can be a life-saving procedure for these children [162].

Placement of a Ventriculo-Peritoneal Shunt

Enlarged ventricles are the rule rather than the exception in achondroplasia. Nonetheless, in some children, the head circumference enlarges more rapidly than expected (see growth chart for head circumference). Imaging of the ventricles in these children often reveals massive enlargement of the ventricles, an indication for the placement of a ventriculo-peritoneal shunt for hydrocephalus. In cases where it is not clear whether the intracranial pressure is increased, it is possible to place an intraventricular pressure monitor intraoperatively. The neurosurgeon may then watch the pressure for two or three days in an intensive care setting, before a decision is reached to place a shunt.

Placement of Pressure-Equalizing (PE) Tubes

Otitis media is a common childhood complication of achondroplasia. Frequent episodes of otitis media may lead to scarring of the tympanic membrane and significant hearing loss. To prevent this complication, PE tubes are sometimes placed to prevent the build-up of pressure in the middle ear and facilitate drainage.

Laminectomy

Because of the high frequency of spinal stenosis in adults with achondroplasia, spinal laminectomy is the most commonly performed surgical procedure in adulthood [166]. The anatomy of the spine in achondroplasia results in narrowing of the spinal canal towards the caudal region. Hence, lumbar stenosis is the most common type. However, thoracic and even cervical stenoses do occur and may require surgical correction by laminectomy.

Osteotomy

Genu varus (bowed legs) are a common orthopedic complication of achondroplasia in childhood. The orthopedic correction of genu varus is through a tibial osteotomy, in which a wedge-shaped piece is removed from the tibia to straighten the bone.

Limb Lengthening

Perhaps the most controversial of surgical procedures for achondroplasia is that of limb lengthening [230]. Technically, the procedure has been refined significantly over the past decade. It involves creating a surgical fracture and inserting pins on either side of the fracture site. The pins are mechanically distracted in millimeter increments over a period of 6–12 months. Fracture callous fills in the space between the distracted ends of the fracture, and the bone is lengthened. When both upper and lower segments of the leg are lengthened, as much as a foot (30 cm) in height may be gained. Potential complications include both neurologic and vascular damage to the limb if the lengthening occurs too quickly. The long-term stability of the new bone has yet to be evaluated.

CONCLUSION

Many questions remain to be answered about the pathogenesis of FGFR disorders. The precise molecular mechanisms of downstream signaling due to allelic mutations have yet to be elucidated. Similarly, an explanation for the extraordinarily high mutation rates at specific FGFR nucleotides is still unknown. Nonetheless, the study of FGFR mutations in human craniosynostosis and skeletal dysplasia syndromes has yielded much new information about the FGF/FGFR signalling pathways and their involvement in skeletal development.

RECENT DEVELOPMENTS

All *FGFR2* mutations in **Pfeiffer syndrome** described to date localize to the extracellular IgIII domain. However, the original family described by Pfeiffer in 1964, although shown to be consistent with linkage to FGFR2, does not have causative mutations in *FGFR2* exons 7 to 9 (IgIII). Recently, Kan and colleagues [240] have identified *FGFR2* substitutions of two adjacent nucleotides, 514GT and 515CT, predicting the amino acid substitution Ala172Phe, in all affected family members who were available for testing. This alanine substitution is in a key position in the IgII domain crucial for the formation of the immunoglobulin domain. This is the first mutation in the IgII domain of FGFR2 (or any FGFR), suggesting that this region may harbor mutations in patients with Pfeiffer and other craniosynostosis syndromes.

Bellus et al. [241] have reported three new mutations at Lys650 in *FGFR3* exon 15, each causing the **hypochondroplasia** phenotype. The three mutations include G1950T and G1950C, both of which result in a Lys650Asn substitution, and A1948C, resulting in a Lys650Gln substitution. Both amino acid substitutions result in constitutive activation of the FGFR3 tyrosine kinase activity, but to a lesser degree than observed with mutations at the same codon resulting in the more severe phenotypes of thanatophoric dysplasia type II and SADDAN.

Several new **animal models** of *FGFR3* disorders have been reported. Iwata and her colleagues have described mouse models for the Lys650Glu and Lys650Met mutations causing thanatophoric dysplasia type II and SADDAN, respectively [242, 243]. Observations in the thanatophoric mice suggest that signaling through Fgfr3 both promotes and inhibits chondrocyte proliferation at different times during development. Chondrocyte differentiation, by contrast, was suppressed throughout embryonic development. Most mice carrying the *Fgfr3* Lys644Met mutation (the equivalent of the human SADDAN mutation) survived the neonatal period and exhibited long bone abnormalities milder than those seen in the thanatophoric dysplasia type II model.

Chen and colleagues [244] have constructed a mouse carrying an *Fgfr3* Ser365Cys mutation, the equivalent of one of the mutations causing thanatophoric dysplasia type I in humans. The mutant mice demonstrated shortened limbs with reduced proliferation and differentiation of chondrocytes at the growth plate. The mutation also caused down regulation of expression of Indian hedgehog (*Ihh*) and parathyroid hormone-related protein (*PTHrP*) receptor genes.

Transgenic mice with altered Fgfr1 and Fgfr3 signaling in growth plate chondrocytes have been reported by Wang et al. [245]. *Fgfr1* was activated in the growth plate in cells that normally express FGFR3, and comparison was made with mice expressing a similarly activated *Fgfr3* construct.

APPENDIX

Saethre-Chotzen Syndrome

Although Saethre-Chotzen syndrome is not caused by FGFR mutations, it is included here because it is one of the major human craniosynostosis syndromes. Saethre-Chotzen syndrome (MIM 101400) is characterized by brachycephaly, a low frontal hairline, facial asymmetry, ptosis of the eyelids, a flat midface, and a thin pointed nose. The mode of inheritance is autosomal dominant, with incomplete penetrance and variable expressivity. The birth prevalence is 1 in 65,000.

Most cases of Saethre-Chotzen syndrome have brachycephaly due to coronal synostosis. Frequently, plagiocephaly and facial asymmetry are also found. Hypertelorism, strabismus, and ptosis of the eyelids are usually noted. The nose is long and pointed, and the nasal septum may be deviated. Maxillary hypoplasia and mandibular prognathism are other findings. The palate is highly arched and narrow and may be cleft. The ears are small and posteriorly rotated, often with a prominent crus [231,232].

Limb findings include brachydactyly and partial cutaneous syndactyly between fingers 2 and 3 and occasionally between toes 2 and 3. The great toes can be broad and deviated towards the other toes. Other skeletal anomalies include contractures of the elbows and defects of the cervical and lumbar spine.

Saethre-Chotzen syndrome is associated with mutations in the *TWIST* gene at chromosome 7p21.1. Mutations may involve cytogenetic deletions, translocations, and heterozygous mutations in the *TWIST* gene [232,233,234].

Chapter 23, Part V

Defects in Skeletal Morphogenesis

Stefan Mundlos and Bjorn R. Olsen

Institut für Medizinische Genetik, Charité, D-13353 Berlin, Germany (S.M.); Department of Cell Biology, Harvard Medical School, Harvard-Forsyth Department of Oral Biology, Harvard School of Dental Medicine, Boston, Massachusetts 02115 (B.R.O.)

SUMMARY

- **Heritable diseases of the skeleton provide insights into skeletal patterning, organogenesis, and growth. Dysostoses are malformation syndromes that affect selected embryologically defined skeletal elements, the remainder of the skeleton being normal. They are generally caused by mutations in transcription factors or cytokines that regulate cell differentiation.**
- **Dysostoses can be divided into four groups: disorders of the craniofacial skeleton; disorders of the axial skeleton; disorders of the appendicular skeleton; and disorders characterized by patterning defects as well as a generalized disturbance of growth (dysostoplasias).**
- **Disorders of the craniofacial skeleton include disorders of neural crest cell migration/differentiation (Treacher Collins-Franceschetti syndrome, Waardenburg syndrome, DiGeorge syndrome/Shprintzen Velocardiofacial syndrome) and midline defects (holoprosencephaly).**
- **Disorders of the axial skeleton include disorders affecting vertebral segmentation (spondylocostal dysostosis) and disorders that affect caudal structures (sacral agenesis).**
- **Disorders of the appendicular skeleton are disorders affecting the patterning of hands/feet (polydactylies, syndactylies, and hypoplasias), disorders affecting dorsal-ventral patterning (nail-patella syndrome), and disorders of growth and joint formation (brachydactylies, acromesomelic dysplasia, and proximal symphalangism).**
- **Dysostoplasias, characterized by phenotypes that share aspects of dysplasias and dysostosis, are caused by mutations in genes that are involved in the formation of cartilage and bone as an organ. They include disorders (campomelic dysplasia, cleidocranial dysplasia) resulting from mutations in transcription factors that regulate chondrocyte and osteoblast differentiation, chondroectodermal dysplasia and short-rib-polydactyly syndromes.**

Connective Tissue and Its Heritable Disorders, pages 993–1023

INTRODUCTION

The identification of genes responsible for human inheritable skeletal disorders is increasingly leading to major advances in our understanding of the molecular and cellular basis of skeletal morphogenesis. Mutations in genes that play a major role during early skeletal development and patterning result in malformations that affect selected, embryologically defined skeletal elements, while the remainder of the skeleton is normal. Such malformations, classified as dysostoses, represent a large group of rare disorders. In this chapter we have included conditions that are well defined clinically, and for which the molecular and/or embryological pathogenesis is relatively clear (for detailed clinical information on these and other related syndromes see Jones 1997 [1]). We have divided the conditions into four broad groups as follows: disorders that primarily affect the craniofacial skeleton; disorders that affect the axial skeleton; disorders that include malformations of the appendicular skeleton; and conditions that include patterning defects as well as a generalized disturbance of skeletal growth. Conditions in this last group share aspects of both dysostoses and dysplasias, dysplasias being disorders that affect the skeleton in a generalized manner because both bone and cartilage are affected. We refer to conditions in this last group as dysostoplasias and discuss how these disorders are caused by mutations in genes that play important roles in skeletal organogenesis.

The general architecture of the vertebrate skeleton is determined by a range of early patterning genes. These genes pattern cells from three distinct embryonic lineages that contribute to the development of bone. The neural crest, the sclerotome, and the lateral plate mesoderm contribute to the craniofacial skeleton, the axial skeleton, and the limbs, respectively (Fig. 1). Organogenesis follows patterning and involves the formation of cartilage and bone as an organ (the skeleton). Chondrocytes or osteoblasts differentiate and form the early anlagen, representing the outlines of the future skeletal elements. Bones then develop, either directly from osteoblastic progenitor cells (intramembranous ossification) or within a temporary framework of hyaline cartilage (endochondral ossification) (for review, see [2]; see also Chapter 1, parts II and III, this volume).

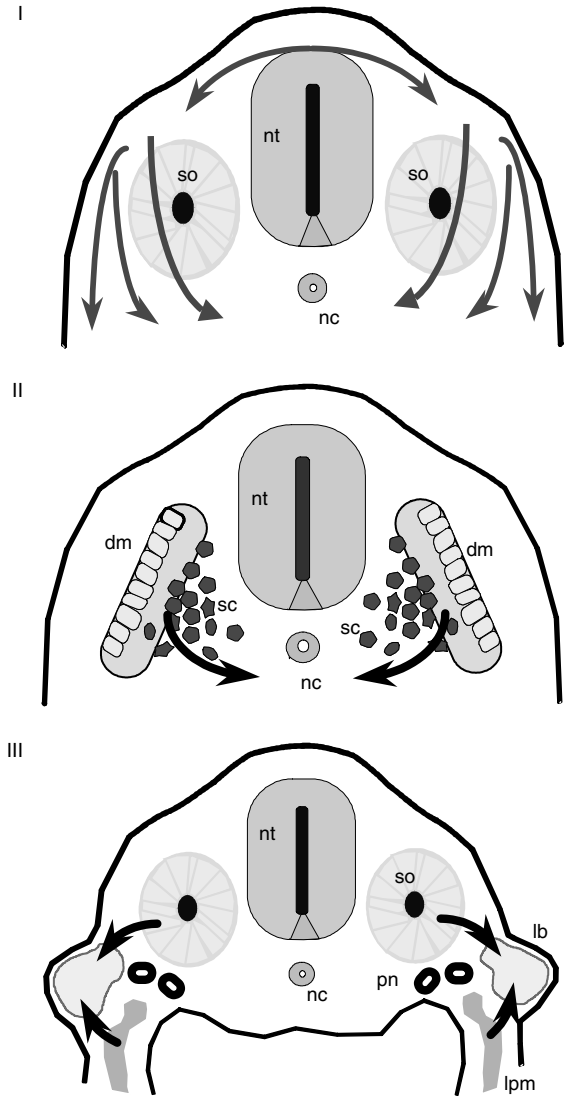

Figure 1. The origin of bone. Patterning of undifferentiated mesenchymal precursor cells involving cell-to-cell signaling and transcriptional regulation leads to migration, determination, and differentiation, processes that will eventually result in the formation of individual skeletal elements. Skeletal precursors originate from three distinct embryonic lineages: the neural crest, the sclerotome, and the lateral plate mesoderm. **I.** Migrational pattern of neural crest cells. Neural crest cells originate from the dorsal part of the neural tube and migrate along specific pathways dorsolaterally and through the somites (arrows). Most cranial bones including the calvaria, the maxilla, the mandible, the teeth and the inner ear are derivatives of the neural crest. **II.** The axial skeleton is derived from the sclerotome. The somites differentiate upon signals from the notochord into the sclerotome and the dermatomyotome. Sclerotome cells migrate towards the notochord where they contribute to the formation of vertebrae and ribs. **III.** Limb development begins with the migration of cells from the lateral plate mesoderm and the somites to form the limb bud and the limb precursor cells. The initial phase of proliferation seems to be under the control of the nearby mesonephros. Limb precursors then differentiate along a genetically determined pattern. Somitic cells contribute to the limb musculature, whereas cells from the lateral plate mesoderm generate the skeletal elements of the limbs. nt, neural tube; so, somite; nc, notochord; sc, sclerotome; dm, dermatomyotome; lb, limb bud; lpm, lateral plate mesoderm; pn, pronephros/mesonephros. Top is dorsal.

Much of what we know about the general mechanisms underlying skeletal morphogenesis is the result of animal studies. Such studies provide a good correlation between specific embryological events and gene function and, consequently, a framework for understanding the fundamental pathways that build and pattern bone. Based on the remarkable conservation of basic developmental mechanisms between animal species, connections to human disorders are frequently possible. The reverse is also true. The identification of genes responsible for human heritable diseases of the skeleton is increasingly leading to major advances in our understanding of the processes that underlie skeletal morphogenesis.

Heritable diseases of the skeleton can be divided into two broad categories. "Dysplasias" are conditions in which bone or cartilage is affected as a tissue and consequently has an abnormal structure and/or function. In contrast, "dysostoses" are malformation syndromes that affect selected, embryologically defined skeletal elements, the remainder of the skeleton being normal. A dysplasia usually affects the skeleton in a generalized manner resulting in disproportionate dwarfism, whereas patients with dysostoses show more localized defects. Genes that are involved in the pathogenesis of dysplasias encode molecules that are important for bone formation and growth, such as extracellular matrix molecules or factors that regulate chondrocyte differentiation/proliferation in growth plates. In contrast, genes that cause a dysostotic phenotype play a major role during early skeletal development and patterning, and their products are frequently transcription factors, for example, *HOX* or *PAX* genes. Dysostoses are consequently disorders of skeletal morphogenesis.

Dysostoses represent a large group of rare disorders, many of which are still ill defined. In the great majority of cases, the molecular pathogenesis is unknown. In this chapter, we will focus on clinically well-defined conditions in which the molecular and/or embryological pathogenesis is relatively clear. Four broad groups can be differentiated. These include disorders that primarily affect the craniofacial skeleton; disorders that affect the axial skeleton; and disorders that include malformations of the appendicular skeleton. Naturally, overlap between these groups is observed. A fourth group is composed of diseases that are characterized by patterning defects as well as a generalized growth disturbance, indicating that the mutated gene is active not only during early embryogenesis but also during fetal and postnatal life. Since these diseases share aspects of both dysplasias and dysostoses, we will refer to them as "dysostoplasias." The results of recent studies indicate that diseases in this group are caused by mutations in genes that are involved in skeletal organogenesis.

DISORDERS OF THE CRANIOFACIAL SKELETON

Development of the craniofacial skeleton involves a complex series of events that are disturbed in many genetic conditions [3–5]. The large number of craniofacial anomalies provide, therefore, an excellent opportunity to study craniofacial development, and a characteristic facial appearance frequently gives a clue to the correct diagnosis in genetic syndromes [6]. The facial bones develop from five primordia — the unpaired frontonasal prominence and the paired maxillary and mandibular prominences. The mandibular and maxillary prominences, derivatives of the first branchial arch, grow toward the midline where they

eventually fuse. The frontonasal prominence gives rise to the frontal bones of the skull, the nose, and the philtrum. In humans, this process begins around 4 weeks of development and by 8 weeks a recognizable face is apparent.

Most of the craniofacial bones are of neural crest origin [7]. Neural crest cells migrate from the dorsal part of the neural tube through the sclerotome into the branchial arches and the frontonasal mass where they contribute to a wide variety of tissues, including bone and cartilage [8,9]. Cell tracing studies in mouse and chick embryos have shown that neural crest cells originating from different rostrocaudal levels migrate into specific areas of the developing face [10]. For example, the first branchial arch is populated by neural crest cells migrating from the caudal midbrain and the first two rhombomeres, while neural crest cells from the fourth rhombomere populate the second branchial arch. Through an as yet unknown series of epithelial–mesenchymal interactions, neural crest cells differentiate and contribute to nerves, muscles, and bones of the head.

Disorders of Neural Crest Cell Migration/Differentiation

Treacher Collins-Franceschetti Syndrome (Mandibulofacial Dysostosis)

Treacher Collins-Franceschetti syndrome (TCOF1 or MFD1; MIM 154500) is a well-characterized craniofacial disorder with autosomal dominant inheritance [11,12]. The clinical features include downward-slanting palpebral fissures with lower lid coloboma or partial to total absence of lower eyelashes, malformations of the auricles, atresia of the external auditory canals, and malformation of the middle ear ossicles resulting in bilateral conductive hearing loss, malar and mandibular hypoplasia, and cleft palate. There is marked phenotypic variation so that some individuals are only partially and mildly affected whereas in others the malformations result in perinatal death due to a compromised airway.

Treacher Collins-Franceschetti syndrome has been mapped to chromosome 5q32–33.1, and a new gene, which the discoverers named *TREACLE*, isolated [13]. *TREACLE* has no strong homology to any other known gene, and the mouse homologue is expressed in a variety of embryonic and adult mouse tissues. The protein is therefore not specific to craniofacial tissues, but it does show high levels of expression at the edges of neural folds and in the branchial arches at the time of critical morphogenetic events [14]. A large number of mutations have been found in *TREACLE*. All of these appear to represent loss-of-function mutations, and Treacher Collins-Franceschetti syndrome is therefore likely to be a consequence of haploinsufficiency for treacle protein [15]. The presence of nuclear and nucleolar localization signals and several phosphorylation sites has led to the hypothesis that treacle is a member of the nucleolar phosphoprotein family, but why mutations result in the characteristic phenotype is not clear [16,17].

Waardenburg Syndrome

The eponym, Waardenburg, covers a group of auditory-pigmentary syndromes that can be separated into several subgroups [18]. Type I Waardenburg syndrome (WS1; MIM 193500) is the type originally described by Waardenburg as a combination of (i) lateral displacement of inner canthi (dystopia canthorum) with short palpebral fissures, a broad and high nasal bridge and hypoplastic alae nasi; (ii) partial albinism manifested by hypopigmented skin lesions, hypochromia iridis (bright blue irises), heterochromia iridis, a hypopigmented ocular fundus and/or a white forelock; and (iii) deafness of the sensorineural type. The hearing loss is congenital and may be unilateral or bilateral and can vary from slight to profound. Dystopia canthorum is the most penetrant of all features, being present in 99% of those affected, the others showing marked interfamilial and intrafamilial variability. WS1 carries a small risk of spina bifida and can be associated with Sprengel's deformity (elevation of the scapula) and cleft lip/palate. Waardenburg syndrome type II (WS2) is similar to WS1 except for the absence of dystopia canthorum. Because this is the most reliable and distinguishing clinical sign of Waardenburg syndrome, the clinical definition of WS2 is somewhat arbitrary, covering any syndrome with deafness/pigmentation defects. WS2 is heterogeneous, with linkage to different loci in different families. Linkage to chromosome 3p13, associated with mutations in the microphthalmia gene (see below), is now classified as Waardenburg syndrome type IIA (WS2A; MIM 193510), while Waardenburg syndrome type IIB (WS2B; MIM 600193) maps to a gene on chromosome 1p21–p13.3. A rare variant of WS1 that includes limb abnormalities with an amyoplasia-like condition affecting the arms has been called type III (WS3; MIM 148820) or Klein-Waardenburg syndrome. A fourth type, characterized by the association of deafness and/or pigmentary disturbances with Hirschsprung's disease (aganglionic megacolon), is called Waardenburg-Shah syndrome or WS4 (MIM 277580).

WS1 and WS3 are caused by mutations in *PAX3* [19–22], whereas WS2 is heterogeneous, being caused by mutations in the microphthalmia (*MITF*) gene in some but not all affected families (see above) [23]. Mutations in endothelin 3 (*EDN3*), or in the gene for its receptor (*EDNRB*), have been identified in patients with Hirschsprung's disease [24,25]. Homozygous individuals can show a WS4 phenotype. In families with dominant inheritance, WS4 is caused by mutations in the *SOX10* gene [26].

DeStefano et al. [27] have attempted to link gene function and phenotype in Waardenburg syndrome. The underlying cause of hearing loss is the requirement for melanocytes in the stria vascularis of the cochlea. The patchy absence of melanocytes leads to the observed pigmentary and auditory defects. Melanocytes are derived from neural crest cells. Considering the involvement of other neural crest derivatives such as the facial bones and the enteric ganglia, it is apparent that the Waardenburg syndromes are neurocristopathies. *PAX3* encodes a transcription factor, one of a family of nine human PAX proteins defined by the presence of a 128 amino acid paired domain [28]. During development, *PAX3* is expressed at the dorsal side of the neural tube, where neural crest cells emerge and start their migration. MITF is a transcription factor known to activate the gene for tyrosinase, a key enzyme in melanogenesis [29,30]. *MITF*, in turn, is directly regulated by PAX3, providing a molecular basis for the similar phenotypes in WS1 and WS2 [31]. *SOX10* is expressed early in development in neural crest cell derivatives [32]. Its role in these cell lineages in unknown.

Animal models. A model for the megacolon associated with WS4 is the dominant spotting mouse (Dom) [33]. The disorder is caused by a premature termination mutation in *Sox10* (MIM 602229), resulting in apoptotic loss of neural crest cells [34]. A defect in neural tube development occurs also in the Splotch mouse, caused by a deletion in the paired

homeodomain of *Pax3* [35]. A mouse model for WS2 is microphthalmia (mi), caused by mutations in *Mitf* [36].

DiGeorge Syndrome/Shprintzen Velocardiofacial Syndrome

The DiGeorge/Shprintzen syndrome (DGS; MIM 188400) comprises with variable expressivity (i) heart defects (mainly of the outflow tract); (ii) hypocalcemia arising from parathyroid hypoplasia; (iii) immune deficiency due to thymic hypoplasia; and (iv) a characteristic facies with telecanthus, a short philtrum, a rather bulbous nose, and submucous or palatal clefting. All phenotypes can be seen within a single family, and most cases have been shown to have deletions of chromosome 22q11. The acronym CATCH22 (cardiac defects, abnormal facies, thymic hypoplasia, cleft palate, and hypocalcemia resulting from 22q11 deletions) has been proposed for this condition [37]. The diagnosis is made by fluorescence *in situ* hybridization using probes corresponding to the deleted segment. Parents should be screened for carrier status. The combination of defects suggests a role for the DiGeorge gene in neural crest cell migration.

Animal models. In the mouse, homozygosity for inactivated alleles of the transcription factor Hoxa3 produces a phenocopy of DiGeorge syndrome [38]. The human *HOXA3* gene is not on chromosome 22q11, but an explanation for why complete loss of *Hoxa3* causes a DiGeorge/Shprintzen–like phenotype in mice, could be that *HOXA3* is an important transcriptional activator of some of the genes that are located within the deletions on 22q11.

Midline Defects

Holoprosencephaly

Holoprosencephaly encompasses an etiologically heterogeneous group of disorders that range from the most severe abnormality with cyclopia (a single eye) and a proboscis above the eye to the occurrence of a single central upper incisor (Fig. 2). Most cases are sporadic, but in some families holoprosencephaly is inherited as an autosomal dominant trait. The condition in such families usually maps to chromosome 7q36 and has been found to be associated with loss-of-function mutations in the sonic hedgehog gene, *SHH* [39]. This form of holoprosencephaly is now designated holoprosencephaly 3 (HPE3; MIM 142945). A second familial form of holoprosencephaly, caused by mutations in the DNA-binding domain of the homeobox protein encoded by *SIX3* on chromosome 2p21, is referred to as holoprosencephaly 2 (HPE2; MIM 157170) [40]. Other forms are associated with alterations in chromosome 21q22.3 (HPE1; MIM 236100) [41] or 18p11.3 (HPE4; MIM 142946) [42].

Animal models. Mice lacking the sonic hedgehog gene die around birth with malformations of the frontal areas of the brain and severe abnormalities of the skeleton. They display cyclopia, and at day 15.5 of gestation, show a proboscis-like extension [43]. These facial features are very similar to those observed in human holoprosencephaly, except that in humans, the phenotype is seen in heterozygous individuals, whereas in mice only homozygous animals are affected.

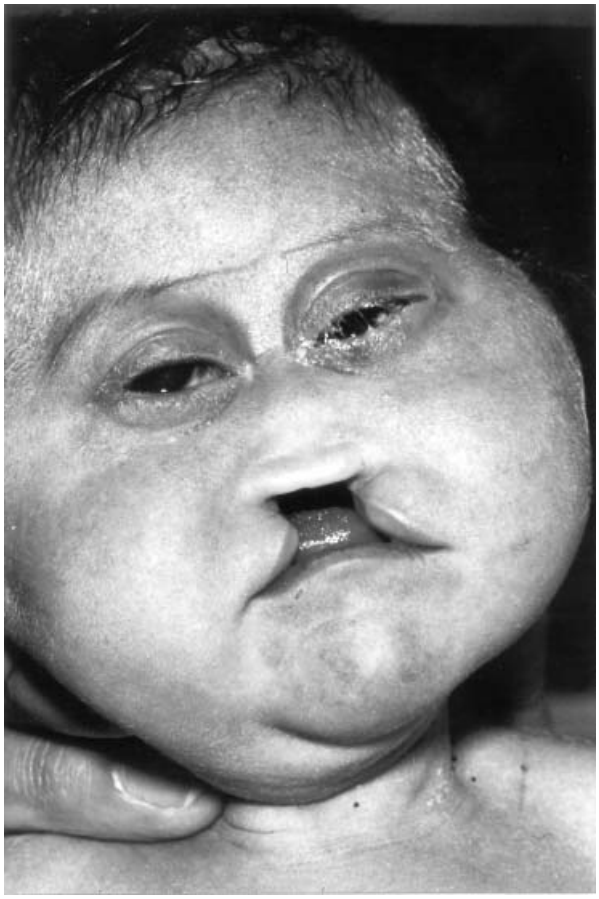

Figure 2. Holoprosencephaly. Patient with holoprosencephaly (newborn) showing midline cleft, hypotelorism, and absence of philtrum and nasal septum.

DISORDERS OF THE AXIAL SKELETON

Malformations of the ribs and/or vertebrae are a relatively common finding. Vertebrae and ribs originate from the sclerotome, a structure formed by the differentiation of somites (Fig. 1). Somites are blocks of epithelial cells with a repetitive, periodic architecture, which originate from the paraxial mesoderm. They determine the migration paths of neural crest cells and give rise to the vertebrae and ribs, the dermis of the dorsal skin, and the skeletal muscles of the body wall and limbs. Somites are laid down sequentially in a head-to-tail order, in a row on each side of the body axis. The budding of somites from the presomitic mesoderm occurs in a precise, regular series with perfect symmetry between the two sides of the body. Recent findings have unraveled some of the basic mechanisms that control somitogenesis [44,45]. The formation of somites involves a molecular segmentation clock that leads to the oscillation of hairy 1 expression in mesodermal cells. The hairy 1 oscillator drives lunatic fringe expression, which in turn drives the decisive pattern of changes in Notch activity and Delta expression in the segmenting mesoderm [46–50]. The Notch-Delta pathway is of crucial importance in somitogenesis as demonstrated by several knock-out mutations — *Mesp2* [51], *Notch1* [52], *Dll1* [53], *lunatic fringe* [54,55], and *Dll3* [56] — and the severe vertebral and rib deformities of homozygous mice with the pudgy mutation (pu), which is caused by a disruption of *Dll3* [56]. Interestingly, these mutations, leading to irregular size and asymmetry of somites, result in similar phenotypes. The skeletal malformations resemble those observed in humans with vertebral malformations.

When the somite is first formed, any of its cells can become any of the somite-derived structures. As the somite

matures, its various regions become committed to form only certain cell types. Patterning of the somite is brought about by the interaction of ventralizing signals from the notochord/floorplate complex and dorsalizing signals from the surface ectoderm and neural tube. Upon these signals, the ventral medial cells of the somite undergo mitosis, become mesenchymal cells again, and migrate towards the notochord. This portion of the somite is called the sclerotome, and will eventually give rise to vertebral and rib chondrocytes. The signalling molecule sonic hedgehog (*Shh*) is the major signal from the notochord/floorplate that initiates and controls sclerotome formation. Mice with inactivated *Shh* alleles develop no sclerotome and are hence devoid of the dorsal parts of ribs and vertebrae [43]. The homeotic (*Hox*) genes are expressed in overlapping domains along the rostrocaudal axis [57,58]. Targeted inactivation or ectopic expression of these genes in the mouse results in the deletion or addition of skeletal elements into shapes resembling other elements [59,60]. Thus, after induction of the sclerotome, *Hox* genes give the positional information necessary for the identity of individual vertebrae.

Spondylocostal Dysostosis

Spondylocostal dysostosis is a genetically heterogeneous group of disorders affecting vertebral segmentation. Clinically, three entities have been delineated. Jarcho and Levin [61] described a severe, recessive form (SCDO1; MIM 277300) that is characterized by severely malformed vertebrae, particularly in the thoracic spine, and a decreased number of ribs that have a crowded origin from the thoracic vertebral bodies and fan out to give a characteristic "crab-like" appearance. Affected individuals frequently die during the neonatal period due to respiratory insufficiency. This type of condition seems to be particularly common in Puerto Rico. A benign form of spondylocostal dysostosis with autosomal dominant inheritance (MIM 122600) has also been described [62]. Its clinical manifestation is extremely variable, ranging from single vertebral defects to multiple affected vertebrae with rib fusions. A third form, also designated spondylothoracic dysostosis (see MIM 277300), is inherited as an autosomal recessive disorder. It is probably the most frequent entity within this group. It is usually more severe than the dominant form but no clinical or radiological feature consistently distinguishes it from the benign dominant form (Fig. 3).

It is likely that these three forms are only the tip of the iceberg. For example, there are many cases of spondylocostal dysostosis with miscellaneous malformations, mostly urogenital. Other types of vertebral malformations affect predominantly the cervical spine with fusion of vertebrae and hemivertebrae. The so-called Klippel-Feil deformity (MIM 148900) is clearly heterogeneous, some forms being genetic in origin, while others have no simple genetic basis, or are due to disruptions. Given the complexity of somitogenesis and the multiple genes involved, it is likely that this phenotypically rather homogeneous group of vertebral segmentation defects is genetically heterogeneous. A locus for autosomal recessive spondylocostal dysostosis has been mapped to chromosome 19q [63] close to the human homologue of the pudgy gene, *Dll3* [56].

Sacral Agenesis/Currarino Triad

Hereditary sacral agenesis (MIM 176450) is an autosomal dominant condition including, with variable expressivity (i) anorectal anomalies such as anal stenosis, anal displacement, or imperforate anus; (ii) a presacral mass with anterior meningocele or presacral teratoma; and (iii) partial sacral agenesis with an intact first sacral vertebra (Fig. 4). The combination of anorectal, sacral and presacral anomalies is known as the Currarino triad. The clinical features of affected individuals can be mild, with constipation being the only complaint, or severe with imperforate anus, anterior meningocele, and the typical sickle-shaped hemisacrum revealed by X-ray of the sacral region, indicative of the Currarino triad.

Figure 3. Spondylocostal dysostosis. Radiograph of a patient at age 3 weeks with spondylocostal dysostosis, short trunk dwarfism, hypospadia, and normal limbs. Extensive malsegmentation throughout the vertebral column with vertebral fusions (arrowhead), hemivertebrae (arrow), and rib anomalies (fusion, abnormal position).

Lynch et al. [64] identified the locus for dominant sacral agenesis on chromosome 7q36 close to the gene for sonic hedgehog. Within the critical region, a homeobox gene, *HLXB9*, was identified, and mutations were characterized in several affected families [65]. The mutations were expected to produce severely truncated products that probably reflect loss-of-function alleles. Haploinsufficiency is likely to explain the phenotype since deletions of the 7q35-qter region have frequently been observed in patients with sacral agenesis. Expression of *HLXB9* was observed in lymphoid and pancreatic tissue and in the anterior horn regions of the spinal cord. Clearly, further work is needed to explain the pathogenesis of this syndrome.

Other types of caudal dysgenesis have been described. Complete absence of the sacrum and lower vertebrae together

Figure 4. Sacral agenesis/Currarino triad. Lateral view at age 4 years showing normal lumbar vertebrae, but absence of sacrum (arrows).

with multiple other congenital anomalies (urogenital, anal, cardiac) occurs on a sporadic basis and is frequently associated with maternal diabetes [66]. The role of *HLXB9* in this and other types of caudal regression remains to be determined. However, the well-established association between sacral agenesis and maternal insulin-dependent diabetes mellitus and the expression of *HLXB9* in pancreas is intriguing.

DISORDERS OF THE APPENDICULAR SKELETON

Malformations of the hands and/or feet are frequently observed in human malformation syndromes. Some are unspecific and only found in association with other major defects, others are more specific and often diagnostic. The study of model systems and the genetic analysis of human syndromes have elucidated the causes of several heritable limb malformations in humans. In many instances, it is now possible to explain in some detail how malformations occur taking advantage of the recent progress that has been made in understanding the mechanisms of limb morphogenesis.

The limb originates from a dual contribution of the lateral plate and the somitic mesoderm (Fig. 1) [67]. After the initial outgrowth of the limb bud, cells from the lateral edges of nearby somites migrate into the limb and contribute to muscles, nerves, and vasculature. All other limb tissues, including the skeletogenic mesenchyme are derived from the lateral plate mesoderm. Outgrowth of the limb bud is the result of a series of interactions between the mesoderm and the overlying ectoderm (for reviews, see [68,69]). Several fibroblast growth factors (FGFs) can initiate the signalling cascade that results in fully formed limbs when applied to mesoderm of the flank. Cells of the growing limb bud are embedded in a dynamic three-dimensional structure that is controlled by multiple signalling molecules. The outgrowth of the limb along the proximodistal axis is directed by signals emerging from the apical ectodermal ridge (AER), a structure of specialized cells at the outermost edge of the limb bud. Cells from the underlying progress zone are kept in a proliferating nondifferentiated state through signals from the AER such as FGF4 and FGF8 [70,71]. Removal of the AER results in the termination of limb outgrowth. The anteroposterior pattern of the limb bud is established by the zone of polarizing activity (ZPA), a group of cells at the posterior margin of the limb bud. Sonic hedgehog (SHH) mediates the activity of the ZPA [72]. Transplantation of the ZPA or SHH-expressing cells to the anterior margin of a limb bud results in mirror duplications of the digits indicating that the polarity has been maintained, but the polarizing activity is now from both directions, anterior and posterior. Anterior extra digits and an ectopic anterior ZPA are also seen in mice homozygous for inactivated alleles of the Aristaless-like 4 (*Alx4*) gene. This gene, encoding a paired-type homeodomain protein that is expressed in anterior mesenchymal cells in the limb bud, is therefore part of the regulatory mechanism that restricts formation of the ZPA to the posterior mesenchyme in the normal limb [73]. Loss-of-function mutations in *Alx4* cause the mouse mutant phenotype Strong's luxoid (lst) [74]. Dorsoventral patterning requires the expression of the signalling molecule Wnt7a in the dorsal ectoderm and the homeobox-containing transcription factor engrailed 1 (EN1) in the ventral ectoderm [75,76]. *HOX* genes from the 5′ region of the A- and D-clusters on chromosome 7 and chromosome 2, respectively, show characteristic stage-dependent expression patterns that determine the shape and identity of the individual elements [77]. How this works and what the downstream targets of the *HOX* genes are is not clear, but it seems that they work in a dose-dependent fashion regulating proliferation and cell adhesion [78].

Patterning through transcription factors and signaling molecules leads to the formation of cartilaginous templates that are laid down in a proximal to distal sequence, so that the humeral anlage is formed first, followed by the radius and ulna, and lastly by the digits. The humerus and ulna, as well as the metacarpals and phalanges, are first formed as continuous cartilaginous rods that are subsequently segmented into the individual bones [79]. Segmentation leads, through apoptotic cell death, to the formation of joints, a process in which bone morphogenetic proteins (BMPs) or related molecules, such as cartilage-derived morphogenetic proteins (CDMPs, also called growth and differentiation factors, GDFs), play a major role [80,81]. Apoptosis is also involved in the separation of the individual digits, a process that is disturbed in syndactyly. Again, BMPs seem to play a significant role [82,83]. The effects of BMPs on cellular processes depend on their local concentrations. It is not surprising, therefore, that they are subject to both positive and negative regulation at several levels. One important regulator is noggin, a secreted protein that binds and inactivates BMPs. Mice that are homozygous for inactivated noggin (*Nog*)

alleles die at birth with multiple defects, including fusion of bones in the appendicular skeleton [84].

Congenital limb deformities are a genetically and clinically heterogeneous group of disorders. Those affecting the hands/feet (autopodia) can be classified into polydactylies (preaxial, involving digits of the radial side of the limb, or postaxial, involving digits on the ulnar side), syndactylies (fusion of soft tissues and/or bones), or hypoplasias affecting variable parts or segments. The most frequently observed limb malformation is post- or preaxial polydactyly, with a prevalence of 7 to 14 per 10,000 live births. Defects of the stylopodium (humerus or femur) or the zeugopodium (radius/ulna or fibula/tibia) can occur with or without associated hand malformations and can usually be classified as hypoplastic defects. This classification, based on clinical appearance and skeletal radiology, is frequently complicated by a large variation in expressivity and considerable overlap between apparently different malformation syndromes. Detailed molecular analyses should help define the phenotypic spectrum associated with certain mutations.

Polydactyly-Disorders Involving the Hedgehog Pathway

Vertebrate sonic hedgehog (*SHH*) is homologous to the *Drosophila* segment polarity gene hedgehog (*Hh*). Given its central role in development, the mechanisms of SHH signaling and the SHH pathway have been of major interest to the research community. Much of what we know has been delineated in *Drosophila*, but the general pathway and the major players in it are conserved between flies and higher animals and are likely to be similar in humans. Hh is a secreted signaling molecule that undergoes autocatalytic cleavage to generate two fragments [85]. The amino-terminal fragment contains the active part of the molecule. It is modified by the covalent attachment of cholesterol, a process that is essential for proper function [86,87]. The receptor for Hh is patched (Ptc), which forms a receptor complex with smoothened (Smo), a seven-pass membrane protein that transduces the Hh signal [88–92]. In the absence of Hh, Ptc inhibits Smo; this inhibition is released after the binding of Hh to Ptc [93]. As a result of signaling from Smo, the transcription factor cubitus interruptus (Ci) is stabilized, activating downstream targets of Hh.

Ci is a zinc finger transcription factor that acts as a bifunctional modulator of gene expression. In the absence of Hh signal, Ci is proteolytically processed in the cytoplasm into a shortened form causing transcriptional repression of Hh target genes including wingless (*wg*), decapentaplegic (*Dpp*), as well as *Ptc* and *Hh* itself. Hh signaling stabilizes full-length Ci, which, following transport to the nucleus, activates transcription of Hh targets [94,95]. Ci has three vertebrate homologues, GLI1, GLI2, and GLI3. Recent evidence suggests that in vertebrates, as in the fly, hedgehog signaling involves two antagonistic operations, one repressing, the other activating. In contrast to *Drosophila*, however, vertebrates may have solved this by gene duplication with GLI1 functioning as an activator, and GLI3 as a repressor [96].

Greig Cephalopolysyndactyly

Greig syndrome (GCPS; MIM 175700) is a dominantly inherited condition characterized by (i) malformations of the hands (broad thumbs, postaxial polydactyly — frequently pedunculated postminimus, syndactyly primarily of the third and fourth fingers) and feet (preaxial polydactyly/broad toes, occasionally postaxial polydactyly, syndactyly primarily of the first to third toes) (Fig. 5); and (ii) craniofacial anomalies consisting of hypertelorism, broad nasal root, frontal bossing, scaphocephaly, brachycephaly, and macrocephaly. Occasional defects include late-closing cranial sutures, mild mental deficiency, a mild degree of hydrocephalus, and other forms of polydactyly.

Greig syndrome was one of the first dysostoses to be characterized at the molecular level. In 1991, Vortkamp et al. [97] identified *GLI3* as the culprit gene, taking advantage of a 7p translocation segregating with the phenotype in one family. In this and other subsequent families, *GLI3* was shown to be completely deleted or truncated upstream or within the region coding for the zinc finger domain. Thus, Greig syndrome is likely to be caused by haploinsufficiency of the GLI3 gene.

Pallister-Hall Syndrome

Pallister-Hall syndrome (PHS; MIM 146510) consists of (i) malformations of the central nervous system including hypothalamic hamartomas (Fig. 6B), hypopituitarism, and, occasionally, holoprosencephaly with midline cleft-ing; (ii) craniofacial anomalies (microtia, an absent external ear canal, a flat nasal bridge, a short nose, micrognathia); (iii) malformations of the limbs with nail dysplasia, variable degrees of syndactyly and polydactyly (central and postaxial) (Fig. 6A), and distal shortening of the limbs; and (iv) anal defects including an imperforate anus and a variable degree of rectal atresia.

Given the phenotypic overlap between Greig syndrome and the Pallister-Hall syndrome, Kang et al. [98] screened several families for mutations in *GLI3*. They identified frameshift mutations that were located 3′ of the zinc finger-encoding domains. Provided these truncated proteins are stable, they are expected to bind to DNA. What the effects of these truncated proteins are, and how they disturb the hedgehog pathway awaits further investigations.

Postaxial Polydactyly, Type A1

Postaxial polydactyly (a supernumerary digit on the ulnar or fibular side of the hands and feet) is one of the most common malformations in humans. A small extra digit, frequently in the form of a skin tag, has a high prevalence among the African-American population (1:300 to 1:1000 live births). It has been suggested that inheritance is autosomal dominant with variable expression, but autosomal recessive forms have been reported. Many genetic syndromes are associated with postaxial polydactyly such as trisomy 13, the Meckel-Gruber syndrome, or the Bardet-Biedl syndrome. There are, however, families in which postaxial polydactyly is inherited as a dominant trait as the only phenotypic manifestation (PAPA1; MIM 174200). In these cases, the extra digit is well formed, articulates with the fifth or the metacarpal/metatarsal, and is usually functional.

Radhakrishna et al. [99] studied a family with a dominant form of postaxial polydactyly and mapped the phenotype to chromosome 7p, colocalizing it with the *GLI3* zinc finger transcription factor gene defective in the Greig and Pallister-Hall syndromes. A frameshift mutation in *GLI3* was identified 3′ of those identified in patients with the Pallister-Hall syndrome [100]. The truncated protein product would thus contain the zinc finger domain as well as the protease cleavage site.

Animal models. Mouse models for *Gli3* mutations are the mutants extra-toes (xt) [101] and polydactyly Nagoya (Pdn) [102].

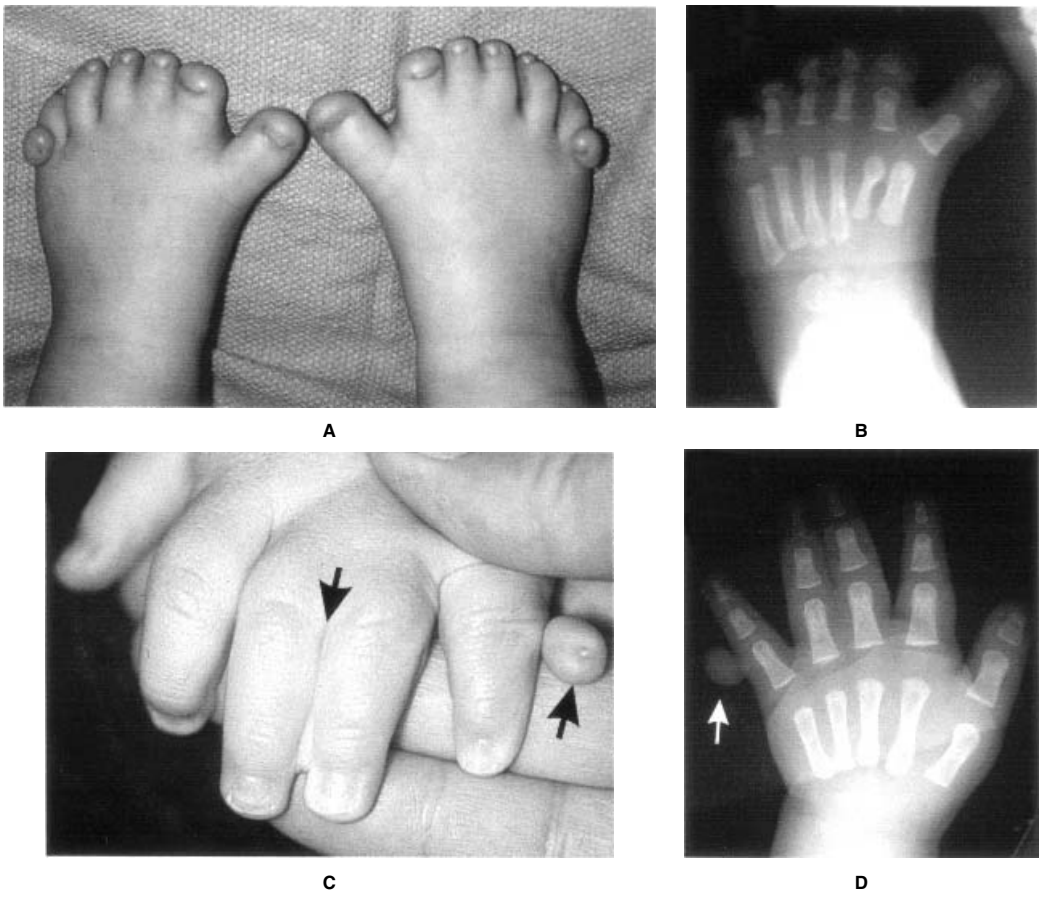

Figure 5. Greig cephalopolysyndactyly. Hands and feet of a female patient with Greig cephalopolysyndactyly syndrome aged 9 months. (**A**) Pre- and postaxial polydactyly of feet with cutaneous syndactyly of toes II to IV, and corresponding radiograph in (**B**) demonstrating complete duplication of first toe. (**C**) Postaxial polydactyly of hands (pedunculated postminimi, arrow) and cutaneous syndactyly of fingers III and IV (arrow). Corresponding radiograph is shown in (**D**). Note postaxial polydactyly without apparent ossification (arrow) and broad thumb.

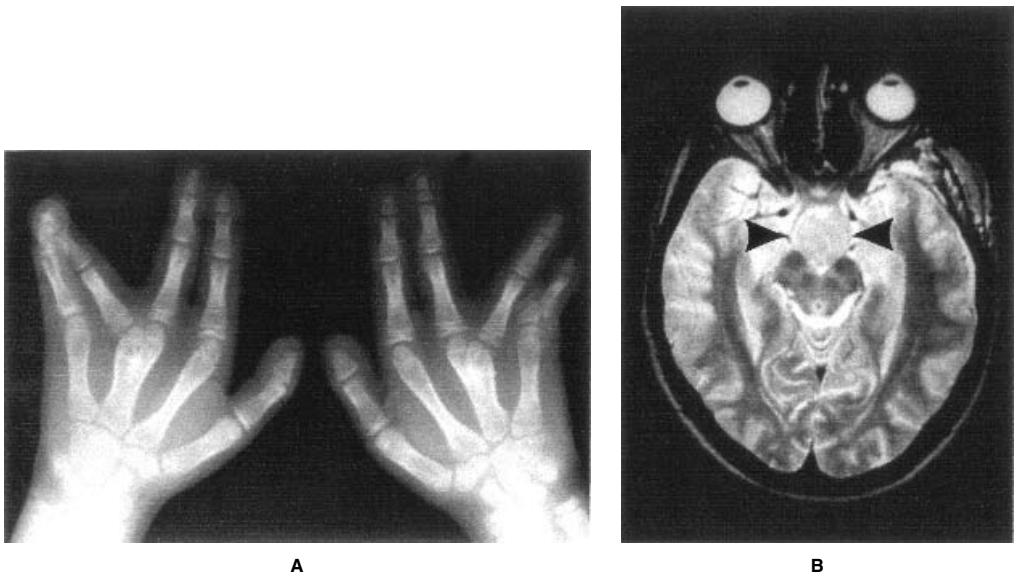

Figure 6. Pallister-Hall syndrome. (**A**) Syndactyly of metacarpals III/IV, surgically corrected postaxial polydactyly. (**B**) Hypothalamic hamartoma (MRI scan, black arrow heads). (With permission from M. Löw et al. [208].)

Townes-Brocks Syndrome

Townes-Brocks syndrome is an autosomal dominant disorder (TBS; MIM 107480) with marked variability in its severity of expression. Clinical features include (i) craniofacial anomalies consisting of external and internal ear malformations (overfolding, large ears, preauricular tags, and conductive and sensorineural deafness) and varying degrees of facial hypoplasia resembling hemifacial microsomia (Goldenhar) syndrome (MIM 141400); (ii) hand anomalies including hypoplastic, broad, or triphalangeal thumbs, preaxial polydactyly, and various other bony defects; (iii) anal defects including imperforate anus, anterior placement, and stenosis; and (iv) different types of renal anomalies (Fig. 7).

Townes-Brocks syndrome is caused by mutations in *SALL1*, the human homologue of the *Drosophila* homeotic gene *spalt* (*Sal*) [103]. SALL1 is a putative C2H2 zinc finger transcription factor similar to GLI3. The mutations described so far probably result in haploinsufficiency, as the predicted truncated proteins are expected to lack all zinc finger domains. In the fly, this transcription factor is required for the specification of posterior head and anterior tail segments; in the developing wing, Sal is activated in response to Hh signaling mediated by Dpp [104,105]. In the fish, *Spalt* has been shown to be a hedgehog target gene and to be expressed in all known hedgehog signalling centers of the embryo [106]. In the mouse, Spalt is expressed in urogenital ridge-derived structures, the notochord, and the limb buds, sites corresponding to the malformations observed in Townes-Brocks syndrome [107].

Smith-Lemli-Opitz Syndrome

Smith-Lemli-Opitz syndrome (SLOS; MIM 270400) is a rather common autosomal recessive malformation syndrome (estimated incidence, 1:20,000 live births) consisting of (i) craniofacial anomalies; (ii) limb malformations such as syndactyly, asymmetrically short fingers, or polydactyly; (iii) genito-urinary abnormalities; and (iv) moderate to severe mental retardation, various defects in brain morphogenesis and seizures. Other occasional defects include cleft palate, abnormal pulmonary lobation, rectal atresia and Hirschsprung disease.

Smith-Lemli-Opitz syndrome is due to a deficiency of 7-dehydrocholesterol-Δ7-reductase, the final enzyme in cholesterol biosynthesis [108]. Many of the features of the syndrome overlap with those found in patients with holoprosencephaly and mutations in SHH. As mentioned above, cholesterol is essential for the proper functioning of SHH [109]. This raises the possibility that the developmental abnormalities associated with defects in cholesterol biosynthesis may be due to impaired sonic hedgehog processing or signaling.

Polydactyly - Other Forms

Synpolydactyly

Syndactyly is the most common congenital malformation of the hand, occurring in approximately 1 in 2,000 live births. Several distinct forms have been delineated, all inherited in an autosomal dominant manner. Synpolydactyly, or syndactyly type II (SPD; MIM 186000), comprises syndactyly between the third and fourth fingers, with digit duplication in the syndactylous web, and syndactyly of the fourth and fifth toes (Fig. 8). Incomplete penetrance and variability both between and within affected families is common. Involvement ranges from partial skin syndactyly without digit duplication to complete duplication extending as far proximally as the metacarpals/metatarsals. Usually, all four limbs are involved, but many individuals have both normal and affected hands/feet indicating the presence of intra-individual variability.

Synpolydactyly is caused by mutations in *HOXD13* [110]. The mutations lead to an in-frame expansion of a 15-residue polyalanine tract, encoded by an imperfect trinucleotide repeat sequence, by 7, 8, 9, 10, or, in one family, 14 additional residues. In an extensive study analyzing a total of 20 families with 99 affected individuals, Goodman et al. [111] found a highly significant increase in the penetrance and severity of phenotype with increasing expansion size. Several nonpenetrant gene carriers were identified, all from families with a 7-alanine expansion. The overall penetrance in the families studied was only 86%, but was close to 100% in families with larger expansions. This has important consequences for genetic counseling. Parents who are clinically unaffected should be tested for carrier status. The authors hypothesized that the polyalanine

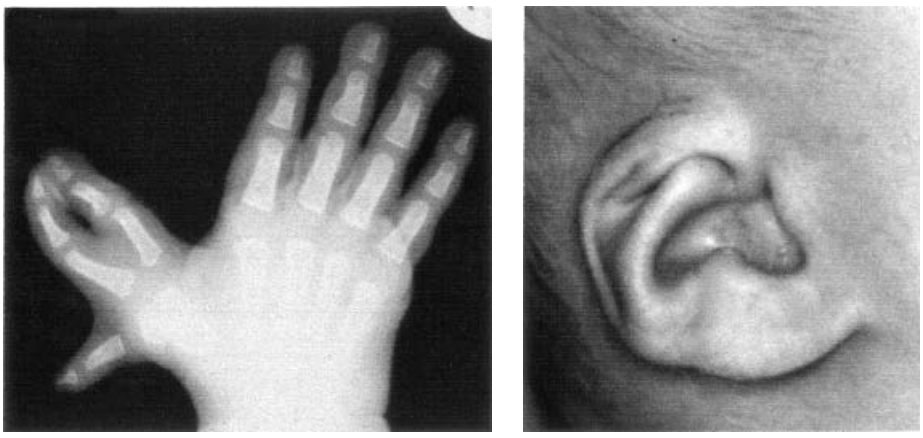

Figure 7. Townes-Brocks syndrome. (**A**) Supernumerary, triphalangeal thumbs. (**B**) Abnormal ear of same patient as in (**A**) with overfolding of the anterior part of the helix and prominent anthelix. (With permission from Kohlhase et al. [103].)

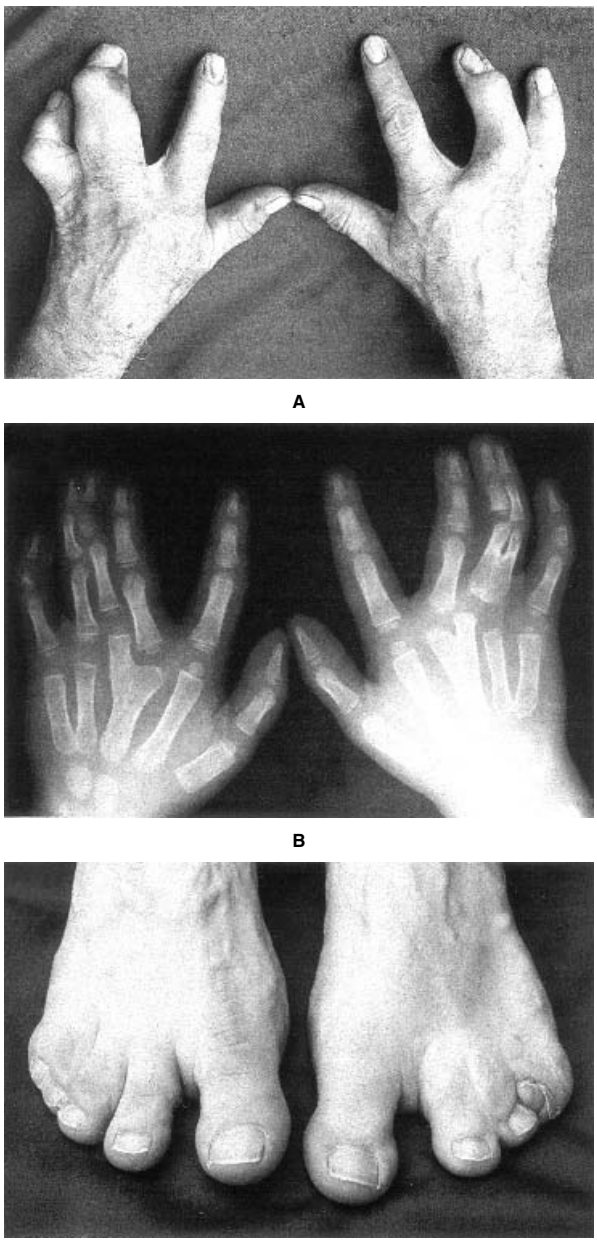

Figure 8. Synpolydactyly. (**A**) Complete membranous and partial osseous fusion of fingers III and IV with an additional finger in the syndactylous web. Frequently, as in this patient, complete cutaneous fusion of finger III, the extra finger and finger IV is observed resulting in a single nail. (**B**) Radiograph of hands of an affected child age 10 showing V-shaped metacarpal III, polydactyly between fingers III and IV, and hypoplastic middle phalanx of finger V. (**C**) Feet of individual in (**A**) showing cutaneous syndactyly of toes V to III/II. The fifth toes are broad and duplicated.

tract expansion leads to a gain of function in direct correlation to the expansion size. Inter- and intra-individual variability, a phenomenon frequently observed in congenital malformations, was more common in families with small expansions indicating that stochastic events are important events in mutations with reduced penetrance.

Recently, two families with frameshift mutations in *HOXD13* have also been described [112]. These mutations are expected to lead to null alleles since the deletions are 5′ of the DNA-binding homeodomain. Interestingly, these patients have the same hand phenotype as those with a polyalanine expansion, but a different foot phenotype consisting of a rudimentary digit between the first and second metatarsal.

The pathogenesis of syndactyly type II has to be considered in the context of the expression of genes in the D-cluster of *HOX* genes in chromosome 2 during development of the limb autopodia (hand/foot). The three most 5′ genes in the cluster, *HOXD11*, *HOXD12*, and *HOXD13*, are expressed in overlapping domains, with *HOXD11* being restricted to the most posterior (ulnar) region, and *HOXD13* being expressed across the entire autopodium. The expression domain of *HOXD12* is intermediate [77]. These expression patterns are controlled by sonic hedgehog, synthesized by the cells of the zone of polarizing activity (ZPA). Thus, the phenotypic abnormalities caused by *HOXD13* mutations are confined to the middle region of its expression domain during development of the distal region of the limb.

Animal models. A murine mutant (spdh) that represents a geno- and phenocopy of synpolydactyly type II has been described [113].

Preaxial/Triphalangeal Thumb

Preaxial polydactyly can occur as an isolated anomaly or as part of a congenital malformation syndrome. Several types have been described. The defect may be unilateral or bilateral affecting hands and/or feet. Isolated unilateral duplication of a biphalangeal thumb is usually sporadic and not associated with thenar abnormalities. Preaxial polydactyly in association with syndactylies and foot anomalies is frequently observed in Greig syndrome. A third type is characterized by triphalangeal thumbs (a long, finger-like thumb with three phalanges instead of two) with variable degrees of preaxial and sometimes postaxial duplication (TPTPS; MIM 190605). This type is inherited as an autosomal dominant trait with new cases most likely representing *de novo* mutations. Zguricas et al. [114] described the variable phenotype and expressivity in three large Dutch families. Severely affected individuals had bilateral triphalangeal index-like digits with additional preaxial digits and hypoplastic thenar muscles. At the mild end of the phenotypic spectrum was an extra delta-shaped phalanx between phalanges I and II leading to an ulnar deviation of the interphalangeal joint of the thumbs.

This type of polydactyly has been mapped by three separate groups to the long arm of chromosome 7, close to the SHH locus (7q36) [115–117]. A mouse mutant with preaxial polydactyly was recently reported as a consequence of a transgene insertion into a site close to the sonic hedgehog locus. In the abnormal limbs, expression of sonic hedgehog (as well as of the transgene reporter) was induced ectopically in the anterior region, suggesting that the transgene had interrupted a regulatory region necessary for the restriction of expression of *sonic hedgehog* to the posterior mesenchyme [118]. It is possible, therefore, that patients with preaxial polydactyly have mutations in such a regulatory region.

Absence/Hypoplastic Defects of Hands

Split-Hand/Foot Malformation

The rather nonspecific descriptive term ectrodactyly, derived from the Greek "ektroma" (abortion) and "daktylos" (finger), is applied to a number of genetic and

nongenetic malformations with absence deformities of the hands. Unilateral transverse defects (terminal aphalangia or aphalangia) can be caused by congenital constriction rings (amniotic bands) and are usually sporadic. Other sporadic atypical unilateral forms have also been described. The split hand malformation, sometimes called lobster claw deformity, is also called ectrodactyly. Phenotypically, two types of split-hand/foot malformation (SHFM) are recognized: (i) deficiency of the central rays with a cleft (the "lobster claw" variety) (Fig. 9); and (ii) monodactyly with absence of the radial rays and no cleft. The fifth finger is usually present. The two types can occur within one family and are thus of no genetic significance. Reduced penetrance and extreme variability in expression has been observed in many large pedigrees with SHFM. A particularly instructive family was described by Spranger and Schapera [119] in which three unaffected sibs with normal parents each produced affected offspring. As pointed out by Emery [120], minor hand anomalies may represent partial expression, and skipping of generations occurs frequently. To further complicate the situation, there seems to be non-Mendelian transmission characterized by the overtransmission of SHFM from affected fathers to sons [121,122].

Several cases of ectrodactyly with interstitial deletions of chromosome 7q have been described, and this locus has thus been designated SHFM1 (MIM 183600). Scherer et al. [123] characterized the translocation or inversion breakpoints in six patients and mapped the critical interval to the region 7q21.3–q22.1. Several candidate genes have been identified within this region including two members of the *DLX* family of homeobox transcription factors that have been implicated in limb development.

In a kindred described by Ahmad et al. [124], exhibiting full expression of the trait, monodactylous or split hand and split foot malformations were present in 33 males and only 3 females. Other females showed a significantly milder phenotype with only partial syndactyly and minor malformations of other bones of the hand indicating X-linked inheritance. This assumption was confirmed by linkage analysis localizing the X-linked form of SHFM (SHFM2; MIM 313350) to Xq26 [125]. In several other multigenerational families, linkage to 7q or Xq was excluded [126,127]. A third locus (SHFM3; MIM 600095) was subsequently localized to chromosome 10q25 [128].

Several other forms of syndromic ectrodactyly exist. One is the tibial aplasia ectrodactyly syndrome characterized by

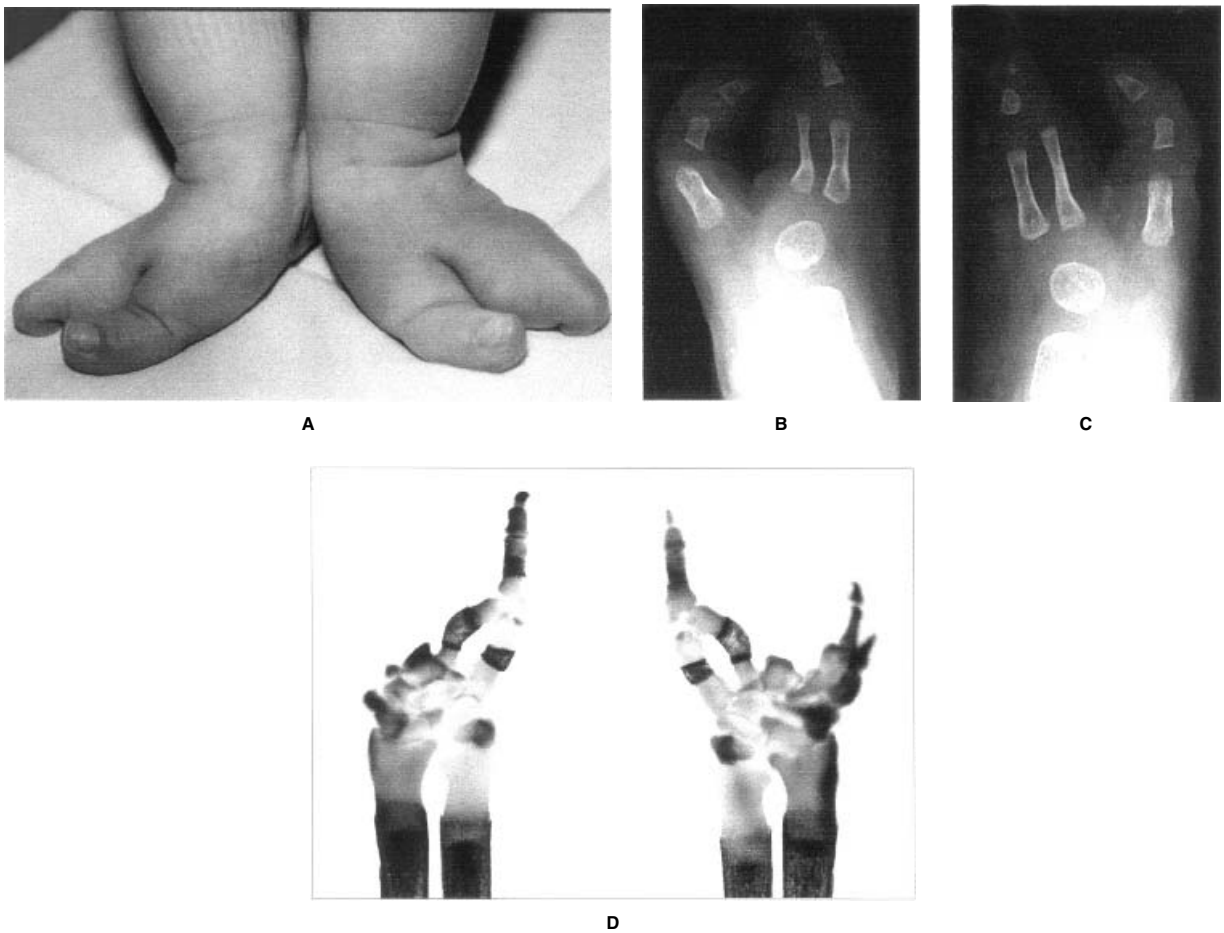

Figure 9. Split-Hand/Foot malformation. (**A**) Split foot in a 6-months-old with corresponding radiographs (**B, C**). This is a typical case with a central defect, absence of digits II and III and fusion of digits IV and V (Courtesy of P. Meinecke, Hamburg). (**D**) Skeletal preparations of limbs from a mouse heterozygous for the dactylaplasia locus. The spectrum of phenotypes frequently observed in one animal includes monodactyly (left) and ectrodactyly (right). The changes resemble those observed in human split-hand/foot malformation. Alizarin red- / alcian blue-stained skeletons.

ectrodactyly of the hands (most commonly split hand with absence of several fingers), variable foot deformities (absence of tarsal, metatarsals and toes), and aplasia/hypoplasia of the tibia and/or fibula. This condition is inherited as a dominant trait with widely variable expression and penetrance. The SHFM phenotype can be associated with ectodermal dysplasia and cleft lip/palate, a combination that has been named EEC syndrome (EEC1, MIM 129900; EEC2, MIM 602077). Other associated anomalies include a characteristic facial morphology with maxillary hypoplasia, a short philtrum and broad nasal tip, lacrimal duct anomalies, choanal atresia, and urogenital malformations. Several cases with anomalies of chromosome 7q have been reported, including a three-generation family with a translocation breakpoint at 7q11.21 [129] suggesting this as an EEC location (EEC1). Another family with EEC syndrome (EEC2) has been mapped to chromosome 19 [130], indicating that this syndrome is genetically heterogeneous. Other defects associated with the SHFM phenotype are split hand with perceptive deafness, split hand with congenital nystagmus, fundal changes and cataract (Karsch-Neugebauer syndrome), and anonychia with ectrodactyly.

Animal models. The mouse mutant "dactylaplasia" (Dac) provides important insights into split hand/foot malformations [131]. This mutation, mapped to the distal portion of mouse chromosome 19, is inherited as an autosomal semidominant trait characterized by absence of the central digital rays. The distal chromosome 19 region is syntenic to the locus for SHFM3 in humans [132]. Interestingly, the loss of central digital rays in Dac limbs appears to be due to cell death in the central portion of the apical ectodermal ridge (AER) [133]. This cell death is associated with a lack of cell proliferation in the mutant AER and this appears to lead to reduced cell proliferation in the mesenchyme below the ridge [134]. Positional cloning has identified a novel member of the *F-box/WD40* gene family as the gene responsible for the Dac phenotype. The product of this gene, called dactylin, may function as an adapter protein that targets specific proteins for degradation by presenting them to the ubiquitination machinery [135]. Intriguing is the finding that the phenotypic manifestation of the Dac mutation depends on alleles in a second locus called mdac. One dominant allele in the mdac locus inhibits manifestation of the phenotype; a second recessive allele allows it. Clearly, further studies of the Dac and mdac mutations will provide exciting insights into the control of AER function and the control of digit outgrowth.

Absence/Hypoplastic Defects of the Radial Ray

Holt-Oram Syndrome

The Holt-Oram syndrome (HOS; MIM 142900) is a dominantly inherited condition characterized by malformations of the heart and upper limbs. The phenotypic spectrum of the hand anomalies ranges from hypoplastic, absent, or triphalangeal thumbs to radial hypoplasia or even phocomelia (Fig. 10). Motion of the shoulder and elbow may be limited due to anomalies of the forearm: hypoplasia or absence of the radius and/or ulna, radio-ulnar synostosis, hypoplasia, or absence of the humerus. Narrow shoulders may be part of the clinical picture caused by anomalies of the humeral head, hypoplasia of the clavicle, rib anomalies, small scapula, and other changes of the shoulder girdle such as deficiency of pectoral and/or other muscles. The vertebrae may also be involved (hemivertebrae, hypoplasia, fusion). Carpal abnormalities, e.g., extra carpal bones, delayed ossification/absence, fusion can be observed as a minimal phenotype and may be more specific of the Holt-Oram syndrome than changes in the thumbs [136,137]. Cardiac involvement is found in the great majority of patients (95%) [138] and may consist of atrial and/or ventricular septal defects, cardiac conduction defects, or other cardiac anomalies such as anomalous pulmonary venous return, or right isomerism suggesting aberrant chamber specification.

The Holt-Oram syndrome was mapped independently by two groups to the long arm of chromosome 12 [137,139]. Positional cloning strategies identified a member of the T-box gene family, *TBX5*, within the interval. Several mutations have been identified that most likely lead to haploinsufficiency [140,141]. *TBX5* is related to the mouse gene *Brachyury* or *T*, encoding a transcription factor involved in the development of the posterior mesoderm during gastrulation. The role of *Tbx5* in limb development has only recently been investigated. The protein is expressed in the atrium and sinus venosus of the developing heart, the forelimb buds, trachea, thoracic wall, and retina [142]. Experiments in the chick demonstrated expression of *Tbx5* in the wing and flank, but not the leg, whereas *Tbx4* was found to be expressed only in the leg [143]. Based on these and other results it is now believed that *Tbx5* and *Tbx4* regulate limb outgrowth and identity [144–147]. The bicoid-related homeodomain transcription factor Pitx1, expressed in developing hindlimbs, the anterior pituitary gland, and first branchial arch, appears to be an upstream regulator of *Tbx4* [148]. Mice that are homozygous for inactivated *Pitx1* alleles show, in addition to changes in the pituitary and cleft palate, abnormalities in the tibia and fibula, patella, and tarsal bones so that the limb more closely resembles a forelimb [149,150]. In addition, expression of *Tbx4* in the hindlimb is reduced. Misexpression of *Pitx1* in the wing-bud of the developing chick embryo, where it is not normally expressed, induces distal expression of *Tbx4* as well as *Hoxc10* and *Hoxc11* genes, and the wings acquire characteristics of hindlimbs. For example, the muscle pattern becomes leg-like and the digits become more toe-like [151].

The Hand-Foot-Genital Syndrome

The hand-foot-genital syndrome (HFG; MIM 140000) is a rare developmental defect with autosomal dominant inheritance consisting of (i) limb anomalies with short thumbs and toes, hypoplasia of the thenar eminence, small feet, clinodactyly V, and fusion or delayed ossification of carpal bones; (ii) urogenital malformations, including duplications of the female genital tract (bifid uterus and cervix, septate vagina), a displaced urethral opening, and malpositioning of ureteral orifices leading to reflux and chronic kidney disease. Hypospadias of varying degrees are observed in affected males.

The gene for the hand-foot-genital syndrome was identified through phenotypic similarities with the mouse mutant hypodactyly (Hd). Hd was shown to be due to a mutation in *Hoxa13* [152], and, based on this observation, *HOXA13* was screened in patients with hand-foot-genital syndrome. A stop codon within the homeodomain was identified in one family indicating that the phenotype is caused by loss of function mutations of the *HOXA13* gene [153].

Absence/Hypoplastic Defects of the Ulnar Ray

The Ulnar-Mammary Syndrome

The ulnar-mammary syndrome (UMS; MIM 181450) is characterized by (i) posterior (ulnar or postaxial) limb

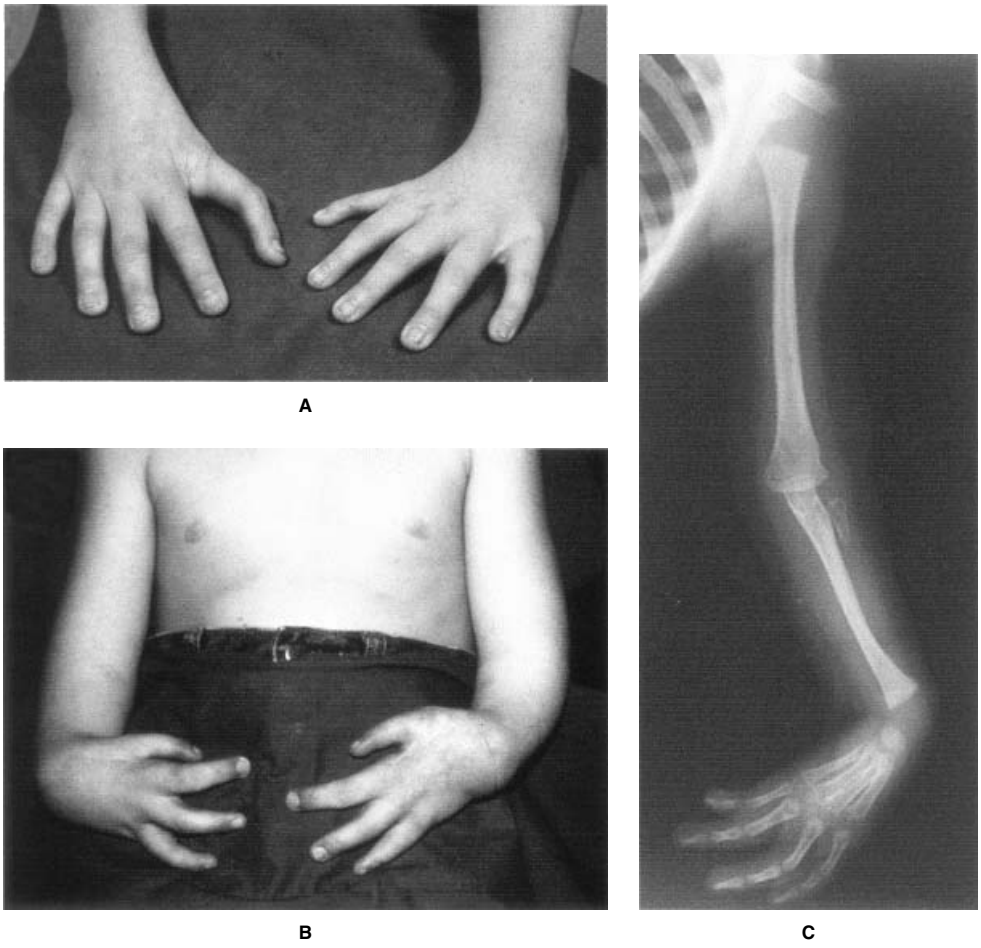

Figure 10. Holt-Oram syndrome. (**A**) 11-year-old patient with Holt-Oram syndrome with triphalangeal thumbs. Note finger-like thumbs and hypoplasia of the patient's left thumb. (**B**) 12-year-old boy with Holt-Oram syndrome showing severe bilateral malformation with hypoplasia of the forearms and left humerus, with limited motion in elbows. Aplasia of both thumbs. (**C**) Radiograph of a similarly affected individual demonstrating hypoplasia of the radius, a hypoplastic humeral head, and absence of the thumb. (Courtesy of S. Spranger, Bremen.)

defects, such as hypoplasia or absence of the most ulnar fingers, including their metacarpals, combined with (ii) apocrine abnormalities that range from diminished perspiration and axillary hair to complete absence of breast tissue, perspiration and axillary hair; (iii) ectopic, hypoplastic, or absent canine teeth; (iv) delayed puberty in males, and (in some affected individuals) micropenis, shawl scrotum, and an imperforate hymen. Known also as Schinzel syndrome and the ulnar-mammary syndrome of Pallister, UMS has been mapped to a region on chromosome 12q that also includes the gene for Holt-Oram syndrome [154]. In fact, the two syndromes are caused by mutations in two closely linked and homologous genes. Holt-Oram syndrome with its anterior (radial) limb abnormalities is the result of mutations in the *TBX5* gene; UMS is caused by loss of function mutations in the *TBX3* gene [155]. UMS is therefore likely to be caused by haploinsufficiency of *TBX3*.

What the downstream targets are for *TBX3* in the different organs that are affected in the UMS syndrome is not known, but further analysis of syndromes displaying phenotypic overlap with UMS may help in identifying such target genes. For example, in a large Dutch family, van Bokhoven et al. [156] have demonstrated linkage to a locus on chromosome 3q27 for a syndrome called limb-mammary syndrome (MIM 603543) with severe hand/foot anomalies combined with hypoplasia/aplasia of mammary glands and nipples, nail dysplasias, hypohidrosis, hypodontia, and cleft palate.

Defects in Dorsal-Ventral Patterning

Nail-Patella Syndrome

The nail-patella syndrome (NPS1; MIM 161200), also referred to as onychoosteodysplasia, is characterized by (i) nail dysplasia (hypoplasia, absence, ridging, flatness); (ii) hypoplastic or absent patella; (iii) characteristic bony projections from the iliac wings (iliac horns); (iv) elbow deformity with an inability to fully extend, pronate, or supinate the forearm due to hypoplasia and/or subluxation/dislocation of the radial head; and (v) nephropathy of various severity and manifestation (glomerulonephritis, nephrotic syndrome) (Fig. 11). Some 10–20% of patients may develop end-stage renal failure. It is caused by mutations in the LIM-homeodomain protein LMX1B [157,158]. This transcription factor is critical for the dorsal/ventral patterning of the limb, and its expression in dorsal limb mesenchymal cells is induced and maintained by Wnt7a secreted

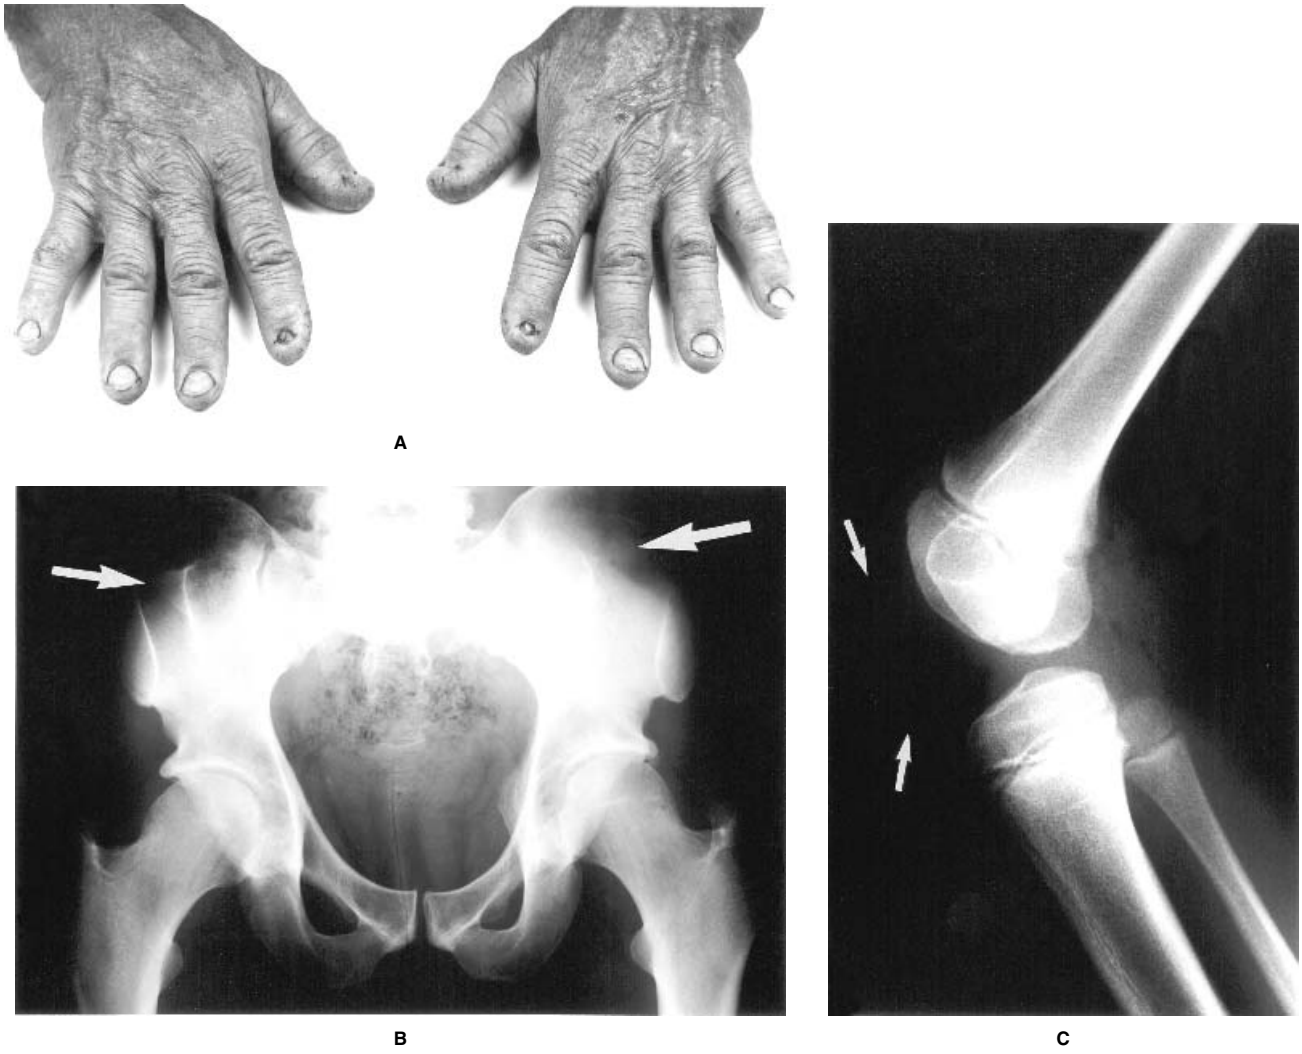

Figure 11. Nail-patella syndrome. (**A**) Hypoplasia of nails in an individual with nail-patella syndrome. (**B**) abnormal pelvis of the patient shown in **A** with flaring of the iliac wings and characteristic iliac horns (arrows). (**C**) Absent patella (arrows) in the affected child.

by dorsal ectodermal cells. Ectopic expression of *LMX1* in ventral mesenchyme generates double-dorsal limbs in chick embryos [159]. *LMX1* is homologous to the *Drosophila* gene *apterous*, a gene that specifies dorsal cell fate and regulates outgrowth of the wing during wing development in the fly [160]. In vertebrates, these two functions are performed by different proteins. While *LMX1* specifies dorsal identity, another *apterous* homologue, *LHX2*, is important for controlling limb outgrowth [160].

Targeted disruption of the *Lmx1b* gene in mice results in a phenotype that is very similar to what is seen in individuals with nail-patella syndrome: skeletal defects that include hypoplastic nails, absence of patellae, and renal dysplasia [161]. The mutations found in patients with the syndrome either affect DNA binding or result in premature termination of translation, consistent with the conclusion that the syndrome is caused by loss-of-function of *LMX1B* [162]. In some families with NPS1, open angle glaucoma has been reported to segregate with the other features of the syndrome [157]. This is also consistent with the mouse knock-out phenotype, in that it includes anterior segment eye abnormalities.

Brachydactyly

Disorders characterized by shortening of fingers and toes, brachydactyly, are divided into a large number of types depending on which bones and/or fingers (toes) are affected. Given what we now know about the specification of digit identity, joint development, and bone growth in hands and feet, this clinical subdivision is useful and appears to reflect the underlying genetic defects.

Brachydactyly, Types A1 and A2

Type A1 brachydactyly (BDA1; MIM 112500) is characterized by (i) rudimentary middle phalanges of all digits, sometimes fused with the terminal phalanges (distal symphalangism); (ii) short proximal phalanges of the thumb and big toe; and (iii) short stature. This form of brachydactyly is also referred to as the Farabee type, in reference to S. W. Farabee who described this disorder in Mendelian terms in his Harvard University Ph.D. thesis in 1903.

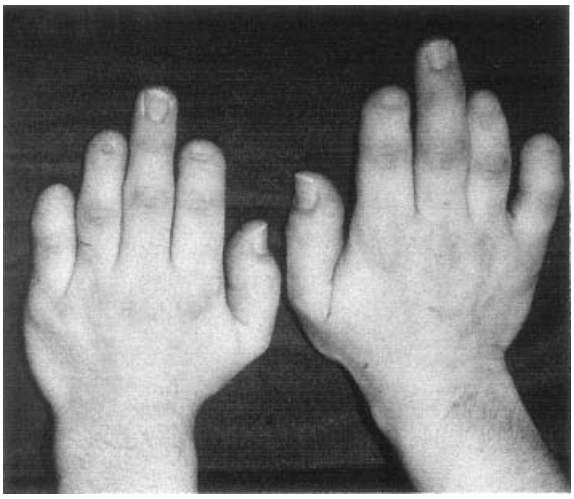
A rare form of brachydactyly type A, with shortening and triangulation of the middle phalanges of only the index finger and the second toe, is classified as brachydactyly, type A2 (BDA2; MIM 112600).

Although several candidate genes have been considered, mutations that result in brachydactyly A1 have not yet been described [163].

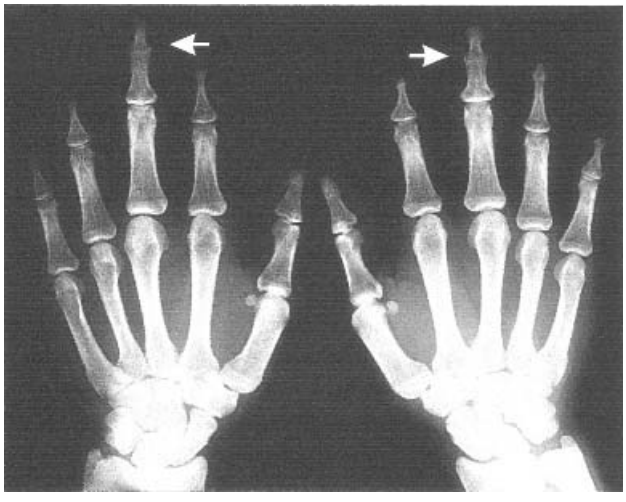
Brachydactyly, Type B

Brachydactyly type B (BDB1; MIM 113000) is characterized by rudimentary or absent distal and middle phalanges of fingers two to five with complete or nearly complete absence of the nails. The thumbs are spared (Fig. 12). In some individuals, the thumbs show a variable degree of flattening, splitting, or duplication of the distal phalanges. The feet show similar changes but are generally less affected. Other features are soft tissue syndactyly, symphalangism, carpal and/or tarsal fusions, and shortening of metacarpals and/or metatarsals. There are no other associated malformations.

Brachydactyly type B has been mapped independently by two groups to chromosome 9q22 but there is evidence of genetic heterogeneity in this condition [164,165].



A



B

Figure 12. Brachydactyly type B. (**A**) Absence or hypoplasia of terminal portions of fingers II to V with mild involvement of finger III and normal thumb in a 31-year-old individual with brachydactyly type B. (**B**) Radiograph of the hands of the individual in (**A**) showing absent middle phalanges of fingers II, IV, and V, hyploplasia of distal phalanges II–V, and distal symphalangism of fingers III (absence of interphalageal joints, arrows).

Brachydactyly, Type C

Type C brachydactyly, also referred to as Haws type brachydactyly (BDC; MIM 113100) is a complex disorder, at least as described by Haws [166] in a large Mormon kindred. The characteristic features include (i) shortening of the middle phalanges of fingers II, III, and V; (ii) a short and frequently oval-shaped metacarpal of finger I; (iii) triangulation of the proximal end of the proximal phalanx of the index finger with prolongation of the radial border, short metacarpals, and symphalangism are occasionally present (Fig. 13).

In a pedigree described by Robin et al. [167], brachydactyly type C mapped to chromosome 20 to an interval previously shown to contain *CDMP1* [168]. *CDMP1*, also known as *GDF5*, is a member of the TGF-β superfamily. Interestingly, the mouse mutant brachypodism, a murine type of brachydactyly, had previously been shown to be caused by homozygosity for functional null alleles in *Cdmp1* [169]. Several mutations in *CDMP1* were identified in patients with brachydactyly type C that are likely to result in functional haploinsufficiency [168].

Acromesomelic Dysplasia, Grebe and Hunter-Thompson Types

Grebe (AMDG; MIM 200700) and Hunter-Thompson (AMDH; MIM 201250) types of acromesomelic dysplasia are autosomal recessive disorders characterized by severe shortening of the four limbs and small digits. The craniofacial and axial skeletons are not affected. The limb abnormalities

Figure 13. Brachydactyly type C. Radiograph of hand of a mildly affected individual aged 30, showing short first metacarpal and hypoplastic middle phalanges II and V. (Courtesy of B. Zabel, Mainz.)

show a proximal-to-distal gradient of increasing severity. While the humerus/femur is relatively normal, the radius and ulna/tibia and fibula are short, carpal/tarsal bones may be fused and metacarpal/metatarsal bones may be absent. Fingers/toes may show poly- and brachydactyly with phalangeal bones missing. Dislocation of hips, knees, ankles, and elbows is also described (Fig. 14).

In their description of patients with AMDH, Langer et al. [170] pointed to similarities with AMDG, but suggested that the two syndromes were distinct clinical entities based on radiological findings. The similarities between the two syndromes can now be understood based on the fact that they are both caused by mutations in the gene encoding cartilage-derived morphogenetic protein-1, *CDMP1* [171].

In a large Brazilian pedigree with the Grebe syndrome [172], Thomas et al. [173] showed linkage to markers close to *CDMP1*. They further demonstrated that affected individuals were either homozygous for a cysteine to tyrosine substitution in CDMP-1, or compound heterozygous for this mutation in one allele and a single nucleotide deletion leading to a frameshift and premature stop codon in the other allele. Thus, Grebe syndrome seems to be the homozygous form of brachydactyly type C. In the family with AMDH reported by Langer et al. [170], Thomas et al. [174] also found a mutation in *CDMP1*. The mutation, a 22-bp tandem duplication, led to a frame-shift and a mutant protein of almost normal size but with the last 43 amino acid residues totally different from those of the wild-type protein.

The phenotypic differences between AMDG and AMDH may reflect different effects of different mutations in *CDMP1*. In the case of AMDH, affected individuals are homozygous for a frameshift, loss-of-function mutation. In contrast, the Cys to Tyr substitution in CDMP1 in patients with AMDG appears to have a dominant-negative effect in that the mutant protein forms heterodimers with other BMPs and prevents their secretion.

Animal models. Brachypodism (bp), is a recessive disorder caused by mutations in *Gdf5*, the murine homologue of *CDMP1* [169].

Brachydactyly with Hypertension

Brachydactyly combined with hypertension, also referred to as Bilginturan syndrome (MTNB; MIM 112410), is characterized by shortening of both phalanges and

Figure 14. Acromesomelic dysplasia Grebe type. (**A**) 4-year-old boy with Grebe dysplasia showing severe mesomelic limb reduction. Both parents show a mild form of brachydactyly type C (radiograph of father's hand is shown in Fig. 13). Note very short fingers and toes. The legs are shorter than the arms. metacarpals. The elevation in blood pressure can be severe, with systolic pressures ranging from 110 to 250 mm Hg and diastolic pressures from 100 to 150 mm Hg. Surprisingly, affected individuals are relatively free from end-organ damage, including an absence of hypertensive retinopathy. Linkage analysis of a large Turkish pedigree placed the locus of the affected gene in the chromosome 12p12.2–p11.2 region [175]. Markers in the same region also cosegregate with the phenotype in other families, and in a Japanese family affected individuals were found to be heterozygous for a deletion within this region [176].

Syndactyly

Type III Syndactyly

Among the many clinical forms of syndactyly, autosomal dominant syndactyly type III (SDTY3; MIM 186100) is characterized by usually complete, bilateral syndactyly between digits four and five. The feet are unaffected. The syndactyly typically involves only soft tissue, but fusion of the distal phalanges can occur; the middle phalangeal bone of finger five can be absent or present as a small rudiment.

SDTY3 has been mapped to chromosome 6q22–q24 [177]. This region also contains the locus for oculodentodigital dysplasia (ODDD; MIM 164200). Since affected individuals of one family included in the mapping study had a facial phenotype resembling that of ODDD associated with their syndactyly, it has been proposed that SDTY3 and ODDD are caused by mutations at the same locus [177].

Disorders of Segmentation

Proximal Symphalangism

The autosomal dominant disorder, proximal symphalangism (SYM1; MIM 185800), is an inherited absence of the proximal interphalangeal joints with fusion of carpal and tarsal bones, often associated with early onset conductive deafness in affected individuals (Fig. 15). Ankylosis of the proximal interphalangeal joints also occurs as part of other syndromes, including diastrophic dysplasia (MIM 222600) and type C brachydactyly (MIM 113100).

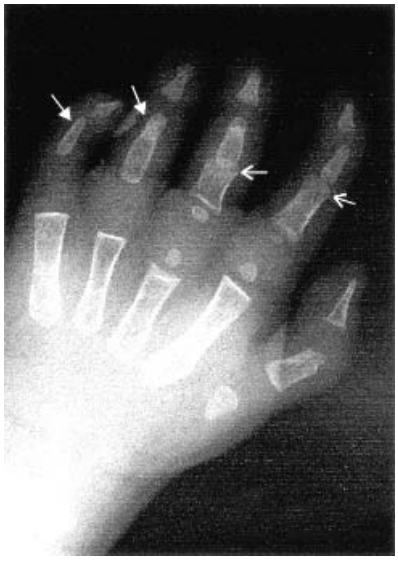

Figure 15. Proximal symphalangism. Radiograph of hand of a 3-months-old patient with conductive hearing loss and decreased mobility of proximal phalangeal joints showing complete bony fusion of the proximal interphalangeal joint of fingers IV and V (arrows), as well as hypoplastic joints and middle phalanges of fingers II and III (arrows). (Courtesy of P. Meinecke, Hamburg.)

SYM1 was mapped to the noggin (*NOG*) locus on chromosome 17q and has been shown to be caused by mutations in *NOG* [178]. A *NOG* mutation also in a family with multiple synostosis syndrome (SYNS1; MIM 186500) suggests that SYM1 and SYNS1 are allelic disorders [178]. The mutations in the human *NOG* gene confirm studies in mice that noggin is essential for the normal formation of joints, and suggest that the protein is particularly important for the development of proximal interphalangeal joints in humans.

THE DYSOSTOPLASIAS

Skeletal organogenesis involves the formation of bone and cartilage as an organ (the skeleton). Condensation of undifferentiated cells follows a preset pattern that outlines the future skeletal elements. The molecular mechanisms that initiate and regulate condensation are largely unknown. The expression of extracellular matrix proteins that promote cell-cell adhesion by providing "sticky" surfaces is likely to be a key event. N-cadherin, N-CAM, and fibronectin are adhesive molecules known to be elevated in sites of precartilaginous condensations [179]. After condensation, mesenchymal precursor cells differentiate into chondrocytes or osteoblasts, and finally these cells produce their specific extracellular matrix (histogenesis). These aspects of early skeletogenesis, the anlage, represent the outlines of the future skeletal elements. Bones then develop either directly from osteoblastic progenitor cells or within a temporary framework of hyaline cartilage. The direct formation of bone is called desmal or intramembranous ossification, and occurs in the flat bones of the skull, the mandible, and part of the clavicle. In contrast, all other bones develop through endochondral bone formation, a process involving the proliferation and differentiation of chondrocytes to form a temporary cartilaginous template which is subsequently replaced by bone (see also Chapter 1, Parts II and III, this volume).

Mutations in genes that are involved in skeletal organogenesis produce phenotypes that share aspects of dysplasias and dysostoses. Among such genes are genes that regulate the differentiation and growth of osteoblasts and chondrocytes. When the genes are expressed only in skeletal tissues, as in the case of that for the transcription factor CBFA1, only bone and cartilage are affected. In contrast, when the gene is important for the differentiation/growth of both skeletal and nonskeletal tissues, as in the case of *SOX9* and the gene for cartilage-hair hypoplasia, characteristic syndromes are produced that combine skeletal abnormalities with disorders of other organ systems.

Cleidocranial Dysplasia

Cleidocranial dysplasia (CCD; MIM 119600) is a dominantly inherited disorder characterized by (i) hypoplasia/aplasia of the clavicles; (ii) delayed ossification of cranial sutures and fontanelles; and (iii) dental anomalies that include delayed eruption of deciduous and permanent teeth and supernumerary teeth of the permanent dentition (Fig. 16A–C) [180]. A large number of other skeletal abnormalities are commonly observed including a narrow, bell-shaped thorax, cervical or missing ribs, and characteristic changes in the pelvis consisting of hypoplastic iliac wings and a wide symphysis pubis. Large femoral epiphyses, and

Alizarin red/alcian blue stained skeletons.

two ossification centers in the second metacarpal and a short middle phalanx of the fifth finger are frequently found. The bone age is generally retarded. The face and skull have a characteristic appearance with a relatively large cranium, frontal and parietal bossing, and a frontal groove originating from ossification defects within the metopic suture. The nose is short and anteverted, and the maxilla is hypoplastic giving the impression of a relative prognathism. The cranial abnormalities are sometimes referred to as the ''Arnold head'' after the founder of a large South African pedigree with the disorder [181]. Growth retardation and slightly retarded skeletal maturation during childhood can lead to short stature in affected individuals. The gene for CCD was mapped to chromosome 6p21 and a small deletion in this region was shown to segregate with the phenotype in one family [182]. This was followed by the demonstration that

CCD is caused by heterozygous loss-of-function mutations in the transcription factor CBFA1 located within the deleted segment [183,184].

CBFA1 is a member of a small family of transcription factor genes that are homologous to the *Drosophila runt* gene. While *CBFA2* is critical for hematopoietic cell differentiation, *CBFA1* is essential for the differentiation of osteoblasts, during both intramembranous and endochondral bone formation [185]. This seems to be true not only during embryonic development, but also during adulthood since some individuals with severe CCD also have osteoporosis [184]. Mice that are heterozygous for inactivated *Cbfa1* alleles show a CCD phenotype (Fig. 16D and E). Homozygous knockouts die at birth with a skeleton consisting entirely of cartilage and no bone [186,187]. In addition, maturation of chondrocytes to hypertrophic chondrocytes is severely reduced, particularly in proximal limb segments, and invasion of cartilage by blood vessels and hematopoietic cells does not occur. A radiation-induced mouse mutant, Ccd, carries a large deletion on chromosome 17, including the *Cbfa1* gene; heterozygous mutant animals have a phenotype identical to that of heterozygous *Cbfa1* knockouts [186,188].

The major features of CCD can easily be understood on the basis of a reduced differentiation of osteoblasts. The clavicular defect and the deficient maturation of chondrocytes in long bones, however, appear to be the consequences of impaired chondrocyte differentiation and maturation [189,190]. It is likely, therefore, that chondrocytes in some regions of the developing skeleton are dependent on *CBFA1*.

Campomelic Dysplasia

Campomelic dysplasia (CMD1 or CMPD1; MIM 114290) is a dominant disorder caused by haploinsufficiency of the transcription factor SOX9. The phenotypic abnormalities include (i) bowing and angulation of long bones; (ii) hypoplasia of the scapula and pelvis; (iii) abnormalities of the vertebral column with a decreased number of ribs; and (iv) craniofacial abnormalities (cleft palate, micrognathia, hypertelorism, and a flat facies) as a consequence of a small chondrocranium (Fig. 17). Most affected babies die in the neonatal period or early infancy of respiratory distress caused by a small rib cage, narrow airways (defective tracheobronchial cartilage) and hypoplastic lungs. Heart and kidney malformations and the absence of olfactory bulbs and tracts have also been reported.

The major skeletal features of the syndrome suggest a defect in cartilage development. Not only is there a defective formation of cartilage in the airways, but the chondrocranium is much smaller than the neurocranium and many of the craniofacial defects are similar to those associated with mutations in cartilage-specific extracellular matrix molecules such as collagens II and XI. A significant and striking difference between campomelic dysplasia and other chondrodysplasias, however, is that CMD1 is often associated with male-to-female sex reversal [191]. This interesting association can now be understood from the molecular defect in the syndrome. The disease-causing

Figure 17. Campomelic dysplasia. Radiographs of a female newborn with dwarfism (39 cm), short limbs, severe hypoplasia of the thorax and neonatal death due to respiratory distress. (**A**) Narrow, bell-shaped thorax, 11 pairs of ribs, lateral clavicular hooks, severely hypoplastic scapulae. (**B**) Hypoplastic iliac wings, poor ossification of os pubis, hip dislocation, long and angulated femurs, short angulated tibiae and hypoplastic/absent fibulae, no ossification in feet. (Courtesy of J. Spranger, Mainz.)

mutations are either heterozygous loss-of-function mutations in the *SOX9* gene or chromosome rearrangements that interrupt important transcriptional regulatory elements scattered over a large region in the 5′ flanking region of *SOX9* [192–194].

SOX9 is a member of a family of transcription factors that contain an SRY-related high-mobility-group (HMG) homology domain [195]. In the mouse, it is expressed in mesenchymal condensations before and during chondrogenesis [196]. One of its regulatory targets is *COL2A1*, the gene encoding the major collagen in cartilage (see Chapter 2, this volume); SOX9 binds specifically to sequences within the first intron of this gene [197]. Loss-of-function mutations in *SOX9* or mutations that decrease transcription of the gene therefore result in decreased expression of collagens II and XI (collagen XI molecules being composed of three different subunits, one of which is the product of *COL2A1*). It has also been demonstrated that the addition of BMP2 to avian embryos results in increased expression of *SOX9* and the induction of ectopic cartilage. Furthermore, ectopic expression of the BMP-binding protein noggin in chick limbs causes loss of *SOX9* expression in digits, suggesting that BMPs may regulate *SOX9* expression [198]. In chimeric mouse embryos containing a mixture of *Sox9* −/− cells and *Sox9* +/+ cells, the *Sox9*-deficient cells are excluded from all cartilages, but are present in perichondrial tissues [199]. This exclusion appears to occur during the condensed mesenchyme stage of chondrogenesis, suggesting that *SOX9* is critical for mesenchymal cell condensation leading to chondrocyte differentiation.

Loss-of-function mutations in *SOX9* are therefore expected to affect chondrogenesis at an early stage as well as the expression of cartilage-specific extracellular matrix molecules by differentiated chondrocytes. *SOX9* is also expressed in differentiating Sertoli cells and it is believed that it plays an essential role in sex determination, thus providing a logical explanation for the sex reversal associated with campomelic dysplasia [200,201].

Ellis-van Creveld and Short-Rib-Polydactyly Syndromes

Ellis-van Creveld syndrome (EVC; MIM 225500) is also referred to as chondroectodermal dysplasia. It is a recessive disorder and, as the designation chondroectodermal implies, the clinical features are a combination of skeletal and ectodermal abnormalities. The major features consist of (i) short stature of prenatal onset that is most pronounced in the distal segments; (ii) skeletal defects including polydactyly, short and broad middle phalanges and hypoplastic distal phalanges, fusion of wrist bones (hamate and capitate), an abnormal pelvis, a narrow thorax with thin ribs, and hypoplasia of the upper lateral tibia (Fig. 18); (iii) hypoplastic fingernails; (iv) cardiac defects, most commonly atrial septal defects and a single atrium; (v) neonatal teeth, or small teeth with delayed eruption; (vi) a frenulum from the alveolar ridge to the upper lip, and defects in the alveolar ridge.

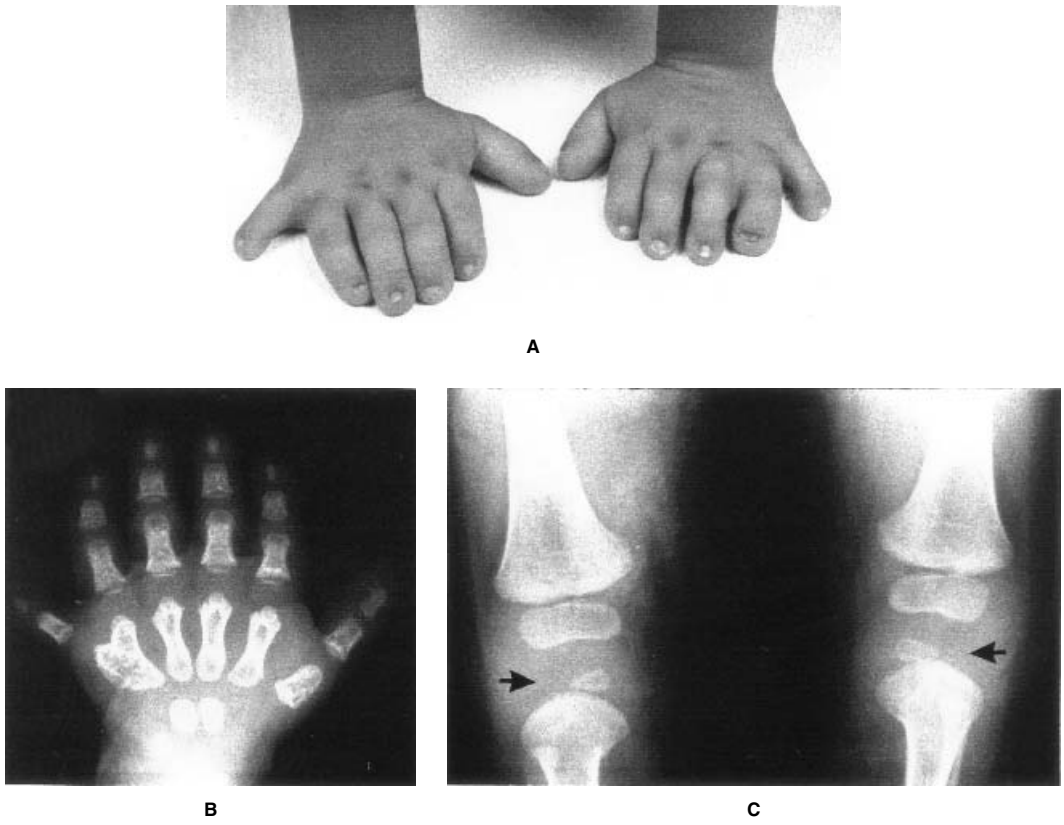

Figure 18. Ellis-van Creveld syndrome. (**A**) Hands of a 2-year-old girl with Ellis-van Creveld syndrome showing broad fingers, hypoplastic nails and postaxial polydactyly. (**B**) Radiograph of individual in (**A**) showing postaxial polydactyly with bony fusion of extra metacarpal and metacarpal V, short and broad middle phalanges with partial duplication of middle and terminal phalanx of finger IV, cone shaped epiphyses and hypoplastic distal phalanges. (**C**) Hypoplasia of lateral part of tibial epiphysis (arrows) is a frequent finding in Ellis-van Creveld syndrome.

Figure 19. Leri-Weill dyschondrosteosis. (**A**) Radiograph of forearm and hand in a 25-year-old patient with dyschondrosteosis. The radius is bowed and short, the distance between radius and ulna is widened, and there is triangulation of the distal radius. (**B**) Lateral view of same forearm showing Madelung deformity with dorsal subluxation of the distal end of the ulna and volar displacement of the hand (arrowhead).

The syndrome has been mapped to the distal region of chromosome 4p. Two homeobox genes, *MSX1* and *HMX1*, initially proposed as candidate genes for EVC, have both been excluded [202,203].

The short-rib-polydactyly syndromes are a group of at least seven distinct conditions, among them Jeune syndrome, or asphyxiating thoracic dystrophy (ATD; MIM 208500). This group of diseases is characterized by (i) short ribs and subsequent thoracic and pulmonary hypoplasia; (ii) polydactyly, preaxial or postaxial (variable); (iii) short limbs with dysplastic bones, and associated malformations of the heart, the urogenital system and other organs, and clefts. Many of the skeletal changes in the chest, limbs and pelvis are not unlike those seen in Ellis-van Creveld syndrome.

Leri-Weill Dyschondrosteosis

Caused by heterozygous mutations in the pseudoautosomal gene *SHOX*, Leri-Weill dyschondrosteosis (LWD; MIM 127300) is characterized by (i) mild to moderate short stature; (ii) mesomelic shortening of the forearms and lower legs with shortening and bowing of the radius, triangulation of the distal radial epiphysis, distal hypoplasia of the ulna, and widening of the distance between the radius and the ulna. Dorsal dislocation of the distal ulna may lead to elbow dislocation, cubitus valgus. The altered osseous alignment at the wrist leads to the dorsal subluxation of the distal end of the ulna and volar displacement of the hand, an abnormality referred to as Madelung deformity (Fig. 19).

The abnormalities are the consequences of heterozygous loss-of-function mutations (deletions or point mutations) in the *SHOX* gene within the pseudoautosomal region (PAR1) on the X and Y chromosomes [204,205]. Homozygosity for mutations within the gene leads to the Langer type of mesomelic dysplasia (MIM 249700), characterized by severe hypoplasia or aplasia of the ulna and fibula, and a bowed radius and tibia [206]. Two alternatively spliced transcripts of the *SHOX* gene have been found to be expressed in several tissues, including bone marrow fibroblasts [207], but why mutations in the gene should result in short stature and the characteristic abnormalities in forearms and lower legs, is unclear.

RECENT DEVELOPMENTS

Disorders of the Craniofacial Skeleton

Parietal Foramina

Parietal foramina (MIM 168500) are oval defects of the calvaria caused by deficient ossification of the parietal bones. Inheritance is frequently dominant. Mutations in *MSX2*, a transcription factor gene located on chromosome 5q, have been associated with this condition [209]. The presence of a large deletion encompassing the entire gene suggests a loss of function mechanism. Interestingly, *MSX2* has also been found mutated in a family with Boston-type craniosynostosis [210,211]. The *MSX2* mutation in this family is located in the homeodomain and the mutant protein was shown to bind with enhanced affinity to the MSX2 DNA target sequence, implying that the mutation operates through gain of function [212]. These mutations demonstrate that MSX2 dosage is fundamental for human skull development and calvarial osteogenic differentiation.

Another locus for parietal foramina is on chromosome 11p11-12. This region contains *ALX4*, a transcription factor gene previously identified as the cause of the mouse mutant Strong's luxoid [213]. In mice, heterozygous mutations of *Alx4* cause preaxial polydactyly, while homozygotes manifest delayed ossification of the parietal bones and several other

abnormalities. Mavrogiannis et al. [214] were able to identify mutations in *ALX4* in several families with parietal foramina, and concluded that haploinsufficiency of *ALX4*, as in the case of *MSX2*, results in ossification defects of the skull.

Opitz G/BBB Syndrome

Opitz G/BBB syndrome (MIM 300000) is a congenital disorder primarily affecting midline craniofacial development. Manifestations include a typical facial appearance, ocular hypertelorism, cleft lip and palate, mental retardation, and dysplasia of the corpus callosum. Other features of this condition include tracheo-esophageal fistulae, cardiac anomalies, genitourinary malformations, and imperforate anus. The condition is genetically heterogeneous, one locus being on chromosome 22q11.2, another on Xp22.3. The X-linked condition is caused by mutations in *MID1*. *MID1* encodes a microtubule-associated protein that functions as a ubiquitin ligase which targets phosphatase 2A for degradation [215].

Disorders of the Axial Skeleton

Spondylocostal Dysostosis

One form of recessive spondylocostal dysostosis (MIM 277300) has been shown to be due to mutations in *DLL3* [216], the human homologue of the mouse *Dll3* gene, which is the cause of the pudgy mutation in the mouse. The mutations identified predict truncations within the conserved extracellular domains of DLL3 or are missense mutations within other conserved domains.

Robinow Syndrome

Recessive Robinow syndrome (MIM 268310), a skeletal dysplasia with mesomelic short stature, hypogenitalism and heart defects, is frequently associated with malformations of the axial skeleton, mimicking spondylocostal dysostosis. Robinow syndrome has been shown to be due to mutations in the tyrosine kinase receptor ROR2 [217,218]. Inactivation of *Ror2* in the mouse produces a severe lethal skeletal phenotype with vertebral defects, rib fusions, and severe shortening of the extremities [219,220]. The phenotype is comparable to Robinow syndrome, but more severe. The ligand for this receptor and the signalling pathway downstream of the receptor, as well as its function during skeletal patterning and growth are largely unknown. Recessive Robinow syndrome is allelic with brachydactyly type B.

Disorders of the Appendicular Skeleton

Polydactyly Disorders

Oral-facial-digital syndrome type I (MIM 311200) is transmitted as an X-linked condition with lethality in males. It is characterized by a variety of digital anomalies including asymmetric shortening of digits, unilateral polydactyly of feet, clinodactyly, syndactyly and/or brachydactyly. The oral abnormalities consist of frenula, pseudoclefting of the upper lip, and clefts of the palate and tongue. The facies is dysmorphic and hypoplasia of the alar cartilages is frequently found. Other features of this condition include brain malformations and mental deficiency, dry skin, sparse hair, and adult polycystic kidney disease. Mutations have been identified in the *OFD1* gene (formerly *Cxorf5/71-7a*), a gene with unknown function [221].

Absence/Hypoplasia Defects of Hands/Feet

Split-hand split-foot malformation. van Bokhoven and colleagues have mapped one form of split-hand split-foot malformation, which they termed limb mammary syndrome (MIM 603543), to chromosome 3q27. In addition, they were able to show that several families with EEC syndrome, which comprises ectrodactyly, ectodermal dysplasia, and cleft palate (MIM 604292), map to the same region suggesting that these disorders are allelic. Analysis of the p63 gene, a homologue of the tumor suppressor gene p53, revealed heterozygous mutations in several families with EEC syndrome and limb mammary syndrome [222]. Using transactivation studies, the authors provided a molecular explanation for the dominant character of the p63 mutations. A knock out of p63 shows a strikingly similar pattern of involved structures. $p63^{-/-}$ mice have a truncated secondary palate, a hypoplastic maxilla, and a wide variety of abnormalities of the limbs, including syndactyly and central ray defects resembling the split-hand split-foot phenotype [223].

Further analysis of a large number of patients showed that mutations in p63 are the cause of several related disorders, indicating that p63 mutations have highly pleiotropic effects. In a study by van Bokhoven et al. [224], three distinct phenotypes were associated with p63 mutations: limb-mammary syndrome, which is characterized by ectrodactyly, cleft palate, and mammary gland abnormalities, EEC syndrome, and non-syndromic split-hand split-foot malformation. In addition, Hay-Wells syndrome has been shown to be due to p63 mutations [225]. This condition is characterized by ankyloblepharon (congenital partial fusion of the eyelids), ectodermal dysplasia and clefting. Linkage studies and phenotypic overlap suggest that the list for p63 associated conditions is even longer and may include acro-dermato-ungual-lacrimal-tooth (ADULT) syndrome (MIM 103285), recessive cleft lip/palate-ectodermal dysplasia (CLPED1; MIM 225060), and lacrimo-auricular-dental-digital (LADD) syndrome (MIM 149730) [225,226].

Acheiropodia (MIM 200500) is a rare, recessive condition characterized by congenital amputations of the upper and lower extremities. The phenotype consists of a severe reduction deformity resulting in the absence of the radius, ulna, and fibula, and the carpal, metacarpal, tarsal, metatarsal and phalangeal bones. The condition was mapped to chromosome 7q36 in close proximity to the *SHH* gene. Ianakiev et al. [227] were able to identify mutations in the human orthologue of the mouse *Lmbr1* gene. They identified a deletion within the gene in all families tested. Interestingly, expression of the gene is significantly reduced in the mouse mutant hemimelic extra-toes (Hx), which also maps in this region [228]. Hx mice show an ectopic expression of Shh indicating that Lmbr1 may act as a repressor of *Shh*.

Brachydactyly

Brachydactyly type A1 (MIM 112500) has been shown to be due to mutations in the Indian hedgehog (*IHH*) gene [229]. Ihh is one member of the hedgehog family, the more well known being Sonic hedgehog (Shh). Ihh has previously been shown to regulate chondrocyte differentiation via Gli, PTH and the PTH-receptor [230]. The present finding points to the possibility that Ihh also has a function during early condensation/differentiation of phalangeal chondrocytes.

Brachydactyly type B (MIM 113000) has been shown to be caused by mutations in *ROR2*, a gene encoding a receptor tyrosine kinase with unknown function [231,232]. Interestingly, the mutations observed so far cluster in two distinct regions of the gene. The intracellular part of the ROR2 receptor consists of the tyrosine kinase domain and a C-terminal serine-proline-rich domain. Frame shift and premature stop codon mutations are located exactly before or after the tyrosine kinase domain, resulting in truncated proteins that lack either the entire intracellular domain or

the serine-proline-rich domain. Brachydactyly type B is allelic with Robinow syndrome. In contrast to Robinow syndrome mutations, the brachydactyly type B mutations are likely to function as dominant mutations through an as yet unknown mechanism.

Disorders of Segmentation

Mutations in *HOXA11* have been identified in two families with radio-ulnar synostosis and megakaryocytic thrombocytopenia (MIM 605432) [233]. The mutations were single base pair deletions within the homeodomain coding region resulting in a premature stop codon and, presumably, a truncated protein without DNA-binding capacity. The phenotype reflects the developmental expression pattern of Hoxa11, but it remains unclear whether the mutations act as null alleles or exert a dominant-negative effect.

Dysostoplasias

Ellis-van Creveld Syndrome

Ellis-van Creveld syndrome (MIM 225500) is a recessive skeletal dysplasia with short limbs, short ribs, postaxial polydactyly and hypoplastic nails and teeth. In addition, approximately 60% of affected individuals have a heart defect, most commonly a common atrium. The gene for Ellis van-Creveld syndrome has been identified and named *EVC* [234]. It encodes a 992 amino acid protein of unknown function.

ACKNOWLEDGMENTS

Studies from the authors' laboratories that are included in this chapter were supported by grants AR36819 and AR36820 from the National Institutes of Health to BRO, and by grants Mu880/3-2 and Mu880/4-1 from the Deutsche Forschungsgemeinschaft to SM. Mrs. Yulia Pittel provided expert secretarial assistance.

Chapter 24

Disorders of Keratinization

Meral J. Arin, Daniel Hohl, and Dennis R. Roop

Departments of Molecular and Cellular Biology and Dermatology, Baylor College of Medicine Houston, Texas 77030 (M.J.A., D.R.R.); Department of Dermatology, CHUV-DHURDV, Lausanne Switzerland (D.H.)

SUMMARY

- **The disorders of keratinization are a clinically and genetically heterogeneous group, characterized by scaling and hyperkeratosis. The identification of mutations in various components of the keratinization process allows a new classification of these disorders according to their genetic defects.**
- **The keratin disorders are caused by mutations in keratins, leading to a collapse of the intermediate filament network in keratinocytes of the epidermis and the hair shaft. They comprise bullous congenital ichthyosiform erythroderma, ichthyosis bullosa of Siemens, epidermolytic palmoplantar keratoderma, pachyonychia congenita types I and II, and monilethrix. The clinical presentation corresponds to the expression pattern of the mutant keratin.**
- **The disorders of the cornified cell envelope are characterized by impaired formation of the protective barrier of the epidermis. The prototype is lamellar ichthyosis type 1, which is caused by mutations in the *TGM1* gene coding for transglutaminase 1. Mutilating keratoderma with ichthyosis and progressive symmetric erythrokeratoderma are caused by loricrin mutations, leading to impaired incorporation of loricrin into the cornified cell envelope.**
- **The disorders of abnormal lipid metabolism are characterized by an altered lipid composition of cell membranes in various organ systems, accounting for the wide range of symptoms. Defects in several pathways have been identified, including oxidation of fatty alcohol (Sjögren-Larsson syndrome), ceramide metabolism (Gaucher disease), and cholesterol biosynthesis (X-linked dominant chondrodysplasia punctata and CHILD syndrome).**
- **The peroxisomal disorders are characterized by a deficiency of one or more peroxisomal proteins, that normally function in pathways related to lipid metabolism. In rhizomelic chondrodysplasia punctata type 1 several enzymes fail to be imported into the peroxisome, leading to defects in several organ systems. Refsum disease is characterized by ophthalmologic, neurological, and skin manifestations that are the result of inactivating mutations of phytanoyl-CoA-hydroxylase and subsequent accumulation of phytanic acid in various tissues.**
- **The sulfatase disorders comprise X-linked ichthyosis (XRI), X-linked recessive chondrodysplasia punctata (CDPX1), and multiple sulfatase deficiency (MSD). XRI and CDPX1 are monogenic disorders caused by deficiencies of steroid sulfatase and arylsufatase E, respectively. In MSD, several singular sulfatases are catalytically inactive due to a lack of co- or post-translational modification. The clinical presentation can be explained by accumulation of the corresponding substrates in various tissues.**
- **The contiguous gene deletion disorders are caused by deletions of several adjacent genes that are located on the distal short arm of the X chromosome (Xp). The phenotype results from a combination of two or more monogenic disorders and relates clinical findings to corresponding genotypes. The combination of XRI, CDPX1, and Kallmann syndrome has been described as a contiguous gene deletion syndrome due to deletion of the terminal part of Xp.**
- **The proteinase disorders are characterized by defective proteinases or their inhibitors. Netherton disease consists of hair shaft abnormalities and ichthyotic skin changes and is caused by mutations in the serine proteinase inhibitor LEKTI. In Papillon-Lefèvre syndrome, palmoplantar keratoderma is often combined with severe periodontitis. Inactivating mutations of cathepsin C, a lysosomal proteinase, have been demonstrated, which suggests that regulation of proteolysis is critical in epithelial formation and differentiation.**
- **The amino acid metabolism disorder is the Richner-Hanhart syndrome. This is caused by a deficiency of hepatic tyrosine aminotransferase, leading to hypertyrosinemia. It is the only hereditary palmoplantar keratoderma that can be treated efficiently by a dietary regimen through restricting the dietary intake of tyrosine and phenylalanine.**

Connective Tissue and Its Heritable Disorders, pages 1025–1068

- **The disorder of nucleotide excision repair is trichothiodystrophy. This is caused by mutations in the genes *ERCC2* and *ERCC3*, that code for a transcription/repair factor, that normally corrects nucleotide defects at an early stage in DNA excision repair. The clinical presentation consists of generalized ichthyosis, characteristic hair abnormalities, short stature, and mental retardation.**
- **Defects in intercellular communication are caused by connexin mutations or defective calcium-ATPases. In Vohwinkel syndrome, connexin 26 is defective and causes congenital deafness and characteristic skin changes. Connexin 31 mutations are causative in erythrokeratoderma variabilis. Darier-White and Hailey-Hailey diseases are caused by a dysfunction of calcium pumps, which seem to play a role in the differentiation pathway.**

INTRODUCTION

The ichthyoses comprise a large group of disorders characterized by scaling and hyperkeratosis, often associated with other defects and abnormalities. "Ichthyosis" derives from the Greek term *ichthys*, fish, which is descriptive of the scale-like appearance of the skin. Historically, the ichthyoses were divided into subgroups according to distinct clinical features and several classifications have been proposed.

In 1808, Willan first classified the disorders of keratinization and used the term "ichthyosis" for this group of diseases [1]. Brocq separated bullous from nonbullous congenital ichthyoses (congenital bullous erythroderma) and Cockayne and later Siemens introduced the Mendelian thinking of medical genetics into the field. More than 30 years ago, Frost and Van Scott added biological approaches and divided the ichthyoses into two subgroups, the retention and hyperproliferative hyperkeratoses [2], while Schnyder and his collaborators promoted ultrastructural research by electron microscopy [3]. Another major step was the clinical and histopathological differentiation of noncongenital vulgar ichthyoses, that is, the autosomal dominant and X-linked recessive forms, by Wells and Kerr [4,5]. This was rapidly followed by the first identification of a molecular defect in ichthyoses by defining X-linked recessive ichthyosis as a steroid sulfatase deficiency [6,7]. This discovery focused attention on the lipid compartment of the epidermis for nearly two decades and led to the proposal of the "bricks and mortar" model. This model defines the stratum corneum as a two compartment system consisting of corneocytes and intercellular membranes [8]. In 1987, Williams and Elias classified the disorders of cornification into 24 different subgroups (DOC 1-24) [9] and Traupe subsequently distinguished the common ichthyoses of the vulgar type from more severe congenital forms with or without associated multisystemic disease [10]. This practical classification has been adopted to a large extent in recent textbooks [11]. Today, a number of underlying genetic defects and biochemical deficiencies have been identified, necessitating a new and revised classification. In an attempt to classify the disorders of keratinization according to the underlying genetic defect or metabolic deficiency, we first have to understand the mechanisms that regulate keratinization in normal skin.

Keratinocytes represent the most abundant cell type of the epidermis, and keratins are their major gene products. Keratins are members of a multigene family of cytoskeletal proteins, called intermediate filaments (10 nm filaments)(see also Chapter 6, this volume). More than 50 intermediate filament proteins have been identified, of which the keratins constitute the largest group. According to their biochemical properties, keratins are divided into two types, the acidic type I keratins (K9–K20) and the neutral-basic type II keratins (K1–K8) [12]. One of each type is required for the formation of specific pairs of keratin filaments that form a network in the cytoplasm of epithelial cells [13]. The formation of intermediate filaments is a dynamic process, whereby newly synthesized proteins are integrated into the existing network. Filament assembly takes place in several stages and begins with the heterodimerization of one type I (K9–K20) and one type II (K1–K8) keratin in a coiled-coil fashion. Head-to-tail overlaps between heterodimers yield higher order polymers that eventually make up the filament network of the keratinocyte [14]. Keratins consist of a central, α-helical rod domain of approximately 310 amino acids that is divided into four regions, 1A, 1B, 2A, 2B, separated by three linker regions, L1, L12, L2. The rod domain is composed of a seven residue repeating amino acid sequence $(a\text{-}b\text{-}c\text{-}d\text{-}e\text{-}f\text{-}g)_n$ termed a "heptad repeat," in which positions "a" and "d" represent hydrophobic residues that are considered crucial for stabilization of the heterodimer [15]. The beginning of the 1A region and the end of the 2B region, also known as helix initiation and termination motifs, are highly conserved among keratins and other intermediate filaments. These regions are critical for the lateral alignment of heterodimers in which the "head" domain of one heterodimer overlaps with the "tail" domain of a second. The expression of keratins is specific for both the tissue and the stage of differentiation. In the normal epidermis, basal cells express keratins K5 and K14; on migration to the suprabasal layers, the expression of the differentiation-specific keratins, K1 and K10, is induced, while K5 and K14 are down-regulated [16] (Fig. 1). K9 is expressed suprabasally in the epidermis of palms and soles, and K2e is expressed in the granular layer of the epidermis [17]. The K6 isoforms, predominantly K6a and K6b, together with K16, have an additional expression pattern in hair, nail, and mucosa. K17 is found in basal cells of complex epithelia.

The normal differentiation process, also known as keratinization or cornification, involves the transformation of a germinative cell in the basal layer to the deceased corneocyte in the corneal layer (Fig. 1). It involves the formation of the cornified cell envelope as a protective barrier against the environment and water loss [18,19]. Cornified cell envelope formation starts in keratinocytes of the upper granular layer with the cross-linking of various molecules that form a rigid structure at the inner side of the plasma membrane [20]. During this process, the plasma membrane is replaced by a lipid layer that is bound to the outer surface of the protein envelope [18]. The initial incorporation of involucrin and cystatin A involves binding of these components to the lipid envelope which is followed by the incorporation of small proline-rich proteins (SPRRs) and loricrin. Whereas involucrin, SPRRs, and loricrin serve as a mechanical barrier [21], proteinase inhibitors, such as cystatin A, elafin and plasminogen activator inhibitor 2 function as a biological barrier against proteinases [22]. Involucrin is expressed in the upper spinous cells as one of the major initial components of the cornified cell envelope. It is thought to act as an initial scaffold that consolidates after fusion with the other components of the cornified cell envelope [23]. SPRRs are synthesized in the upper spinous to granular cells and function as molecular bridges to connect two proteins of the cornified cell envelope [24]. In the

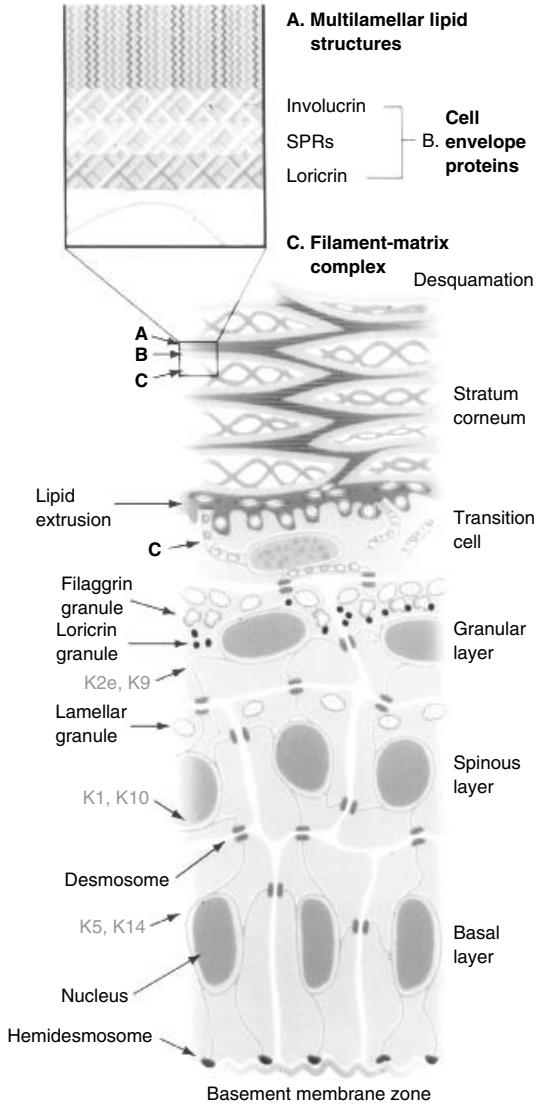

Figure 1. Schematic illustration of the epidermis, showing the normal differentiation process. The epidermis consists of four histologically distinct cellular layers (basal layer, spinous layer, granular layer, and stratum corneum), each with a unique maturation stage of the keratinocyte. The components of the cornified envelope are shown in the inset.

granular layer, keratohyalin granules appear in the cytoplasm and are composed of profilaggrin, which is dephosphorylated and undergoes proteolysis at the zone between the granular and corneal layers, thus yielding filaggrin [25]. Filaggrin is involved in the packing of intermediate filaments into microfibrils through the parallel alignment of already existing intermediate filaments and, to a lesser extent, contributes to the formation of the cornified envelope [26]. S100 family proteins are positioned beneath the plasma membrane in a calcium-dependent manner by annexins, and are covalently linked to the cornified cell envelope by transglutaminase 1 (TGase1) [24]. Loricrin is another protein that accumulates in keratohyalin granules of the superficial granular cells [27]. Loricrin is an insoluble basic protein due to its high content of glycine and other basic amino acids, and represents the major component of the cornified cell envelope [28]. Involucrin, cystatin A, filaggrin, S100 proteins, loricrin and SPRRs are cross-linked by TGase1, one of the four transglutaminases in the epidermis [29]. TGase1 activity is mostly found bound to plasma membranes, whereas TGases 2 and 3 are located in the cytosol. Only TGase1, which is found in the upper spinous and granular layers [30], and TGase3, which is expressed in the granular layer [31], play a role in the formation of the cornified envelope. Moreover, evidence exists that membrane-bound TGase1 is also involved in ceramide lipid attachment to involucrin during protein envelope assembly [32]. Finally, paralleling the formation of the protein envelope, lamellar bodies discharge their contents into the interface between the granular and corneal layers, thereby forming the lipid lamellae. Lamellar bodies are located in the granular layer of the epidermis and contain fatty acids, sphingolipids, cholesterol, and catabolic enzymes such as lipases and proteases [33]. Hydrolases are thought to play an important role in the process of desquamation by dissolving intercellular bridges [34].

In the past few years, the identification of various mutations in components of the keratinization process has revealed the molecular basis of many of the disorders of cornification and provided new insights into the mechanisms that regulate keratinization *in vivo*. Our knowledge today allows a new classification of the disorders of cornification according to their underlying genetic defects (Table 1). However, this classification excludes a group of disorders for which the pathological mechanisms are still unknown. Until the molecular basis of these disorders is identified, we term this group "disorders of keratinization of unknown molecular defect"; the elucidation of the underlying defects behind these disorders will eventually allow us to classify all disorders of keratinization according to their molecular basis.

KERATIN DISORDERS

Bullous Congenital Ichthyosiform Erythroderma (BCIE) (MIM 113800)

Bullous congenital ichthyosiform erythroderma (BCIE) is also known as epidermolytic hyperkeratosis (EHK). The disease was first described by Brocq in 1902 [35]. Subsequently, Lapière termed the disease "granular degeneration," thereby describing his histological findings [36]. The term EHK, which was introduced by Frost and Scott about 10 years later, is often used as a synonym for BCIE and stands for the histopathological picture that is also observed in other keratin disorders such as the two types of pachyonychia congenita, white sponge nevus and Vörners palmoplantar keratoderma [2]. BCIE is an autosomal dominant trait. It has an incidence of 1 in 200,000 to 300,000 newborns, with up to 50% of cases being sporadic. Epidermal nevus of the epidermolytic hyperkeratotic type is a mosaic form of BCIE that is due to postzygotic, spontaneous mutations during embryogenesis. Affected skin alternates with normal skin, and the distribution of the patchy or linear skin lesions is often along the lines of Blaschko. Vertical transmission of the mutation is possible if the germline is involved, causing generalized BCIE in the affected offspring [37].

Clinical and Histological Features

Clinical heterogeneity is high between BCIE families, but rather similar within single families. The onset of the disease phenotype is typically at birth and affected

TABLE 1. Classification of Disorders of Keratinization According to Their Molecular Defects

Disorder	Molecular Defect		Location
	Protein	Gene	
Keratin disorders			
Bullous congenital ichthyosiform erythroderma	K1, K10	*K1, K10*	12q13,17q21–22
Ichthyosis bullosa of Siemens	K2e	*K2e*	12q11–13
Epidermolytic palmoplantar keratoderma	K9	*K9*	17q12–21
Pachyonychia congenita type I	K6a, K16	*K6a, K16*	12q13,17q12–21
Pachyonychia congenita type II	K6b, K17	*K6b, K17*	12q13,17q12–21
Monilethrix	HB1, HB6	*HB1, HB6*	12q13
Disorders of precursor proteins of the cell envelope			
Mutilating keratoderma with ichthyosis	LOR	*LOR*	1q21
Progressive symmetric erythrokeratoderma	LOR	*LOR*	1q21
Autosomal recessive congenital ichthyoses			
Lamellar ichthyosis 1; NCIE 1	TGase1	*TGM1*	14q11.2
Lamellar ichthyosis 2			2q33–35
Lamellar ichthyosis 3; NNCI			19p12–q12; 19p13.2
NCIE 2			3p21
Disorders of abnormal lipid metabolism			
Sjögren-Larsson syndrome	FALDH	*FALDH*	17p11.2
Gaucher disease type II	GCase	*GBA*	1q21
X-linked dominant chondrodysplasia punctata	EBP	*EBP*	Xp11.23–11.22
CHILD syndrome	NSDHL	*NSDHL*	Xq28
Peroxisomal disorders			
Rhizomelic chondrodysplasia punctata type I	PTS2	*PEX7*	6q22-24
Refsum disease	PHYH	*PHYH*	10pter-p11.2
Sulfatase disorders and contiguous gene deletion disorders			
X-linked ichthyosis	STS	*STS*	Xp22.32
X-linked recessive chondrodysplasia punctata	ARSE	*ARSE*	Xp22.3
Multiple sulfatase deficiency	All Sulfatases		Xp22.3
Kallmann syndrome	Anosmin	*KAL1*	Xp22.3
Rud syndrome			X
Proteinase disorders			
Netherton syndrome	LEKTI	*SPINK5*	5q32
Papillon-Lefèvre syndrome	CTSC	*CTSC*	11q14
Amino acid metabolism disorder			
Richner-Hanhart syndrome	TAT	*TAT*	16q22.1-22.3
Disorder of nucleotide excision repair			
Tay syndrome	ERCC2,3	*ERCC2,3*	19q13.2-13.3,2q21
Defects in intercellular communication			
Vohwinkel syndrome	CX 26	*GJB2*	13q11-12
Erythrokeratodermia variabilis	CX 31	*GJB3*	1p35.1
Darier-White disease	SERCA2	*ATP2A2*	12q23-24.1
Hailey-Hailey disease		*ATP2C1*	3q21-24

individuals present with erythroderma, blistering, and peeling (Fig. 2). Erythroderma and blistering diminish during the first year of life and hyperkeratoses develop, predominantly over the flexural areas of the extremities. Maceration of the flexural areas with concomitant bacterial overgrowth often produces a foul odor. A variant of epidermolytic hyperkeratosis with annular and polycyclic erythematous hyperkeratotic plaques on the trunk and proximal extremities has been described [38]. The distinct clinical features with the histopathological finding of epidermolytic hyperkeratosis has led to the term annular epidermolytic ichthyosis (AEI). The same molecular defect that underlies EHK has been identified in two families with AEI [39,40] suggesting that AEI is not a distinct disorder but rather a variant of BCIE. EHK is descriptive of the histopathological findings consisting of perinuclear vacuolar degeneration, lysis of the suprabasal keratinocytes, and a thickened stratum corneum (Fig. 3). Electron microscopy shows clumping of keratin filaments in the suprabasal layers of the epidermis [3,41]: these clumps have been shown to contain keratins K1 and K10 [42].

Molecular Defect

BCIE has been mapped to two keratin gene clusters, the type II keratin gene cluster on chromosome 12q, which contains keratin K1, and the type I keratin gene cluster on chromosome 17q, which contains keratin K10 [43,44]. Several point mutations in the genes for the suprabasal keratins, K1 and K10, have been identified [45–47]. The majority of the mutations in K10 are located in the same

Figure 2. Bullous congenital ichthyosiform erythroderma (BCIE) presenting at birth with generalized erythroderma and blistering. A K1 mutation at the beginning of the rod domain was later identified in this patient. (Courtesy W. Küster, Bad Salzschlirf.)

codon, affecting an evolutionarily highly conserved arginine residue. This site is a "hot spot" due to CpG methylation and deamination [48]. Interestingly, the same arginine residue has been found to be mutated in K14 in the Dowling-Meara form of epidermolysis bullosa simplex (EBS-DM), the most severe form of EBS (see Chapter 15, this volume). An association between the location of the mutation and the severity of the phenotype has been suggested, following the observation that mutations within the initiation and termination motifs lead to more severe phenotypes than mutations located within the rod domain [49]. Clearly, mutations in the highly conserved regions of the rod domain are more disruptive to filament assembly and stability. However, to date a clear genotype-phenotype correlation has not been firmly established for the keratin diseases.

Diagnosis

While a diagnosis can be established clinically in most cases, analysis at the molecular level often facilitates distinction from severe forms of ichthyosis bullosa of Siemens (see below). Prenatal diagnosis by ultrastructural analysis of fetal skin biopsies and amniotic fluid cells has been described [50]. However, both techniques harbor a high number of false-negative results and are thus not considered reliable. Sequence analysis of genomic DNA of chorionic villus samples is a useful tool to identify mutations in the suprabasal keratins, and has been successfully used as early as week 15 [51].

Ichthyosis Bullosa of Siemens (IBS) (MIM 146800)

Ichthyosis bullosa of Siemens is a rare genodermatosis with some clinical features similar to those of epidermolytic hyperkeratosis. Named after Siemens [52], it denotes a milder and more limited form of disease than usually seen with BCIE.

Figure 3. Light micrograph of a skin biopsy from an 18-month-old patient with bullous congenital ichthyosiform erythroderma (BCIE). The epidermis (E) is broadened (acanthosis) and shows pronounced hyperkeratosis (arrow). Note the cytolysis in the suprabasal layer (arrowhead). D = dermis. (Reprinted with permission from [398].)

Clinical Features

At birth, individuals usually present with blistering, and hyperkeratosis develops shortly thereafter. Erythroderma, however, as seen in most BCIE patients, is absent. The fragility of the epidermis is more superficial with shedding and loss of the uppermost layer, the stratum corneum. This leads to characteristic denuded areas, described as "Mauserung" or a "molting effect" by Siemens in 1937 [52]. These areas are often found on the backs of the hands and feet and on the extremities. Hyperkeratoses are usually found at similar sites of the body as in BCIE, with a lichenified appearance over the flexural areas. The absence of erythroderma and blistering caused by minor mechanical trauma often makes a distinction from BCIE easier [53]. The blistering diminishes with age, and in early adulthood lichenification and hyperkeratoses are predominantly found over the flexural areas of the extremities. The severity of the phenotype differs markedly both between kindreds and among members of the same family.

Histological and Ultrastructural Features

Examination of involved skin shows hyperkeratosis and vacuolization confined to the granular layer. Electron microscopy shows tonofilament clumping in the upper spinous layer of the epidermis, the clumps being localized around the nucleus. The overlying stratum corneum is usually less dyskeratotic than in BCIE and areas in the superficial epidermis may be observed that do not exhibit clumping [54].

Molecular Defect

Initially, IBS was linked to the type II keratin gene cluster on chromosome 12q [55]. Subsequently, "hot spot" mutations affecting the same residue in the helix termination motif of K2e were identified as the underlying genetic defect in several families with IBS [56,57]. Interestingly, several of these IBS families were initially diagnosed clinically as having BCIE. However, when obvious mutations in K1 or K10 could not be found, identification of mutations in K2e suggested that these families had been misdiagnosed [56]. Soon thereafter, several groups identified more K2e mutations in IBS, the majority of which were located at the previously described "hot spot" at the end of the rod domain [58–60]. More recently, mutations have also been identified at the beginning of the rod domain of K2e, but these are not as common as the mutations at its end [61]. The resulting amino acid substitutions have been shown to disrupt filament assembly and stability, similarly to the findings in BCIE. As in other keratins, the ends of the rod domain of K2e are highly conserved and substitutions of these particular residues are deleterious to filament assembly. A genotype-phenotype correlation was suggested in two IBS families in which a nonconservative amino acid substitution was associated with a severe disease phenotype in one family, whereas a conservative substitution at the same site correlated with mild clinical features in the second [62].

Ichthyosis exfoliativa presents with circumscribed areas of blistering and hyperkeratoses, clinical features similar to those in IBS [63]. Until 1994, it was thought that both diseases represented distinct entities, but linkage of both disorders to chromosome 12q indicated the type II keratin genes to be candidate genes for both ichthyosis bullosa of Siemens and ichthyosis exfoliativa [55]. Histologic and ultrastructural examination of skin biopsies indicated that ichthyosis exfoliativa was identical to ichthyosis bullosa of Siemens, and this was confirmed by molecular analysis when mutations in K2e were identified as the underlying molecular defect [58].

Epidermolytic Palmoplantar Keratoderma (EPPK) (MIM 144200)

Vörner described an autosomal dominant keratosis of palms and soles with the characteristic histological finding of epidermolytic hyperkeratosis in 1901 [64]. Years earlier, Thost had examined a large German kindred with palmoplantar keratoderma (PPK) in whom histology did not show epidermolytic hyperkeratosis [65]. Unna reported similar clinical features in another PPK family, although histological findings are not available [66]. Soon thereafter, the Unna-Thost form of PPK was distinguished on the basis of histological findings from the rare Vörner type. More recently, the question arose whether both types are indeed different diseases and the existence of the Unna-Thost type was doubted [67–69]. Re-examination of patients diagnosed with the Unna-Thost type and of descendants of the family originally described by Thost in 1880 consistently revealed the histological finding of epidermolytic hyperkeratosis [67–69]. Moreover, K9 mutations, as discussed below, have been identified in several families with epidermolytic palmoplantar keratoderma, including the family originally described by Thost, indicating that both forms are, in fact, one disease, i.e., epidermolytic palmoplantar keratoderma. Nevertheless, nonepidermolytic diffuse palmoplantar keratoderma of Unna exists and is clinically and histopathologically observed. In one such case, a mutation in the ISIS box of the V1 domain of K1 has been identified [70].

Clinical and Histological Features

Epidermolytic palmoplantar keratoderma is an autosomal dominant disorder in which hyperkeratosis is confined to the palms and soles. The onset of the disease is usually early in life and palms and soles are affected with thick hyperkeratoses. The nature of the hyperkeratoses varies markedly between families and among members of the same family. Additional features frequently seen are knuckle pad-like keratoses over the flexural areas of the finger joints and clubbing of the nails [69] (Fig. 4). The histological finding of epidermolytic hyperkeratosis is reminiscent of the findings in BCIE; however, the abnormalities are restricted to palms and soles in EPPK.

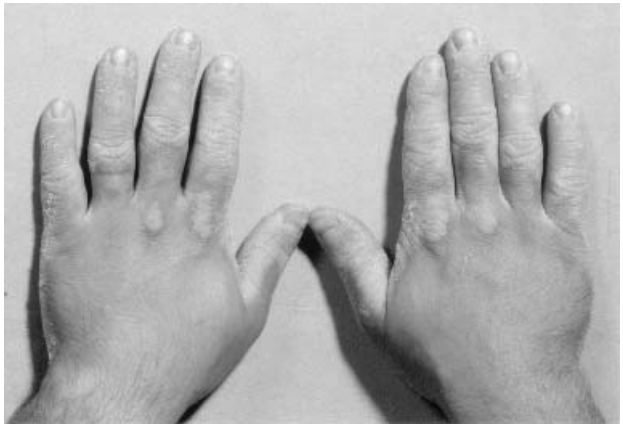

Figure 4. Epidermolytic palmoplantar keratoderma (EPPK) showing hyperkeratosis confined to hands, and pad-like keratoses on the knuckles.

Molecular Defect

The disease has been mapped to the type I keratin gene locus on 17q12-21 [71] and mutations in the suprabasal keratin 9 have been identified in EPPK patients [72–76]. The majority of reported mutations to date lie in the 1A region at the beginning of the central rod domain of K9. Recently, an insertion mutation has been reported in the 2B region of K9, leading to the same EPPK phenotype as previously observed with mutations located in the 1A region [77].

Pachyonychia Congenita (PC); Type I Jadassohn-Lewandowsky Pachyonychia Congenita (MIM 167200); Type II Jackson-Sertoli Pachyonychia Congenita (MIM 167210)

Pachyonychia congenita (PC) is a group of autosomal dominant dysplasias characterized by hypertrophic nail dystrophy accompanied by other features of ectodermal dysplasia. Pachyonychia congenita type I (PC-1) was first described by Jadassohn and Lewandowsky in 1906 [78]. It represents an autosomal dominant ectodermal dysplasia characterized by hypertrophic nail dystrophy, focal nonepidermolytic palmoplantar keratoderma and variable features of oral leukokeratosis and follicular keratosis. In the Jackson-Sertoli form (PC-2, also known as Jackson-Lawler type), pachyonychia and mild focal keratoderma are accompanied by multiple pilosebaceous cysts, natal teeth, and hair abnormalities. It was first reported in 1949 in an Italian family by Sertoli [79] and in six members of a three-generation family by Jackson and Lawler in 1951 [80].

Clinical Features

The clinical features consist of increased thickening and curvature of fingernails and toenails (onychogryphosis), and hyperkeratoses on palms and soles (Fig. 5) and the extensor surfaces of the large joints. In PC-1, leukoplakia of the oral mucosa (Fig. 6) and hyperhidrosis are associated features. When oral candidiasis does not respond to antifungal treatment, oral leukokeratosis associated with PC-1 should be included in the differential diagnosis. In one case, a 2-month-old child presented with oral lesions and was treated for recurrent oral candidiasis. The lesions were unresponsive to antifungals, the development of hypertrophic nail changes was noted, and subsequently the diagnosis of PC-1 was established. At 9 months of age, hyperkeratotic papules, which were not apparent at initial presentation, developed on elbows and knees [81].

The keratoderma in PC-2 is usually milder than that in PC-1 and oral involvement is absent. Multiple epidermoid cysts, pili torti, and teeth abnormalities have been described in PC-2. Moreover, multiple steatocystomas are characteristic and the prominent clinical feature [82]. The presence of epidermoid cysts enables a distinction between the two types. Oligo-symptomatic variants, that is, isolated focal insulated nonepidermolytic keratoderma of the Jadassohn-Lewandowsky type and isolated sebocystoma of the Jackson-Sertoli type, exist, and may be explained by less detrimental mutations in keratins K16 and K17, respectively [83].

Molecular Defect

PC-1 has been associated with mutations in the genes for K6a and K16, located on chromosomes 12 and 17, respectively [84,85]. Most of the mutations reported to date lie in the 1A region of K6a, including deletions and point mutations, suggesting a mutational hot spot [81,86]. Examination of a large kindred affected by PC-2 established linkage of the disease to the type I keratin gene cluster on chromosome 17q and subsequently point mutations in the genes for K6b and K17 were identified [82,85,87].

Monilethrix (MIM 158000)

Monilethrix is a rare hair dystrophy characterized by a variable degree of alopecia due to defects in the structural

proteins of hair and nail, the "hard" keratins. It follows an autosomal dominant inheritance and has been described several times since its first report in 1910 [88].

Clinical and Histological Features

The clinical presentation may be variable, from dystrophic hair confined to a small area to almost total alopecia. Perifollicular hyperkeratosis is a consistent feature and nail defects may be present. Histologically, the hair is beaded as a result of a periodic narrowing of the shaft [89]. Ultrastructural examination of affected hair shows structural defects in the cortex and clumps of the structural proteins of the hair shaft, the hair keratins.

Molecular Defect

Monilethrix maps to the type II keratin gene cluster on chromosome 12q13 [90,91] and has been shown to be caused by mutations in human hair keratins [92]. To date, at least 11 human hair keratins have been identified, of which hair keratins hHB1, 3, and 6 are expressed in the cortex, whereas hHB5 is found primarily in the hair matrix. Heterozygous point mutations in the genes for the hair keratins hHB1 and hHB6 have been identified [92] and one highly conserved glutamic acid residue in the 2B domain of the human hair basic keratin 6 (hHb6) seems to be a mutational hot spot [93].

Treatment of Keratin Diseases

The current treatment of hyperkeratotic skin diseases is symptomatic. Hydration of the skin can be achieved by moistening and lubrication with creams, lotions, oils and ointments. To remove scales, keratolytic and hydrating agents containing urea, ammonium lactate, propylene glycol, and α-hydroxy acids are effective, as well as topical retinoids (e.g., tretinoin) [94]. Topical salicylic acid is nowadays mostly avoided due to its toxicity, particularly when treating large body surface areas in children. It is also increasingly recognized that 12% ammonium lactate in the classical formulation is often not well tolerated due to burning sensations. Thus, it is either used at lower concentrations or combined with other agents. Hyperkeratoses in mild forms of BCIE and IBS respond well to topical treatment with keratolytics and lubricants, which are also effective in minimizing blistering and erosions. In generalized forms of BCIE, and in severe cases of IBS with major skin involvement, systemic retinoids may be considered; however, long-term side effects should be closely monitored. In BCIE patients, good results have been observed with acitretine or, earlier, etretinate, at low doses between 0.2 and 0.5 mg/kg. High doses, however, can cause exacerbation with increased blister formation [95]. Similarly, PC patients benefit from retinoids, and prompt improvement under systemic retinoid therapy has been reported [96,97].

In EPPK, however, retinoid therapy is controversial. Reduction of the palmar and plantar hyperkeratoses has been achieved, but patients do not usually benefit from this treatment because of the development of painful erosions that may impair the normal functioning of hands and feet [95]. Better results have been achieved by removing the hyperkeratoses mechanically. Recently, topical administration of calcipotriol has been proposed [98]. Management of bacterial infections, which frequently occur in BCIE patients, often requires topical and systemic treatment with antibiotics. A decreased frequency of bacterial infections has been observed in BCIE patients under systemic retinoid therapy [94].

DISORDERS OF PRECURSOR PROTEINS OF THE CORNIFIED CELL ENVELOPE

Mutilating Keratoderma with Ichthyosis (MIM 604117)

Mutilating honeycomb keratoderma with associated ichthyosis, also referred to as keratoderma of Camisa, loricrin keratoderma, and variant form of Vohwinkel syndrome, was first described by Wirz in 1930 and Grschebin in 1932 [99,100]. Since then, several cases of palmoplantar keratoderma associated with ichthyosis and constrictions of fingers and toes, leading to auto-amputation have been reported [101–103].

Clinical and Histological Features

The hyperkeratoses and constricting bands on the fingers or toes usually develop during childhood (Fig. 7). The association of three characteristic features has been described by Camisa: diffuse palmoplantar keratoderma with honeycomb appearance, bands constricting the digits (pseudoainhum), and mild ichthyosis [103]. Histologically, the epidermis shows thickening of the granular layer and hyperkeratosis with retention of rounded nuclei in the stratum corneum [104] (Fig. 8).

Molecular Defect

Mutilating keratoderma with ichthyosis is inherited in an autosomal dominant manner. Linkage of this syndrome to markers in proximity to the epidermal differentiation complex on chromosome 1q21 has been demonstrated in a large kindred [105]. Interestingly, the same kindred had been reported previously as three separate families, but it is now possible to connect this large kindred to a common ancestor in the United Kingdom in the mid-1700s. Two different insertion mutations in the loricrin gene (231insG; 209insT) have been identified in unrelated families [102,104,105]. The insertion of an extra guanine or thymidine after codon 231 and at codon 209 produces a mutant protein with a frameshift of its terminal 84 and 107 amino acids, respectively, that is 22 amino acids longer than the wild-type protein. The insertion mutation is considered to be responsible for the disease and is thought to cause accumulation of defective loricrin in the nucleus. The altered protein structure impairs cross-linking by transglutaminases and thus the mutant loricrin is not properly incorporated

Figure 7. Mutilating keratoderma with constrictions of the fingers (pseudoainhum). (Reprinted from [105], with permission of the publisher.)

into the cornified cell envelope. That cornified cell envelope formation is impaired is indicated by the observation that the cornified envelope in mutilating keratoderma with ichthyosis is much thinner than normal [102,103]. It is now clear that loricrin mutations in keratoderma of Camisa are unique to the variant with ichthyosis: in a family with mutilating keratoderma, molecular analysis revealed one of the previously reported insertion mutations in the loricrin gene (231insG), whereas in a second family with sensorineural deafness and localized starfish keratoses rather than generalized ichthyosis (Vohwinkel syndrome), linkage to loricrin was excluded [102]. Therefore, mutilating keratoderma of Camisa with ichthyosis due to loricrin mutations should be delineated from the classic Vohwinkel syndrome, which is now known to be caused by connexin mutations (see below).

Progressive Symmetric Erythrokeratoderma (PSEK) (MIM 602036)

Progressive symmetric erythrokeratoderma was first described by Darier in 1911 [106]. Only about 30 cases have been described since then in the literature [107].

Clinical and Histological Features

At birth, well-demarcated, symmetric, erythematous and hyperkeratotic plaques predominate over extremities, buttocks, and face. These plaques usually remain stable in location and appearance but may progress slightly during childhood. Spontaneous regression of the plaques is also possible [108]. PSEK is usually a localized disorder of keratinization; however, intermittent generalization is frequently reported. The histological findings are similar to those in Camisa keratoderma with hyperkeratosis and parakeratosis.

Molecular Defect

The disease is inherited in an autosomal dominant manner with incomplete penetrance and variable expressivity. A frame-shift insertion mutation of an additional cytosine at nucleotide position 709 in the loricrin gene, only 21 bp upstream of the mutation discovered in Camisa keratoderma, has been found in one family affected by PSEK [107]. The mutation at codon 224 results in a frameshift that changes the terminal 91 amino acids to missense and adds 22 residues to the mutant protein. Clinically, overlaps between PSEK and Camisa keratoderma have been described; moreover, it has been suggested that they are different manifestations of a single condition [109]. The identification of loricrin mutations in both disorders suggests one disease entity; however, it remains to be shown if the site of mutation will correlate consistently with the respective disease phenotype. Interestingly, variants of PSEK with deafness have also been described in the literature [110] that are reminiscent of the true Vohwinkel keratoderma due to connexin 26 mutations (see below).

Treatment of Disorders of Precursor Proteins of the Cornified Cell Envelope

In mutilating keratoderma with ichthyosis, improvement of the condition has been reported with etretinate in a 28-year-old woman and in four members of an affected three-generation family [111]. A similar effect has been reported in an 11-year-old boy [112]. In all cases, the hyperkeratoses diminished and the constricting bands tended to disappear. Likewise, good results have been achieved with etretinate treatment in PSEK patients, and it has been suggested that it should be preferred over isotretinoin [95]. However, hyperkeratoses usually respond better to etretinate treatment than the erythematous component.

ICHTHYOSIS OF THE NEWBORN

Collodion Baby

The collodion presentation at birth can develop into a wide spectrum of ichthyosis phenotypes such as the autosomal recessive congenital ichthyoses, X-linked dominant chondrodysplasia punctata, and Netherton syndrome. Frenk distinguished the self-healing, autosomal recessive collodion baby from the type which develops into lamellar ichthyosis at the ultrastructural level [113]. Larrègue studied 69 collodion babies and found that the majority of cases developed into nonbullous congenital ichthyosiform erythroderma and lamellar ichthyosis [114] (Fig. 9).

Clinical Features

At birth, the newborn is encased in a tight membrane that breaks up during the first weeks after birth, leaving deep fissures and erythroderma. The birth is often premature and impairment of respiration due to the tight membrane, as well as inadequate nutritional and fluid intake, might complicate the infant's condition. Therefore, monitoring of temperature, hydration, and electrolytes is essential.

Figure 9. Collodion baby due to nonbullous congenital ichthyosiform erythroderma.

Molecular Defect

The pathogenesis underlying most disorders leading to collodion presentation at birth has been identified, such as transglutaminase deficiency in lamellar ichthyosis, *EBP* mutations in X-linked dominant chondrodysplasia punctata and LEKT1 mutations in Netherton syndrome (see below). A straightforward test to distinguish transglutaminase 1-deficient lamellar ichthyosis from other forms of underlying ichthyosis is an *in situ* transglutaminase assay to determine TGase activity [115] (see below).

Treatment

Collodion babies need to be transferred to a neonatal intensive care unit due to the high risk of death (1976: 33%, 1984: 11%) [114]. Systemic hydration is crucial and potential skin infections need to be recognized early by repeated microbiological swabs. Nevertheless, preventive antibiotic treatment is not recommended, to avoid the development of resistant, uncontrollable strains. Topical treatment should be inert (e.g., cold cream, petrolatum). The desquamation of the collodion membrane takes about 10 days: during that time the newborn should be placed in a humidified incubator and treatment of the skin with wet compresses and lubricants may further hydrate the membrane.

Harlequin Ichthyosis (MIM 242500)

Harlequin ichthyosis is a very severe, usually fatal condition. As a result of improvements in therapy and survival rates, the term harlequin ichthyosis may replace the term harlequin fetus [116]. Less than 100 cases have been described in the literature. The condition is inherited in an autosomal recessive fashion, but dominant mutations may play a role in some sporadic cases [117].

Clinical and Histological Features

Most infants with harlequin ichthyosis are born prematurely. At birth, thick plates of stratum corneum cover the whole body in a diamond-like configuration, reminiscent of the suit of a harlequin clown (Fig. 10). The horny shell restricts vital functions such as respiration and swallowing, and constrictions of limbs and digits may lead to deformations. The nose and ears are deformed and often even completely absent. Water loss and infections are serious complications. The skin of harlequin babies surviving the neonatal period resembles that seen in severe forms of nonbullous congenital ichthyosiform erythroderma (NCIE). Histologically, the stratum corneum is enlarged in most cases [118]. The size of the granular layer is variable and the thickness of the epidermis appears small compared to the broadened stratum corneum. Studies suggest that lamellar bodies, which normally form the lipid lamellae of the stratum corneum, are present in harlequin ichthyosis, but are defective and thus contribute neither to the formation of the lipid lamellae nor to desquamation [119].

Molecular Defect

The underlying genetic defect is unknown. An alteration in the expression pattern of profilaggrin/filaggrin and keratins K6/K16 has been proposed following the observation that filaggrin is absent [117]. Decreased activity of a serine/threonine protein phosphatase has been shown in keratinocytes of affected individuals, suggesting

Figure 10. Harlequin fetus that died at birth.

impaired conversion of phosphorylated profilaggrin to the non-phosphorylated form [120]. Calcium-activated neutral proteases are believed to participate in signal transduction in the epidermis; diminished levels in harlequin skin implicate calcium-mediated signaling events in the alteration of differentiation that occurs in harlequin ichthyosis [121]. The corresponding phenotype to harlequin ichthyosis arose spontaneously in a colony of BALB/CJ mice. The mutant gene was mapped to the proximal end of mouse chromosome 19. The disease showed an autosomal recessive mode of inheritance with full penetrance [122].

Management

Management of harlequin ichthyosis remains symptomatic. To date, no generally accepted therapeutic regimen has been established. Systemic retinoid therapy has been shown to improve survival rates [123] and topical administration of paraffin ointment leads to skin improvement allowing movement of the limbs and normal nourishment [124].

AUTOSOMAL RECESSIVE CONGENITAL ICHTHYOSES

Lamellar Ichthyosis Type 1 (LI 1) (MIM 242300), Type 2 (LI 2) (MIM 601277), and Type 3 (LI 3) (MIM 604777); Nonbullous Congenital Ichthyosiform Erythroderma 1 (NCIE 1) (MIM 242100) and 2 (NCIE 2) (MIM 604780), Nonlamellar Nonerythrodermic Congenital Ichthyosis (NNCI) (MIM 604781)

The autosomal recessive congenital ichthyoses (ARCI) are a clinically heterogeneous group that have been distinguished in the past on the basis of clinical presentation and/or ultrastructural findings [125]. Three types of lamellar ichthyosis (LI 1–3), two forms of nonbullous congenital ichthyosiform erythroderma (NCIE 1 and 2), and a nonlamellar, nonerythrodermic ichthyotic type (NNCI) can be distinguished on the basis of chromosomal location. The inheritance pattern of each is recessive, although some cases of dominant inheritance have been described [126]. As more patients are being characterized at the molecular level, it might soon be possible to classify this heterogeneous group still further.

Clinical and Histological Features

The subtypes all have distinct clinical features (Table 2) that range from generalized large brown scales to fine white scales with associated erythroderma [10]. About 60% of collodion babies evolve to the NCIE phenotype or the LI phenotype, the former being slightly more frequent [114].

LI 1 accounts for about 50% of all ARCI. In the case of presentation as a collodion baby, the newborn is encased in a collodion membrane. Mortality in such cases in the first months of life is high as the infant may die of complications, such as sepsis, or protein and electrolyte loss. Other patients, however, do not show collodion presentation at birth. Erythroderma is often present and large, brown, plate-like scales develop, covering the whole body [125] or only the trunk with spared extremities in others [127]. These two distinct phenotypes are most likely due to less detrimental mutations, with slightly retained transglutaminase activity in the "trunk only" phenotype. Involvement of palms and soles ranges from moderate hyperkeratosis to extensive palmar and plantar keratoderma with large fissures. The facial skin may also be affected and ectropion and eclabium are often associated features. If left untreated, severe ectropion can lead to blindness. Additionally, many patients exhibit scarring alopecia. Hypohidrosis is often present and patients should be made aware of the potential risk of hyperpyrexia, especially in hot temperatures and during physical exercise [128]. Prenatal diagnosis has been performed at 13 weeks of gestation by

TABLE 2. Autosomal Recessive Congenital Ichthyoses. Classification of Subtypes According to Distinct Clinical Features and Chromosomal Location

	LI 1	LI 2	LI 3	NCIE 1	NCIE 2	NNCI
Scales	Medium to large, brown	Very large, brown	Large, brownish, adherent	Medium to large, brown	Fine, white, semiadherent	Fine, white, mild
Erythema	Variable	None	Variable	Variable	Intense, widespread	None
Nails	Normal	Normal	Normal	Normal	Normal	?
Hair	+/− Scarring alopecia	Normal	Normal	+/− Scarring alopecia	Diffuse alopecia	?
Linkage	14q11 (*TGM1*)	2q33–35	19p12–q12	14q11	3p21	19p13

identification of TGase1 mutations by molecular analysis of chorionic villus samples in LI 1 [129] and by histological examination of fetal skin biopsies and amniotic fluid cells in the second trimester [130,131].

LI 2 is characterized by collodion presentation at birth that usually evolves to a generalized ichthyosis with involvement of the large folds. The scales are brownish in color and larger in size than those seen in LI 1 and erythroderma is absent. Ectropion may also be present and ranges from mild to moderate [132,133].

LI 3 patients usually present at birth as collodion babies. Large brownish adherent scales and palmoplantar keratoderma are typical features; erythroderma, ectropion, and eclabium may or may not be present. Hair, nails, and teeth are not affected [134].

NCIE is an inflammatory form of ichthyosis characterized by thin, white scales and prominent erythroderma (Fig. 11). In NCIE 1, presentation at birth ranges from ichthyotic skin, through erythema to collodion skin. Later, thin white scales cover the entire body. The flexures and palms and soles are involved in the majority of patients, ectropion is usually present, and alopecia may or may not be an associated feature.

NCIE 2 has collodion presentation at birth and widespread erythema with fine, superficial, semiadherent white scales that cover the entire body are characteristic features. In addition to erythema, palmoplantar hyperkeratosis, diffuse alopecia, ectropion, and eclabium are also seen in most patients [134].

Figure 11. Nonbullous congenital ichthyosiform erythroderma with severe erythema and fine whitish nonadherent scales.

NNCI is a nonlamellar, nonerythrodermic type of ichthyosis that resembles neither lamellar ichthyosis nor erythrodermic congenital ichthyosiform erythroderma. At birth, the affected infant presents with ichthyotic skin or as a collodion baby, while later the skin develops fine, white scales, that predominate over flexural folds, ankles, and ears. The clinical picture at birth can be severe, but later develops into a remarkably mild scaling, distinct from that observed in NCIE. Palms and soles exhibit hyperlinear, hyperkeratotic skin. Erythroderma and ectropion are usually absent [135].

Histopathology in ARCI shows variable acanthosis, hypergranulosis, and hyperkeratosis. Keratinocytes of the stratum corneum have been shown to contain lipid droplets [136,137], the significance of which remains to be elucidated. Keratinocytes in culture bearing mutations in TGase 1 are unable to form cross-linked envelopes, which could serve as a tool to distinguish LI 1 and NCIE 1 from other ichthyotic diseases by a simple test [138]. Determination of TGase activity in combination with immunohistochemistry for TGase protein in frozen skin sections allows a rapid distinction between the different forms of autosomal recessive congenital ichthyosis [115].

Molecular Defect

Initially, linkage studies implicated the keratinocyte-specific transglutaminase 1 gene locus (*TGM1*) on chromosome 14q11 in LI [139] and subsequently mutations have been identified in the *TGM1* gene in patients with LI 1 and NCIE 1 [140–143]. The transglutaminase 1 (TGase1) enzyme is critical for the assembly of the cornified cell envelope in terminally differentiating keratinocytes. It is a complex enzyme, existing as both cytosolic and membrane-bound forms, and it is the membrane-bound isoform that is the major functionally active form [144]. The membrane-bound isoform catalyzes Ca^{2+}-dependent cross-linking of proteins through the transfer of the γ-carboxyl group from protein-bound glutamine to the ε-amino group of protein-bound lysyl residues. During formation of the stratum corneum, TGase1 catalyzes the cross-linking of involucrin, loricrin, SPRRs, and other minor components, to form a protein complex that builds the cornified envelope on the inner side of the plasma membrane [145].

LI patients with normal transglutaminase 1 activity have been described suggesting the involvement of other gene loci [140,146]. Indeed, a second locus for LI has

been mapped to chromosome 2q33–35 [132] and the corresponding type of lamellar ichthyosis has been designated LI 2. Three further loci have recently been identified for ARCI. A region on chromosome 19p12–q12 is linked to lamellar ichthyosis type 3 (LI 3) [134] and a region on chromosome 19p13 has been assigned to a nonlamellar, nonerythrodermic type of ichthyosis (NNCI) in a Finnish family [135]. The fifth locus that has been linked to ARCI is a region on chromosome 3p21. This locus is associated with NCIE 2, the second form of congenital nonbullous ichthyosiform erythroderma [134]. A mouse model lacking the *Tgm1* gene has been established and mutant mice have erythrodermic skin with abnormal keratinization. Skin barrier function is impaired and these mice die a few days after birth [147].

Treatment of Autosomal Recessive Congenital Ichthyoses

Systemic treatment with retinoids (acitretin and isotretinoin) has proven particularly effective in LI and NCIE. Patients should be closely monitored because continued benefit usually requires long-term treatment [94]. Regular topical treatment is very important and needs to be practiced by all means, especially in the lamellar variants. Rehydrating topical treatments should be applied at least twice daily. A recent cream formulation using Locobase^{TM} with 5% ammonium lactate and 20% propylene glycol has proven to be particularly effective [148], also, in our own experience (D. Hohl, unpublished observation). Some patients prefer cold cream with 5% ammonium lactate in a more hydrophilic cream formulation, especially for the scalp, where it is desirable that topical preparations be easily removable. Other patients, however, prefer ointments containing 12% urea, 1% dexpanthenol, and 0.03% tretinoin and many diverse commercial and magistral formulations are in use by different specialists and patient groups. In addition, scales should regularly be removed by bathing with the addition of oils (e.g., paraffinum liquidum), marine salt, and antiseptics against malodorous superinfections.

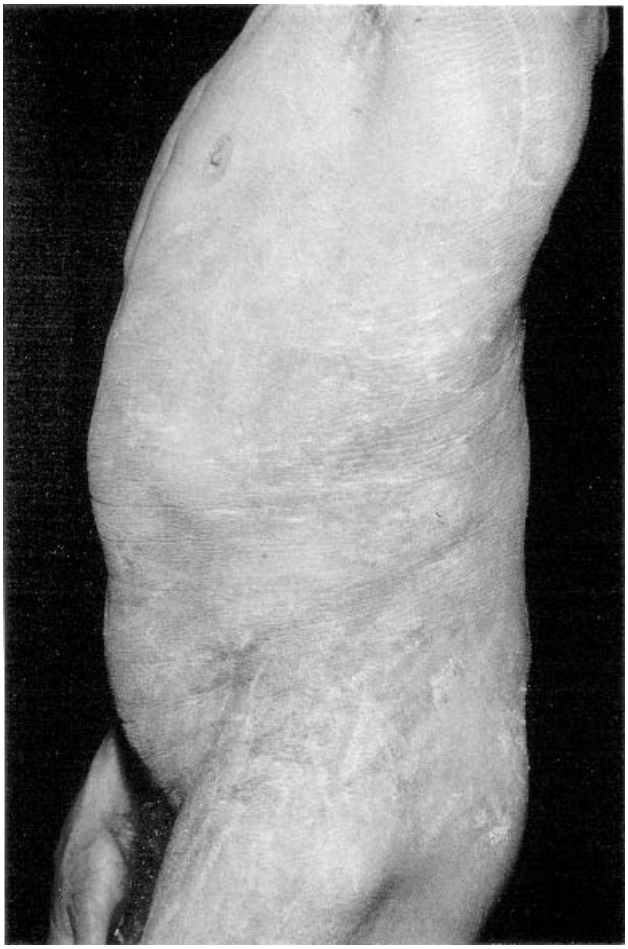

Figure 12. Sjögren-Larsson syndrome; lichenified keratotic lesions typical of adult patients.

DISORDERS OF ABNORMAL LIPID METABOLISM

Sjögren-Larsson Syndrome (SLS) (MIM 270200)

This autosomal-recessive syndrome was first described in northern Sweden where several large kindreds presented with ichthyosis that occurred in association with spastic paralysis and mental retardation [149]. SLS is distributed worldwide; however, half of all reported cases originate from northern Sweden, suggesting a founder mutation [150].

Clinical and Histological Features

The ichthyosis presents at birth with congenital erythroderma with fine to large scales and a varying degree of hyperkeratosis, predominantly over the flexural areas of the extremities, neck, and abdomen. The characteristic features develop during the first months of life and consist of yellowish to dark brown hyperkeratoses, the palms, soles, and face being spared. Hair and nails are clinically unaffected. Pruritus is a characteristic feature in SLS and continuous scratching leads to severe lichenification that is typical of the clinical picture in older patients [151] (Fig. 12). Less severe pruritus may also be observed in other cutaneous lipid disorders, but usually not in ichthyoses due to defects in keratins or transglutaminases. During the second year of life, a spastic di- or tetraplegia develops, seizures occur frequently, and mental retardation is always associated with the disease. Eye involvement is frequently observed and consists of glistening dots in the fundus due to focal microglial degeneration. Histologically, the skin in SLS cannot be distinguished from that in LI. Both diseases show orthokeratotic hyperkeratosis with parakeratosis. Ultrastructurally, lipid vacuoles in the horny layer are rarely seen and the tonofibrils have a stiffer appearance than normal [152].

Molecular Defect

The disease has been linked to chromosome 17p11.2 in Swedish pedigrees and this linkage has been confirmed in non-Swedish pedigrees [153,154]. A deficiency of fatty aldehyde dehydrogenase (FALDH) has been associated with the syndrome and mutations in the *FALDH* gene have been identified [155]. FALDH is a component of the microsomal enzyme complex, FAO (fatty alcohol: nicotinamide adenine dinucleotide (NAD) oxidoreductase), which catalyzes the oxidation of fatty alcohols to fatty acids. In SLS, there is a concomitant reduction of both FALDH and FAO activities, resulting in accumulation of fatty alcohols in blood and tissues. The incorporation of fatty alcohol into lipids alters the lipid composition and leads to the impaired cell membrane function thought to be the cause of the symptoms seen in SLS [156]. Neurological

manifestations and abnormal desquamation are the clinical correlates of abnormal lipid composition of nerve sheaths and keratinocytes. To date, more than 35 mutations have been identified in the *FALDH* gene, including deletions, insertions and point mutations [157–160]. Interestingly, a single point mutation has been identified in patients from both northern Europe and Sweden, supporting the hypothesis of a common ancestor in whom this point mutation originally occurred [158].

Gaucher Disease, Type II (Infantile Cerebral Type; Acute Neuronopathic Type) (MIM 230900)

Gaucher disease is an autosomal recessive disorder involving various organ systems (see also Chapter 22, this volume). It has been divided into three subtypes, only one of which shows skin involvement. Type II Gaucher disease, the rarest type, is progressive and fatal. Several sporadic cases have been reported in the literature in which newborns presented with ichthyotic skin at birth and later developed neurological symptoms. Death occurred within the first months of life [161,162].

Clinical and Histological Features

Newborns often show a collodion-like presentation at birth. A variation in severity of the skin phenotype may be due to differences in the levels of residual enzyme activity of β-glucocerebrosidase [163]. Upon histological and ultrastructural examination, hyperkeratosis and disruption of the lamellar structure of the stratum corneum are noted.

Molecular Defect

The genetic defect lies in the *GBA* gene encoding β-glucocerebrosidase (GCase), leading to enzyme deficiency [164,165]. GCase is located generally in lysosomes, including those in the stratum corneum of the epidermis, and catalyzes the hydrolysis of glucosylceramides to ceramides. In the skin, ceramides are a crucial component of intercellular lamellae between corneocytes and play an important role in barrier function and desquamation [166]. The persistence of glucosylceramides rather than the decreased concentration of ceramides is thought to be the cause of the structural abnormalities in the stratum corneum [163]. The lipid alteration in the intercellular lamellae may induce corneocyte adhesion through increased hydrogen bonding, consequently leading to retention of the abnormal stratum corneum [163,167,168]. An animal model for Gaucher disease has been developed that shows ichthyotic skin changes and increased transepidermal water loss corresponding to the findings in the most severely affected patients [169].

X-Linked Dominant Chondrodysplasia Punctata (CDPX2; Conradi-Hünermann Syndrome; Happle Syndrome) (MIM 302960)

The term Conradi-Hünermann syndrome has been used in the literature for the X-linked dominant form of chondrodysplasia punctata. "Happle syndrome" denotes the occurrence of X-linked dominant chondrodysplasia punctata, ichthyosis, cataract, and short stature. About 60 cases of familial X-linked dominant chondrodysplasia punctata have been described [170], most of which are sporadic, suggesting *de novo* mutations [171,172]. A mild form of chondrodysplasia punctata with autosomal dominant inheritance has been reported, in which patients had a characteristic facies and symmetric stippling of the limbs, which disappeared after childhood [173]. The existence of the autosomal dominant form has been questioned, because some cases initially described as being autosomal dominant were later shown to follow an X-linked dominant inheritance [174], while other sporadic cases could be attributed to warfarin embryopathy [175].

Clinical and Histological Features

The X-linked dominant form is characterized by asymmetric chondrodysplasia punctata, ichthyosiform erythroderma, limb skeletal defects, and segmental cataracts. The phenotype in CDPX2 females ranges from stillbirth to mildly affected individuals identified in adulthood. The X-linked dominant inheritance pattern is presumed lethal in males, although a few affected males have been reported. Genetic heterogeneity, variable gene expression, and incomplete penetrance have been proposed to explain the wide range of clinical and radiological manifestations.

The newborn presents with a generalized erythema and blaschkoid disposition of scales and follicular keratoses that are arranged in a linear pattern and diminish over the first weeks to months, leaving hypochromic areas, follicular atrophoderma, and alopecia of the scalp. At birth, segmental collodion membranes may be observed particularly over peripheral extremities. The linear cutaneous findings, which follow the lines of Blaschko, are interpreted as an example of random X chromosome inactivation in each cell (Lyonization). The skeletal abnormalities are characterized by marked asymmetry. At birth, endochondral punctate calcifications can be observed in areas of spine, ribs, pelvis, long bones and scapula, that may disappear spontaneously later in life (Fig. 13). Impaired endochondral bone formation can result in short stature, asymmetric leg length, kyphoscoliosis, and an asymmetric facial appearance due to hypoplasia on one side. Cataracts occur in one third of cases, are often unilateral, and may be confined to one quadrant of the eye as a manifestation of functional X-chromosomal mosaicism [176]. Histopathology shows prominent follicular and interfollicular compact hyperkeratosis containing specific and unique calcium deposits revealed by histochemistry [177] (Fig. 14). Electron microscopy demonstrates cytoplasmic vacuoles in keratinocytes of the granular layer, which have been shown to contain calcium crystals [178].

Molecular Defect

Inborn errors of the cholesterol biosynthetic pathway have been identified in several dysmorphogenetic syndromes, such as CDPX2, CHILD syndrome (see below), and Smith-Lemli-Opitz syndrome [179]. The X-linked semidominant mouse mutation "tattered" (*Td*) [180] has been shown to cause a phenotype in mice similar to that seen in heterozygous human females with CDPX2. The defect in *Td* mice has been identified as a single amino acid substitution in the Δ8Δ7-sterol-isomerase, also known as emopamil-binding protein (Ebp) [181]. In humans, a candidate gene (*EBP*), encoding a sterol-Δ8-isomerase has been identified and mapped to Xp11.22–p11.23. Several different mutations in the human *EBP* gene have been identified in unrelated CDPX2 patients [181,182]. The mechanism whereby cholesterol deficiency and/or accumulation of intermediates of the synthetic pathway lead to different phenotypes remains to be elucidated. It has been shown that members of the hedgehog (Hh) family of secreted signaling proteins play a role in animal development, and alteration of one of the members, "patched" (Ptc), has been associated with nevoid basal cell carcinoma syndrome (NBCCS or Gorlin syndrome) [183,184]. The discovery that "dispatched" (Disp), a novel member of this family, is required to

Figure 13. X-linked dominant chondrodysplasia punctata: stippled epiphyseal calcifications.

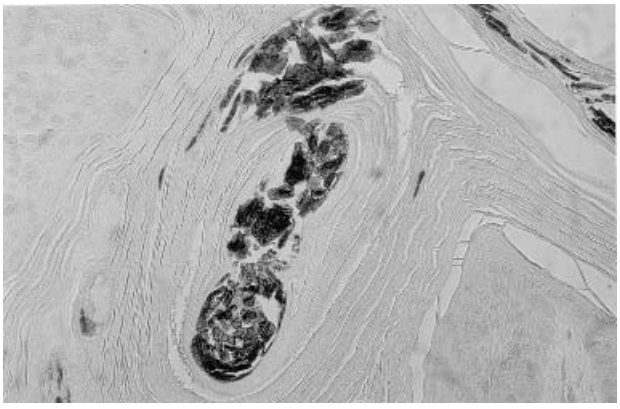

Figure 14. X-linked dominant chondrodysplasia punctata: von Kossa stain revealing calcification within the stratum corneum.

release cholesterol-anchored hedgehog to ensure effective Hh signaling [185], suggests that the cholesterol biosynthetic pathway may be closely linked to the hedgehog-patched signaling cascade. Thus, the Hh-Ptc signaling cascade might be a candidate for cellular processes that require an intact cholesterol pathway, and defects in either pathway could be associated with impaired terminal differentiation.

CHILD Syndrome (Congenital Hemidysplasia with Ichthyosiform Erythroderma and Limb Defects) (MIM 308050)

The term CHILD syndrome was introduced in 1980 by Happle to describe congenital hemidysplasia with unilateral inflammatory nevus and limb defects [186]. X-linked dominant inheritance with lethality in hemizygous male embryos has been proposed following the observation that far more females than males are affected [187]. The unilateral distribution of the defects can be explained by Lyonization.

Clinical and Histological Features

The clinical features are similar to those of rhizomelic chondrodysplasia punctata and X-linked dominant chondrodysplasia punctata. The CHILD nevus is usually present at birth, but may also develop during the first months of life. The erythematous and ichthyosiform lesion has a sharp demarcation, is usually covered with waxy scales, and is located predominantly over flexural areas and body folds. The distribution is either diffuse over one side of the body or arranged along the lines of Blaschko [188]. The skeletal anomalies are unilateral and involve mainly long bones. Epiphyseal chondrodysplasia punctata can be seen shortly after birth and can lead to skeletal defects that may vary from minimal asymmetry of limbs to the complete lack of one extremity [189]. Associated defects in other organ systems include ipsilateral hypoplasia of brain or spinal cord and ipsilateral visceral anomalies. Early death has been associated with congenital heart disease due to cardiovascular malformations [188]. Histology reveals acanthosis, areas of parakeratosis, and areas of orthohyperkeratosis. The dermis shows lymphohistiocytic infiltrates, which makes a distinction from psoriasis difficult. Ultrastructurally, the corneocytes contain lipid vacuoles.

Molecular Defect

Mutations in the gene encoding NAD(P)H steroid dehydrogenase-like protein (*NSDHL*), leading to impaired protein function, have been identified in CHILD patients [190]. NSDHL is a 3β-hydroxysteroid dehydrogenase that functions in one of the later steps of cholesterol biosynthesis upstream of EBP, the defective protein in CDPX2. It is thought that the defective enzyme is responsible for decreased synthesis of cholesterol, accounting for the skin and bone phenotype. Two X-linked semidominant mouse mutations, "bare patches" (Bpa) and "striated" (Str) have been associated with mutations in the *Nsdhl* gene [191] and can be used as animal models for the study of CHILD syndrome.

Treatment of Disorders of Abnormal Lipid Metabolism

Treatment of Sjögren-Larsson syndrome by reducing fatty acid intake is controversial [192,193]. Skin changes, including the severe pruritus of SLS, are markedly improved by moderate doses of systemic retinoids such as acitretin and etretinate [193,194]. Nevertheless, such treatment does not change the neurological symptoms. Topical treatment with moisturizing and lubricating preparations, e.g., a lipophilic lotion or cream containing 5% ammonium lactate and 20% propylene glycol, is well tolerated in our own experience in SLS (D. Hohl, unpublished observation). While type 1 Gaucher disease responds clinically to enzyme replacement, such response has not been seen in patients with type

2 disease [195]. Controversial results have been achieved with systemic retinoid treatment in CHILD patients. With isotretinoin, corneal deposits have been reported; low dosage, however, was effective in reducing the extent of erythroderma [196].

PEROXISOMAL DISORDERS

Rhizomelic Chondrodysplasia Punctata Type 1 (RCDP1) (MIM 215100)

Peroxisomes function in a number of essential metabolic pathways, especially those related to lipid metabolism. Peroxisomal proteins are synthesized in the cytosol and targeted to the peroxisome via specific targeting signals. Defects in those import routes may result in single or multiple enzyme deficiencies. In rhizomelic chondrodysplasia punctata type 1 (RCDP1), one import pathway is blocked, resulting in a deficiency of multiple peroxisomal proteins.

Clinical Features

Clinically, RCDP patients present with symmetrical proximal shortening of the limbs (rhizomelia), epiphyseal calcifications, cataract, severe mental retardation, and, less frequently, ichthyosis. The generalized discrete ichthyosis differs from the blaschkoid pattern of the follicular hyperkeratosis observed at birth in CDPX2. The ocular phenotype is also helpful in its distinction from the X-linked dominant form: in RCDP the opacities are bilateral and symmetric, whereas in the X-linked form they are usually asymmetric and unilateral [176].

Molecular Defect

Deficiency of plasmalogens from red cells and decreased dihydroxyacetonephosphate acyltransferase (DHAPAT) in platelets and fibroblasts, with concomitant elevation of phytanic acid but normal oxidation of very long chain fatty acids, is a characteristic finding in RCDP patients [197]. RCDP is classified as a protein-targeting disease characterized by the unique feature that the biogenesis of most peroxisomal proteins is normal, but a specific subset of peroxisomal matrix proteins fails to be imported from the cytosol [198–200]. Two of the targeting sequences that are required for import into peroxisomes have been identified and are referred to as peroxisome targeting sequences (PTS). The PTS2 receptor is defective in RCDP, and several mutations have been identified in the *PEX7* gene [198–200]. Several peroxisomal matrix proteins are mistargeted in this disease; consequently, RCDP is characterized by multiple enzyme deficiencies [201], accounting for the severe symptoms.

Refsum Disease (MIM 266500)

Refsum disease is prevalent among populations in or from northern Europe and Scandinavia and follows a recessive mode of inheritance. It was first described in 1946 by the Norwegian neurologist, Sijvald Refsum, who reported the symptoms in two inbred families in Norway [202].

Clinical and Histological Features

A variable ichthyosis develops during the second or third decade of life with small white scales over the trunk and extremities (Fig. 15), resembling ichthyosis vulgaris. The flexural areas and palms and soles are usually spared. Ophthalmologic and neurological manifestations include retinitis pigmentosa, peripheral neuropathy and cerebellar ataxia. Other abnormalities include cardiomyopathy, impaired renal tubular function and epiphyseal dysplasia. Several cases of fatal outcome have been reported, mostly due to cardiopulmonary complications, such as arrythmia or respiratory paralysis [203]. Histologically, vacuoles in epidermal and dermal cells are characteristic and correspond to lipid accumulation. Electron microscopy shows lipid droplets in the cytoplasm of keratinocytes and melanocytes, which are located close to degenerated mitochondria or the endoplasmic reticulum. The degenerated mitochondria, which are characteristic of Refsum disease, have a poorly developed internal membrane system [204].

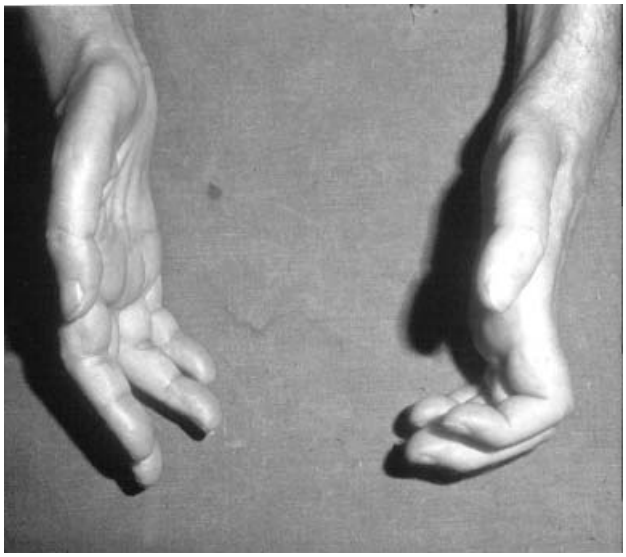

Figure 15. Refsum syndrome with mild palmar keratosis and spastic polyneuritis.

Molecular Defect

Refsum patients exhibit an accumulation of phytanic acid, an exclusively exogenous branched-chain fatty acid, that originates from the degradation of plant chlorophyll in cattle and other vegetarian animals. Phytanoyl-CoA-hydroxylase (PhyH), which normally catalyzes the conversion of phytanoyl-CoA to 2-hydroxyphytanoyl-CoA in peroxisomes, is deficient [205]. The *PHYH* (*PAHX*) gene has been mapped to chromosome 10 [206] and inactivating mutations have been identified, including deletions and point mutations [207,208]. Thus, dietary phytanic acid accumulates in serum and tissues, where it substitutes for essential fatty acids in all lipid subfractions, especially phospholipids. In the epidermis, decreased degradation of altered epidermal lipids may account for the impaired desquamation [209]. Phytanic acid is a natural ligand for RXR (retinoid X receptor) α and promotes the formation of RXRα/RXR response element complexes similar to 9-*cis*-retinoic acid, the natural ligand for RXRα. It has been proposed that phytanic acid may play a role in the regulation of transcription of specific genes and that high levels of phytanic acid may lead to a disturbed regulation of metabolism through stimulation of RXR receptors [210,211]. However, the role of the RXR pathway in Refsum disease remains unclear.

Treatment

As phytanic acid is derived exclusively from exogenous sources, a diet lacking phytanic acid and phytol, or their precursors, thus excluding dairy products, is recommended [212]. Plasmapheresis performed regularly has been proven effective to prevent progression of the symptoms.

SULFATASE DISORDERS AND CONTIGUOUS GENE DELETION DISORDERS

Multiple Sulfatase Deficiency (MSD) (MIM 272200)

To date, 11 human sulfatases have been characterized and their corresponding genes identified [213]. Sulfatase enzymes catalyze the hydrolysis of sulfate ester bonds. Arylsulfatases represent a subset of sulfatases that additionally catalyze the hydrolysis of aromatic compounds. Most sulfatases are located in lysosomes; however, steroid sulfatase (arylsulfatase C) is microsomal in location, the recently identified arylsulfatases D and F are found in the endoplasmic reticulum, and arylsulfatase E is present in the Golgi apparatus. The sulfatase genes are clustered on the short arm of chromosome X (Xp22.3) and share a high sequence homology that suggests a gene duplication event from a common ancestral gene [214]. The sulfatase deficiencies lead to an accumulation of substrates in various tissues and this determines the clinical phenotype. Multiple sulfatase deficiency (MSD) is a fatal disorder caused by a defect of all known sulfatases, resulting in clinical features also seen in single enzyme deficiencies [215].

Clinical Features

The diagnosis of MSD is confirmed by the absence of several singular sulfatases. Consequently, glycosaminoglycans, gangliosides, and sulfatides accumulate in brain and various tissues of affected individuals. Ichthyosis, which is usually mild, is the clinical correlate of steroid sulfatase deficiency and resembles that seen in X-linked ichthyosis (see below). The scales have been shown to contain increased amounts of cholesterol sulfate. The neurological symptoms are severe and are the result of arylsulfatase A deficiency, this enzyme also being defective in metachromatic leukodystrophy (MLD). In the second year of life, psychomotor retardation develops, and shortly thereafter children exhibit motor deficits and mental regression. The neurological symptoms progress and death occurs in the first decade of life. Other clinical features like growth retardation, hepatosplenomegaly, and lumbar kyphosis can be attributed to arylsulfatase B deficiency.

Molecular Defect

A major contribution to the understanding of the pathogenesis of MSD was the identification of the lack of co- or post-translational modification of the sulfatases, a step that is required for their catalytic activity [216]. Normal sulfatases undergo the conversion of a highly conserved cysteine residue to 2-amino-3-oxopropionic acid or serine semialdehyde during post-translational modification, yielding a catalytically active sulfatase. In MSD, lack of this modification leads to the enzyme deficiency. However, an underlying mutation has not yet been identified.

X-Linked Ichthyosis (XRI) (MIM 308100)

The linkage of X-linked recessive ichthyosis to other X-linked markers was demonstrated in the early 1960s [217]. Soon thereafter, two groups discovered that patients with X-linked sulfatase deficiency developed ichthyosis and it was established that these two conditions are the same disease entity [6,7]. X-linked ichthyosis is inherited in an X-linked recessive manner, with an incidence of 1 in 2,000–6,000 males [218].

Clinical and Histological Features

At 1–3 weeks of age, peeling of the skin is observed with light and loosely attached scales covering the entire skin. These light gray scales may persist into adulthood or be replaced by large, dark scales during the following weeks, and are found typically over flexural and extensor areas of the extremities (Fig. 16). The scalp may be mildly involved and scaling is observed preauricularly, but the face, palms, and soles are usually spared. Corneal opacities that do not affect vision are present in half of all adult patients, often facilitating its distinction from other forms of ichthyosis. The deposits in the cornea have been shown to be composed of cholesterol sulfate [219]. The human placenta normally shows high concentrations of sulfatases, a deficiency of which is associated with insufficient cervical dilatation, weakness of labor, and a prolonged delivery with increased stillbirth frequency [7]. Histologically, an extended granular layer, an increased Malpighian layer, and orthohyperkeratosis with slight parakeratosis are characteristic features that enable a distinction from autosomal dominant ichthyosis vulgaris in which the granular layer is diminished or even absent [4]. However, depending on the severity of the phenotype and the site of biopsy, a clear distinction between these two ichthyoses may not always be possible.

Molecular Defect

Biochemical analysis in X-linked recessive ichthyosis demonstrates a deficiency of steroid sulfatase on chromosome Xp22. The enzyme deficiency is caused by deletions and point mutations at this locus, and 80–90% of patients have been shown to have a complete deletion. Approximately 10% of patients have point mutations that affect residues that are conserved within the sulfatase family [220–222]. Rare patients with steroid sulfatase deficiency have a complex phenotype due to deletions of additional disease genes on the short arm of the X chromosome, resulting in a contiguous gene deletion syndrome [10].

Deficiency of steroid sulfatase in the epidermis leads to impaired hydrolysis of cholesterol sulfate. The retention hyperkeratosis may be due to increased adhesiveness of the cornified cells due to the negative charge of the lipid [223], abnormal hydrogen bonding of cholesterol sulfate with plasma membrane fatty acids [224], alteration of lipid metabolism, or inhibition of proteases that would normally act upon desmosomes by high levels of cholesterol sulfate [225]. Recently, the activation of the protein kinase family by cholesterol sulfate has been appreciated [226] and should also be considered in the pathogenesis of XRI. Topical application of cholesterol to XRI skin reduces the amount of scaling [227], whereas topical application of cholesterol sulfate in hairless mice induces the XRI phenotype [228]. Recent data indicate that cholesterol sulfate accumulation rather than cholesterol deficiency is responsible for the perturbed stratum corneum [229].

Treatment

XRI can usually be controlled by topical rehydration with preparations containing either 5% ammonium lactate, 5% urea or up to 20% propylene glycol. Higher concentrations are often irritating. Nevertheless, good cosmetic results have been achieved with 12% ammonium lactate, a keratolytic agent that is effective and well-tolerated when applied twice daily [230]. Systemic retinoids (acitretine/etretinate) are well tolerated and very efficient in XRI [231]. They are an excellent treatment option in severe cases with dark and dirty appearing scales of the "ichthyose noire" phenotype.

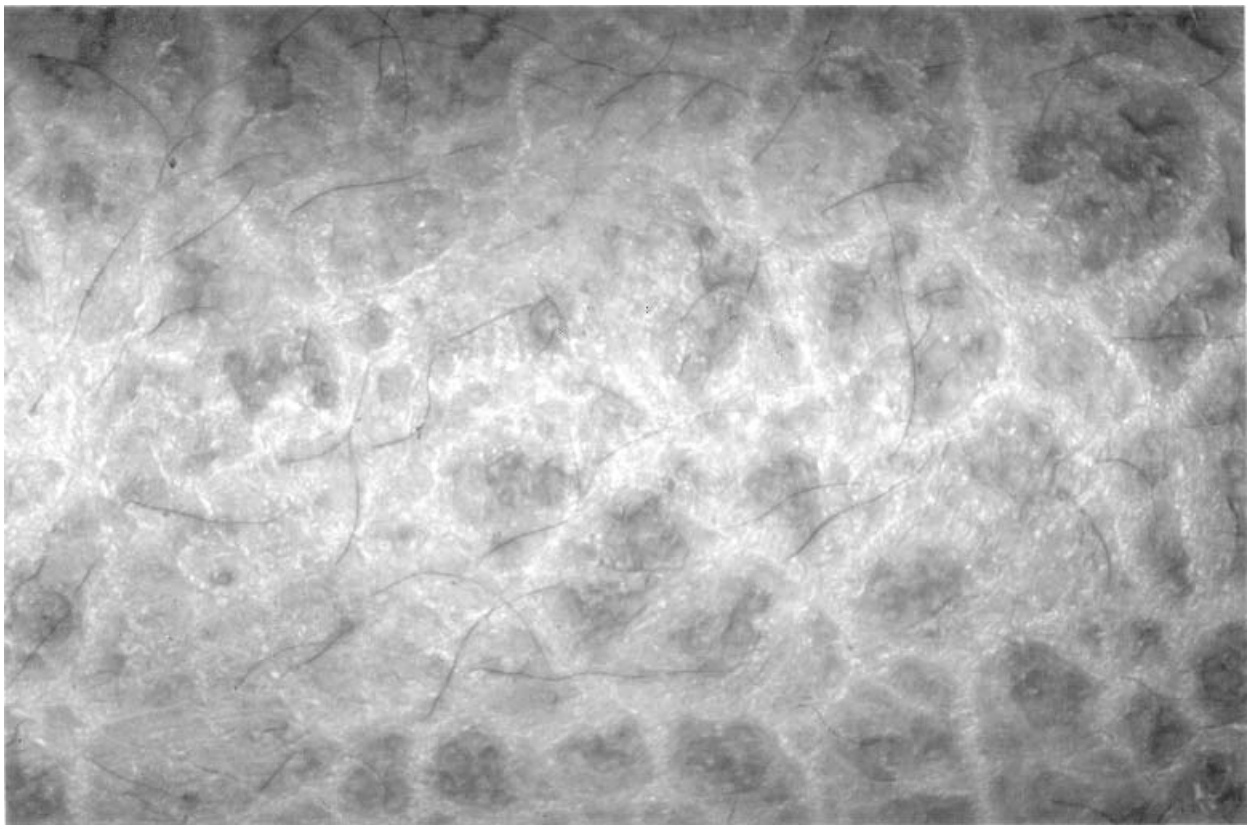

Figure 16. X-linked recessive ichthyosis with large brown-gray scales with ''dirty'' appearance.

Nevertheless, retinoids are usually not indicated in this relatively mild ichthyosis [95]. Gene therapy approaches have been tested by introducing the steroid sulfatase gene into cultured basal keratinocytes from XRI patients, thereby inducing enzyme activity in these cells [232,233].

X-Linked Recessive Chondrodysplasia Punctata (CDPX1) (MIM 302950)

Clinical Features

The X-linked recessive form of chondrodysplasia punctata (CDPX1) is a defect of bone and cartilage development and presents with symmetric ichthyosiform hyperkeratosis, alopecia, short stature, cataract and deafness. Hypoplasia of the distal phalanges as a distinctive feature in CDPX has been described in a family with atypical ichthyosis, and cholesterol levels are elevated in affected males [234]. The clinical features seen in CDPX1 resemble those observed in warfarin embryopathy [235] and vitamin K epoxide reductase deficiency [236].

Molecular Defect

The disease gene is located on the most distal part of Xp, which is pseudoautosomal [237]. In two families, a deletion at Xp22.32 was identified in affected males, their carrier mothers and several potential carrier females, and a reciprocal X-Y translocation involving the region distal to Xp22.3 was observed, thus confirming the assignment of the *CDPX1* gene to this locus [234,238]. The Xp22.3 locus contains genes of the sulfatase family that share high homology: arylsulfatases C, D, E, and F. Ancient duplications are thought to be responsible for the contiguous location of these genes of closely similar sequence and structure. This region is particularly susceptible to deletions that can extend to neighboring genes, causing a contiguous gene deletion defect. X-linked recessive chondrodysplasia punctata has been described as part of a contiguous gene deletion syndrome, and may therefore be associated with X-linked recessive ichthyosis, Kallmann syndrome, mental retardation, and short stature [237]. The gene encoding arylsulfatase E (*ARSE*) has been identified as the disease gene in CDPX1 and mutations within it have been identified, including missense and premature stop mutations that lead to accumulation of cholesterol sulfate in various tissues [239,240]. It has been shown recently that cholesterol metabolism is directly linked to the activation of the protein kinase C family of serine/threonine kinases that play critical roles in the regulation of cellular differentiation and proliferation of diverse cell types [226]. One of the isoforms of protein kinase C is activated by cholesterol sulfate, which leads to stimulation of the differentiation pathway that may account for the defective skin, bone and cartilage development in CDPX1.

Kallmann Syndrome (MIM 308700)

Kallmann syndrome describes the association of hypogonadotropic hypogonadism and anosmia. Autosomal dominant, autosomal recessive, and X-linked recessive inheritance have been reported, suggesting genetic heterogeneity. Occasionally, patients with Kallmann syndrome also manifest features of other X-linked disorders, such as ichthyosis,

chondrodysplasia punctata, short stature, mental retardation, and ocular albinism. The combination of features of several X-linked disorders is due to deletions of the distal short arm of the X chromosome, leading to a contiguous gene syndrome [237].

Clinical Features

X-linked Kallmann syndrome is characterized by a reduced secretion of gonadotropin-releasing hormone by the hypothalamus leading to hypogonadism and a eunuchoid habitus. The ability to smell can be either reduced (hyposmia) or completely absent (anosmia). Depending on the extent of the deletion on the short arm of the X chromosome, Kallmann syndrome patients may also exhibit clinical signs found in other disorders associated with Xp deletions. Thus, deletion of the Kallmann syndrome gene (*KAL1*) and the steroid sulfatase gene would lead to the association of hypogonadism, anosmia, and generalized ichthyosis. In such a case, the cutaneous phenotype would correspond to that observed in XRI. The combination of ichthyosis, Kallmann syndrome, and chondrodysplasia punctata has been described as a contiguous gene syndrome due to deletion of the terminal part of Xp, with the breakpoint at Xp22.31 [241].

Molecular Defect

The *KAL1* gene has been localized to a region on the short arm of the X chromosome (Xp22.3) in Kallmann patients and mutations identified that prove causality [242,243]. The *KAL1* gene product, anosmin, exhibits neural cell adhesion properties and appears to provide a scaffold for gonadotropin-releasing hormone (GnRH) neurons and olfactory nerves to migrate and synapse during embryogenesis. When anosmin is defective or absent, these neurons fail to synapse normally, and Kallman syndrome results [242,243].

Rud Syndrome (Ichthyosis and Male Hypogonadism) (MIM 308200)

Rud syndrome describes the association of ichthyosis with hypogonadism, retinitis pigmentosa, mental retardation and epilepsy. The Danish physician Rud described two patients in 1927 and 1929, who presented with similar symptoms: a 22-year-old male with ichthyosis, hypogonadism, epilepsy, polyneuritis, and anemia, and a 29-year-old female with ichthyosis, hypogenitalism, diabetes mellitus, and partial gigantism, respectively [244,245]. The inheritance pattern is controversial: in a family in which anosmia was an additional clinical finding, linkage with Xg was excluded [246]. However, the finding that the ratio of affected males to affected females is 2:1 suggests an X-linked pattern of inheritance [247]. Most likely, Rud syndrome also represents a contiguous gene deletion syndrome.

Clinical Features

The major findings include mental retardation, epilepsy, ichthyosis, and, in most cases, hypogonadism [246,248–251]. However, the criteria for the diagnosis of this syndrome vary greatly and different combinations of symptoms leading to a diagnosis of Rud syndrome have been reported. Two different types of ichthyosis have been reported on the basis of clinical and histological findings: one similar to that seen in X-linked recessive ichthyosis or atypical ichthyosis vulgaris [252] and another similar to lamellar ichthyosis [253], but an exact classification is sometimes not possible. Likewise, the hypogonadism has been found to be both hypo- and hypergonadotropic. Münke et al. proposed that the main symptoms of the Rud syndrome should be ichthyosis, hypogonadism, mental retardation, and epilepsy [254]. Traupe et al. reviewed the initial reports by Rud showing that the 22-year-old male was the only one affected of 16 brothers and sisters and was mentally alert. The second, female, patient had three family members who suffered from ichthyosis but had no other abnormality. He suggested that the term Rud syndrome be abandoned because it refers to a heterogeneous condition, not even described by Rud [10].

Molecular Defect

Ichthyosis with male hypogonadism was previously thought to be a distinct X-linked recessive, single gene disorder. However, it has been shown that Kallmann syndrome and X-linked ichthyosis are closely linked by demonstrating that deletions on the short arm of the X chromosome lead to the coexistence of these disorders [237]. The concurrence of hypogonadism and ichthyosis in Rud syndrome suggests in this condition also the possibility of a contiguous gene syndrome as the underlying defect. Indeed, steroid sulfatase levels are deficient in some Rud syndrome patients, but cases with normal levels do exist, suggesting genetic heterogeneity [254].

PROTEINASE DISORDERS

Netherton Disease (Comel-Netherton Syndrome) (MIM 256500)

Ichthyosis linearis circumflexa (ILC) was first characterized by Comel in 1949 [255], and Netherton described the hair abnormalities in 1958 in a patient with congenital ichthyosiform erythroderma [256].

Clinical and Histological Features

Netherton disease is an autosomal recessive syndrome that usually presents at birth or soon thereafter. It consists of hair shaft abnormalities (trichorrhexis invaginata) (Fig. 17), ichthyosis linearis circumflexa, and atopic diathesis. Abnormal cornification of the internal root sheath leads to trichorrhexis invaginata and trichorrhexis nodosa (''bamboo hair''). It is thought to be caused by an impairment of disulfide bonding in the hair shaft [257], and is often confined to the eyebrows after childhood. Ichthyosis linearis circumflexa (Fig. 18) occurs later in the disease course and is characterized by red, annular, and serpiginous patches on the trunk and extremities, which have a distinctive double-edged border. These patches are predominant in flexural areas, together with lichenification and scaling. Palms and soles are not usually affected. Ichthyosis linearis circumflexa is not a consistent feature in patients with Netherton syndrome and can be an isolated finding unrelated to Netherton syndrome. High IgE levels are commonly seen in most patients and have been considered a sign of atopy or atopic diathesis [258]. Histologically, parakeratotic cells can be seen in large areas of the stratum corneum and premature secretion of lamellar body contents with impaired transformation into mature lamellar membrane structures may account for the impaired barrier function [259].

Molecular Defect

Netherton syndrome has been mapped to chromosome 5q32 by linkage analysis [260]. The *SPINK5* gene (serine proteinase inhibitor, Kazal type 5), which encodes the serine proteinase inhibitor LEKTI (lymphoepithelial Kazal-type-related inhibitor) [261], also maps to this region and

Figure 17. Trichorrhexis invaginata in Netherton syndrome.

mutations have been identified in the *SPINK5* gene in unrelated families [262]. The majority of mutations generate premature termination codons. Consistent with the recessive mode of inheritance, null expression of the mutated *SPINK5* alleles is predicted through accelerated mRNA decay. LEKTI is the first serine-proteinase inhibitor shown to be primarily involved in a skin disorder or hair morphogenesis, highlighting the significant role of the regulation of proteolysis in epithelial formation and keratinocyte terminal differentiation. Impaired LEKTI expression in the thymus of Netherton patients may account for the abnormal maturation of T lymphocytes and the severe atopic manifestations.

Treatment

Erythrodermic children are at risk of hypernatremic dehydration, especially in the neonatal period. Associated atopy may lead to nutritional intolerance. Topical treatments should be inert, because corticoid treatment is often not effective. Systemic etretinate, psoralen ultraviolet A-range therapy, and cyclophosphamide result in improvement, but the side effects of long-term treatment with these substances may outweigh their benefits [95,263].

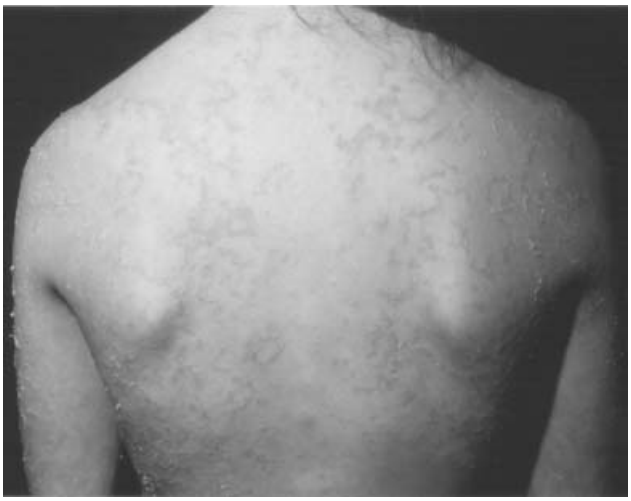

Figure 18. Comel-Netherton syndrome with erythematous, circinate, and polycyclic patches.

Papillon-Lefèvre Syndrome (PLS; Keratosis Palmoplantaris with Periodontopathia (MIM 245000)

Papillon-Lefèvre syndrome is a rare autosomal recessive disease with an incidence of 1:1,000,000, generally observed in children of consanguineous parents.

Clinical Features

Clinically, affected individuals present with diffuse palmoplantar keratoderma, often combined with hyperhidrosis and severe periodontitis leading to premature loss of both deciduous and permanent teeth [264]. The skin phenotype, varying from mild psoriasiform scaly skin to hyperkeratosis, typically develops within the first 3 years of life. Apart from the early appearance of palmoplantar lesions, Papillon-Lefèvre syndrome often involves the exposed skin over joints (knees, elbows, knuckles) and thus may be confused with psoriasis. Most patients display both periodontitis and hyperkeratosis; however, in some patients, only one or the other is encountered.

Molecular Defect

Mapping of the disease to a chromosomal locus has been undertaken in several consanguineous families and linkage to the region at 11q14–q21 has been demonstrated [265–267]. The gene for cathepsin C (*CTSC*), a lysosomal proteinase, has been identified as the disease gene and mutations in affected individuals have been identified, including nonsense, missense, and splice site mutations [268]. Cathepsins are cysteine proteinases that constitute a major component of the lysosomal proteolytic system. Loss of cathepsin C activity has been demonstrated in PLS patients, with reduced activity in obligate carriers. The skin phenotype implicates a role for cathepsin C in epithelial differentiation, which, in addition

to resulting in a reduced host response against bacteria in dental plaque, may contribute to periodontitis.

Treatment

Patients benefit from treatment with acitretin and it has been suggested that if treatment is started at an early age, the development of normal adult dentition is possible [269]. In addition, professional dental hygiene is recommended to minimize permanent dental loss. Topical treatment of the skin can be performed with diverse keratolytic agents, but should include antiseptics and treatment of the hyperhidrosis to prevent recurrent malodorous infections.

AMINO ACID METABOLISM DISORDER
Richner-Hanhart Syndrome (Tyrosine Transaminase Deficiency) (MIM 276600)

Richner-Hanhart syndrome is a rare congenital disorder of amino acid metabolism that follows an autosomal recessive inheritance. It was first described by Richner in 1938 [270] and was further characterized by Hanhart in 1947 [271].

Clinical and Histological Features

Clinical features include palmoplantar hyperkeratosis, eye involvement with bilateral dendritic keratitis, and mental retardation [272]. The skin manifestations usually develop within the first year of life; however, reports exist of the phenotype developing in early adulthood. Bullae and erosions are the first signs of skin involvement, which gradually diminish while hyperkeratoses develop. Painful palmoplantar keratoderma — probably induced by tyrosine crystals — is typical, and often accompanied by hyperhidrosis. The eye manifestations are usually present shortly after birth, comprising photophobia, redness and tearing, and develop into corneal ulcerations, neovascularizations, and corneal opacities. Mental retardation has not been described in all reported cases, suggesting that it is a variable feature. High levels of tyrosine in serum and urine are characteristic. Histological findings include a thickened granular layer with hyperkeratosis, acanthosis, and parakeratosis. On ultrastructural examination, multinucleated keratinocytes, and clumping of intermediate filaments are the striking feature, as well as intracytoplasmic tyrosine crystals [273]. Tyrosine crystals are also present in the corneal epithelium [274] and are thought to induce cross-linking of keratin filaments, leading to intermediate filament aggregation.

Molecular Defect

This rare disorder is caused by a deficiency of hepatic tyrosine aminotransferase (TAT), which is involved in amino acid metabolism and gluconeogenesis, leading to hypertyrosinemia. The gene for tyrosine aminotransferase has been mapped to chromosome 16 [275] and deletions and point mutations within it have been identified in affected individuals [276,277].

Treatment

Richner-Hanhart syndrome is the only hereditary palmoplantar keratoderma that can be treated efficiently by a dietary regimen. Restriction of dietary intake of tyrosine and phenylalanine has a positive effect and improves early skin and eye symptoms. An early diagnosis and immediate dietary intervention are crucial as regards the prevention of symptoms, especially mental retardation and reversal of the disease process [272,278]. Systemic retinoids have proven effective in the treatment of skin and eye symptoms [272,279].

DISORDER OF NUCLEOTIDE EXCISION REPAIR
Tay Syndrome (Trichothiodystrophy; TTD; IBIDS) (MIM 601675)

Tay syndrome was first described by Tay in Singapore in 1971 in three children of consanguineous parents [280]. It is also found in the literature as IBIDS, which summarizes multiple symptoms as ichthyosis, brittle hair, intellectual impairment, decreased fertility, and short stature.

Clinical and Histological Features

Patients commonly have a collodion presentation at birth. During the first months of life, the erythema subsides and a generalized ichthyosis develops that may present as fine scaling or prominent hyperkeratoses that may cover the trunk, extremities, and palms and soles, but usually spare the flexural areas. Polarized microscopy of cut hair shows transverse fracture points (trichoschisis), trichorrhexis nodosa (transverse, frayed fractures), and alternating dark and bright bands that are reminiscent of a tiger tail. It was found that the abnormal hair of these patients (Fig. 19) has a low sulfur content due to a lack of sulfur-containing amino acids, a finding termed "trichothiodystrophy" [281]. Low birth weight and short stature are striking, while psychomotor development is generally delayed and mental retardation has been present in all reported cases. In males, cryptorchidism is often found, which manifests as hypogonadism. Similarly to IBIDS, the BIDS syndrome features similar abnormalities without ichthyosis, while in the PIBI(D)S syndrome, patients present with additional photosensitivity, the ichthyosis is usually mild, and hypogonadism is absent [282]. Skin histology of TTD patients shows moderate orthokeratotic hyperkeratosis, acanthosis, and papillomatosis.

Molecular Defect

TTD has been linked to disorders of nucleotide excision repair. UV-induced DNA damage is corrected by nucleotide excision repair systems [283]. The transcription/repair factor, TFIIH, consists of several subunits, such as ERCC2 (XPD), ERCC3 (XPB) and p44. *ERCC* genes, or excision-repair cross-complementing genes, are named after the rodent repair defects that they correct, and the number designates the rodent complementary group that is corrected by the human gene. To date, the human genes for ERCC1-3 and ERCC5-6 have been isolated. The human *ERCC3* gene on chromosome 2q21 corrects nucleotide defects at an early stage in DNA excision repair in the xeroderma pigmentosum cells of complementation group B (XPB). In cells of complementation group D, the human *ERCC2* gene on chromosome 19q13.2–q13.3 has been shown to be involved in later steps of the repair pathway. Mutations in the *ERCC2* (*XPD*) gene have been associated with xeroderma pigmentosum, Cockayne syndrome, and TTD [283]. In TTD patients, mutations at different positions throughout the *ERCC2* gene have been identified [284]. A point mutation in the *ERCC3* gene has been described in siblings of a consanguineous marriage who both presented as collodion babies at birth and were later diagnosed with TTD [285]. A second excision repair complementation group has been identified in another TTD patient [286] and it has been suggested that this complementation group should be referred to as TTD-A [287]. The *TTD-A* gene product is thought to be another component of the transcription factor TFIIH. Interestingly, in a large group of TTD and XPD patients, the site of the mutation determined the nature of the phenotype [288]. A mouse model

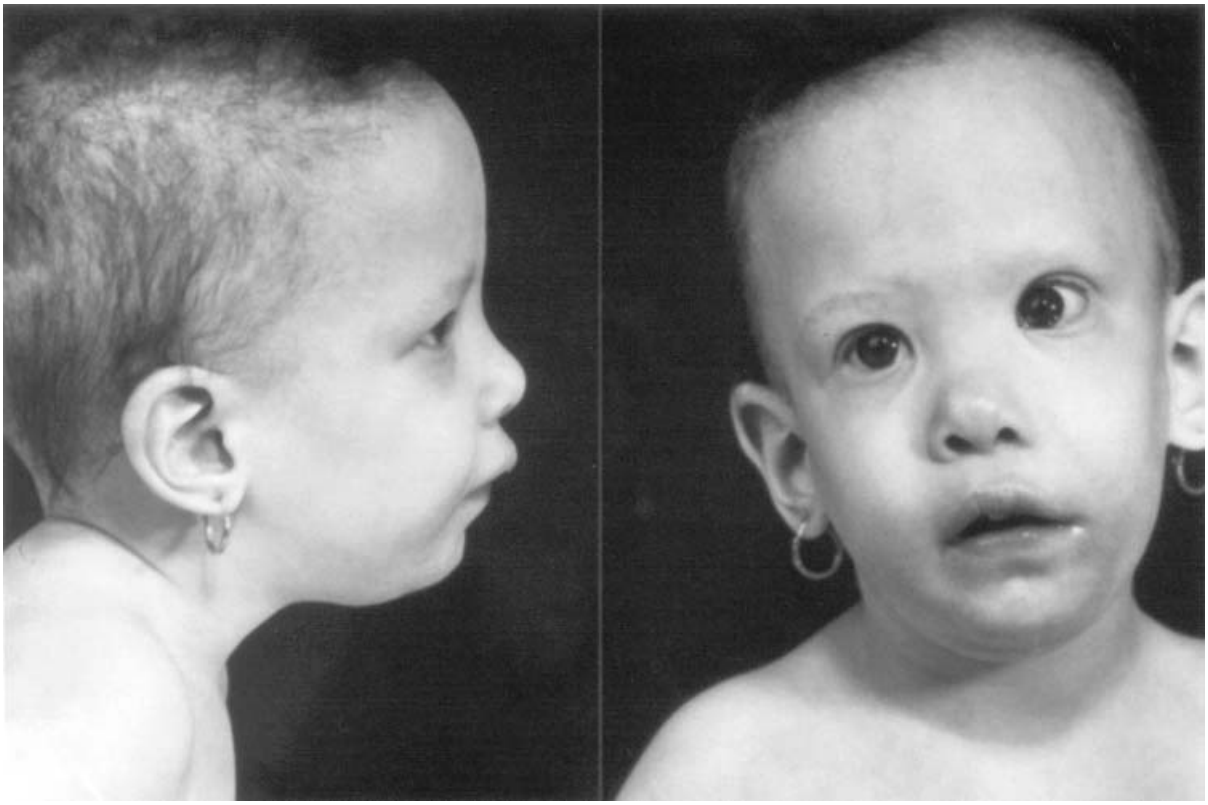

Figure 19. Tay syndrome in a 2-year-old child with sparse, brittle, and broken scalp hair.

for TTD has been generated by the introduction of an XPD point mutation previously identified in a TTD patient [289].

DEFECTS IN INTERCELLULAR COMMUNICATION

Vohwinkel Syndrome (Congenital Deafness with Keratopachydermia and Constrictions of Fingers and Toes) (MIM 124500)

This disorder was first reported by Vohwinkel in 1929 in a 24-year-old man and his 14-month-old daughter [290]. The syndrome, consisting of pseudoainhum of fingers and toes, palmar and plantar hyperkeratosis, and bilateral symmetric hearing loss of cochlear origin is referred to as Vohwinkel syndrome.

Clinical Features

Patients present with congenital deafness, honeycomb type palmoplantar keratoderma, and fibrous constricting bands at the interphalangeal joints of one or several fingers or toes. The hyperkeratoses on palms and soles develop during the first years of life and may progress during adolescence. The ring-shaped constrictions around the digits usually develop later, and can lead to autoamputation. In addition, verrucous papules and starfish-like hyperkeratoses are observed over articulations and tendons on the dorsal side of hands and feet as well as often on knees and elbows (Fig. 20). The nails, hair, and mucous membranes are usually normal [291].

Molecular Defect

Recently, the multigenic connexin family has been linked to Vohwinkel syndrome [292]. Connexins (Cx) play an important role in gap-junction mediated intercellular metabolic and electrical communication. Gap junction channels are involved in communication between cells through exchange of ions and second messengers and consist of connexin protein subunits that are encoded by a multigene family. Cx26 is located in the cochlea and has been found in the spinous and granular layers of rodent epidermis, but only in small amounts in human epidermis [293]. Mutations in *GJB2*, the gene encoding Cx26, have been identified in autosomal recessive sensorineural nonsyndromic hearing loss and in deafness associated with palmoplantar keratoderma. Mutations identified to date include nonsense mutations, missense mutations, and deletions/insertions [294–297]. The most common genetic defect is a single base pair deletion (35delG) in the *GJB2* gene, leading to a premature stop codon, and thus RNA degradation. This may suggest that the phenotype is due rather to haploinsufficiency than to a dominant negative effect. In three unrelated families affected by mutilating keratoderma and deafness, all affected individuals were shown to harbor a heterozygous non-conservative missense mutation at a highly conserved residue at the beginning of the connexin 26 molecule [298].

Erythrokeratodermia Variabilis (EKV) (MIM 133200)

Erythrokeratodermia variabilis is a very rare disorder of cornification transmitted in an autosomal dominant manner. Mendes da Costa first described this disorder in 1925, in a mother and her daughter who both showed fixed patches of hyperkeratosis and migrating erythematous areas [299]. Since then only about 30 patients have been

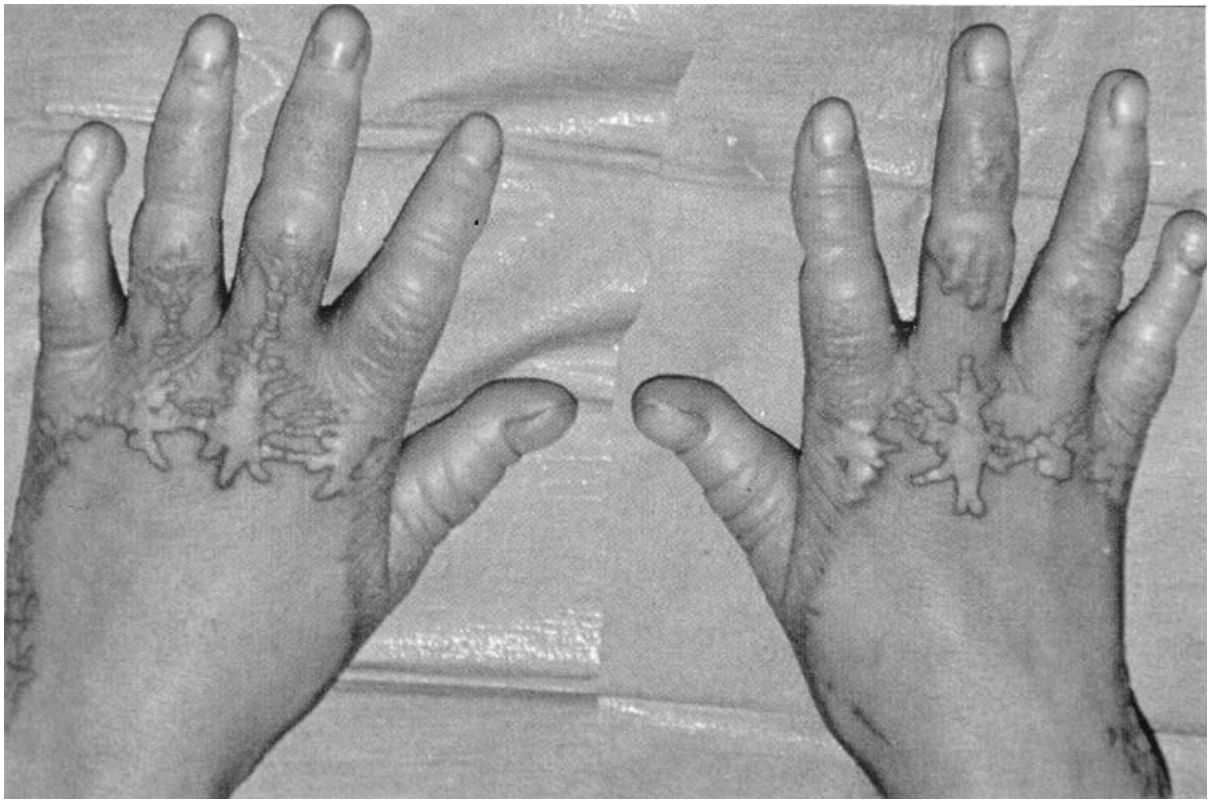

Figure 20. Vohwinkel syndrome with starfish hyperkeratoses on the knuckles.

described in the literature. Greither's disease, which primarily affects palmoplantar and neighboring surfaces, is sometimes confused with EKV, even to the extent that it is included under the same MIM number. Nevertheless, molecular data provide clear evidence that these two diseases do not cosegregate and are not allelic [300].

Clinical Features

The phenotype is present at birth or develops during the first year of life, but a delayed onset of the condition as late as early adulthood has been described. Affected individuals present either with generalized brown hyperkeratoses or with sharply demarcated hyperkeratotic plaques with fixed localization. The second distinct morphological feature includes migratory red patches (Fig. 21) that may appear or regress within minutes to hours. The development of the patches may be triggered by trauma or temperature changes. The predilection sites are the neck, the extensor surfaces of arms and legs, and the buttocks. Palmoplantar hyperkeratoses are present in about half of all cases.

Molecular Defect

After initial linkage to the Rh locus [301], EKV has been mapped to a region on chromosome 1 (1p34–p35), and the *GJB3* gene has been identified as the disease gene [302,303]. Point mutations in *GJB3*, which encodes connexin Cx31, have been identified in four families with EKV. The amino acid substitutions that were identified affected conserved residues and a dominant negative effect of the mutant connexin on the structure and function of the gap junction channel has been predicted. These findings highlight the role of connexins in epidermal differentiation. Examination of eight other EKV families did not reveal any *GJB3* mutations, indicating heterogeneity of the disorder [304]. Indeed, we have recently identified mutations in a novel human gene in EKV patients, proving molecular heterogeneity [305].

Treatment

Topical treatment using keratolytic agents such as urea, ammonium lactate, or propylene glycol, are often used. Alternatively, systemic retinoid treatment has proven effective and may be used in more severe cases [306].

Erythrokeratodermia with Ataxia (Giroux-Barbeau Type) (MIM 133190)

This syndrome was described by Giroux and Barbeau in 1972, when they discovered neurocutaneous findings in 25 members of a family in Montreal over five generations [307].

Clinical Features

Like erythrokeratodermia variabilis, erythrokeratodermia with ataxia is an autosomal dominant disease and symmetric hyperkeratotic plaques develop over extensor surfaces of the extremities. During adulthood, the skin involvement diminishes and spino-cerebellar symptoms develop. The neurological symptoms consist of severe ataxia, nystagmus, dysarthria, and decreased tendon reflexes.

Molecular Defect

The Giroux-Barbeau type of erythrokeratodermia has been mapped to the same locus on chromosome 1 as EKV [300], where a cluster of several connexin genes is located that are also expressed in the epidermis. Most likely, the Giroux-Barbeau type of EKV is not caused by *GJB3* mutations.

Figure 21. Erythrokeratodermia variabilis with variable, polycyclic annular, and gyrate erythema.

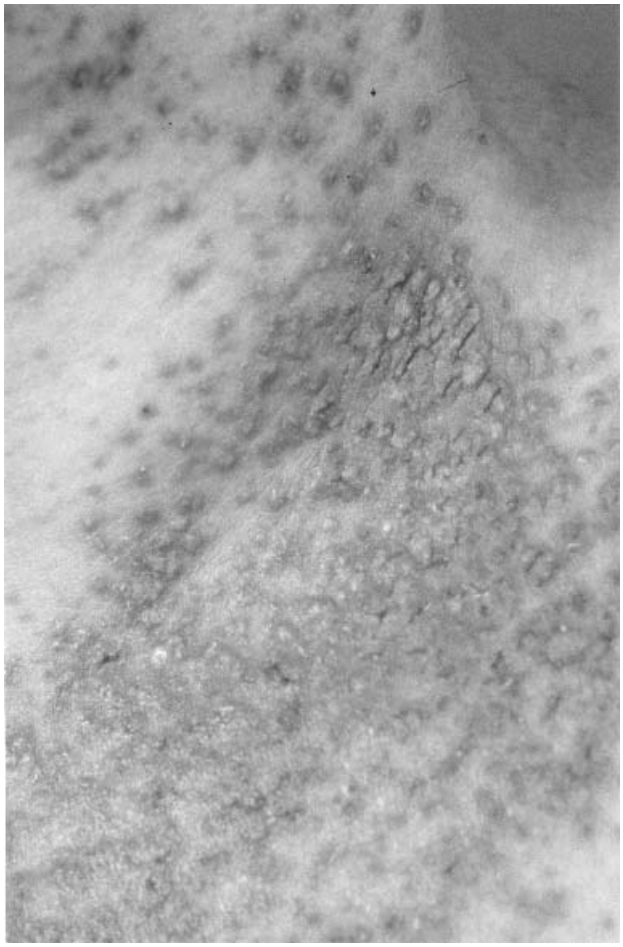

Figure 22. Darier-White disease with classical keratotic papules in the presternal area.

Darier-White Disease (DD; Keratosis Follicularis) (MIM 124200)

Darier-White disease is an autosomal dominant disorder with complete penetrance in adults, but variable expressivity. The incidence ranges from 1 in 100,000 in Denmark to 1 in 36,000 in north-east England [308,309]. It was first described by Darier and White in separate reports in 1889 [310,311].

Clinical and Histological Features

Darier-White disease typically presents between the ages of 10 and 15 years and is characterized by multiple, pruritic keratotic papules located predominantly in seborrheic areas of the skin such as flexures, scalp, face, forehead, chest, and back (Fig. 22). Lesions may, however, also occur in areas that lack sebaceous glands, such as palms and soles, and in epithelia such as mucous membranes and cornea. Mucous membranes may exhibit white, centrally depressed papules in the form of a "cobblestone" appearance. Initially, the lesions are skin colored, but are soon covered with a yellowish crust and may coalesce into large plaques and hypertrophic warty masses. The hair is usually normal; however, as a result of extensive scalp involvement with thick scales, alopecia has been observed. The nails are thin, exhibit longitudinal streaks and notches, and show a characteristic subungual thickening. Multiple plane keratoses, similar to those observed in acrokeratosis verruciformis (see below), are seen on the dorsum of the hands and feet. Disease severity ranges from mild affection of one or two areas to severe involvement of the entire skin, and several variants have been described. Unilateral, or segmental, Darier-White disease is characterized by one affected area, often with a zosteriform distribution of lesions, resembling epidermal nevus [312]. It is considered to be caused by postzygotic mutations, resulting in mosaicism. In the case of germline involvement, offspring with generalized DD can result, as described for the mosaic form of BCIE [37]. The most severe expression includes bullous, erosive and vegetating variants with involvement of the flexures or hypertrophic disease of the lower legs [313]. A hemorrhagic form with acral distribution of hemorrhagic vesicles and macules has been described [314]. Factors that precipitate exacerbations are heat and humidity, UV light, and mechanical friction. Bacterial and herpes simplex virus infections may cause exacerbations and complications [315]. Several neurological and psychiatric symptoms have been

associated with DD, including mood disorders, epilepsy, mental retardation, and progressive encephalopathy [316]. Mental retardation is usually of mild to moderate severity and may appear in up to 10–20% of patients. A few cases of slowly progressive encephalopathy have also been associated with Darier-White disease [317,318].

Histologically, suprabasal cleft formation is seen due to acantholysis within the spinous layer of the epidermis. Hyperkeratosis and dermal villi protruding into the epidermis are common. Eosinophilic, dyskeratotic round keratinocytes (*corps ronds*) in the spinous layer and the stratum corneum (grains) are characteristic of Darier-White disease. Ultrastructural examination reveals cytoplasmic vacuolization, perinuclear keratin filament clumps, and loss of desmosomal attachments. Grains occur in groups embedded in a hyperkeratotic horny layer within dyskeratotic lesions and are probably due to advanced acantholysis, whereas *corps ronds* form individually in regions lateral to grains, where hypergranulosis is prominent [319].

Molecular Defect

Extensive linkage studies have been performed on various families suggesting a region on 12q23–q24.1, close to the type II keratin gene cluster, which is located at 12q11–q13 [320–324]. Mutation analysis of several candidate genes has revealed mutations in the *ATP2A2* gene, which encodes the sarcoplasmic/endoplasmic reticulum calcium-ATPase type 2 isoform (ATP2A2 or SERCA2). SERCA pumps play a critical role in calcium signal transduction. In epithelial cells, IP_3 (inositol 1,4,5-triphosphate) acts a second messenger and triggers release of Ca^{2+} from the endoplasmic reticulum. Calcium pumps actively transport calcium back from the cytosol into the lumen of the endoplasmic reticulum by coupling ATP hydrolysis to the transfer of calcium ions [325]. Repetitive cycles of release and uptake of Ca^{2+} generate fluctuations in intracellular calcium concentration, thereby influencing gene expression and terminal differentiation [326]. The SERCA2b isoform is expressed predominantly in the epidermis and mutations are thought to result in loss of cellular adhesion and impaired differentiation [326]. The majority of mutations cause a frameshift and predict a premature termination of translation with nonsense-mediated RNA decay. The identified missense mutations cause nonconservative amino acid substitutions that result in a structurally abnormal polypeptide. This may impair specific interactions between functional domains of the ATP2A2 molecule [327]. The observation that missense mutations lead to severe or atypical clinical manifestations suggests that the corresponding domains are important for appropriate ATP2A2 function [326]. The clearest association between a missense mutation and an atypical phenotype is found with the familial hemorrhagic variant [327]. In neuropsychiatric cases, nonrandom clustering of mutations at the 3′ end of the gene, with a predominance of missense mutations, has been found [318].

Treatment

Mild variants can be treated with inert emollients and by sun avoidance. Moderate disease needs topical treatment with keratolytics, antiseptics, and antibiotics. More severe disease can be improved by topical 5-fluorouracil or tretinoin. Systemic retinoids such as acitretin at 0.25 mg/kg are initially efficient but require long-term contraception in fertile females [328,329]. Systemic antibiotic or antiviral treatment is advised in case of exacerbation by bacterial or herpes infections. All these treatments result in only transitory improvements which are followed by relapses. Surgical intervention in hypertrophic disease [330], CO_2 or YAG laser evaporization and earlier dermabrasion are also possible and may induce long-term remission, but can also be followed by relapses or even cause exacerbations.

Acrokeratosis Verruciformis (Hopf Disease) (MIM 101900)

Acrokeratosis verruciformis follows an autosomal dominant inheritance pattern and usually presents at birth or in early childhood. It was first described by Hopf in 1931, and studied in an affected pedigree by Niedelman and McKusick in 1962 [331].

Clinical Features

Small, warty hyperkeratotic lesions present predominantly on the dorsal aspect of the hands and feet and on the knees and elbows. They have a reddish-brown appearance and resemble flat warts. The palms may show punctate keratoses and the nails appear white from subungual hyperkeratosis [315]. Clinically similar or identical lesions are sometimes observed in Darier-White disease to the extent that it has been proposed that Darier-White disease and acrokeratosis verruciformis are manifestations of the same disease entity [332]. Nevertheless, the two diseases have a different histological picture and thus should not be confused. Indeed, we have observed a mother and two of her children in one of our own pedigrees who presented with isolated acrokeratosis verruciformis without associated signs of Darier-White disease and without its histological characteristics (D. Hohl, unpublished observation). Molecular analysis in such families should clarify this issue.

Hailey-Hailey Disease (HHD; Benign Chronic Pemphigus) (MIM 169600)

Hailey and Hailey first described this blistering dermatosis in 1939 [333]. It follows an autosomal dominant inheritance pattern and usually presents in the third or fourth decades of life.

Clinical and Histological Features

Hailey-Hailey disease is characterized by persistent blistering and erosions of the skin. The involvement of the skin can be limited to folds and intertriginous areas (Fig. 23), although widespread involvement is also possible [334]. Painful vesicles and blisters that develop into erosions and erythematous plaques due to friction and secondary infection present on an erythematous skin. The lesions tend to extend peripherally, thus producing a characteristic annular shape. Vesicles, blisters, and crusty and scaly areas are found over flexural areas of the body, predominantly in the neck, axilla, and groin. Lesions may also occur on the trunk, and in the antecubital and popliteal fossae, and a seborrheic dermatitis-type involvement of the scalp has been reported [335]. Painful rhagades appear in flexural areas, and these regions may become hypertrophic; bacterial overgrowth can lead to infections. Mucosal involvement is rare; however, oral, esophageal, vulvovaginal, perianal, and conjunctival involvement has been described [336]. Nail changes taking the form of asymptomatic longitudinal white bands in the fingernails may be present in up to 50% of patients and are a helpful physical sign [337]. The

Figure 23. Hailey-Hailey disease with erythematous and exudative eroded plaques in the submammary intertriginous fold.

onset of clinical signs is usually in the second to fourth decades, but can be as soon as the first decade or delayed until after the age of 40 [337]. The course of the disease is characterized by recurrent exacerbations that can be triggered by UV light, mechanical friction, and infections, and there may be intermittent remissions that can last up to several years [337]. Histology shows the separation of suprabasal cells that leads to a loss of cohesion (acantholysis). The characteristic histological picture is reminiscent of a "dilapidated brick wall," and is due to extensive loss of intercellular bridges between keratinocytes. Ultrastructurally, aggregates of keratin filaments that are dissociated from desmosomes and are distributed perinuclearly can be seen in acantholytic cells.

Molecular Defect

Linkage analysis mapped the gene for Hailey-Hailey disease to a region on chromosome 3q [338] and mutations in a gene encoding a calcium ATPase, ATP2C1, have been identified in Hailey-Hailey patients [339]. Mutations identified include missense, nonsense, splice site, and frameshift mutations that are predicted to produce a truncated or absent protein. ATP2C1 is the human homolog of an ATP-powered pump that sequesters calcium in the Golgi apparatus in yeast. It is highly expressed in epidermal keratinocytes and may play an important role in maintaining calcium concentrations in the cytosol and within compartments of the Golgi apparatus. The regulation of cytoplasmic calcium is important in maintaining the adhesion and differentiation of stratified epithelia. In the epidermis, a calcium gradient exists with increasing concentration from the basal compartment to the granular layer, thus implying an important role for calcium in terminal differentiation. Dysfunction of the ATP2C1 pump may decrease intraluminal calcium stores in the endoplasmic reticulum and the Golgi apparatus, thus affecting post-translational modifications of key molecules of cell-to-cell adhesion that are carried out in the lumen of the Golgi apparatus. A defective calcium pump could also affect cytosolic calcium concentrations, thus impairing intracellular signalling pathways that regulate cell adhesion through the phosphorylation of target proteins or the regulation of gene transcription [340]. Dysfunction of a second ion-transport ATPase, ATP2A2, which is defective in Darier-White disease, seems to lead to similar alterations in calcium metabolism. However, dysfunction of the different calcium pumps seems to have distinct consequences in the differentiation pathway and it remains to be elucidated how *ATP2A2* mutations lead to dyskeratosis as a prominent feature in Darier-White disease and *ATP2C1* mutations cause erosions and blisters in Hailey-Hailey disease.

Treatment

Topical or systemic administration of anti-infective agents is the mainstay of therapy. Combination of antibiotics with topical corticosteroids has proven an effective treatment, especially when started early [337]. Short courses of systemic glucocorticoids seem to be useful in controlling major exacerbations, with the risk, however, of rebounds after withdrawal of the drugs [334]. Surgical intervention may be required to achieve prolonged remission or cure. Dermabrasion has been used and reepithelialization could be demonstrated to be complete after a week, followed by excellent functional and cosmetic long-term results [341]. Recently, patients have been treated with continuous CO_2 or erbium:YAG laser ablation that effectively removed lesions of both Hailey-Hailey and Darier disease and yielded excellent long-term results in chronic cases [342,343].

DISORDERS OF KERATINIZATION OF UNKNOWN MOLECULAR DEFECT

Autosomal Dominant Ichthyosis (ADI; Ichthyosis Vulgaris) (MIM 146700)

Autosomal dominant ichthyosis (ADI) is the most common of the ichthyoses and follows an autosomal dominant mode of inheritance. It has an incidence of 1 in 250 to 2000 individuals, and the onset of the disease phenotype is within the first year of life.

Clinical and Histological Features

The affected individual presents with mild xerotic and translucent scaling (Fig. 24), mostly prominent on the trunk and extensor surfaces, the flexural areas being spared. In comparison to X-linked recessive ichthyosis (XRI), the scales in ichthyosis vulgaris are smaller. Hyperlinear palms and soles with accentuated palmoplantar creases and keratosis pilaris are often associated with the disease. As with most ichthyoses, the condition improves in warm, humid weather. In 50% of cases, a family history of atopy is common [344]. This fact hides the key to why ADI has so far resisted elucidation by molecular genetic approaches. Indeed, xerotic dry atopic skin is often difficult to separate clinically from moderate "vulgar" ichthyosis. Additionally, the very frequent isolated follicular keratosis that occurs in up to 80% of the population further obscures the phenotypic classification. Past genetic linkage analysis may have failed for these reasons, suggesting that ADI might be a genetically heterogeneous group of diseases. Histological examination shows mild retention hyperkeratosis, that is, without acanthosis, and a diminished granular layer. Electron microscopy usually reveals small, abnormally shaped keratohyalin granules that may be reduced or totally absent.

Molecular Defect

Keratohyalin granules, an ultrastructural landmark in the granular layer of the epidermis, are decreased in number and structurally abnormal in ichthyosis vulgaris patients [345]. Filaggrin and its precursor, profilaggrin, are major components of keratohyalin granules. They play a role in the aggregation of keratin filaments in the stratum corneum of the epidermis and are found to be decreased

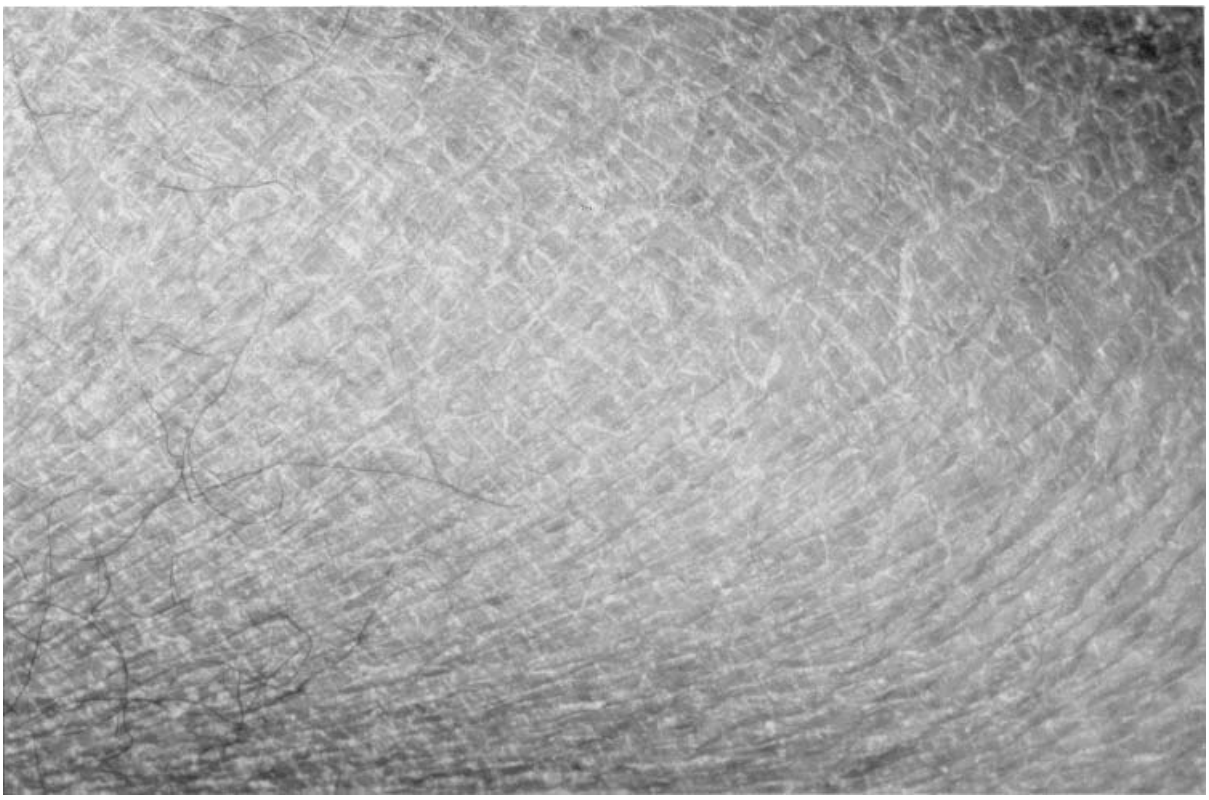

Figure 24. Autosomal dominant ichthyosis with fine adherent and translucent scaling.

in ichthyosis vulgaris [346–348]. A correlation has been established between the severity of the disease phenotype and the extent of filaggrin and profilaggrin reduction [349]. It has been proposed that the defective profilaggrin expression in ichthyosis vulgaris is the result of selectively impaired post-transcriptional control [350].

It has been demonstrated that desmosomes, which usually degrade in the granular layer, persist up to the stratum corneum in patients with ichthyosis vulgaris, although the number of desmosomes in the spinous layer of these patients is not significantly different from that in normal subjects [351]. The decreased enzymatic activities of trypsin-like and chymotrypsin-like serine proteases that are normally involved in desmosome breakdown may be responsible for the defective degradation of desmosomes that leads to the accumulation of excessive corneocytes in the stratum corneum, with the clinical formation of scales [352].

Treatment

Mild forms of ichthyosis vulgaris can be treated with creams and lotions that contain water and lipid. Urea is effective because of its water-binding capacity and keratolytics can be applied when hyperkeratoses predominate. Retinoids are not indicated in this relatively mild ichthyosis due to their potential adverse effects, especially in atopic patients.

Ichthyosis Hystrix of Curth and Macklin (IHCM) (MIM 146590)

Ichthyosis hystrix of Curth and Macklin is an extremely rare autosomal dominant disorder. Besides the family originally described by Curth and Macklin in 1954 [353], only one more family [354] and solitary cases have been reported to date [355,356]. Interestingly, the members of the originally described family exhibited both severe generalized and mild localized forms often restricted to physically exposed skin. The second family, however, presented with a mild localized form characterized by scaly plaques and mild hyperkeratoses on the knees, elbows, and ankles [354,357]. Solitary cases have all shown a generalized form of the disease.

Clinical and Ultrastructural Features

The clinical features are reminiscent of bullous congenital ichthyosiform erythroderma (BCIE), but blistering does not usually occur. The onset and clinical presentation of the disease are variable. In the generalized form, hyperkeratosis presents over extensor areas and is often widespread with a verrucous (histrix) appearance. In the mild localized form, rough skin areas or scaly plaques over extensor surfaces, such as the knees, elbows, and ankles may be the only clinical signs. Interestingly, one male patient in the family with localized IHCM [354] and one solitary case [356] exhibited undescended testes and possibly short stature in addition to the skin phenotype. Sulfatase deficiency was excluded as a potential underlying defect. It remains to be seen, however, if other genes on the short arm of the X chromosome might be defective in IHCM. Histological examination reveals severe orthokeratotic hyperkeratosis, acanthosis, and papillomatosis, similar to the findings in BCIE. Unbroken shells of tonofilament clumps surrounding the nucleus in keratinocytes of the upper spinous and granular

layers are characteristic features seen by electron microscopy. In contrast to BCIE, these concentric shells are unbroken, which allows a distinction from BCIE at the ultrastructural level.

Molecular Defect

Altered keratin expression has been suggested in the pathogenesis of IHCM [354]. However, linkage analysis has failed to identify keratin mutations as the underlying genetic defect [357]. It has been proposed that proteins involved in interactions with keratins, e.g., constituents of desmosomes, might be defective in IHCM [358].

Chanarin-Dorfman Syndrome (Neutral Lipid Storage Disease) (MIM 275630)

The Chanarin-Dorfman syndrome is a rare autosomal recessive disorder. To date, less than 30 cases have been reported in the literature. The accumulation of triglycerides in various tissues leads to multisystemic triglyceride storage. In granulocytes, fat-containing cytoplasmic vacuoles are seen upon ultrastructural examination. This phenomenon was described in two brothers with muscular dystrophy by Jordans and has been termed "Jordans' anomaly" [359]. A year after Dorfman first described "ichthyosiform dermatosis with systemic lipidosis" [360], Chanarin named the disease "neutral lipid storage disease" [361]. Today, the Chanarin-Dorfman syndrome is distinguished from a second type of neutral lipid storage disease in which ichthyosis is not present [362]. The incidence is higher among Arabic populations, which might be the result of a founder mutation many centuries ago. Heterozygotes can be identified by demonstrating vacuoles in circulating eosinophils [363].

Clinical and Histological Features

Generalized ichthyosis usually presents at birth, with fine, white scales and hyperkeratosis. Erythroderma, ectropion, and eclabium may be present. Nail and hair abnormalities in the form of nail ridging and scarring alopecia are complications in older patients. Cataracts, myopathy, fatty degeneration of the liver, and neurological symptoms, including horizontal nystagmus, ataxia and bilateral neurosensory hearing loss, are further abnormalities observed in association with the skin phenotype. These noncutaneous findings can vary in severity and may be progressive during adulthood [364]. Identification of lipid vacuoles in neutrophil granulocytes in the peripheral blood in association with ichthyosis usually leads to the diagnosis (Fig. 25). Histology reveals lipid accumulation in dermal and basal epidermal cells. Upon electron microscopic examination, lipid deposition is seen within the cytoplasm of basal and granular cells and within lamellar bodies. The stratum corneum is thickened and the broadened epidermis shows hyperkeratosis, acanthosis and papillomatosis.

Molecular Defect

The pathogenesis of Chanarin-Dorfman syndrome is poorly understood, but appears to be related to a perturbed intracellular triglyceride catabolism. The accumulation of triacylglycerol may be due to defects in synthesis and degradation of phospholipids [365].

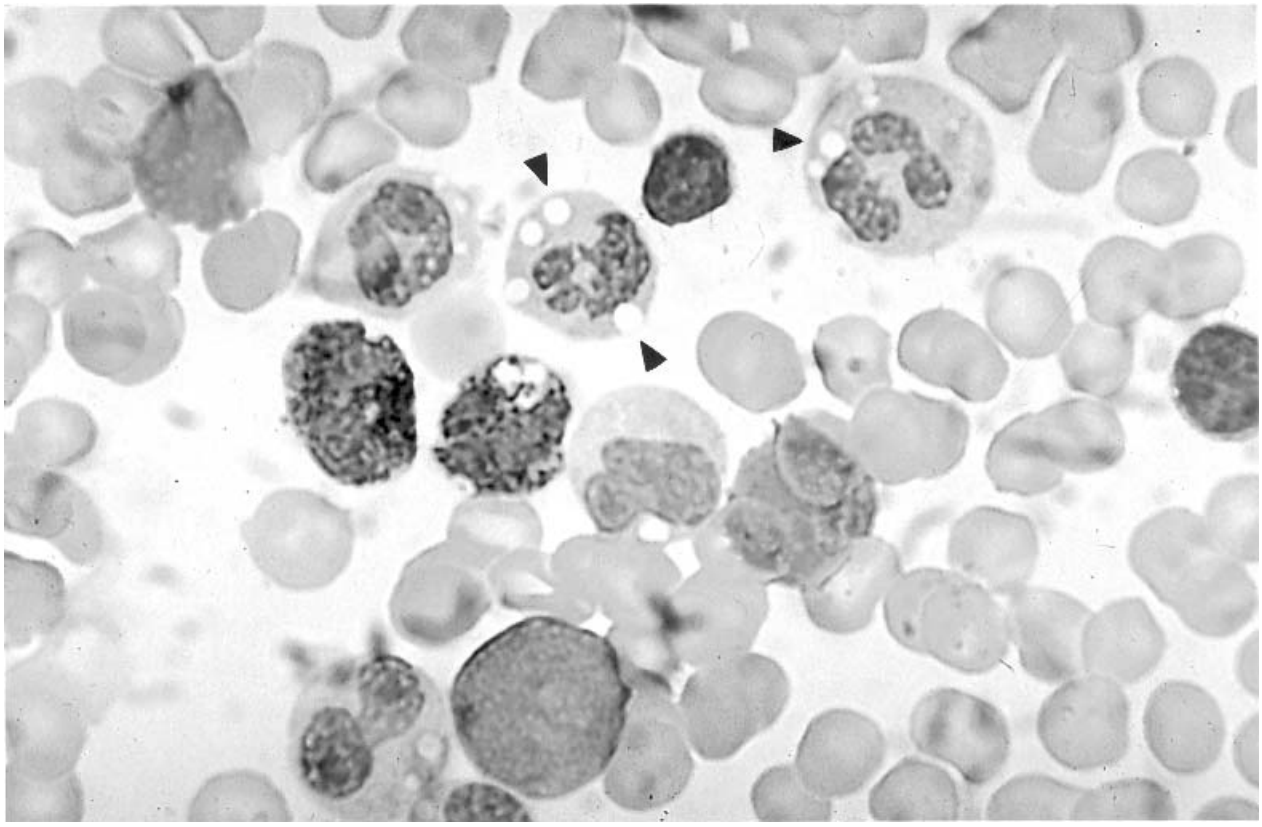

Figure 25. Chanarin-Dorfman syndrome: multiple lipid vacuoles in leucocytes (arrowheads). (Courtesy M. Landau, Tel Aviv.)

KID Syndrome (Keratitis-Ichthyosis-Deafness Syndrome) (MIM 148210)

The keratitis, ichthyosis, and deafness (KID) syndrome is a rare congenital disorder first described by Burns in 1915 [366] and called the KID syndrome by Skinner more than half a century later [367]. It affects ectodermal tissues such as epidermis, corneal epithelium, and the inner ear, which has prompted Caceres-Rios to propose renaming the syndrome as keratodermatous ectodermal dysplasia (KED) [368]. Its mode of inheritance is still unclear, and both autosomal dominant and autosomal recessive forms may exist. Three reports have suggested a dominant mode of inheritance [369–371]. Furthermore, the KID syndrome has been diagnosed in two siblings with unaffected parents, which does not exclude the possibility of gonadal mosaicism with dominant transmission [372]. In contrast, a report of two sisters born to consanguineous parents and a description of two half siblings born to the same unaffected mother favor an autosomal recessive mode of inheritance [373,374]. Spontaneous new mutations as the cause of the disease have also been proposed [375].

Clinical and Ultrastructural Features

At birth, erythroderma is usually present, but it diminishes during the first days of life. Ichthyosis usually develops during the first months and presents as a hyperkeratotic state with erythematous plaques that have a verrucous appearance. The plaques are well demarcated and predominate on the face and physically exposed areas of the limbs. Palmoplantar hyperkeratosis is almost always present. Children with KID syndrome look prematurely aged [375]. Congenital alopecia and scarring alopecia due to follicular hyperkeratosis have been described as a major feature in KID patients [368]. Eyelashes and eyebrows are often absent and nail dystrophy is frequent. Furthermore, patients suffer from neurosensory deafness and impaired vision caused by a keratitis with neovascularization of the cornea that can eventually lead to blindness [376]. Additional findings include increased susceptibility to skin infections, defective dentition, and hypohidrosis [368]. The risk of developing squamous cell carcinoma is increased [377] and oral leukoplakia, a premalignant lesion, was originally described by Burns [366]. Histologically, the stratum corneum is thickened, with acanthosis and papillomatosis, and the granular layer shows vacuolization [378]. Keratin filament clumping and accentuated insertion of intermediate filaments into desmosomes have been noted. Moreover, keratohyalin granules are distributed in a shell-like manner around the nucleus [375].

Treatment

Therapy with systemic retinoids has shown contradictory results in severely affected patients, the aromatic retinoid etretinate having brought about improvement of hyperkeratotic plaques [379] or having had only little effect [375]. Treatment with isotretinoin may result in an exacerbation of corneal neovascularization that makes close monitoring necessary [380].

HID Syndrome (Hystrix-Like Ichthyosis with Deafness) (MIM 602540)

The concurrence of ichthyosis hystrix and bilateral hearing loss was first described in a 17-year-old male [381,382]. Traupe named this syndrome hystrix-like ichthyosis with deafness (HID) [10].

Clinical and Ultrastructural Features

Clinical features include scarring alopecia and red patches that develop shortly after birth and evolve into verrucous, hyperkeratotic plaques, affecting the entire skin. The son of the individual reported in 1977 [381,382] has been diagnosed with HID syndrome: he showed the typical skin involvement in association with neurosensory hearing loss [383]. The differential diagnosis is the KID syndrome. The involvement of palms and soles is a feature characteristic of KID syndrome, and has not been reported in HID syndrome. Furthermore, the hyperkeratotic plaques seen in KID syndrome never involve the trunk, in contrast to their appearance anywhere on the skin in HID. Differentiation at the ultrastructural level is also possible. Characteristic features seen in HID include excess formation of mucous-containing granules and reduction of tonofibrils [10].

Peeling Skin Syndrome (PSS; Keratolysis Exfoliativa Congenita) (MIM 270300)

Peeling skin syndrome is a rare, autosomal recessive disorder that is characterized by lifelong peeling of the epidermis, and the easy ability to separate the stratum corneum mechanically from the rest of the epidermis [384]. PSS is, in fact, a heterogeneous group of disorders and designates several different clinical entities with large overlaps that were classified by Traupe into two distinct types, A and B [10]. This classification has been expanded to incorporate a third type, PSS type C [385].

Clinical and Histological Features

The clinical presentation in PSS type A starts at birth or in early childhood with generalized peeling of the stratum corneum. Thin, superficial flakes cover the entire skin, including the face [386]. The peeling is usually noninflammatory and asymptomatic [387]. Ultrastructural analysis shows orthohyperkeratosis and separation of corneocytes above the granular cell layer. The cleavage occurs within the cytoplasm of corneocytes, leaving the plasma membrane firmly adherent to the underlying cell, while the upper part of the cell is exfoliated [388].

In PSS type B, congenital ichthyosiform erythroderma is present at birth and develops into erythematous migratory patches with a peeling border over the entire skin, usually sparing palms and soles [384]. The erythematous lesions have an exfoliative character, and can be accompanied by pruritus [389]. Associated noncutaneous anomalies and abnormal laboratory findings include short stature, aminoaciduria and elevated IgE levels. Seasonal variations have been reported, and patients are usually more susceptible to skin infections [390]. Histologically, parakeratosis and acanthosis are seen and the granular layer is absent [384]. The entire stratum corneum separates from the underlying acanthotic epidermis and, in contrast to the A type, the split occurs intercellularly [390].

A further variant of PSS has been delineated on the basis of distinct clinical findings and designated PSS type C [385]. The onset of the skin phenotype in this case was at birth, with generalized scaling and peeling. Pruritus and an elevated IgE level were associated features and the patient was more susceptible to skin infections. In contrast to the two other types, superficial blisters formed on palms and soles early in childhood and developed into hyperkeratoses. Moreover, a severe fissured cheilitis developed and crusted keratoses were seen on the eyelids, nostrils, and lips. Ultrastructural examination showed a

cleavage at the interface between the stratum corneum and stratum granulosum, on the corneocyte side of the desmosomal plaque [385].

Another variant form of PSS was reported in a patient with features similar to the previously reported case of PSS type C [385], but with associated hair defects. The authors classified this case as a typical PSS type B [391]. In addition to generalized ichthyosiform erythroderma with peeling on hands and feet, the patient exhibited cheilitis and fissuring of the nostrils, and conjunctivitis and blepharitis. The cleavage occurred at the corneal-granular cell desmosomal connection. Additionally, this patient exhibited trichorrhexis invaginata-like changes, pili torti-like changes, and hair shaft torsions, features that have not been described in PSS before, suggesting that these dysmorphic hair changes might be an integral component of this form of PSS. Given the marked overlaps between the two cases, the question arises as to whether they are indeed different subtypes or rather different manifestations of the same PSS subtype. Analysis at the molecular level and identification of the disease gene(s) might eventually allow a clearer classification.

A localized form of PSS, with strict localization of the lesions on the palms and dorsal aspects of the fingers has also been reported [392]. Another case with involvement of arms and legs was classified as "acral PSS" [393]. The splitting was found to be in the stratum corneum without inflammatory changes, similar to the findings in PSS type A, whereas the underlying erythema is a feature of PSS type B. Due to the strict palmar localization of the disease, it was proposed that this form should be referred to as "localized PSS."

Treatment

Oral acitretin has been shown to improve the skin condition. However, a persistent erythema has been observed.

Ichthyosis Follicularis, Atrichia, and Photophobia Syndrome (IFAP Syndrome) (MIM 308205)

The IFAP syndrome is a rare neuroichthyosis that has been described to date in only 10 males [394]. It is considered to be an X-linked recessive trait.

Clinical Features

Patients with IFAP syndrome present with congenital absence of hair (atrichia), generalized ichthyotic skin changes with extensive noninflammatory follicular hyperkeratoses, and photophobia [395]. A mild collodion presentation at birth has been reported [10]; later, follicular keratosis is seen on the scalp, abdomen, and extensor surfaces of the limbs, especially the knees. Associated features are severe photophobia, retardation of growth and psychomotor development, seizures, bronchial asthma, urticaria, skin infections, and nail dystrophy [396].

Another presumably X-linked recessive disorder is the dermotrichic syndrome, which presents with similar features to IFAP syndrome, such as generalized ichthyosiform lesions and baldness from birth. Whereas photophobia and recurrent respiratory infections are characteristic of the IFAP syndrome, nail dystrophy, hypohidrosis, megacolon, and vertebral defects are characteristic of dermotrichic syndrome [397]. Histological examination in IFAP syndrome shows acanthokeratosis and a well preserved granular layer. The hair follicles are poorly developed and shortened and sebaceous glands are completely absent. The IFAP syndrome is characterized by a wide clinical variability and some features, such as growth and motor development retardation, torticollis, and proneness to infections, have only been observed in a few cases. Therefore, it has been speculated that these cases might be the expression of a contiguous gene defect [10].

RECENT DEVELOPMENTS

Mal de Meleda (MDM) (MIM 248300)

Mal de Meleda belongs to the family of hereditary palmoplantar keratodermas and is characterized by hyperkeratosis of palms and soles, keratotic skin lesions, perioral erythema, brachydactyly and nail abnormalities. The progressive lesions often lead to severe impairment of hands and feet including spontaneous auto-amputation. The disorder is transmitted in an autosomal recessive mode, and the MDM gene has recently been identified as *ARS* (component B), encoding a protein named SLURP-1 (for secreted Ly6/uPAR-related protein 1 [399]. Three different homozygous mutations were detected in 19 families of Algerian and Croatian origin, suggesting founder effects.

Members of the leukocyte antigen-6 (Ly6)/urokinase-type plasminogen activator (uPAR) superfamily are either secreted or receptor proteins and have been implicated in transmembrane signal transduction, cell activation and cell adhesion. SLURP-1 is preferentially expressed in palmoplantar skin and thought to function as a ligand for an as yet unknown receptor.

Clouston Syndrome (Hydrotic Ectodermal Dysplasia, HED) (MIM 129500)

Patients with Clouston syndrome present with diffuse palmoplantar hyperkeratosis, hair defects ranging from partial to total alopecia, and severe dystrophy of the nails. Hyperpigmentation of the skin, especially over the joints, strabismus, hearing impairment and mental deficiency occur in some.

A recent study has confirmed linkage of Clouston syndrome to chromosome 13q11-q12.1 in a large French family and demonstrated two dominant missense mutations (resulting in Gly11Arg and Ala88Val) in the gene encoding connexin 30 (*GJB6*) [400]. The *GJB6* mutations might cause Clouston syndrome by a dominant-negative effect on normal connexin 30 activity, or through haploinsufficiency of gap-junction channels. Another missense mutation in the *GJB6* gene (resulting in Thr5Met) was associated with autosomal dominant nonsyndromic sensorineural deafness [401]. To understand how different mutations of the same gene cause non-syndromic deafness and HED, respectively, it will be important to study the mutant connexins in the context of other connexins expressed in the affected tissues. It is intriguing to speculate that other genetic and environmental factors may modify the penetrance of the mutations.

Erythrokeratodermia Variabilis (EKV) (MIM 133200)

In addition to the previously reported mutations in the gene encoding connexin 31 (*GJB3*), mutations in the novel human connexin 30.3 have been identified in a form of EKV with erythema gyratum repens, highlighting the genetic heterogeneity of this disorder [402]. The mutation in the *GJB4* gene affects a highly conserved phenylalanine residue in the third transmembrane region of the connexin 30.3 molecule, known to be implicated in wall formation of the gap-junction pore. Replacement of phenylalanine by leucine may lead to a faster closure of the gap-junction channel,

thereby inhibiting the transfer of signal molecules that are important for normal epidermal growth and differentiation. In classical EKV, migratory erythematous lesions tend to turn gradually into fixed keratotic plaques. In annular EKV caused by connexin 30.3 mutations, rapidly migrating erythematous lesions often appear as figurate erythema with an annular or spiral arrangement, sometimes presenting even as erythema gyratum repens [402]. In fact, this distinct phenotype has been described previously [403,404], but has passed largely unnoted.

Ichthyosis Hystrix of Curth and Macklin (IHCM) (MIM 146590)

Even though earlier studies have provided evidence against the linkage of IHCM to the keratin genes [357], a mutation in the variable tail domain V2 of the keratin 1 molecule has been identified in a patient with IHCM [405]. The heterozygous frameshift mutation creates a premature termination codon and is predicted to result in a truncated protein. Loss of a region that is almost exclusively composed of glycine and hydrophilic residues results in different chemical characteristics of the mutant protein. Structural analysis has revealed a failure of keratin filament bundling, retraction of the cytoskeleton from the nucleus, and failed translocation of loricrin to the desmosomal plaque. It is proposed that the V2 domain of keratin 1 mediates the supramolecular organization of keratin intermediate filaments and facilitates the translocation of loricrin to the cell periphery during cornified cell envelope formation.

Autosomal Recessive Congenital Ichthyoses (ARCI)

Linkage to a sixth locus has been described for the group of autosomal recessive congenital ichthyoses [406]. In pedigrees from Germany and Turkey a new ARCI locus has been identified on chromosome 17p. It could be shown, however, that the disease in two Arab families could neither be linked to 17p, nor to one of the five loci described previously, suggesting further heterogeneity.

Chapter 25

Alport Syndrome

Karl Tryggvason and Paula Martin

Division of Matrix Biology, Department of Medical Biochemistry and Biophysics, Karolinska Institutet, Stockholm, Sweden (K.T.) and Biocenter Oulu and Department of Biochemistry, University of Oulu, Oulu, Finland (P.M.)

SUMMARY

- **Alport syndrome is a progressive hereditary nephritis characterized by hematuria. Extrarenal complications, such as sensorineural hearing loss and ocular abnormalities, are often associated with the disease. Typical ultrastructural changes, such as thinning, thickening, and splitting of the glomerular basement membrane (GBM) can be observed by electron microscopy.**
- **Alport syndrome is mainly inherited as an X-linked dominant trait that affects males more severely than females. The disease is caused by mutations in the *COL4A5* gene that encodes the basement membrane-specific type IV collagen α5 chain.**
- **In the rarer autosomal recessive and dominant forms of Alport syndrome, males and females are equally severely affected. However, the symptoms are milder in the autosomal dominant form. Mutations have been found in the *COL4A3* and *COL4A4* genes encoding the type IV collagen α3 and α4 chains, respectively.**
- **Numerous deletions involving the 5′ ends of both the *COL4A6* gene and the adjacent *COL4A5* gene have been reported to cause a rare disorder, diffuse leiomyomatosis, associated with Alport syndrome.**
- **For unknown reasons, a minority of Alport syndrome patients develop a severe anti-GBM nephritis after transplantation, leading to eventual rejection of the allograft.**
- **About 300 different mutations have been reported in type IV collagen genes in Alport syndrome patients. These include large and small deletions and insertions, as well as single base changes. Different mutations cause different phenotypes, but it is difficult to predict the consequences of a particular mutation. However, in most cases, mutations can be considered somehow to disturb the normal formation of basement membrane.**
- **Studies with both produced and naturally occurring animal models of Alport syndrome are of help for better understanding the molecular pathology of the disease.**
- **Promising results have been achieved in animals concerning development of gene therapy for Alport syndrome.**

INTRODUCTION

Alport syndrome, also termed hereditary nephritis, was the first basement membrane disease the pathogenesis of which was elucidated at the gene level [1,2]. The disease was initially described in 1927 by A.C. Alport as an inherited kidney disease characterized by hematuria and sensorineural deafness [3]. Later, ocular lesions were also noted to be associated with the syndrome and, with the introduction of the electron microscope, irregularities and disruptions in the glomerular basement membrane (GBM) were shown to be typical of this disorder as well [4]. The disease is progressive, usually leading to renal failure during adolescence or before middle age. Based on the age of onset of end-stage renal disease (ESRD), Alport syndrome is divided into two clinical subgroups. In the juvenile type the mean age of ESRD in men is about 18 years, while in the adult type it is about 37. A good dividing line between the two types is 31 years of age [5].

Alport syndrome is mainly inherited as an X-linked dominant trait (MIM 301050) with an estimated gene frequency of 1:5,000, but autosomal forms also exist [4]. The defective gene in X-linked Alport syndrome was localized in 1988 and 1989 to the long arm of the X chromosome [6–8]. In 1990, the *COL4A5* gene encoding the type IV collagen α5 chain was discovered and localized to the Alport gene region on chromosome X, and this was soon followed by the identification of mutations in this gene in Alport patients [1,2,9]. More recently, mutations have also been reported in the genes for the α3 and α4 type IV collagen chains in the rarer autosomal forms of Alport syndrome [10–13]. Presently, about 300 different mutations have been identified in type IV collagen genes in Alport patients, almost all of them in the *COL4A5* gene [14–19,22]. These mutations can be considered responsible for abnormalities in the structural framework of the GBM, with resultant kidney manifestations.

Connective Tissue and Its Heritable Disorders, pages 1069–1102

CLINICAL FEATURES, DIAGNOSTIC CRITERIA, AND FORMS OF ALPORT SYNDROME

Clinical Findings and Natural History

The clinical picture of Alport syndrome is somewhat heterogeneous [4,5]. Characteristically, Alport patients have recurrent microscopic or gross hematuria in childhood, earlier in males than in females. It usually leads to end-stage renal disease in affected males and, in rare cases, also in females. The hearing loss is sensorineural and primarily affects high tones. Electron microscopy usually reveals thinning and thickening of the GBM with longitudinal splits into thin layers with a basket-weave pattern (Fig. 1). These changes are most evident in male patients, except in boys of a very young age. Lenticonus, a conical protrusion of the substance of the crystalline lens, is also frequently observed in Alport patients. Thrombocytopenia is sometimes associated with the syndrome. The disease is inherited and there is a family history in 85% of cases, the remaining 15% probably representing new mutations [4].

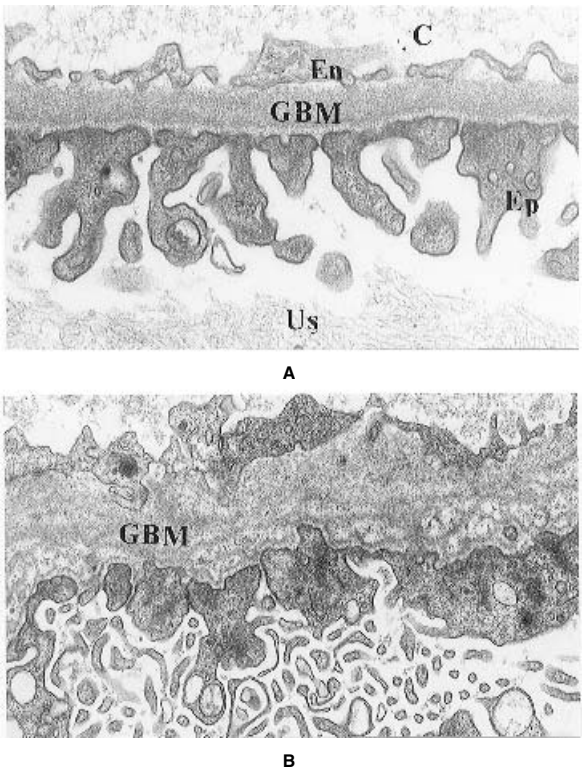

Figure 1. Electron microsopic picture of the glomerular basement membrane (GBM) of normal and Alport syndrome kidneys. **A**, The normal filtration barrier consists of the fenestrated endothelial layer (En) of the glomerular capillary (C), the ~300–350-nm-thick GBM, and the epithelial podocytes (Ep) partially covering the GBM on the urinary space side (Us). The podocytes are separated by ~25-nm-wide filtration slits. Note the uniform thickness and even amorphous pattern of the GBM. **B**, Electron micrograph of a glomerular capillary loop showing characteristic glomerular basement membrane (GBM) lesions in an Alport syndrome patient. The GBM has irregular thinning and thickening, as well as lamination of the structure. C, capillary lumen; En, endothelial cell; Ep, epithelial podocyte; Us, urinary space. Magnification ×22,000. Diagnostic Criteria

For decades, physicians have expected hearing loss to be an essential part of hereditary nephritis. Flinter et al. [20] proposed that a diagnosis of Alport syndrome should be made in hematuric patients who fulfilled three of the following criteria; (a) familial history, (b) hearing loss, (c) ocular lesions, and (d) GBM abnormalities. However, recent data have shown that there are numerous examples of patients with progressive renal disease and mutations in type IV collagen genes who do not fulfil these criteria. Thus, inheritance cannot always be demonstrated, as *de novo* mutations may account for as many as 15% of cases. Also, it has been demonstrated that quite a large proportion of patients with renal failure and mutations in type IV collagen genes do not have hearing loss or eye manifestations [14,21,22]. So, how should Alport syndrome be defined? We have recently proposed that the disease should be defined as progressive hematuric hereditary nephritis caused by mutations in type IV collagen genes [22]. As discussed above, present data indicate that these genes are those encoding the α3(IV), α4(IV), and α5(IV) chains of type IV collagen, i.e., *COL4A3*, *COL4A4*, and *COL4A5*, respectively. However, as pointed out by Gregory et al. [5], physicians do not always have enough information to make a genetic diagnosis, and need an operational definition as a basis for action. Based on the new information accumulated on the disease, they have, therefore, proposed a new clinical definition requiring 4 out of 10 criteria (Table 1). This definition probably provides the diagnosis needed for clinical action. The ultimate diagnosis will, however, always require DNA analysis.

TABLE 1. Criteria for the Clinical Diagnosis of Alport Syndrome According to Gregory et al. [5]: 4 of the 10 Criteria Should be Fulfilled to Provide a Positive Diagnosis

1. Family history of nephritis or unexpected hematuria in a first degree relative of the index case or in a male relative linked through any number of females.
2. Persistent hematuria without evidence of another possibly inherited nephropathy such as thin GBM disease, polycystic kidney disease, or IgA nephropathy.
3. Bilateral sensorineural hearing loss in the 2000–8000 Hz range. The hearing loss develops gradually, is not present in early infancy, and commonly presents before the age of 30 years.
4. A mutation in *COL4A3*, *COL4A4*, or *COL4A5*.
5. Immunohistochemical evidence of complete or partial lack of the Alport epitope in glomerular, or epidermal basement membranes, or both.
6. Widespread GBM ultrastructural abnormalities, in particular thickening, thinning, and splitting.
7. Ocular lesions including anterior lenticonus, posterior subcapsular cataract, posterior polymorphous dystrophy, and retinal flecks.
8. Gradual progression to ESRD in the index case and in at least two other members of the same family.
9. Macrothrombocytopenia or granulocytic inclusions.
10. Diffuse leiomyomatosis of the esophaghus or female genitalia, or both.

Autosomal Recessive Alport Syndrome (MIM 203780)

As discussed above, Alport syndrome is mainly transmitted as a dominant X-linked trait. However, in about 15% of kindreds, autosomal transmission is obvious, including both autosomal recessive and, in very rare cases, autosomal dominant modes. Autosomal recessive disease should be suspected in cases of symptomatic individuals lacking a positive family history, especially when females are as severely affected as males [23]. In the much less common autosomal dominant form of the disease, males and females are equally severely affected. Still, individuals show a milder phenotype than is usually found in the X-linked form, i.e., an older age of onset of ESRD, minimal deafness, and an absence of eye signs [24].

Alport Syndrome–Associated Diffuse Esophageal Leiomyomatosis (MIM 308940,303631)

There is presently no direct evidence showing that mutations in the α6(IV) collagen chain *COL4A6* gene alone can cause Alport syndrome. Numerous deletions in the 5′ end of the *COL4A6* gene extending into the adjacent *COL4A5* gene have been reported to cause an Alport syndrome and diffuse leiomyomatosis (DL-AS) association first described by Garcia-Torres and Guarner in 1983 [25]. DL is a rare disorder characterized by benign proliferation of smooth muscle cells in the esophageal wall [26,27]. Both sporadic and hereditary cases have been described [27–30]. In addition to the esophagus, other organs such as the female genital tract and tracheobronchial tree may be affected. The clinical features and molecular genetics of DL have been reviewed by Antignac and Heidet [27]. The first report on mutations in DL-AS involved three patients with deletions at the 5′ end of the *COL4A5* gene and extending beyond it [31]. Later, it was shown that the upstream breakpoints were located within intron 2 of the *COL4A6* gene, which lies in a head-to-head fashion with *COL4A5* only 450 bp upstream [32]. Because *COL4A6* has been shown to be expressed in smooth muscle, it has been hypothesized that inactivation of this gene is the cause of DL-AS [32]. However, larger deletions of *COL4A6* associated with deletions initiating in *COL4A5* have been reported in a few patients with Alport syndrome without DL [33]. These results indicate other potential explanations for the development of DL than simply inactivation of *COL4A6*. For example, it is possible that there are other as yet unidentified genes located within the 5′ ends of the *COL4A5* or *COL4A6* genes. Intron 2 of *COL4A5* and intron 3 of *COL4A6* are possible locations as these introns are huge in size, the latter being estimated to be 340 kb [34–36] (see also Chapter 2, Part II, this volume).

Alport Syndrome with Antiglomerular Basement Membrane Disease (MIM 301050,203780)

Electron microscopic studies carried out in the late 1960s already indicated molecular abnormalities in a structural component(s) of the GBM. In 1976, McCoy et al. [37] showed by immunohistochemical staining with autoantibodies from Goodpasture syndrome patients that some Alport patients lacked the Goodpasture antigen, a finding that was confirmed later in several studies. The Goodpasture antigen has been shown to be located in the NC1 domain of the α3(IV) chain [38]. This NC1 domain, which can be purified from the GBM after digestion with bacterial collagenase, has a molecular weight of 28 kDa. This led researchers to believe that the α3(IV) chain gene was defective in Alport syndrome. However, as shown later and described above, this could not be the case in the X-linked form of the disease, since this gene resides on chromosome 2. Indications for the existence of another as then unidentified component of type IV collagen that might be involved in Alport syndrome came from studies by McCoy et al. [39], and later by several other investigators, showing that some Alport patients developed antibodies against renal allografts. Some of these antibodies have been shown actually to react with the 28 kDa NC1 domain of the α3(IV) chain, but some identify an NC1 domain-like protein of 26 kDa [40]. This 26 kDa component is now known to represent the NC1 domain of the α5(IV) chain, which is known to be mutated in a number of patients with X-linked Alport syndrome. Recently, Brainwood et al. [41] studied the targets of the alloantibodies of 12 Alport patients who had developed post-transplant anti-GBM disease. Western blot analysis of recombinant NC1 domains produced in insect cells showed selective binding to α5(IV)NC1 in nine cases. In one case, antibody showed binding to both α5(IV)NC1 and α3(IV)NC1, while two cases showed predominant binding to α3(IV)NC1. Seven of the patients who had X-linked inheritance all showed anti-α5 reactivity, and one with α3 reactivity had a *COL4A3* mutation. In spontaneous anti-GBM disease (anti-GBM or Goodpasture syndrome, MIM 233450), the major target of autoantibodies is the α3(IV)NC1 domain [42–44], but the primary target in most Alport anti-GBM patients is the NC1 domain of the α5 chain of type IV collagen [41].

STRUCTURE AND MOLECULAR BIOLOGY OF THE GLOMERULAR BASEMENT MEMBRANE

General

The basement membrane is a thin, ubiquitous, sheet-like type of extracellular structure that is located at the interphase of cells of organized tissues and the connective tissue. Basement membranes are found beneath all epithelia and endothelia, as well as surrounding muscle fibers, fat cells and peripheral nerves (Fig. 2). They perform important biological roles by providing structural support for cells, and mediating differentiation, adhesion, and migration, as well as proliferation of cells. They also function as filters for macromolecules, as exemplified by the renal glomerular basement membrane (GBM), and they are important in tissue regeneration, such as reepithelialization and renervation [45].

The thickness of a basement membrane can vary between 50 and 350 nm. By electron microscopy, it is often observed to contain two morphologically distinct layers, the lamina lucida (rara) and lamina densa. Some basement membranes, such as the GBM, have three layers, the lamina rara interna, lamina densa, and lamina rara externa, as this particular type of basement membrane is formed by two oppositely located cell layers, the capillary endothelium and the epithelial podocytes of the urinary space (Fig. 1). These layers may be artefacts of the routine fixing techniques, as studies of tissue samples made by the quick-freeze method have shown the basement membranes not to contain any distinct layers [46].

The Glomerular Filtration Barrier

The major complications of Alport syndrome, hematuria and proteinuria, are caused by structural alterations and consequent malfunction of the glomerular filtration barrier. The renal glomerulus functions as the ultra-filtration unit for plasma (Fig. 3). There are about one million glomeruli

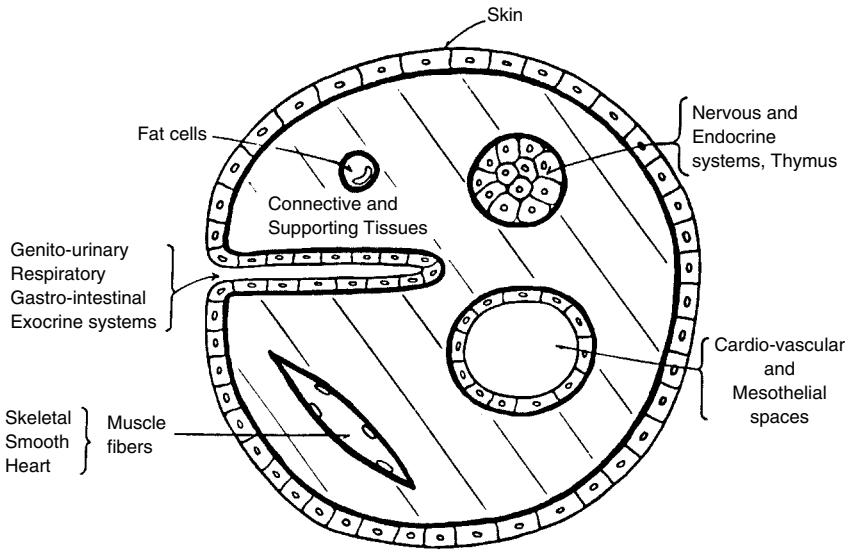

Figure 2. Schematic illustration of the distribution of basement membranes in the human body. The basal laminae are shown as heavy lines located in a characteristic manner between organized tissue cells and the interstitial connective tissue. The organ cells include all epithelial cells of epidermis and epidermal appendages of the respiratory, gastrointestinal, and genitourinary tracts, all exocrine glands, endothelial cells of the cardiovascular system, mesothelial cells of body cavities, cells of the central and peripheral nervous systems, endocrine glands, muscle fibers, and fat cells. The connective tissue (dashed area) includes interstitial stroma, bone, and cartilage and their associated cells. (Reprinted, with permission from [45].)

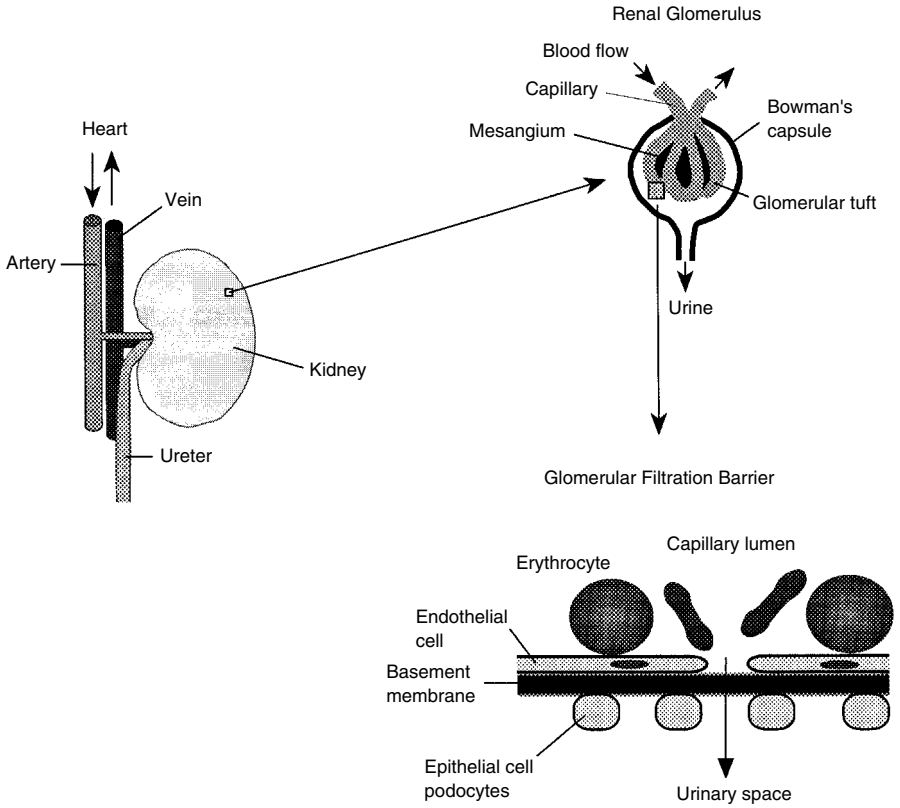

Figure 3. Schematic illustration of the kidney, a filtration unit (glomerulus), and the glomerular filtration barrier. Each kidney contains about one million ball-shaped glomeruli in which the filtration of blood occurs. The glomerular capillaries divide and form a set of loops (glomerular tuft) which are located inside Bowman's capsule. The filtration of blood occurs in the capillaries so that only small proteins and waste products together with water can pass into the urinary space. The actual filtration barrier consists of the fenestrated capillary endothelium, the glomerular basement membrane, and the filtration slits located between the foot processes (pedicels) of the glomerular epithelial cells (podocytes). The illustrations are not drawn to scale.

per human kidney. During morphogenesis, a glomerulus is formed by the invagination of a capillary with mesenchymal mass into the epithelial lining of a Bowman's capsule. The capillary divides into several loops (glomerular tuft). The inner part of the capillary faces the mesangium, while the outer part forms the filter. The filtration barrier consists of three layers: (a) a fenestrated endothelial layer, (b) a basal lamina (glomerular basement membrane; GBM) of about 300–350 nm in thickness, and (c) podocytes, interdigitating epithelial cells, that almost completely cover the external surface of the GBM. The adjacent processes are separated by 20–30 nm wide slit pores, or filtration slits, which are covered by thin diaphragms [47]. Under normal conditions, the filtration barrier practically completely excludes from the filtrate plasma proteins of the size of albumin (67 kDa) or larger, while exhibiting an extremely high permeability to water and small solutes. Filtration across the barrier depends on the size of the molecules, i.e., it is a size-dependent permeability barrier [48]. Filtration decreases with increasing molecular radius. Additionally, the filtration barrier discriminates between molecules according to their charge, cationic and neutral molecules traversing the membrane more readily than anionic molecules of the same size [49].

Molecular Composition of the Glomerular Basement Membrane

In general, the molecular structure of the GBM does not differ from that of basement membranes in other tissues. Type IV collagen is the major structural component that forms a tightly cross-linked meshwork connected through entactin (nidogen) to a less dense laminin network. In addition to contributing to the three-dimensional structure, laminin is a major adhesion molecule which also plays a role in cell differentiation and migration (see also Chapter 5, this volume). Type IV collagen and laminin are both complex heterotrimeric proteins that exist in numerous more or less tissue-specific isoforms. Other minor components include BM40 (osteonectin, SPARC), fibulins, and agrin, that are present in some specialized types of basement membranes [50,51].

Type IV Collagen

The scaffold of the basement membrane is a dense, tightly cross-linked protein meshwork made up of type IV collagen (see also Chapter 2, Part I, this volume), which is specific to the basal lamina [52]. The type IV collagen molecules that form the building blocks of the basement membrane are typical elongated triple-helical collagen molecules composed of three α chains. Each α chain is composed of an approximately 1,400-residue collagenous domain with Gly–X–Y repeats interrupted at several sites by short noncollagenous sequences, an aminoterminal ~15-residue noncollagenous segment and a carboxyl-terminal ~230-residue noncollagenous (NC1) domain (see Fig. 4A). The noncollagenous amino terminus and its short neighboring cysteine-rich collagenous sequence is referred to as the 7S domain [53]. The presence of a glycine residue as every third amino acid in the collagenous domain is essential, as it is the only amino acid small enough to fit into the center of the collagen triple helix. The interruptions in the Gly–X–Y repeat sequences are thought to provide the triple helical molecules with flexibility. The type IV collagen α chains are highly glycosylated, with about 50 hydroxylysine-linked disaccharide units and an asparagine-linked oligosaccharide unit in the 7S domain [54,55].

Six genetically distinct type IV collagen α chains, α1(IV)–α6(IV), have been characterized. The most abun-

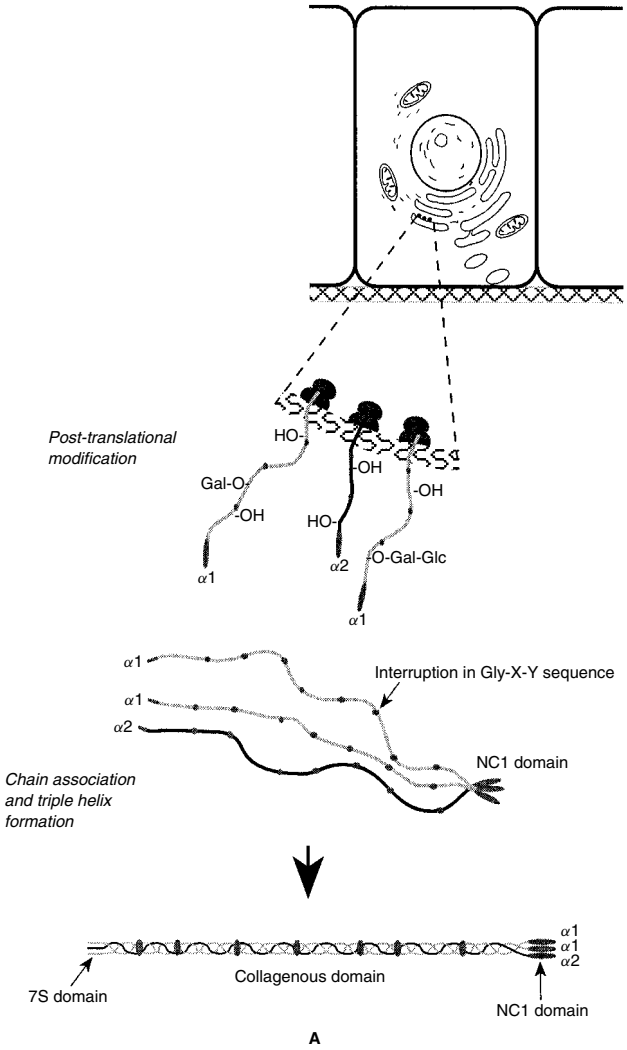

Figure 4. A. Biosynthesis of type IV collagen in a cell resting on a basement membrane follows the general pattern of synthesis of collagenous proteins [70] (see also Chapter 2, Part I, this volume). After transcription and processing of the primary transcript, the mRNA is transported to the cytosol to ribosomes upon which translation occurs. Post-translational prolyl and lysyl hydroxylation and hydroxylysyl glycosylation reactions take place on the nascent α chains in the cisternae of the rough endoplasmic reticulum. This is followed by chain association, disulfide bonding and formation of the triple helix of three appropriate α chains. Single chains not incorporated into triple helices are degraded, while the triple-helical molecules are transported through the Golgi apparatus to the extracellular space where supramolecular assembly occurs. **B.** Schematic illustration of the structure and supramolecular assembly of type IV collagen. Individual monomers associate into dimers via disulfide bonds between NC1 domains or into tetramers through disulfide bonds between the amino termini. A supramolecular network is formed by the assembly of dimers and tetramers and strengthened by the lateral association and partial winding of some molecules around each other. Other basement membrane components — such as laminin, proteoglycans, and nidogen — are bound into the type IV collagen meshwork. (Modified from [205].)

(*continued overleaf*)

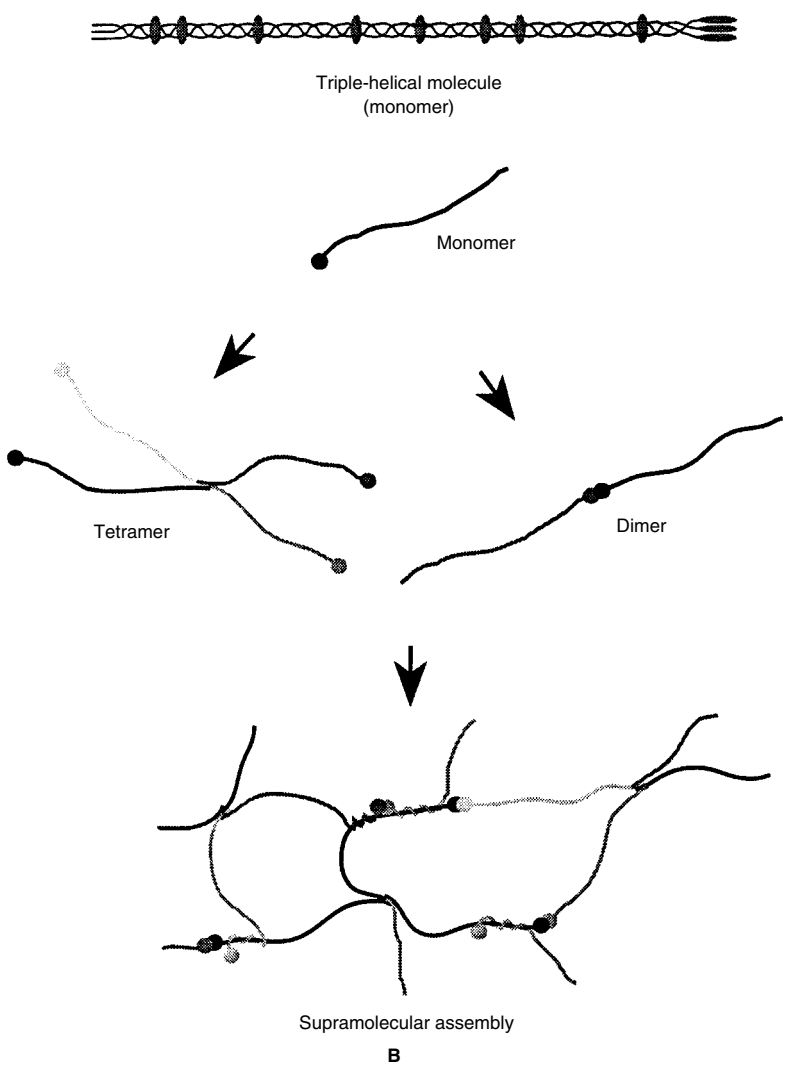

Figure 4. (*Continued*)

dant α1(IV) and α2(IV) chains have been sequenced in man [56,57], mouse [58,59] and *Caenorhabditis elegans* [60,61]. Additionally, the α1(IV) sequence is known for *Drosophila* [62] and sea urchin [63], and the α2(IV) sequence in *Ascaris suum* [64]. The primary sequences of the tissue-restricted α3(IV) [65], α4(IV) [66], α5(IV) [34,67], and α6(IV) [68,69] chains have been determined in man. The collagen IV chains are very homologous to each other and can be divided into two classes. The α1(IV), α3(IV), and α5(IV) chains belong to an α1-like class, and the α2(IV), α4(IV), and α6(IV) to an α2-like class.

The biosynthesis of type IV collagen involves similar post-translational modifications to those of collagenous proteins in general (Fig. 4A) [70] (see also Chapter 2, Part I, this volume). The secreted triple-helical type IV collagen monomers self-assemble into a complex network structure (Fig 4B). Several modes of interaction have been demonstrated in *in vivo* studies. Linear dimers are formed through association of the NC1 domains of two molecules. The resulting hexameric NC1 complex is mostly stabilized by interchain disulfide bond formation [71]. Tetrameric structures are formed through noncovalent interactions, namely parallel and antiparallel associations of the aminoterminal ends of four monomers. The dimers and tetramers further assemble, forming a network of highly branched filaments that include laterally aligned molecules and molecules twisting around each other [50,72]. The result is a three-dimensional, tightly meshed structure to which other basement membrane components bind. The short, noncollagenous interruptions in the collagenous domain of the type IV collagen molecules presumably provide the network structure with flexibility.

Several different molecules with variable compositions are possible, because of the existence of six different α chains. The most common form of type IV collagen, present in most basement membranes, is a heterotrimer containing two α1(IV) chains and one α2(IV) chain [53]. Homotrimers of α1(IV) chains have also been found [42,73]. The existence of combinations of the other four α chains (α3–α6) has been intensively investigated and evidence for different networks has been presented. Heterotrimers of two α3(IV) chains and one α4(IV) chain, and homotrimers of α3(IV) chains appear to exist in the glomerular basement membrane [42,74].

Recently, Gunwar et al. [75] identified a novel disulfide-cross-linked network of the α3(IV), α4(IV) and α5(IV) chains of type IV collagen in the kidney. This finding explains several features of the GBM abnormalities in Alport syndrome.

Other Glomerular Basement Membrane Components

Laminin. The laminins are a group of complex extracellular glycoproteins that are ubiquitous components of the basement membrane [76–79] (see also Chapter 5, this volume). Laminin was initially isolated and characterized from a murine basal lamina matrix-forming Engelbreth-Holm-Swarm (EHS) tumor as a trimeric protein containing 400 kDa, 220 kDa, and 200 kDa subunit chains, referred to as A, B1, and B2 chains, respectively [80]. Later, laminin was shown actually to represent a large protein family existing in numerous isoforms [76–78]. With the identification of multiple new laminin subunit chains and trimeric isoforms, a new, more systematic nomenclature has been adopted [81]. According to this new nomenclature, the A, B1, and B2 chains are now designated α, β, and γ, respectively. Similarly, the genes for these chains are termed A, B, and C, respectively. The laminins have been shown to perform numerous biological functions, which are general but also specific for certain cell-lineages and tissues. These functions include cell adhesion, migration, differentiation, and proliferation [76–78] and, furthermore, laminin is part of the structural framework [82]. In addition to its physiological roles, it has been implicated in tissue repair and in cell migration events such as occur during tumor invasion [76,83,84].

Laminin molecules are heterotrimers composed of α, β, and γ chains that vary in size, being 165–400 kDa, 140–220 kDa, 130–220 kDa, respectively. These chains are multidomain polypeptides that all share certain structural features, although they clearly form three distinct classes. To date, five α, three β, and two γ chains have been identified, these chains forming ten, or even more, different types of heterotrimers (isoforms) [76]. The sequences of all the human chains, except for the laminin α5 chain, have now been determined [85–93]. All the chains have a region at the carboxyl terminal end (domains I and II) that assembles with the other chains to form a coiled coil structure, the long arm. Additionally, the α chains have a large carboxyl terminal globular domain (G-domain) not present in the β and γ chains. The amino termini of the chains have a varying number of cysteine-rich laminin repeats and globular domains.

Knowledge of the tissue-specificity of laminin variants implies unique cell and tissue specific functions for different laminin isoforms. The laminin α chains are particularly interesting, because they have been shown to have a remarkably limited tissue distribution. For example, as determined by Northern analysis and *in situ* hybridization, the α1 chain appears to be important in the early embryo, as it is expressed in the embryo primarily in the brain and to some extent also in epithelial cells of the forming proximal nephron [86], while little expression is observed postnatally. The laminin β1 and β2 chains seem to be mutually exclusive [94], the β1 chain, however, having almost ubiquitous expression. It is of interest that the β2 chain is expressed in a restricted manner during late development of the kidney, being particularly prominent in the GBM, as well as in the tubular basement membrane [95]. It is also expressed in endoneural and perineural basement membrane, as well as in the synaptic basement membrane, blood vessels and trophoblasts. Inactivation of the gene in transgenic mice resulted in a phenotype showing severe proteinuria and renal failure, as well as ultrastructural abnormalities in the synaptic basement membrane [96].

Proteoglycan. Proteoglycans are extracellular proteins containing large carbohydrate (glycosaminoglycan) side chains that increase the volume of tissues by binding water through their hygroscopic properties (see also Chapter 4, this volume). The basement membrane has been shown to contain proteoglycans which differ from those of other connective tissues such as stroma and cartilage. The best studied and most abundant basement membrane proteoglycan is a large heparan sulfate proteoglycan termed perlecan [97,98]. The human perlecan core protein belongs amongst the largest polypeptides in the human body with a size of 467 kDa [99]. The human core protein contains five distinct domains; an amino-terminal domain I containing three attachment sites for heparan sulfate side chains; domain II containing two regions of homology to LDL receptor-like repeats and one IgG-like domain; domain III with cysteine-rich repeats similar to those in domains III and V of laminin as well as regions similar to the globular domains IV and VI of laminin; domain IV containing 21 copies of IgG-like repeats; and domain V containing three subdomains similar to the five subdomains present in the G-domain of laminin α chains.

Perlecan is likely to serve several functions in basement membrane, but present knowledge as to what they might be, is still very limited. However, Farquhar and co-workers have shown strong evidence for heparan sulfate side chains being important for the filtration function of the glomerular basement membrane due to their high anionic charge [100–102]. Loss of heparan sulfate has also been reported in the GBM in many diseases characterized by proteinuria. Heparan sulfate chains on other proteoglycans have also been proposed to provide a kind of extracellular reservoir of growth factors, such as fibroblast growth factors, which bind heparan sulfate. Due to its complex multidomain structure, it seems likely that perlecan has multiple functions within the basement membrane.

Nidogen. Nidogen [103], also described as entactin [104], is abundant in all basement membranes (see also Chapter 5, this volume). It has a molecular weight of 148 kDa including 5% of carbohydrates [105,106]. The human cDNA-derived protein sequence [107], together with electron microscope analysis [108], shows the secreted protein to contain three globular domains, G1, G2, and G3, separated by two rod-like domains, which consist of cysteine-rich EGF-like repeats.

Nidogen is probably essential for a functional basement membrane, as it appears to maintain the three-dimensional structure by linking the independent type IV collagen and laminin meshworks. The carboxyl-terminal end of the nidogen molecule has been shown to bind to a single, internal cysteine-rich repeat in domain III of the laminin γ1 chain [109–111], which is present in the basement membrane of most, if not all tissues in the body. The G2 domain of nidogen, in turn, binds to type IV collagen, but in a more complex manner, and possibly to several sites of that molecule [112,113]. Nidogen has been shown to interact, also, with the core protein of perlecan [114], so nidogen may truly function as a major link between the various structural proteins of the basement membrane. Nidogen has also been shown to bind *in vitro* to fibronectin and fibrinogen, which are not authentic basement membrane proteins [108].

Other Components. Other proteoglycans have been identified in basement membrane, but knowledge of their structure and other properties is still very limited. Several other proteins such as fibronectin, BM-40 [115] (also termed

osteonectin [116] or SPARC [117]) and fibulin have been localized to the basement membrane, but they are also, or mainly, present in other extracellular components and their actual role in basement membrane function is not known.

Type IV Collagen Genes

The six mammalian type IV collagen genes have an exceptional arrangement in that they are located pairwise in a head-to-head fashion on three different chromosomes (Fig. 5); (for the gene structure of collagens, see also Chapter 2, Part II, this volume). This arrangement implies that they have evolved from a common ancestor gene, and careful analysis of the sequences of the six α-chains, together with the available data on the structure of the genes, has allowed us to envisage the probable evolutionary pattern of the genes. Present data predict that the first event involved a duplication and inversion of the ancestor gene at the initial locus, so that the genes came to lie head-to-head. This was followed by extensive divergence of the two genes into α1-like and α2-like genes. Later, the gene pair was duplicated in its entirety to another chromosome, giving rise to the *COL4A3*/*COL4A4* gene pair (on human chromosome 2) coding for the α3(IV) and α4(IV) chains, respectively [118]. Still later, the original gene pair was duplicated to chromosome X to form the *COL4A5*/*COL4A6* gene pair encoding the α5(IV) and α6(IV) chains, respectively [32]. The original gene pair became the *COL4A1*/*COL4A2* genes on chromosome 13 that code for the α1(IV) and α2(IV) chains, respectively [119]. It is to be noted that a similar evolution has knowingly not taken place in lower organisms, as the two type IV collagen *COL4A1* and *COL4A2* genes in *C. elegans* are located on two different chromosomes [120], for example.

The 5′ ends of each gene pair are adjacent to each other, separated by sequences which contain motifs involved in the regulation of transcriptional activity [121]. The 5′ ends of the *COL4A1* and *COL4A2* genes overlap each other, and the region between transcription start sites is only about 130 bp. The genes are transcribed from opposite DNA strands and share a common bidirectional promoter [122]. The arrangement of the *COL4A5* and *COL4A6* genes is similar, but the distance between transcription start sites is longer, 442 base pairs. In addition, the *COL4A6* gene has two alternative promoters, indicating usage of different regulatory elements for the expression of the gene, resulting in two distinct transcripts in a tissue-specific manner [123]. Studies of the murine genes have shown the bidirectional operation model for the promoter elements of the α3(IV) and α4(IV) genes [124]. Recently, Momota and co-workers [125] showed that the human *COL4A3* and *COL4A4* genes are also transcribed in opposite directions and share the same promoter region. Additionally, the *COL4A4* gene has two alternative transcripts, the expression of which appears to be tissue-specific. One transcription start site of *COL4A4* is only 5 bp away from the transcription start site of *COL4A3* and the other starts 373 nucleotides downstream from the first. Two kinds of transcript are generated that differ in the 5′ untranslated region, thus resulting in the same deduced amino acid sequences.

All the genes encoding the human type IV collagen α1 to α6 chains are very large in size, because of the large sizes of the introns. It has been estimated by macrorestriction mapping that the size of the α1(IV) gene is 100–160 kb, as is that of the α2(IV) gene [126]; the α5(IV) gene is 230–250 kb, and the α6(IV) gene is at least 425 kb [127]. The combined size of the *COL4A3*/*COL4A4* gene pair has been estimated to be about 500 kb [118], the *COL4A4* gene being at least 113 kb [13]. The α1(IV) gene contains 52 exons, the sizes of which vary from 27 to 213 base pairs [128]. The number of exons in the *COL4A2* gene is 47, the smallest being 36 bp and the largest 287 bp [129]. Previously the exons encoding the most 3′ end of the *COL4A3* and *COL4A4* genes had been characterized [130,131], but recently Boye et al. [13] showed the *COL4A4* gene to have 48 exons, of which the smallest is 9 bp and the largest 287 bp. The type IV collagen α5 chain gene contains 51 exons and they are almost the same size as those of the α1(IV) gene, the smallest being 27 bp and the largest 213 bp [34]. The *COL4A6* gene contains 46

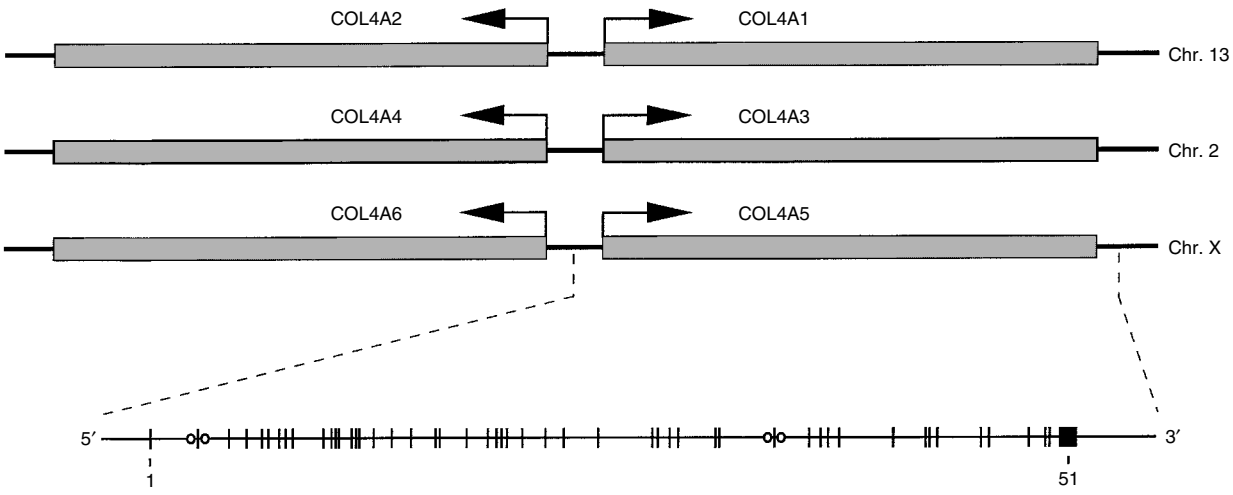

Figure 5. Illustration of the organization and chromosomal location of the human type IV collagen genes. The genes encoding the six type IV collagen chains are located pairwise in a head-to-head fashion on three different chromosomes. The genes are designated by boxes and flanking sequences by solid lines. The chromosome number is shown on the right. For the *COL4A5* gene, the arrangement of exons is shown beneath by vertical bars, and that of introns by the horizontal line. The exons are numbered from the 5′ end of the gene. Intron sequences of unknown size are indicated by circles. (Modified from [52].)

exons including exon 1′ which is alternatively transcribed with exon 1 from alternative promoters. The sizes of exons vary from 36 to 222 bp [35].

TISSUE DISTRIBUTION OF THE TYPE IV COLLAGEN α CHAINS

The cloning of the six type IV collagen α chains and the production of recombinant proteins as antigens, has enabled the generation of chain-specific nucleotide probes and antibodies which have revealed cell-specific expression and tissue location of the different α chains. These studies have demonstrated that the six type IV collagen α chains differ quite remarkably in their tissue distribution (Table 2). This, in turn, suggests that the different isoforms serve different functions *in vivo*. The α1(IV) and α2(IV) chains that form the most common $[\alpha1(IV)]_2\alpha2(IV)$ isoform are present in practically all basement membranes where they are frequently the only chains present. This emphasizes a major general role of this isoform in basement membranes. The other, minor chains have a highly restricted distribution [52].

Normal Tissue Distribution

The α3, α4, and α5 chains of type IV collagen are expressed in the kidney, and their expression is highly enriched in the glomerular basement membrane, but they are also found in a subset of tubular basement membranes, i.e., Bowman's capsule and the distal tubules [132,133]. The α5(IV) chain is present, furthermore, in the collecting ducts. α6(IV) chain expression is almost identical to that of α5(IV) throughout the kidney, but it is notably absent from the GBM [132]. In the glomerulus, the α1(IV) and α2(IV) chains are present in the mesangium, where expression of the α3(IV)–α6(IV) chains cannot be seen [133,134] (Table 2). Those basement membranes that are known to be affected in Alport syndrome express the α3(IV), α4(IV), and α5(IV) chains. In addition to the GBM, these include the anterior lens capsule, the internal limiting membrane of the retina, Bruch's membrane, and Descemet's membrane in the eye, as well as several basement membranes of the cochlea [23]. Type IV collagen chains are also known to be present in extrarenal non-Alport target tissues; the α3(IV) and α4(IV) chains are expressed in lung, brain [135], and synaptic fibers [94] and the α5(IV) and α6(IV) chains in lung, esophagus, and skin [135].

Immunohistology of Basement Membranes in Alport Syndrome

Immunohistochemical studies have shown that the type IV collagen α3, α4, and α5 chains are absent from the GBM of many male patients with X-linked Alport syndrome, whereas the expression of the α1(IV) and α2(IV) chains

is even increased [132,136]. Expression of the α6(IV) chain is normally seen in Bowman's capsules and tubules but not in such patients; this is also the case with the α3(IV), α4(IV), and α5(IV) chains [133]. Women who are heterozygous for the X-linked disease exhibit segmental expression of the α3(IV), α4(IV), and α5(IV) chains in the GBM, while expression of the α1(IV) and α2(IV) chains is preserved [137].

Immunohistochemical analyses of skin tissue from males with X-linked Alport syndrome have shown a complete absence of α5(IV) and α6(IV) chain expression. A discontinuous or mosaic staining for these two chains is seen in the epidermal basement membrane (EBM) of female heterozygotes [133,138]. Cheong et al. [139] have studied the expression of type IV collagen α chains in another Alport target tissue, the anterior lens capsule, in X-linked cases, and demonstrated the same features as in the GBM, namely, a lack of the α3(IV) to α5(IV) chains (Table 2).

The distribution of α(IV) chains in autosomal recessive cases of Alport syndrome has been studied by Gubler et al. [140]. Usually, no expression of the α3(IV), α4(IV), and α5(IV) chains can be seen in the GBM, but deviating from the X-linked expression pattern, the α5(IV) chain is normal in Bowman's capsule and distal tubular basement membrane. A similar expression pattern can be seen in both sexes. In addition, the α5(IV) chain shows normal staining in the EBM, while the α3(IV), α4(IV), and α5(IV) chains are absent from the GBM (Table 2). This combination cannot be seen in X-linked Alport syndrome, as it is well known that only the α5(IV) chain of these three is present in the EBM [140]. This differential pattern of staining may be a useful method for distinguishing between X-linked and autosomal recessive forms of Alport syndrome [23].

MOLECULAR PATHOLOGY OF THE ALPORT SYNDROME

General

As discussed above, Alport syndrome is caused by abnormalities in the genes encoding the basement membrane-specific type IV collagen α3, α4, and α5 chains—i.e., *COL4A3*, *COL4A4*, and *COL4A5*, respectively. In the most common, X-linked dominant form of Alport syndrome, close to 300 different mutations in the *COL4A5* gene have thus far been identified (Tables 3 and 4). Large deletions spanning the 5′ ends of the *COL4A5* and *COL4A6* genes have been shown to be associated with a rare combination of Alport syndrome and diffuse esophageal and/or genital leiomyomatosis, a condition characterized by benign smooth muscle cell proliferation [27]. The rarer autosomal inheritance, including both autosomal recessive and autosomal dominant cases, has been estimated to account for up to 15% of affected families. Autosomal disease is caused by abnormalities in the *COL4A3* and *COL4A4* genes, and to date 17 different mutations have been characterized in these genes [13,18]. Recently, Lemmink et al. [141] detected a glycine substitution in the collagenous domain of the *COL4A4* gene in a case of autosomal dominant benign hematuria.

Mutations in the *COL4A5* Gene in X-linked Alport Syndrome

Since the first mutations described in the type IV collagen α5 chain gene in X-linked Alport syndrome by Barker et al. [2], nearly 300 mutations have been elucidated by different groups [18,19]. Southern blot analysis using cDNA probes has been utilized to detect large rearrangements of the *COL4A5* gene. The main method of screening of small mutations has been SSCP analysis of PCR amplified products. However, direct sequencing of PCR amplified exon regions has revealed the highest mutation detection frequency [19].

The *COL4A5* mutations identified in the disease to date are listed in Tables 3 and 4. They include large and small gene rearrangements such as deletions, insertions, inversions, and duplications, as well as single base changes. Furthermore, complete loss of the gene has been reported in two cases [33,142,143]. A striking finding is that the mutations identified in *COL4A5* so far are highly dispersed in this huge gene, which contains 51 exons and exceeds 250 kb in size [34,144]. The same mutation has been found in only a few cases in two or more unrelated kindreds. This contrasts sharply with findings in other diseases such as cystic fibrosis, in which approximately 70% of patients have the same mutation [145]. The dispersion of mutations in *COL4A5* resembles the situation reported for osteogenesis imperfecta, a brittle bone disease that involves a variety of mutations in type I collagen genes [146] (see also Chapter 8, this volume).

The mutations in the *COL4A5* gene in Alport syndrome can, in most cases, well explain the structural and pathophysiological changes in the GBM. They can result in changes that affect many of the steps in type IV collagen biosynthesis and assembly, such as: (a) synthesis of the primary transcript, (b) post-transcriptional modification of the transcript, such as splicing, (c) translation of the mRNA, (d) post-translational modifications of nascent α chains, (e) assembly and folding of three α chains into a triple-helical molecule, (f) the stability of the helical structure, and (g) the formation of cross-links between individual triple-helical molecules. Large gene rearrangements can result in a total loss of expression of the gene, and small mutations in regulatory elements can have the same effects. Large and small mutations can also affect splicing of the primary transcript. Abnormal splicing and skipping of exons can cause two types of change. First, if the exon skipping is in frame, the result is a shortened polypeptide lacking a segment while, second, if the exon skipping occurs out of frame, the result is a protein containing a nonsense amino acid sequence. Duplications of the gene segments can lead to abnormally long α chains.

All mutations leading to absence of the α5(IV) chain or extensive alterations in protein size would certainly lead to the abnormal structure of any type IV collagen network in which the α5(IV) chain is required as a normal component. Complete loss, or the presence of an abnormal α5(IV) chain, may explain the clinical manifestations observed in Alport syndrome. In the kidney, the α5(IV) chain is practically present only in the GBM as shown by immunostaining techniques, with a similar GBM staining pattern observed for the α3(IV) and α4(IV) chains. Although it is not known in what molecular chain combinations the α5(IV) chain is present in the GBM, it was recently shown by Gunwar et al. [75], that an α3:α4:α5 network is formed in the GBM. Thus, the absence of a normal α5(IV) chain would most probably weaken the structural network of the GBM, leading to leakage of large proteins or even large blood cells into the urinary space. It is important to note, however, that heterozygous females usually exhibit only mild phenotypes and seldom develop end stage renal disease. This suggests that the synthesis of low amounts of a normal α5(IV) chain is sufficient to maintain normal GBM function, even though an abnormal chain may be present. This fact is particularly

TABLE 3. Small Mutations of the *COL4A5* Gene in Alport Syndrome Patients with X-Linked Disease

[e]ND means no data available for the deleted area.

important when considering future possibilities for gene therapy.

Single base mutations in exons leading to amino acid changes in the α5(IV) chain can be expected to render the protein malfunctional in most, but not necessarily all cases, because such changes can affect proteins in a number of ways. Therefore, the question is how can we know whether an amino acid substitution actually causes disease instead of being silent? This is an important question, especially from a clinical point of view when making a decision about the termination of pregnancy after a mutation has been identified in a fetus. This is also a very difficult question to answer and, in fact, the only definite way of proving that a mutation is causative for the disease is to generate transgenic animals with the same mutation and observe if it results in an Alport syndrome-like phenotype. However, it is possible that a mutation causing disease in man does not cause the same disease in mice. Therefore, one has to rely on strong "circumstantial" evidence when predicting the potential pathogenic effect of mutations. Such evidence can be linkage or the segregation of a mutation with the phenotype in an Alport kindred, knowledge of the role of a certain amino acid in the function of the protein, or the conservation of an amino acid during evolution. It is assumed that amino acid residues conserved in a protein between widely distant species during evolution have such functional importance that their substitution cannot be tolerated. This can be illustrated by several examples.

The approximately 230 residue amino acid sequence of the C-terminal NC1 domain of type IV collagen α chains consists of two homologous halves, with about 50% of amino acid residues being conserved in all six mammalian chains and also in type IV collagen α chains of *Drosophila*, *C. elegans*, and sea urchin [1,57–60,62,63,147–151]. The conserved amino acid residues include 12 cysteines, 6 in each homologous half of the NC1 domain. It is apparent that the NC1 domain of all type IV collagen chains has the same biological function and that the highly conserved amino acids and three-dimensional structure of the NC1 domain are essential for the correct alignment of three α chains prior to their folding and twisting into a triple helix, and subsequently for the formation of intermolecular cross-links in the extracellular space. Therefore, substitution of conserved amino acids in this domain may affect these functions. Thus far, several single base mutations leading to amino acid substitutions in the NC1 domain of the α5(IV) chain have been published in relation to Alport syndrome. For example, one mutation resulted in the change of cysteine1564 to serine [9]. The mutation would abolish one of the intra-chain disulfide bonds, destroying either that between cysteine residues 1476 and 1564, or that between cysteines 1509 and 1564 (Fig. 6). The mutation, which would alter the conformation of the NC1 domain, could have several effects. One possibility is that the mutation would interfere with the alignment of chains and formation of the triple helix so that helix formation would be slowed down, abolished completely, or the alignment of Gly–X–Y repeats would be out of register. Alternatively, the triple-helical molecule may be formed and the protein secreted from the cell, but the loss of the cysteine residue might cause weak intermolecular cross-links in the type IV collagen in the basement membrane meshwork.

The effects of amino acid changes in the NC1 domain other than of cysteine are more difficult to predict as the function of those amino acids is not known. Examples of such mutations are Pro1517Thr, Trp1538Ser, and Arg1563Gln (Table 3) [152–154]. In such cases, one could, if possible, (a) study whether the mutation co-segregated in the families with the Alport phenotype, (b) determine whether the mutation was the result of a normal polymorphism and existed in normal individuals or, (c) examine whether the amino acid had been conserved during evolution. As can be seen in Figure 7, each of the amino acids listed above is conserved in all known type IV collagen α chains, even between distant species. Consequently, it may be assumed that these amino acids are essential for the normal function of the NC1 domain and that their change cannot be tolerated.

A large number of mutations converting a glycine residue in the Gly–X–Y repeat-containing collagenous domain to another amino acid have been described (Table 3). These mutations undoubtedly affect the stability of the triple helix of the molecule because, as mentioned above, glycine is the only amino acid small enough to fit in the center of the triple helix, and an uninterrupted Gly–X–Y repeat sequence is essential for maintenance of the triple-helical conformation. The result of glycine substitution would, therefore, be that the helix was destabilized, creating kinks in the molecule which would not be tolerated. Although this has not been demonstrated at the protein level for type IV collagen, a number of similar glycine mutations, either inhibiting helix formation or causing kinks in the molecule, have been described in type I collagen in osteogenesis imperfecta [146] (see also Chapter 8, this volume).

The dispersion of mutations throughout the *COL4A5* gene is a characteristic of Alport syndrome. Thus far, no "hot spots" particularly prone to mutagenic changes have been found, and are not likely to be. Regions highly susceptible to mutation would be of significant clinical value because they could greatly facilitate the search for mutations in Alport patients.

Different *COL4A5* Mutations Cause Different Phenotypes

Alport syndrome is a heterogeneous disease, with onset of end-stage renal disease at varying ages, and with or without manifestations such as hearing loss or deafness, ocular lesions, and thrombocytopathy. Because so many mutations have been identified in the *COL4A5* gene, it is of interest from a clinical point of view to try to correlate them with the phenotypes they produce. As can be seen from Table 3 and references therein, such an analysis is disappointing in the sense that it does not seem to be possible to predict the phenotype on the basis of the nature of a mutation. For example, the point mutations that result in a substitution of glycine residues in the collagenous domain or of conserved amino acids in the NC1 domain generate quite a wide spectrum of phenotypes. Most, but not all patients have a juvenile onset of end-stage renal disease, and the presence of hearing loss and ocular lesions varies between individuals.

A similarly heterogeneous picture is seen for large changes in the gene (Table 4). Even the entire loss of the gene does not necessarily produce more severe disease than a single glycine substitution in the collagenous domain of the α5(IV) chain. Although disappointing, this does not come as a surprise as the same phenomenon has been observed with defects in the genes for fibrillar collagens resulting in osteogenesis imperfecta, chondrodysplasia, Stickler syndrome, and Ehlers-Danlos syndrome [146] (see also Chapters 8,9,23, this volume). One particularly interesting Alport phenotype displays diffuse leiomyomatosis in addition to the classical

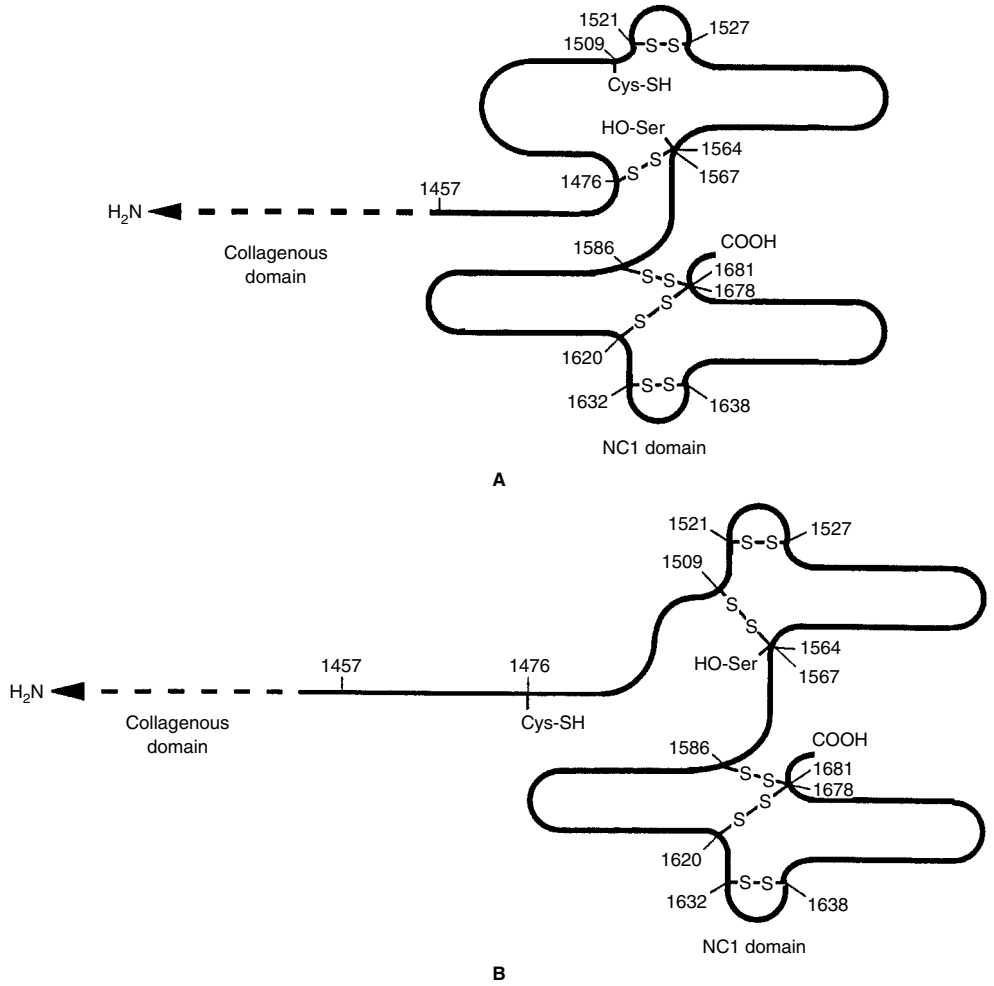

Figure 6. Hypothetical consequences of a Cys1564Ser mutation in the *COL4A5* gene. The mutation abolishes a disulfide bond connecting cysteine1564 to either cysteine1509 (**A**) or cysteine 1476 (**B**). This would, in turn, cause a change in the conformation of the NC1 domain, with a possible rearrangement of intrachain bonds and subsequent interference in helix formation. The mutation may also seriously influence the rearrangement of the disulfide bonds and formation of interchain bonds, with the simplest change reducing the number of cross-links from eight to six. However, the mutation might interfere more seriously with dimerization by even completely inhibiting the formation of interchain cross-links between NC1 domains. (Modified from [9].)

Figure 7. Comparison of substituted amino acids in three Alport patients with corresponding residues in the homologous halves of the NC1 domain in all known type IV collagen α chains [14]. Gaps (..) have been introduced to maintain alignment. Capital letters indicate the amino acid residues. Amino acids that are conserved through evolution are shown in boxes. The proline, tryptophan, and arginine residues (boldface) that are mutated in the three patients [152–154] are conserved in both symmetrical halves of the NC1 domain in all known type IV α chains.

symptoms [31]. A clinically important group is the ~15% of post-transplantation Alport patients who develop anti-GBM antibodies. About one-third of those patients subsequently reject the transplant. Initial studies on Alport mutations and phenotypes gave hope that, depending on the nature of the mutation, it might be possible to predict which patients would develop anti-GBM nephritis and, thus, who should receive a transplant and who not. It seemed reasonable to presume that a mutation deleting the highly antigenic NC1 domain of the α5(IV) chain would cause a patient to recognize the corresponding domain in an allograft as a foreign protein and should, therefore, not receive an allograft as he would develop anti-GBM nephritis. However, more recent data on transplanted patients with similar kinds of gene defects have shown that this expectation is not entirely valid. In the light of current, still limited knowledge, it is not yet possible to predict which patients are likely to develop anti-GBM nephritis following kidney transplantation.

Mutations in the *COL4A3* and *COL4A4* Genes in Autosomal Recessive Alport Syndrome

A distinct form of autosomal recessive Alport syndrome was suspected for several years by French investigators, because involvement of the *COL4A5* gene was excluded by polymorphism studies of certain pedigrees [155]. It was logical to search for mutations in the *COL4A3* and *COL4A4* genes, encoding the α3(IV) and α4(IV) collagen chains, respectively, in the autosomal form of the disease, as these chains are also prominent in the GBM. Such mutations have now been found in both the *COL4A3* and *COL4A4* genes in different Alport kindreds (Table 5).

The first mutation in the *COL4A3* gene was found in a girl with juvenile Alport syndrome accompanied by sensorineural deafness [10]. To date, five different mutations have been found in the *COL4A3* gene [10–12,156], two of them in two unrelated patients. These have been found as either homo- or heterozygous mutations in different patients. The parents have been shown to be unaffected carriers, indicating an autosomal recessive pattern of inheritance. Two of the *COL4A3* mutations are nonsense, two are small deletions in exons and one is a splice site mutation. All five mutations create premature translation stop codons, which would lead to a truncated malfunctional polypeptide.

The first mutations in the *COL4A4* gene were reported by Mochizuki and co-workers in two families with Alport syndrome (Table 5) [10]. One mutation is a glycine substitution in the collagenous domain with the probable impairment of triple helix formation. The other causes a premature stop codon in the collagenous domain and a truncated protein as a result. Recently, Boye et al. [13] analyzed the *COL4A4* gene in 31 unrelated autosomal recessive Alport syndrome patients and found ten novel mutations among eight of them (Table 5). Five of the mutations result in premature stop codons or a shift in the

[a]Mutations are designated according to Beaudet and Tsui [196].

[b]Nucleotide and amino acid residue numbering is based on Mariyama et al. [65] for *COL4A3* and on Boye et al. [13] for *COL4A4*.

[c]Exon numbering of *COL4A3* starts at the 3′ end.

[d]Exact location not known; splice-mediated insertion of an *Alu* fragment leading to two different mRNA transcripts.

reading frame, and are therefore potential null mutations. One mutation probably causes a deletion of two Gly–X–Y repeats in the collagenous region, thereby shortening the protein. Two mutations affect splicing and two are missense mutations, one a glycine substitution in the collagenous region and the other a highly conserved proline to leucine substitution in the carboxyterminal NC1 domain.

Defects in the *COL4A3* and *COL4A4* Genes in Autosomal Dominant Alport Syndrome

A much less common autosomal dominant form of the disease had already been described in 1985 [157], but recently Jefferson et al. [24] performed genetic linkage analysis of a large family with autosomal dominant Alport syndrome. X-linkage was excluded by negative results with *COL4A5* markers. Polymorphic markers across the *COL4A3/COL4A4* region showed strong linkage. Furthermore, SSCP analysis of five exons from the 3′ end of the *COL4A3* gene resulted in a band shift in exon 5, which segregated with one of the maternal haplotypes and not with the disease. Sequencing revealed a missense mutation in exon 5, changing the evolutionarily conserved leucine to proline. Lemmink et al. [11] have previously reported this mutation as nonpathogenic in two families; in this case the mutation is not pathogenic in itself, but it may lead to a more severe phenotype in affected patients who carry this abnormality. In the autosomal dominant form, males and females within a family are equally severely affected, but the phenotype is usually milder than that found in the X-linked dominant form.

ANIMAL MODELS OF ALPORT SYNDROME

To understand better the molecular pathology of Alport syndrome, several animal models have been studied. *Col4a3* knockout mice have also been produced as a model for the autosomal recessive form of the disease. In addition, there is a naturally occurring model of this same type in the English cocker spaniel. X-linked hereditary nephritis in Samoyed dogs and bull terrier hereditary nephritis are also naturally occurring models of Alport syndrome.

X-Linked Dominant Inheritance

Canine X-linked hereditary nephritis is an animal model of human X-linked Alport syndrome. Clinical manifestations are similar to those in the human disease. Studies of affected male dogs [158] showed persistent hematuria at 3–4 months of age and the occurrence of end-stage renal failure at the age of 8–15 months. By electron microscopy, bilamellar splitting of the GBM could already be seen at one month of age, progressing to GBM multilamellation and confluency by 3–4 months of age.

Genetic study of this model revealed a single base substitution, changing a conserved glycine codon (GGA) to a stop codon (TGA) in exon 35 of the α5(IV) gene [159]. Canine α5(IV) cDNA is greater than 90% identical to human α5(IV) cDNA at both the nucleotide and amino acid levels. The highly conserved noncollagenous domain (NC1) shows 93% identity at the DNA level and 97% identity at the protein level between the species. Furthermore, the sequences of the other α(IV) NC1 domains are ≥88% identical at the DNA level and ≥92% identical at the protein level to the respective human α(IV) NC1 domains [160].

The glycine substitution creating a premature stop codon is associated with an approximately 90% reduction in the amount of α5(IV) mRNA in the kidneys of affected male dogs. The single family of Samoyed dogs has provided an opportunity to study the effects of a selective absence of the α5(IV) chain on other basement membrane components. It was shown that the levels of mRNA for the α3(IV), α4(IV), and α5(IV) chains are all significantly reduced in affected dog kidney. Supporting evidence in human disease is not available, most probably as a consequence of the limited amount of material available from patient biopsies. The mechanisms for this kind of coordination are currently not understood, and as speculated by Thorner et al. [160], could include factors acting at either the transcriptional or the translational level. Western blot analysis with chain-specific antibodies revealed that α3(IV), α4(IV), and α5(IV) chains are present in the GBM of normal dogs, but undetectable in affected male dogs. Thus, a comparable situation exists between canine and human X-linked disease [160].

Autosomal Recessive Inheritance

Col4a3 Knockout Mouse

The collagen *Col4a3* knockout mouse is a model of the autosomal form of Alport syndrome [161]. These mice are homozygous for a mutation leading to the development of a progressive glomerulonephritis with microhematuria and proteinuria. By clinical examination, microhematuria was already observed at the age of two weeks, and proteinuria at about 5 weeks of age. The disease progressed to end-stage at the age of 14 weeks. By transmission electron microscopy of the GBM, it was seen that focal multilaminated thickening and thinning begins in the external capillary loops at 4 weeks and spreads throughout the GBM by 8 weeks. Half of the glomeruli were fibrotic with collapsed capillaries by end-stage.

Immunofluorescence analysis of the GBM showed the absence of the α3, α4, and α5 chains of type IV collagen. According to Northern blot data, the α3(IV) mRNA was absent from the kidneys of *Col4a3* knockout mice, whereas the α4(IV), and α5(IV) mRNAs were intact and present at levels observed in normal littermates. This is consistent with a mechanism that involves processes downstream of the mRNA and does not support the argued suprastructure destabilization theory [140], which suggests that a mutated *COL4A* gene in Alport patients might be translated into an abnormal protein that is incorporated into the suprastructure in a destabilizing manner, leading to a loss of all three components.

An absence of the α3(IV) and α4(IV) chains throughout the membranous labyrinth was revealed by immunohistochemical analysis of the *Col4a3* knockout mouse cochlea [161]. The α5 chain was absent from all cochlear basement membranes except those in the vessels of the stria vascularis. Electron microscopic examination of the cochlear membranes showed significant thinning of the basement membranes from the spiral limbus up to the spiral prominence [161], and thickening of the basement membranes surrounding the vessels of the stria vascularis. All in all, these results illustrate changes in the basement membranes of the strial vessels that bear a resemblance to Alport GBM pathology.

English Cocker Spaniel

Hereditary nephritis in English cocker spaniel dogs is a naturally occurring animal model of the autosomal recessive form of Alport syndrome. Affected dogs have proteinuria and juvenile-onset chronic renal failure. Lees et al. [162] studied 10 affected dogs, 3 obligate carriers, and 4 unaffected dogs. The dogs appeared healthy at 3–4 months of age, and proteinuria was the first abnormality detected at 5–8

months of age. Hematuria was associated with proteinuria. No signs of impaired hearing or ocular abnormalities were observed in the dogs despite a thorough examination. The disease progressed to terminal renal failure at 8–27 months of age. Ultrastructural examination of the kidneys showed thinning and thickening of the GBM in 6-month-old dogs. In dogs nearing the end-stage, marked GBM thickening and multilamellation was seen.

Immunohistochemical study showed no expression of the α3(IV) or α4(IV) chains in the kidneys of affected dogs. Interestingly, labeling for the α5(IV) chain was observed in the GBM; however, its intensity was reduced compared with normal staining. Additionally, GBM staining was positive for the α6(IV) chain in all affected dogs. Furthermore, unaffected dogs showed variable α6(IV) labeling. Adolescent dogs had no GBM labeling for the α6(IV) chain, but in older dogs labeling was segmental or diffuse. In humans, the α6(IV) chain is absent from the GBM [132], but in these cocker spaniels the α5(IV) and α6(IV) chains seemed to be co-expressed.

Autosomal Dominant Inheritance

Hereditary nephritis in bull terriers is a model of autosomal dominant Alport syndrome [163]. Common clinical features resemble those in X-linked Alport syndrome, except the lack of hearing impairment. Hematuria is much more likely to occur in animals with proteinuria than in those without, but still less than half of animals with proteinuria have hematuria. In contrast, in humans, hematuria is an early and preceding indication of the subsequent development of significant proteinuria. The ultrastructural findings of the kidney sections were identical to those seen in X-linked Alport syndrome. Immunohistologic study of kidney sections of affected bull terriers with monoclonal antibodies against Goodpasture and Alport antigens showed positive staining for both the α3(IV) and the α5(IV) chains [163].

THERAPY AND GENE THERAPY

To date, there is no satisfactory and curative conservative treatment available for Alport syndrome [164,165]. Patients developing end-stage renal disease are treated by hemodialysis, and also by kidney transplantation whenever possible. However, about 5% of transplanted patients develop anti-GBM nephritis and reject the allografted kidneys.

As a result of recent advances in molecular genetics, gene therapy may be developing into a real possibility for the treatment of a variety of hereditary diseases in the future. Although gene therapy has not yet come of age as a real therapeutic alternative for human diseases, extensive research efforts are being made in that direction. Alport syndrome, which primarily affects the renal glomeruli, is an attractive disease target for gene therapy for two reasons [165]. First of all, as it almost solely affects the kidney glomeruli, extrarenal complications not being life-threatening or occurring in all patients, the therapy can, at least initially, be targeted to the kidney alone. Secondly, the "isolated" kidneys with their well separated circulatory system lend themselves extremely well to organ-targeted gene transfer. Extensive research still needs to be carried out before we can expect to be able to do successful gene therapy of Alport syndrome in man, and there are numerous questions that need to be answered before we know if gene therapy is even theoretically possible for this disease. In the following, some of the key questions [165] concerning the possibility of gene therapy of Alport syndrome are discussed.

Can Genes be Efficiently Transferred to Renal Glomerular Cells?

The GBM is located between layers of endothelial and epithelial cells, which are both believed to contribute to the biosynthesis of the GBM type IV collagen. Due to a lack of sensitivity, methods such as *in situ* hybridization have not confirmed if one or both cell types produces the type IV collagen isoform, α3:α4:α5, characteristic of the GBM. However, from the gene therapy point of view, these cells are considered the prime targets.

In our recent work, we have shown that it may not be impossible to target gene transfer into these cells, as we have been able to achieve transfer of the β-galactosidase reporter gene into an estimated 85% of the glomeruli in pigs using an adenovirus vector (Fig. 8) [165]. The key to this high transfer efficacy was prolonged perfusion of the kidney, which allowed a long contact time between the cells and the viruses. In contrast, intra-arterial injections of the virus have not yielded efficient gene delivery to the glomeruli, as has been noted by others [166–168]. The perfusion method is relatively easy to apply to the kidney; it can be applied *in*

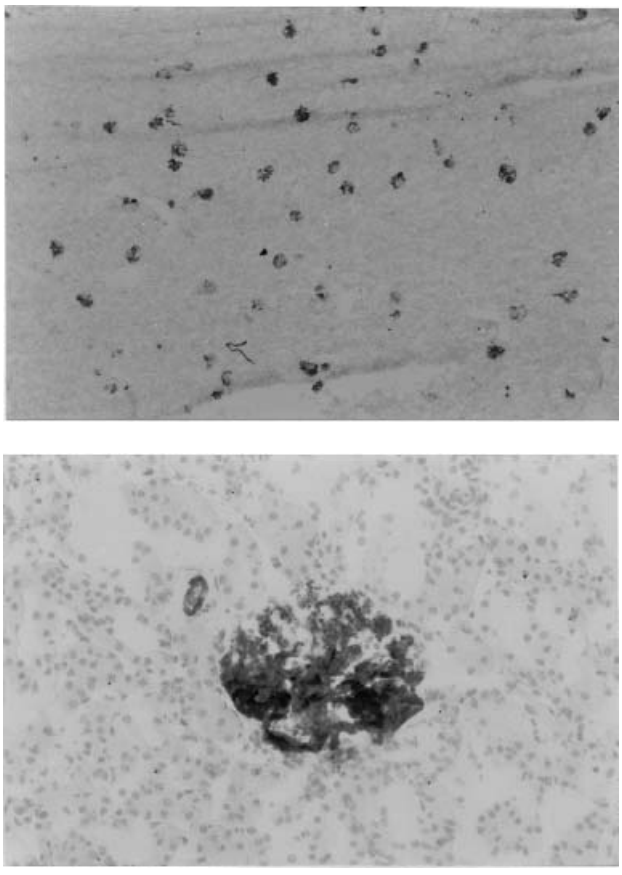

Figure 8. Expression of the β-galactosidase gene in pig kidneys following organ perfusion with a solution containing adenovirus carrying the β-galactosidase reporter gene. **A**, Intense expression can be seen in a large proportion of the glomeruli of the kidney cortex, while little if any expression is observed in other regions of the kidney. Magnification ×21. **B**, Expression of the reporter gene is generally achieved in all regions of the glomerulus, including the epithelial podocytes [165]. Magnification ×214.

situ, and may also prove useful for the transfer of genes to other organs with a well-separated blood supply.

Is It Possible to Obtain Life-Lasting and Controlled Expression of the Transferred Gene?

This is a serious problem that is the main hurdle of gene therapy in general, and it poses one of the main challenges that research in this field faces today. The adenovirus used in our experiments carried out in pigs, in its current form, provides expression for only 6–8 weeks, as it remains extrachromosomal and is not integrated into the genome [165]. Even though the half-life of type IV collagen is estimated to be between 1 and 2 years, this means that the treatment would need to be frequently repeated during life. This is not easy as, at least presently, it requires an operation. Retroviruses would theoretically be better, but they cannot integrate large DNA inserts and, also, they are only integrated into replicating DNA which is not appropriate for the stationary glomerular cells. Therefore, successful gene therapy of Alport syndrome in man will have to depend on future developments in research on gene transfer vectors.

Will a Transferred Type IV Collagen cDNA or Gene Coupled to an Appropriate Promoter be Expressed in a Controlled Manner, and Will the Corrected Chain be Incorporated into Normal α3:α4:α5 Heterotrimers?

We have already been able to express the full-length α5 chain transferred by adenoviruses in cultured cells, as well as in pig glomeruli *in vivo* (unpublished data). The fact that GBM type IV collagen is a heterotrimer is probably favorable, because it means that the limiting factor for intracellular synthesis of the trimer is likely to be the availability of the two other partner chains. Thus, if one chain is produced in excess, it will be degraded intracellularly. It has been shown that α1(IV) mRNA can exist in 3- to 15-fold excess over α2(IV) mRNA, even though the ratio of the respective chains in the protein is 2:1 [169]. If production of the defective chain can be corrected to some extent, the secretion of normal molecules is likely to occur, even in the presence of some abnormal malfunctional molecules. However, only experimental work will prove or disprove such a speculation.

Can Corrected Type IV Collagen Trimers be Incorporated into the GBM and Restore Its Structure and Function?

This is still an open question that will have to be addressed experimentally in animal models. However, observations from heterozygous female dogs have shown that although the glomeruli are chimeric for the gene defect, it appears that normal molecules can spread within the GBM to restore its structure [170]. Thus, it can be anticipated that this may not turn out to be a major obstacle to gene therapy of Alport syndrome.

RECENT DEVELOPMENTS

The fairly late onset of end-stage renal disease (ESRD) in Alport syndrome can be explained by a failure of the developmental switch between the fetal α1:α2 type IV collagen network and the adult α3:α4:α5 network in the GBM, as demonstrated by Harvey et al. [207]. Their studies of glomerular development in the X-linked canine model indicated that the α1:α2 network is essential for normal development, whereas the α3:α4:α5 network is essential for the long-term stability of the GBM and the maintenance of glomerular function. Thus, progression to ESRD, at least in X-linked Alport syndrome, results from a congenital malformation of the GBM which, alone, is not sufficient to cause disease. Rather, the GBM composed of the "fetal" collagen network is more prone to postnatal deterioration that, in the long term, leads to kidney dysfunction.

How a mutation in one of the genes coding for one of three α(IV) chains in the GBM leads to malfunction of the whole α3:α4:α5 network remains an open question. To clarify this issue, Boutaud et al. [208] studied the NC1 domain of type IV collagen and noted that there are recognition sequences within the NC1 monomers that specify the selection of chains and monomers, and thereby regulate the assembly of two different networks in the GBM. Mutations in the NC1 domain may, then, interfere with the assembly of the α3:α4:α5 network through a failure in the assembly of the NC1 hexamer. Further studies with the NC1 domains of smooth muscle basement membrane [209] has revealed an identical mechanism for specifying the chain-specific assembly of the α1:α2 and α1:α2:α5:α6 networks. The failure of such a mechanism when applied to a network containing both the α5 and the α6 chain, may explain the loss of both of these chains from basement membranes in X-linked Alport syndrome patients in whom the α5 chain is mutated.

Thus far, prediction of the phenotype produced by a particular mutation in the *COL4A5* gene has been difficult. Jais et al. [210] have now reported a multicenter study of 195 European Alport syndrome families demonstrating genotype-phenotype correlations in males. All patients had hematuria and the rate of progression to ESRD and deafness correlated with the type of mutation. Those affected male patients with large deletions, nonsense mutations, or small mutations changing the reading frame, had a 90% probability of developing ESRD before 30 years of age. The comparable risk was 70% in patients with splice-site mutations and 50% in those with missense mutations. The risk of developing hearing loss before the age of 30 years was 60% in male patients with missense mutations, and 90% in those with the other types of mutations. Three of the 118 male patients who had received kidney transplants, each of whom had a large *COL4A5* deletion, developed anti-GBM nephritis. Nevertheless, even if it is the case that some types of mutations may constitute a higher risk, it is still unclear which factors would influence the initiation and elaboration of the immune response to an allograft.

Even with the most powerful methods currently available for mutation analysis of the *COL4A5* gene, about 10% of mutations have remained unidentified in documented cases of X-linked Alport syndrome. We determined to see if an alternatively used 18 bp sequence, described in the type IV collagen α5 chain mRNA from human kidney [211], might provide any explanation for the situation in such cases [212], and have shown this 18 bp sequence to be composed of two separate, novel 9 bp exons. The predicted amino acid sequence encoded by each of these exons contains a Gly–X–Y repeat sequence, either one or both of which is used depending on the tissue [212]. Mutation analysis has not revealed any sequence variations in the two exons to date.

Chapter 26, Part I

Corneal Dystrophies Due to Mutations in the Kerato-Epithelin Gene (β*ig-h3*)

Joel Rosenbloom

Department of Anatomy and Histology, School of Dental Medicine, University of Pennsylvania, Philadelphia, Pennsylvania, 19104

CLINICAL ASPECTS

Groenouw type I (MIM 121900) and lattice type I (MIM 122200) corneal dystrophies are the most frequent heritable blinding diseases of the cornea. The phenotypes are characterized by autosomal dominant transmission with complete penetrance but variable morbidity. Painful corneal erosions usually develop in the second decade, resulting in progressive visual impairment often necessitating corneal transplantation. White granular opacities form in granular corneal dystrophy Groenouw type I (GCD), often accumulating subepithelially and between stromal lamellae [1]. In lattice type 1 corneal dystrophy (CDL1), linear, branching, fibrillar amyloid deposits opacify the cornea [2]. In the combined Avellino (ACD) granular-lattice phenotype, both granular and lattice alterations occur [3,4]. The Reis-Bucklers (CDRB) type (MIM 121900) appears mainly to affect Bowman's membrane and the superficial stroma [5]. Compelling genetic and DNA sequence evidence prove that all of these dystrophies are caused by mutations in βig-h3 (called kerato-epithelin in the ophthalmologic literature) as follows: Arg555Trp in GCD, Arg555Gln in CDRB, Arg124Cys in CDL1, and Arg124His in ACD [6]. Recently, the late-developing lattice IIIA type characterized by thick, ropy branching lattice lines has been shown to be caused by a Pro501Thr missense mutation (see Fig. 1) [7].

There have been relatively few studies directly linking βig-h3 expression to abnormal deposits in the dystrophic corneal stroma. By *in situ* hybridization of human cornea with Fuchs' dystrophy (MIM 136800), Hirano localized βig-h3 mRNA to both the corneal epithelium and endothelium. Immunohistochemical studies demonstrated positive antibody staining of the subepithelial matrix, an abnormal Descemet's membrane, and a posterior collagenous layer [8]. In a study of CDL1, Takacs showed positive staining of subepithelial matrix deposits, and, in addition to a 68 kDa protein band, a 42 kDa band was detected by Western blot analysis using a βig-h3 polyclonal antibody [9]. Corneas from patients with GCD showed βig-h3 reactive subepithelial deposits as well [10]. In the most comprehensive localization study to date, Streeten et al. [11] demonstrated that in normal corneas, immunoreactivity for βig-h3 was strongest in Bowman's membrane, and next strongest along stromal interlamellar junctions and attachment sites of collagen to Descemet's membrane. Antibody binding was intense on dystrophic aggregates found in GCD, CDL1, ACD, and CDRB. Collectively, these data support the hypothesis that βig-h3 is a major component of the deposits, if not the main one. However, there is clearly a need for more definitive information concerning the expression of βig-h3 during normal corneal development and progression of the dystrophic conditions.

MOLECULAR ASPECTS

Identification and Cloning of β*ig-h3*

cDNA encoding the protein, βig-h3, was originally isolated by differential screening of a cDNA library prepared from the human adenocarcinoma cell line, A549, which had been treated with TGF-β1 [12]. The encoded 70 kDa protein of 683 amino acids contains a secretory signal at the amino terminus and is composed largely of four repeats of approximately 135 residues. Subsequently, a highly homologous murine protein was cloned [13]. The human gene was localized to chromosome 5q31 and the mouse gene to the syntenic chromosome 13 region B to C1 [13]. A number of cultured cell lines were shown to express the protein, usually at low levels, and TGF-β1 markedly up-regulated expression in many, but not all, cells tested. Northern analysis demonstrated that βig-h3 was expressed in a variety of human and mouse tissues with the highest levels found in uterus, but easily detectable levels of mRNA were found in heart, mammary gland, prostate, skeletal muscle, testis, thyroid gland, kidney, liver, and stomach. Expression was absent in brain, spleen, and parathyroid gland. At the time of its original identification, the only protein exhibiting limited homology to βig-h3 was fasciclin-1, a glycoprotein expressed in the grasshopper and *Drosophila* central nervous systems which may be involved in growth cone guidance [14].

In 1996, Gibson et al. [15] demonstrated that the sequences of five peptides isolated from a protein found in bovine ligamentum nuchae, a tissue particularly rich in elastic fibers, were very similar to sequences in βig-h3. This suggested that this protein, designated MP70, was a bovine

Connective Tissue and Its Heritable Disorders, pages 1103–1106

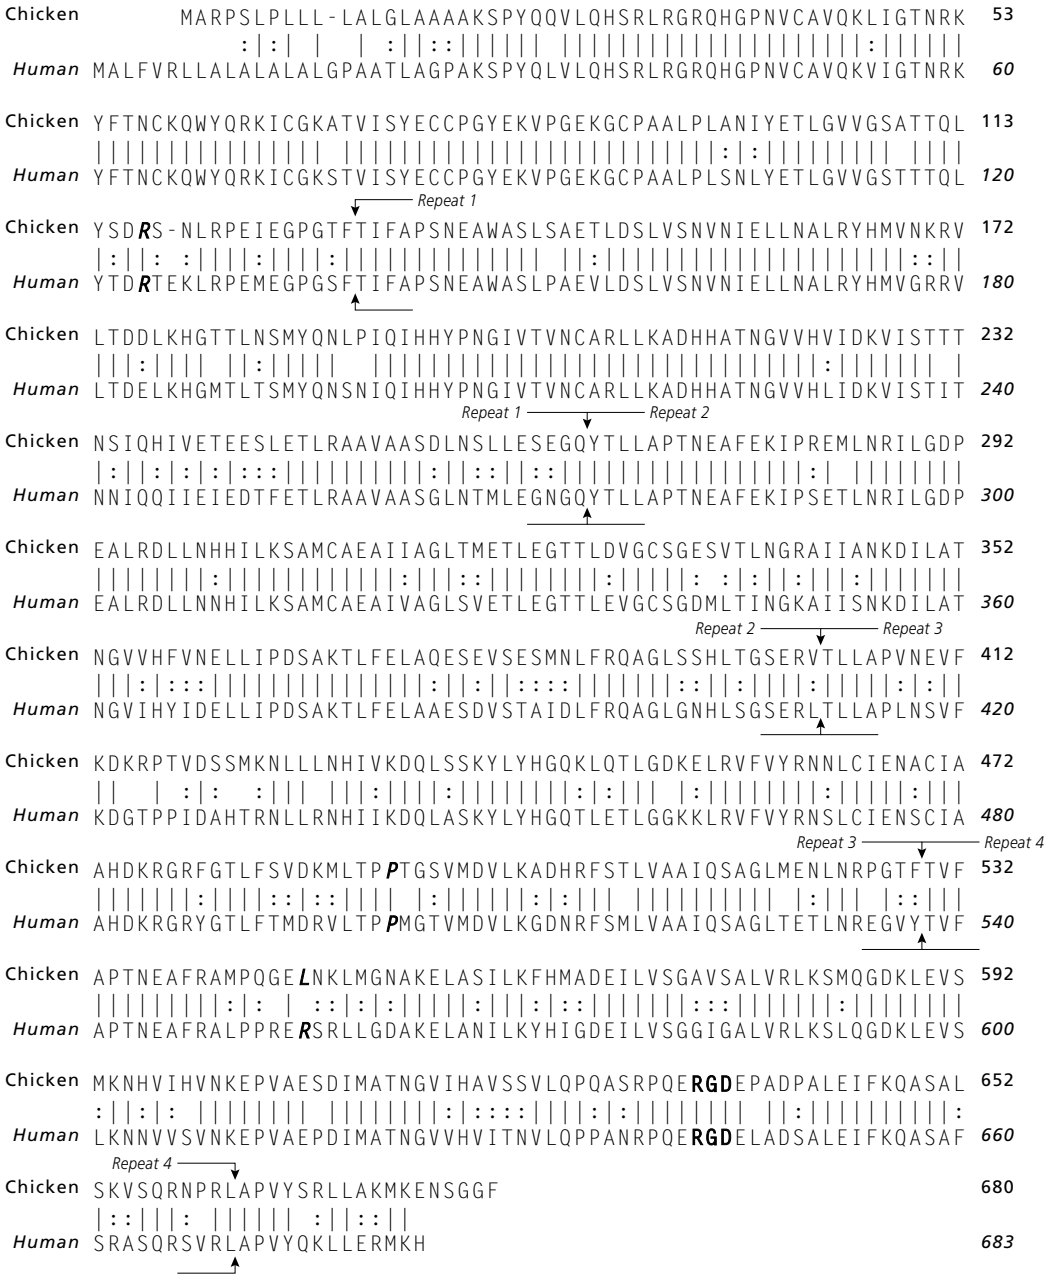

Figure 1. Comparison of the amino acid sequences of human and chick βig-h3 with the four repeat domains indicated. Within each repeat, there are two highly conserved sequences of 10 (H1) and 11 (H2) residues that are not shown in the figure. A vertical line (|) indicates complete identity, a colon (:) indicates amino acid residues with similar characteristics, and a space indicates no homology. The bolded RGD (Arg–Gly–Asp) is the consensus sequence for integrin binding. Italicized and bolded are residues 124, 501, and 555 in the human sequence which are mutated in the corneal dystrophies.

form of βig-h3. The isolation procedure used by Gibson et al. [15] was designed specifically to solubilize the microfibrillar component of elastic fibers and MP70 has tentatively been identified as a microfibrillar protein.

cDNAs encoding chick, pig, and rabbit βig-h3 have also been cloned [16–18]. Sequence analysis has demonstrated that the mammalian protein is highly conserved (~90–92% identity among species), and that there is strong homology between mammalian and chick βig-h3 (~77% identity). Such strong structural conservation argues for an important, although presently unknown, function(s). Other proteins having more limited homology to βig-h3 include osteoblast-specific factor 2 (OSF2) and several bacterial proteins [19,20].

Analysis of βig/h3 Primary Structure

Figure 1 contains a comparison of the amino acid sequence of human and chick βig-h3 with the four repeat domains indicated. Within each repeat, there are two highly conserved sequences of 10 (H1) and 11 (H2) residues (not identified in

the figure). The three residues of the human sequence (124, 501, and 555) shown to be mutated in corneal dystrophies are also identified in bold. Note that while residues 124 and 501 are conserved between species, residue 555 is not. A Leu residue is found in this position in the chick, while Arg is found in all other species analyzed. Interestingly, as discussed above, mutation of this residue to Trp or Gln appears causal for corneal granular dystrophies Groenouw type 1 and Reis-Bucklers, respectively. Note that the presence of a Leu in chick indicates that at least one type of hydrophobic residue in this position is compatible with normal function and it remains a challenge to determine why others are not.

Potential Functions of βig-h3

βig-h3 has been shown to enhance the attachment and spreading of dermal fibroblasts, suggesting that it functions as an extracellular attachment protein in skin [21]. Indeed, the protein contains an RGD cell attachment/integrin recognition site in its C-terminal region. The distribution of βig-h3 has been examined in fetal bovine tissues by immunohistochemical analysis [22]. This analysis showed that βig-h3 was associated with collagen fibers in developing nuchal ligament, aorta, lung, and mature cornea. Immunoreactive material was also present in reticular fibers in fetal spleen, as well as in capsular and tubular basement membranes in developing kidney. From this study, it was concluded that the staining pattern closely resembled that of Type VI collagen microfibrils. Type VI collagen copurified with βig-h3 upon extraction from rabbit corneas [18] and was colocalized in double immunolabeling experiments [8]. In addition, βig-h3 has been reported to bind in a non-ionic fashion to types I, II and IV collagens [16], and to the globular domain of type VI collagen [23]. These data suggest that βig-h3 may act as a link protein interconnecting specific matrix components, such as collagens, with each other and resident cells.

Expression of βig-h3 in the Cornea

The most detailed studies of the expression of βig/h3 expression have been carried out in the cornea. The major function of the corneal stroma is to act as a strong transparent structure that is responsible for greater than 50% of the refraction required to focus light on the retina. Thus, the biochemical composition and molecular interactions of its extracellular components, including βig-h3, are crucial to its function. Similar levels of βig-h3 mRNA were detected by reverse transcriptase/polymerase chain reaction in 23-day fetal and neonatal rabbit corneas, while it was not detectable in adult corneas [24]. In normal human corneas, Hirano et al. [8] showed that βig-h3 was present in Bowman's membrane and that it appeared to be associated with collagen in the stroma, while Escribano et al. [25] and Takacs et al. [9] showed that βig-h3 was preferentially localized to the corneal epithelium. It is likely that βig-h3 is expressed by corneal epithelium and endothelium as well as by stromal fibroblasts. Further studies are needed to define more precisely the expression of βig-h3 during normal development and to delineate its function.

RECENT DEVELOPMENTS

βig-h3

The murine gene has been cloned and characterized [26]. The gene spans 30 kb on mouse chromosome 13 and is very similar in structure to the human gene, with conservation of exon/intron organization. In the developing mouse, expression is observed as early as day 11.5 in the first and second branchial arches, and the gene is strongly expressed in many mesenchymal tissues throughout development. Expression is seen at day 11.5 in the mesenchyme surrounding the optic stalk, by day 14.3 in the sclera and choroid, and by day 17.5 in the cornea.

Progressive Pseudorheumatoid Dysplasia

Wafaa M. Suwairi and Matthew L. Warman

Department of Pediatrics, Riyadh Armed Forces Hospital, Riyadh, Kingdom of Saudi Arabia (W.M.S.); Case Western Reserve University School of Medicine and University Hospitals of Cleveland, Cleveland, Ohio 44106 (M.L.W.)

INTRODUCTION

Progressive pseudorheumatoid dysplasia (PPD) (MIM 208230) was initially reported by Wynne-Davies et al. as spondyloepiphyseal dysplasia tarda with progressive arthropathy [1], and by Spranger et al. [2] as progressive pseudorheumatoid arthropathy of childhood. Several additional patients and families have since been described [3–15]. The hallmark features of this syndrome are childhood-onset joint swelling, stiffness, contractures, and pain. Joint involvement is noninflammatory. Radiographic examination indicates a spondyloepiphyseal dysplasia; however, radiographic changes may not be present in very young children. There are no extraskeletal manifestations in PPD. In contrast to other forms of spondyloepiphyseal dysplasia tarda, the joint involvement in PPD is unremitting and often debilitating. The disorder has been mapped to human chromosome 6q22 [16]. Locus homogeneity appears likely [17,18] and a responsible gene, *WISP3*, has been identified [19]. This gene encodes a member of the CCN (connective tissue growth factor, cysteine-rich protein 61, nephroblastoma overexpressed) family of secreted growth regulators [20–23]. The precise function of WISP3 during skeletal growth and homeostasis is not known.

CLINICAL FEATURES

Nearly all affected patients appear normal at birth and during infancy. Signs and symptoms of disease usually have their onset between three and 11 years of age. Signs in young children may include muscle weakness, easy fatiguability, and difficulty walking. Several affected children have come to medical attention because of a waddling or awkward gait, or bowed legs. Fusiform swelling or an enlargement of finger joints, particularly the proximal interphalangeal joints, often precedes other joint complaints (Fig. 1). This feature suggests a diagnosis of juvenile rheumatoid arthritis; however, patients have neither local nor systemic inflammatory disease. Patients have normal intelligence, a normal facial appearance, and no extraskeletal findings. With advancing age, multiple joints become affected. Stiffness and contractures occur first, followed by unremitting pain, particularly in the hips and knees. By young adulthood, nearly all joints are affected (Fig. 1). Clinical spinal involvement may manifest as scoliosis, lordosis, or kyphosis. Joint pain is often debilitating and poorly controlled by steroidal or nonsteroidal anti-inflammatory agents. Affected patients often become wheelchair dependent by their second and third decades of life. Surgical release of joint contractures does not appear to provide long-term relief. In contrast, joint replacement surgery has been performed in several patients and has been noted to improve mobility and to alleviate pain.

HISTOPATHOLOGY

Results of an iliac crest biopsy have been reported in a single patient [2]. This biopsy revealed abnormal clustering of chondrocytes in the resting and proliferating cartilage. Growth zone cell columnization was defective and many cells had pycnotic nuclei. Skin biopsies and synovial biopsies have been normal in several patients.

RADIOGRAPHIC FEATURES

Because signs and symptoms have not been apparent in most affected patients until mid-childhood, few published reports describe pre-symptomatic radiographic findings. At least three children with PPD have had limited radiographic studies in infancy for unrelated respiratory disease. None had a recognized skeletal dysplasia.

Evidence of skeletal dysplasia becomes apparent with advancing age. By late childhood, most children will have clear radiographic signs of PPD. These include large-appearing epiphyses and metaphyses (particularly in the hips, hands, and knees), joint space narrowing, and peri-articular osteopenia. Platyspondyly develops in all patients, but may not be apparent in younger children [12]; for example, a child presumed to be affected with PPD had platyspondyly at 9 years of age, but a normal-appearing spine at 7 years of age [24].

DIFFERENTIAL DIAGNOSIS

The common joint disorder juvenile rheumatoid arthritis (JRA) must be considered in all young children. In contrast to children with JRA, children with PPD have no evidence of inflammatory joint disease. With advancing age, radiographic findings clearly differentiate PPD from JRA and other inflammatory arthropathies [7,11].

Connective Tissue and Its Heritable Disorders, pages 1107–1109

Also note wheelchair reliance due to severe large joint pain. **Top right**: Bony enlargement and flexion contractures at the elbows. **Bottom**: Bony enlargement affecting all proximal and distal interphalangeal joints. (Photographs courtesy of Dr. J. Kenneth Herd.)

Patients with type II and type XI collagenopathies can also have enlarged epiphyses and signs of a spondyloepiphyseal dysplasia (see also Chapter 23, Part II, this volume). Such patients often have extraskeletal features such as mild facial dysmorphism, myopia, retinal detachment, a bifid uvula, cleft palate, or sensorineural hearing loss. However, in contrast to collagenopathies that lead to precocious osteoarthritis necessitating joint replacement surgery, the joint pain in PPD appears more severe and is more rapidly progressive.

X-linked spondyloepiphyseal dysplasia also can present in mid-childhood to late childhood. Boys are principally affected and the clinical course is generally much milder than that of PPD [25,26] (see also Chapter 23, Part II, this volume).

GENETICS

PPD is an autosomal recessive disorder. Its prevalence has been estimated at one per million in the United Kingdom [1]. It is likely to be greater in countries with higher rates of consanguinity [27]. The majority of published patients with PPD have been offspring of consanguineous unions. Penetrance appears complete. The locus for PPD has been mapped to human chromosome 6q22 using DNA from a single large consanguineous kindred [16]. Linkage studies in eight other families are consistent with this map location and suggest that PPD is locus homogeneous [17–19].

Linkage analysis suggested the PPD candidate interval would be 2 million megabases in size. A sequenced bacterial artificial chromosome could be placed within this interval because it contained a genetic marker that was fully linked to the PPD phenotype. This bacterial artificial chromosome also contained a putative gene that was similar to, but clearly distinct from, the gene encoding connective tissue growth factor. This new gene, *WISP3*, was tested as a candidate for PPD, with the result that nine published and several unpublished disease-causing mutations were identified in affected patients [19].

Mutations include both large and small deletions, reading frame-shifts, and nonsense and missense mutations. The latter typically alter one of the protein product's highly conserved cysteine residues. It is hypothesized, but not yet proven, that the disease-causing mutations result in a loss of WISP3 function. Whether dominant skeletal phenotypes may result from dominant-negative mutations in this protein is not known. While the PPD work was in progress, the gene was independently identified and named *WISP3* (Wnt-induced secreted protein-3) by investigators interested in downstream genes in the Wnt signaling pathway that may be involved in malignant transformation [20]. WISP3 coding sequence is contained within five exons. Coding sequence mutations have been found in most, but not all, patients that are clinically diagnosed with PPD [19]. At this time, it is not known whether the inability to find mutations in all patients reflects locus heterogeneity, phenocopy, or mutations in as yet uncharacterized *WISP3* regulatory elements.

WISP3 PROTEIN

WISP3 is a member of the CCN (connective tissue growth factor, cysteine-rich protein 61, nephroblastoma overexpressed) protein family [21]. At present, this family has six different members (CTGF, Cyr-61, Nov, WISP1, WISP2, WISP3), all of which appear to be cysteine-rich, secreted proteins likely to be involved in regulating cell growth and differentiation and morphogenesis [22,23]. The different patterns of expression and the effects upon cells in culture of CCN family members indicate that they have nonredundant roles. WISP3 mRNA is not detected by standard Northern blot analysis; however, it can be amplified by reverse-transcription PCR from several tissues including cartilage, synovium, kidney, prostate, and testis [19,20]. The precise function of WISP3 during skeletal growth and homeostasis is not presently known.

Chapter 26, Part III

The Camptodactyly-Arthropathy-Coxa Vara-Pericarditis Syndrome

Wafaa M. Suwairi and Matthew L. Warman

Department of Pediatrics, Riyadh Armed Forces Hospital, Riyadh, Kingdom of Saudi Arabia (W.M.S.)
Case Western Reserve University School of Medicine and University Hospitals of Cleveland, Cleveland, Ohio 44106 (M.L.W)

INTRODUCTION

Familial arthropathy associated with congenital flexion deformity of the fingers was described by Jacobs in 1965 [1]. Additional families have since been reported and the phenotypic spectrum of this autosomal recessive disease (MIM 208250) has broadened [2–11]. The hallmark features of the syndrome remain congenital or early-onset camptodactyly and noninflammatory, childhood-onset, large-joint arthropathy. Other features can include progressive coxa vara deformity, noninflammatory pericarditis, and occasionally pleuritis and peritonitis. The disorder has been mapped to chromosome 1q25 and it appears to be locus homogeneous [10]. The responsible gene, *CACP*, has been identified [12], and encodes a large, highly glycosylated protein that is synthesized and secreted by synoviocytes and superficial zone chondrocytes [12–14]. The precise function of this protein is unknown; however, it may be involved in the lubrication of joints and tendons and in the regulated growth of intimal cells.

CLINICAL FEATURES

Camptodactyly principally affects the first metacarpophalangeal joint and the proximal interphalangeal joints (Fig. 1). Camptodactyly, which has occurred in all published cases, has either been present at birth or has been recognized during the first few months of life. Involvement is bilateral, but need not be symmetrical. Finger contractures are generally painless, but may be progressive. Tendon releases have improved function. Toes can also be affected.

Arthropathy begins during early childhood and is most apparent in large joints, such as the wrists, hips, knees, elbows, and ankles (Fig. 1). It has been present in all published cases. Affected joints appear swollen and feel "boggy" due to thickening of the synovium, but do not appear inflamed and are neither red nor warm to the touch. Joint swelling and a reduced range of motion are early signs of the arthropathy. Symptoms of pain and stiffness are reported by some patients. Little information is available regarding the long-term prognosis of the arthropathy. Joint pain is temporarily relieved by nonsteroidal anti-inflammatory drugs and by physiotherapy. Synovectomy has been performed in some patients; however, the long-term effects of this procedure have not been reported. Joint involvement is not debilitating in many patients; however, some patients do require hip and/or knee joint replacement surgery for progressive joint disease.

Coxa vara deformity has been observed in 60% of published cases and is progressive. It can be detected by radiographic examination in younger patients and is often suspected on the basis of clinical examination in older patients. The precise cause of the deformity is unknown. It may represent a primary dysplasia or a secondary abnormality of femoral neck growth associated with the arthropathy.

Clinical pericarditis has been observed in 30% of published cases. Siblings have been discordant for this feature, yet concordant for other component features. Pericarditis does not respond to anti-inflammatory agents. It may clinically disappear or it may progress to life-threatening constrictive heart failure. The latter has been successfully treated by pericardectomy.

HISTOPATHOLOGY

The absence of inflammation in synovial aspirates and synovial biopsies distinguishes the camptodactyly-arthropathy-coxa vara-pericarditis syndrome (CACP) from the more common childhood disorder, juvenile rheumatoid arthritis. Patients with CACP can have synoviocyte hyperplasia, diffuse villous hypertrophy with necrosis, and islands of free floating villi in synovial fluid. Multinucleate giant cells are occasionally seen; however, there is no other evidence of inflammation, such as infiltrating lymphocytes, plasma cells, neutrophils, or perivascular cuffing. Scarring between tendon and tendon sheath has been described in pathological material removed during tenosynovectomy for camptodactyly. Affected fibrous pericardium has shown both intimal cell hyperplasia and subintimal thickening, again without evidence of inflammation. Fibrin deposition has been observed on the intimal surfaces of synovium, tenosynovium, and pericardium.

Connective Tissue and Its Heritable Disorders, pages 1111–1114

RADIOGRAPHIC FEATURES

Coxa vara deformity has been observed in the majority of patients and is progressive. Subchondral bone cysts may occur in the femoral head and acetabulum. Periarticular osteoporosis may occur at affected joints. Significant skull, spine, and apical extremity involvement have not been described.

DIFFERENTIAL DIAGNOSIS

CACP is a noninflammatory, nongranulomatous disease. It is thus distinguished from the more common disorder, juvenile rheumatoid arthritis, and rare autosomal dominant disorders such as Blau syndrome [15] (MIM 186580), familial arthritis and camptodactyly [16] (MIM 108050), and familial erosive arthritis with camptodactyly [17]. Patients with CACP have a normal facial appearance, and do not show signs of respiratory distress, which distinguishes CACP from the syndrome of progressive laryngotracheal stenosis with short stature and arthropathy [18] (MIM 603391).

GENETICS

CACP is an autosomal recessive disorder, the precise incidence of which is not known. Many patients affected with CACP have been the offspring of consanguineous unions. The number of published cases remains small (less than 50 patients); penetrance appears complete, whereas clinical expression is variable. The locus for CACP was mapped to human chromosome 1q25 using DNA from four consanguineous kindreds. Unpublished linkage analyses and mutation detection studies in other affected families suggest that the disorder is locus homogeneous.

The identification of the responsible gene, *CACP*, was facilitated by random sequencing of a bacterial artificial chromosome contig across the 2 mb CACP candidate interval on chromosome 1. Sequence encoding the megakaryocyte stimulating factor precursor protein was found. Because this sequence was also represented as an expressed sequence tag (that is, a cDNA fragment) in a synoviocyte cDNA library, it was tested positively as a candidate for causing CACP [12]. To date, seven published, and several unpublished, disease-causing mutations have been identified within it, all of which have been reading frame-shifts or nonsense mutations causing truncation of the protein. Coding sequence mutations have not been identified in all patients with clinical CACP, for which there are two likely explanations. First, one of the 12 coding exons within the gene is quite large and difficult to sequence rigorously. Second, noncoding regulatory regions of the gene are not known and therefore have not been systematically screened for mutations. A

third possible explanation for the failure to find all disease-causing mutations is locus heterogeneity; however, this is least likely, since several affected patients have had one of their two mutant *CACP* alleles detected and other patients with undetected mutations still demonstrate genetic linkage to human chromosome 1q25.

CACP PROTEIN

The precise biologic function of the *CACP* gene is not known. Its mRNA is highly expressed in synoviocytes and pericardiocytes, but it is also expressed in several other tissues, including liver. Because the protein product was initially identified as a megakaryocyte stimulating factor [19], one of its roles may be to regulate cell growth. The *CACP* gene encodes a 1404 amino acid residue polypeptide with a predicted molecular weight of 151 kDa; however, its megakaryocyte stimulating factor activity is contained within a 25-kDa fragment. The *CACP* gene product has also been identified in bovine and human joints as a proteoglycan expressed by superficial zone chondrocytes [20,21] and as a major boundary lubricant [14]. The *CACP* gene product has a large mucin-like domain that is rich in serine and threonine residues and highly glycosylated with O-linked oligosaccharides. Other protein domains may be involved in cell surface binding or matrix binding. Taken together, these biochemical and biophysical properties of the *CACP* gene product suggest it will be involved in lubricating and protecting cells on the surfaces of tendons and joints. The protein may also have this role at other intimal cell surfaces such as those of pericardium, pleura, and peritoneum.

RECENT DEVELOPMENTS

Faivre et al. [22] have reported clinical and linkage data for 12 individuals affected with CACP from eight unrelated families. The authors note that the earliest description of the condition may be that of Didier, in 1953 [23], and that spine and hip involvement may be more common than previously thought. In providing a follow-up of Didier's patient after more than 40 years, they observed "joint involvement gradually increased and tended to become incapacitating with age" in this individual. In addition to adding to the clinical delineation of CACP, the authors also support locus homogeneity for CACP based upon their genetic linkage analyses.

Chapter 26, Part IV

Bruck Syndrome

Beat Steinmann and Peter M. Royce

Division of Metabolism and Molecular Pediatrics, Department of Pediatrics, University of Zurich, Switzerland

CLINICAL FEATURES

Bruck syndrome (BRKS; MIM 259450) presents with symmetrical joint contractures and pterygia of elbows and knees at birth. Recurrent fractures of ribs and long bones reminiscent of osteogenesis imperfecta occur in infancy and early childhood, as well as bowing of long bones, dimpling of the skin, osteopenia, Wormian bones and basilar impression. Normal anthropometric measurements are seen at birth and in infancy. Growth deficiency from early childhood results in short stature. Kyphoscoliosis is seen in all patients. In contrast to osteogenesis imperfecta (OI), most patients do not have blue sclerae, hearing loss or dentinogenesis imperfecta; also atypical of OI is the presence of clubfoot which occurs in Bruck syndrome. None of the reported patients is able to walk without aids. Some older patients have died from restrictive lung disease. The presence of pterygia suggests that lack of movement of the affected joints commences early during embryological development.

Bruck syndrome is exceptionally rare. Mackenzie [1], in a series of 37 cases of arthrogryposis multiplex congenita, found only one infant with associated osteogenesis imperfecta, who seems to have been the first reported case of Bruck syndrome, although no clinical description was given. The first clinical description of a patient with Bruck syndrome among the total of 21 patients known today was reported from India [2]; among the other 20 are one from India [3], four from South Africa and one from Zimbabwe [4], two from Pakistan [5], one from Germany [6], one Caucasian from North America [7], five from Kurdistan [8], one from Egypt [9], three from Belgium [10], and one from Australia [11].

Viljoen et al. [4] believed that Bruck [12] was the first to describe the particular combination of clinical manifestations of arthrogryposis multiplex congenita and osteogenesis imperfecta, and eponymously attached Bruck's name to the disorder. Steinmann [13], however, pointed out that Bruck's patient had a normal postnatal stature and quite different progressive bone changes (fractures, deformations), and joint contractures starting only at the ages of 14 and 18 years, respectively, and thus did not have what we now call Bruck syndrome.

INHERITANCE

Bruck syndrome is most likely an autosomal recessively inherited disorder because of its multiple occurrence in sibs of both sexes and the existence of several patients born to consanguineous parents. It has a wide geographic distribution (see above). Obligate heterozygotes seem to be asymptomatic although no densitometric studies of bone have been performed.

The disease locus has been localized by homozygous mapping in the family reported by Breslau-Siderius et al. [8] to chromosome 17p12, within a region of maximally 18 cM between markers D17S969 and D17S2196 [14], but the gene itself has not yet been characterized (R.A. Bank, personal communication 2001). In two families, including that of the patient of Sillence et al. [11], linkage analysis suggests a second location other than 17p12 (D. Sillence and R. Bank, personal communications 2001); the patients in these two families, therefore, justify a splitting of Bruck syndrome to include a type II form contrasting with the type I form in the family reported by Bank et al. [14]. The urinary pyridinoline profile is the same in patients with either type (see below). In the two Bruck syndrome type II patients, two different disease-causing mutations in a conserved region of a lysyl hydroxylase gene have been identified (R. Bank, personal communication, 2001).

PATHOGENESIS

Bank et al. [14] provided convincing, though indirect, evidence that a bone-specific collagen telopeptidyl lysyl hydroxylase is deficient in Bruck syndrome. In bone collagen I from patients with the type I form of the disorder, substantial amounts of bifunctional cross-links were found, indicating that collagen in the extracellular matrix met the spatial requirements for cross-linking. However, the relative abundances of different bifunctional (lysinonorleucine [LNL] and hydroxylysinonorleucine [HLNL]) and trifunctional cross-links (lysyl pyridinoline [LP] and hydroxylysyl pyridinoline [HP]) were completely different from what is observed in normal bone, in that there was a preponderance of cross-links derived from lysyl residues in the telopeptides compensating for the very low amounts of

Connective Tissue and Its Heritable Disorders, pages 1115–1117

telopeptidyl hydroxylysine-derived cross-links. In contrast, the normal levels of unmodified and glycosylated hydroxylysine in the triple helix indicated that the hydroxylation defect was limited to the telopeptides and thus different to that in the kyphoscoliotic type of the Ehlers-Danlos syndrome (EDS VI; see Chapter 9, this volume). The most likely explanation for these results is that Bruck syndrome is caused by the lack of an enzyme capable of hydroxylating telopeptidyl lysyl residues. The normal cross-linking in ligament (collagen I) and cartilage (collagen II) indicate a normal telopeptidyl lysyl hydroxylation in these tissues. Thus, Bruck syndrome not only provides circumstantial evidence for the existence of a telopeptidyl-specific lysyl hydroxylase; it also suggests the existence of a tissue-specific form, in that only bone collagen I is affected. Identification of the specific gene, the possibility of its transcriptional/translational control by a gene on chromosome 17p12, and mutations in each of these in Bruck syndrome type II and type I, respectively, provide further very strong support for the existence of the enzyme postulated by Royce and Barnes [15] and Steinmann et al. [16].

In the turkey leg tendon mineralization model, major changes occur in the cross-link profile of collagen I during transition of the tendon from unmineralized to mineralized tissue [17], this being characterized in the latter by a high proportion of bifunctional cross-links, a relatively low HP content, and the presence of significant amounts of LP. These findings suggest that correct cross-linking is critical for proper mineralization, a suggestion supported by the observation that, in the almost complete absence of HP and LP, a deficiency of mineral in relation to the organic matrix is seen, as well as an increase in size of the hydroxyapatite crystals [6]. The bone brittleness observed in Bruck syndrome is most likely caused by a combination of diminished cross-linking via the telopeptidyl hydroxylysine route and subsequent defective mineralization.

Earlier reported findings are compatible with those of Bank et al. [14]. Collagen extracted from bone with pepsin is normal with regard to hydroxylysine content and the relative proportions and electrophoretic mobilities of the α1(I), α2(I), β, and γ chains of collagen I [6,14], and collagens produced by fibroblasts are also normal in these respects [7,8,10].

DIAGNOSIS, DIFFERENTIAL DIAGNOSIS, AND MANAGEMENT

The diagnosis of Bruck syndrome is suspected clinically, and confirmed by a low urinary excretion of total pyridinolines (LP + HP) expressed in relation to creatinine, a lower than normal ratio of LP/HP (R.A. Bank, personal communication 1999; normal ratio 0.20 ± 0.10; see Chapter 9 and Appendix II, this volume), and the finding of collagens produced by fibroblasts being normal with regard to relative proportions and electrophoretic mobilities upon SDS-PAGE.

A differential diagnosis comprises osteogenesis imperfecta, mainly types III and IV, and, among these, especially the rare autosomal recessively inherited forms (see Chapter 8, this volume), the various forms of arthrogryposis multiplex, and congenital contractural arachnodactyly (CCA; MIM 121050).

The management of Bruck syndrome is the same as that of osteogenesis imperfecta (see Chapter 8, this volume). Bisphosphonate has been given to one patient with apparent success [11]; the patient died, however, from complications resulting from progressive cervical kyphosis (D. Sillence, personal communication 2001).

Chapter 26, Part V

Osteoporosis-Pseudoglioma Syndrome

Beat Steinmann and Peter M. Royce

Division of Metabolism and Molecular Pediatrics, Department of Pediatrics, University of Zurich, Switzerland

CLINICAL FEATURES

The osteoporosis-pseudoglioma syndrome (OPPG, OPS; MIM 259770) is characterized by visual loss at birth or in infancy and by a fracturing bone disease that presents in childhood. The term "pseudoglioma" alludes to the histological appearance of the eyes, which were sometimes mistakenly removed because of presumed retinoblastoma (for review, see [1]), and is a nonspecific term for any condition more or less mimicking retinoblastoma.

Many OPPG patients are born with severe eye involvement such as phthisis bulbi (shrinkage and wasting of the eyeball), microphthalmia, corneal opacity, absence of the anterior eye chamber, iris atrophy, secondary glaucoma, lens opacity, posterior synechiae, and leukokoria (white retrolental masses behind the pupil resembling retinoblastoma); in such patients the eyelids are constantly closed. In patients with milder eye involvement there is persistent hyperplasia of the primary vitreous, which has led to speculation that the ocular pathology results from a defect in the normal involution of the primary vitreal vasculature that begins during the 13th gestational week [2]. In patients with delayed blindness, an acute episode (such as "eye infection" or "glaucoma") is often reported as immediately preceding final loss of vision [1]. The sclerae are white.

Patients have fractures in the long bones and axial skeleton with subsequent deformations, multiple crush fractures, bone pain, kyphosis, and short stature, and become progressively immobile and wheelchair-bound. Radiological findings are generalized osteopenia affecting the axial as well as the appendicular skeleton, decreased bone density, thin cortical and coarse trabecular structures, a thin cortex, and often Wormian bones. The teeth are normal.

Intelligence and hearing are normal in most cases; sometimes microcephaly, muscular hypotonia and ligamentous laxity are noted. Interfamilial and even intrafamilial variability may be considerable. The natural history of the disease has not yet been well described.

CHEMICAL AND HISTOLOGICAL FINDINGS

OPPG patients have normal anabolic and catabolic hormone levels, calcium homeostasis, endochondral growth, and bone turnover, as indicated by normal urinary excretion of pyridinolines [3] (and B. Steinmann, unpublished results). Collagen synthesis by fibroblasts is also normal [4,5] (and B. Steinmann, unpublished results). Histology of bone biopsies reveals a deficient trabecular bone volume, but a normal surface density and appearance of osteoblasts and osteoclasts on bone surfaces [6]. In the eyes, pseudogliomatous tissue is observed (for review, see [1]). Collagen fibrils in the dermis are ultrastructurally normal [5].

INHERITANCE AND MOLECULAR DEFECT

OPPG is a rare disease which is autosomal recessively inherited as evidenced by the occurrence of affected sibs of both sexes, and of several patients born to consanguineous parents. Although Frontali et al. [1] mentioned that the disease may be more prevalent in Mediterranean countries, actual review of the literature indicates that it occurs world-wide [1,5–7]. Some, but not all, obligate carriers of OPPG display an increased incidence of osteoporosis-related fractures and a reduced bone mass (dominant effect of the mutation) [6,7].

The OPPG locus was earlier assigned to chromosome 11q13 [7]. Using the positional candidate approach, the gene responsible for OPPG has now been identified as *LRP5*, a member of the low density lipoprotein (LDL) receptor-related family [6].

LRP5 comprises 23 exons that span >100 kb and has an open reading frame of 4.9 kb [8,9]. The gene encodes a 29 amino acid residue signal peptide, 20 Tyr–Thr–Trp–Asp spacer repeat domains interspersed with four epidermal growth factor (EGF)-like domains, a transmembrane domain, and a 200 amino acid residue intracytoplasmic domain. Gong et al. [6] have described six different homozygous frameshift or nonsense mutations and two different homozygous missense mutations in unrelated patients born to consanguineous parents, and four heterozygous nonsense, frameshift, or missense mutations in patients from non-consanguineous families; (in these latter four cases the other mutant allele has not yet been determined). The different mutations indicate that there is no ancestral mutation or founder effect.

PATHOGENESIS

LRP5 is expressed by osteoblasts *in situ* and its expression pattern changes over time when mesenchymal cells differentiate to osteoblasts *in vitro* [6]. LRP5 localizes

Connective Tissue and Its Heritable Disorders, pages 1119–1121

to cell membranes when expressed in transfected human fibroblasts and is capable of binding Wnt-4. These observations, in combination with similar phenotypic findings in an *Lrp5* knockout mouse model (see below), suggest that accrual of bone mass occurs during Wnt-mediated osteoblastic proliferation and differentiation [6].

Loss of function seems to be the general mechanism for the mutational effect in OPPG. This is especially convincing in respect of the homozygous nonsense codon at the 10th amino acid (Trp10Stop) within the signal peptide [6] in two affected siblings described by Oexle et al. [10]. Furthermore, transiently transfected COS-7 cells containing either wild-type *LRP5* or two disease-causing alleles (Gln853Stop and 1270fs1438stop) synthesize normal and mutant proteins, respectively [6]. In contrast to this, COS-7 cells containing an artificial LRP5 construct lacking the transmembrane domain do secrete mutant LRP5; conditioned medium containing this truncated protein reduced bone formation in calvarial explant cultures. Thus, this artificial LRP5 is able to inhibit bone growth, presumably by binding to, and interfering with, secreted growth factors [6].

The precise cause of low bone mass in OPPG patients is not known. However, several independent observations suggest that LRP5 regulates osteoblasts at the level of their proliferation and differentiation. Since reduced LRP5 expression appears to regulate bone mass negatively, it may be speculated that other *LRP5* mutations, or common polymorphisms, which enhance the expression of LRP5, will positively regulate bone mass. In this context, it is of interest that a genetic high bone mass phenotype (bone mineral density variation 1; MIM 601884) [11] and a bone mass quantitative trait locus (bone mineral density variation 2; MIM 605833) [12] have also been mapped to the genetic interval that contains *LRP5*; in the former condition, a mutation in this gene has been described [12a].

Gong et al. [6] suspect that transient expression of LRP5 by cells within the vitreal vasculature is responsible for the involution process and that in OPPG failure of this process leads to fibrosis and contracture. Traction on other ocular structures by this fibrotic process affects vision by creating retinal folds, retinal detachment, and, in extreme cases, phthisis bulbi.

Two other autosomal dominantly inherited ocular disorders leading to blindness, familial exudative vitreoretinopathy (EVR1; MIM 133780) and neovascular inflammatory retinopathy (VRNI; MIM 193235) also map to an interval containing *LRP5* ([13] and [14], respectively). EVR1 appears to result from impaired growth of the peripheral retinal vasculature, with the resultant formation of fibrovascular vitreal membranes that leads to retinal traction and detachment, while VRNI appears to result from an inflammatory process leading to occlusion of the peripheral retinal vasculature and subsequent new vessel growth. It is reasonable to speculate that different *LRP5* mutations, in addition to causing OPPG, also cause EVR1 and VRNI via different mechanisms.

LRP5 is expressed in several tissues [8,15]. It is, therefore, surprising that the phenotypic consequences of mutations are restricted to the skeleton and the eye; it is possible that LRP6, which is also broadly expressed, shares a functional redundancy with LRP5 in many tissues [16].

DIAGNOSIS, DIFFERENTIAL DIAGNOSIS, AND MANAGEMENT

The importance of establishing the correct diagnosis and distinguishing OPPG from osteogenesis imperfecta is critical in the context of genetic counseling of the healthy parents, the risk of recurrence in a subsequent child being 25%. The demonstration of ocular calcification by computed tomography or a persistent hyperplastic primary vitreous by color Doppler imaging [17] in a blind patient with generalized osteopenia supports the diagnosis of OPPG, which can now be proven at the molecular level.

OPPG is not always easily distinguished from osteogenesis imperfecta and there is phenotypic confusion between the two which is reflected by historical reports (for review see [1]); older synonyms, such as the "ocular form of osteogenesis imperfecta" [18] and "pseudoglioma with bone fragility", should no longer be used [19]. The visual problems typically begin early in life, before osteopenia has become pronounced. This makes the early diagnosis of OPPG difficult because the differential diagnosis of leukokoria is quite elaborate. In the absence of microphthalmia it includes retinoblastoma (MIM 180200), retrolental fibroplasia of prematurity, posterior cataract, congenital retinal detachment, and coloboma of iris, choroid and retina (MIM 120200); while in the presence of microphthalmia, it includes Norrie disease (congenital progressive oculo-acousticocerebral degeneration; MIM 310600), Coat disease, Reese retinal dysplasia (MIM 266400), toxoplasmosis, and congenital cataract. Calcifications of the eye are seen in retinoblastoma, toxoplasmosis, and OPPG.

The management of brittle bones in OPPG is similar to that in osteogenesis imperfecta (see Chapter 8); bisphosphonates have also been tried with apparent success [3] and are under current trial. In OPPG patients with mild eye involvement, treatment is symptomatic.

ANIMAL MODEL

Analysis of the *Lrp5* knockout mouse supports a role for Lrp5 in osteoblast proliferation and differentiation, and confirms the observation that *LRP5* mutations may have recessive as well as dominant effects, such as reduced bone mass in the heterozygous state. Homozygous *Lrp5* knockout mice have ocular abnormalities (G. Karsenty, personal communication 2001).

Interestingly, the same investigator also finds that statins (HMG Co-A reductase inhibitors) can abrogate the skeletal phenotype of *Lrp5* deficiency. (Statins have also been reported to increase bone mass in mice [20] and postmenopausal women [21]). Although the mechanism by which they do so remains unclear, it is tempting to speculate that reducing cellular cholesterol leads to an increased expression of LRP5 or other superfamily members, and that this, in turn, directs uncommitted cells into an osteoblastic differentiation pathway.

Chapter 26, Part VI

Myopathies Due to Defects in Collagen VI

Beat Steinmann and Peter M. Royce

Division of Metabolism and Molecular Pediatrics, Department of Pediatrics, University of Zurich, Switzerland

BETHLEM MYOPATHY (BENIGN CONGENITAL MYOPATHY WITH CONTRACTURES; MIM 158810)

Clinical Features

The eponym "Bethlem myopathy" was coined by Mohire [1] to describe a mild and slowly progressive congenital myopathy affecting mainly the proximal muscles, with contractures predominantly of the distal joints (elbows, wrists, fingers, and ankles), but often without significant disability. It is inherited as an autosomal dominant trait. The features of Bethlem myopathy can be present from birth onwards, manifesting in some patients as torticollis and contractures or neonatal floppiness, suggesting a congenital nature. Many patients, however, do not develop significant weakness before the first years of life and gross motor development may be normal. Patients have moderate weakness and atrophy of trunk and limb muscles, the proximal muscles being more involved than the distal ones, and the extensors more so than the flexors [1–4].

In addition to a limb-girdle type of muscular weakness, the extensor digitorum communis muscle is invariably involved. Flexion contractures of the elbows, the interphalangeal joints of the last four fingers — a hallmark of this myopathy [5] — and the ankle joints are found frequently. There is no relationship between contractures and the severity or duration of the muscular weakness [1,3]. Some patients experience muscle cramps following exercise [6].

Cardiac and facial muscles are not involved [1,2,7]; at autopsy, the hearts of two patients were normal in all respects [1], and moderate facial involvement has been reported only once [8]. Despite earlier reports of an absence of respiratory muscle involvement, progressive respiratory compromise has been reported [9] in a patient from the family described by Pan et al. [10], which expands the clinical spectrum of the disorder. Life expectancy is normal [1,2,5].

Bethlem myopathy appears to be a rare condition; however, careful examination may reveal that it is more common than assumed. In one study [5], nearly half of the individuals labeled by the authors as affected were unaware of their disease. Sporadic or familial oligosymptomatic individuals with mere clumsiness may escape medical attention.

Despite a relatively uniform clinical picture, variations do exist between patients from different families and also between patients within single families [11]. The onset of weakness may occur before 5 years of age, with mildly delayed motor milestones [1,3,11–13], or it may occur at a later stage, in the fourth [14] or sixth decades [11]. As some adults remain unaware of their weakness, an age of onset cannot always be reliably established [5]. The investigation of two novel kindreds and a reevaluation of previously reported families [2,3] as part of a genetic linkage study [15], disclosed aspects that differed from previous observations, shedding new light on the onset and natural course of Bethlem myopathy [16]. The analysis showed that nearly all affected children exhibit weakness or contractures and torticollis during the first 2 years of life. Early features include diminished fetal movements, neonatal hypotonia, slightly delayed motor milestones, and congenital torticollis and contractures which are of a dynamic nature during childhood. A slight worsening of the muscular weakness often ensues, to be followed by relative recovery during puberty. Apart from contractures, many patients are almost asymptomatic during early adult life. From middle age onwards, muscular weakness becomes obvious and sufficiently severe to warrant a wheelchair in more than two-thirds of patients over 50 years of age [16]. Thus, the course of Bethlem myopathy in adults is less benign than previously thought.

Biochemical, Histologic, Electromyographic, and Computed Tomographic Findings

Serum creatine phosphokinase is usually normal or moderately elevated, especially in younger patients [1,2,5,6,14,16]. Histopathological findings are nonspecific, showing a marked variation in muscle fiber diameter, a moderate increase in the number of fibers with internal nuclei, lobulated type I fibers, and a marked increase in the endomysial fatty tissue, but no significant fibrosis. There is a normal distribution of type I and type II fibers [1,2,4,5,11]. In one large family [5], Merlini et al. [17] found an age-related progressive deficiency of laminin β1 in the muscle fiber basal lamina. The expression of laminin β1, however, was well preserved in the blood vessels, demonstrating that the reduction of this protein in muscle fiber basal lamina represents a secondary and selective defect (see below).

Connective Tissue and Its Heritable Disorders, pages 1123–1127

Electromyography has shown myopathic abnormalities in several families [1,4,5,11,18], whilst computed tomography has shown that muscle impairment is mild but more diffuse than clinically apparent and demonstrates an unexpected progressive fatty replacement of paravertebral muscles (the gluteal muscles are relatively preserved) [4,5,11], a finding which clinical examination has failed to show [5].

Genetics

Bethlem myopathy is inherited in an autosomal dominant fashion and is genetically heterogeneous. Linkage studies by Jöbsis et al. [19] and Speer et al. [20] first suggested that collagen VI was involved, and the disorder is now known to be due to mutations in the three genes coding for the α(VI) chains of collagen VI, i.e., *COL1A6* and *COL2A6*, located on chromosome 21q22.3, and *COL3A6*, located on 2q37.

Eight mutations have been characterized to date, five of which are substitutions for glycine. Except for one Gly substitution found in the NH_2-terminal globular domain of the α3(VI) chain, the other missense mutations are all localized in the triple helical regions of the three chains, and thus, most likely, exert a dominant negative effect. The remaining three mutations are splice-site mutations in the *COL6A1* gene, one of which leads to a premature termination codon (PTC), the other two of which lead to exon skipping; all three splice-site mutations cause haploinsufficiency (see below).

The eight described mutations and their consequences (in brackets) are as follows:

- α1(VI) Gly286Val [15] (N.B., the numbering is based on +1 being the first amino acid of the secreted chain without the signal peptide; if the ATG codon were considered as +1, the mutation would be Gly305Val); α1(VI) IVS14 + 1G > A (skipping of exon 14) [21]; α1(VI) IVS14 + 2T > C (skipping of exon 14) [18]; α1(VI) IVS11-1delG (PTC) [22];
- α2(VI) Gly250Ser [15] in two kindreds (N.B., the numbering in these cases also is based on +1 being the first amino acid of the secreted chain without the signal peptide);
- α3(VI) Gly1679Glu [10]; α3(VI) Gly2056Arg [23] (in these cases the numbering is based on ATG being +1).

Pathogenesis

Collagen VI, a major protein of the interstitial matrix, is composed of three genetically distinct α(VI) chains, [α1(VI)α2(VI)α3(VI)]. Tetrameric aggregates of collagen VI trimers are secreted and form the basic unit of collagen VI microfibrils deposited in the extracellular matrix. They aggregate end-to-end through interaction of their "outer-terminal" globular domains, giving rise to characteristic long, thin, beaded filamentous structures which have a widespread tissue distribution and localize close to cells, nerves, blood vessels, and large collagen fibrils, and are considered to have an anchoring function, linking cells and the extracellular matrix (see Chapter 2, Parts I and II, this volume).

Collagen VI consists of a central, short collagenous region flanked by several von Willebrand factor type A modules at the N- and C-terminal ends. Both types of domain participate in specific molecular interactions. The collagenous domain binds cell membranes through integrins α1β1 and α2β1, as well as such matrix constituents as proteoglycans such as perlecan, decorin, biglycan and fibromodulin, along with collagen II, whereas the type A modules bind collagens I, IV and VI, as well as fibronectin, heparin, and hyaluronic acid.

In general, muscular dystrophies are caused by a disturbance of the attachment of muscle cells to their basement membranes [24,25]. The normal attachment structure in muscle consists of a submembranous dystrophin network, a dystrophin-associated glycoprotein complex (composed of α-, β-, γ-, and δ-sarcoglycans and α- and β-dystroglycans), and laminin (merosin) and collagen IV, which are both basement membrane components. A second attachment structure has been described, the α7β1 integrin receptor that also binds to (extracellular) laminin [26]. Kuo et al. [27] have shown strong binding of collagen VI to collagen IV *in vitro*, a general co-distribution of collagens IV and VI in human muscle by double-label immunofluorescence microscopy, and an intimate association of collagen VI with basement membranes surrounding muscle fibers by immunoelectron microscopy. Collagen VI is, therefore, part of the muscle cell attachment structure that provides an important physical connection between muscle cells and their extracellular matrix and may also play a role in myofiber regeneration.

Haploinsufficiency due to mutant *COL6A1* genes is a well documented pathogenic mechanism in Bethlem myopathy, as shown in three separate families [18,21,22]. In one large family, Lamandé et al. [22] characterized a G deletion at the conserved splice acceptor site in intron 11 of *COL6A1* (IVS11-1delG), and as a consequence thereof, a PTC due to a splicing defect in the mRNA leading to nonsense-mediated mRNA decay. (Residual protein expression was predicted to result in a 37 kDa truncated product). While the α(VI) chains produced by fibroblasts from affected individuals migrated normally under reducing conditions in SDS-polyacrylamide gels, analysis under non-reducing conditions revealed the accumulation of a disulfide-bonded intermediate which was more abundant and migrated faster than that observed in normal cells; this observation is consistent with the association of α2(VI) and α3(VI) chains proceeding normally, but further assembly being limited by a reduced availability of α1(VI) chains. Such an α2(VI)-α3(VI) assembly intermediate containing only two chains could not be triple-helical and would not be secreted, and thus the net effect of α1(VI) haploinsufficiency is the assembly and secretion of reduced amounts of collagen VI. Reduced amounts of deposited collagen VI have been documented by immunofluorescent staining of the matrix laid down by Bethlem fibroblasts in long-term culture [22].

In two further families, Lamandé et al. [21] and Pepe et al. [18], respectively, showed that skipping of exon 14 led to truncated α1(VI) chains (lacking 18 amino acids together with a unique cysteine residue thought to be involved in dimer formation) which were clearly detectable within Bethlem fibroblasts, but not in their medium, that only half amounts of dimeric and tetrameric aggregates were formed, and that trimers containing a mutant α1(VI) chain accumulated intracellularly. Hence, the shortened mutant α1(VI) chains were able to assemble with normal chains to form monomeric trimers, but the mutant chain-containing trimers were unable to form disulfide-bonded dimeric and tetrameric aggregates, probably for sterical reasons or the absence of a necessary cysteine residue, and were not secreted. Because stable monomeric trimers of helical collagen VI only form with an equimolar stoichiometry of α1(VI), α2(VI), and α3(VI) chains, half of the monomeric trimers contained the mutant α1(VI) chain and were not secreted, resulting

in a functional haploinsufficiency of collagen VI in the extracellular matrix. It is worthy of note that members of the two different families displayed markedly different severe phenotypes despite the fact that all have the same shortened α1(VI) chain; the affected family members reported by Pepe et al. [18] have the most severe phenotype reported so far. Haploinsufficiency of mutant *COL6A2* genes has not yet been observed (see below and Ullrich Disease, this chapter).

Single glycine substitutions in one of the three α(VI) chains may also cause Bethlem myopathy [10,15,23]. However, biosynthetic studies have not been performed in such cases and it remains to be determined whether the mutations interfere with intracellular assembly and secretion, thereby resulting in collagen VI haploinsufficiency, or whether the disease may result from the presence of structurally abnormal collagen VI in the extracellular matrix exerting a dominant negative effect, as may be inferred from the effects of Gly substitutions in the triple-helical domains of several other collagens (see Chapters 8, 9, 15, 23 Part II, 25, and 26 Part VII, this volume). A Gly1679Glu mutation in the N2 motif of the N-terminal globular domain of *COL6A3* is at a conserved residue in the center β sheet of the von Willebrand A motif [10], and recombinant protein and molecular modeling studies suggest that it is likely to impair protein folding, consistent with radioimmunoassay data showing reduced levels of N2-epitopes in cultured fibroblasts from two patients possessing the mutation [28].

All these findings identify collagen VI as a contributor to normal skeletal muscle integrity and suggest that a reduced collagen VI microfibrillar network may no longer adequately anchor muscle cells to the surrounding connective tissue, and that collagen VI may also play a role in myofiber regeneration. The age-related secondary decrease in laminin β1 expression that occurs in individuals with Bethlem myopathy is restricted to skeletal muscles [17] (see Animal Model and Cell Expression Studies, below).

It appears that the interaction of collagen VI with basement membranes involves multiple interaction sites since the basement membrane proteoglycan perlecan also interacts with α2(VI) and there are other binding partners. It is, therefore, not possible to say exactly which interactions will be disturbed in Bethlem myopathy. The fact that there are multiple binding sites on basement membranes for collagen VI could also explain the mild phenotype, since the connection would not be completely broken, but only weakened, depending on the type of mutant collagen VI. This, together with the existence of various differently spliced isoforms (with distinct tissue-specific distribution and probably subtly different functional properties) may explain the distinct pattern of muscular involvement as well as the sparing of involvement of other tissues.

Considering the wide distribution of collagen VI, it is surprising that mutations within it produce a muscle-specific disease rather than a more general one. Collagen VI is also abundant in skin and cornea and is found in cartilage and bone; however, these tissues are apparently not affected in patients with Bethlem myopathy. It may be worthwhile examining affected individuals in greater detail with reference to, for example, the thickness, stiffness, deformability, and turbidity of the cornea, which normally contains a considerable amount of collagen VI (~25% dry weight [29]) (see Ullrich Disease and Animal Model and Cell Expression Studies, below).

Diagnosis, Differential Diagnosis, and Management

The detection of Bethlem myopathy depends on recognition of the clinical pattern and, given its autosomal dominant inheritance, the careful examination of family members, with a systematic search for contractures, the use of muscle computed tomography, and measurements of muscle strength.

In contrast to Bethlem myopathy, the dominant limb-girdle muscular dystrophies (LGMD1A-LGMD1D) show no early contractures and onset is in adulthood. In Emery-Dreifuss muscular dystrophy (MIM 310300), contractures of the cervical spine and the elbows are combined with cardiac conduction defects. The rigid spine syndrome (MIM 602771) is mostly sporadic, preferentially affects males, and presents with scapulohumero-pelvic weakness, progressive scoliosis, and reduced life span due to respiratory failure. Congenital muscular dystrophies are characterized by autosomal recessive inheritance, proximal muscular weakness, generalized muscular hypertrophy, usually grossly elevated creatine phosphokinase, and early respiratory failure.

The management of Bethlem myopathy is symptomatic. Tenotomy for lengthening of the Achilles tendon is necessary in many patients. From middle age onwards, slow deterioration becomes apparent in sufficient degree to warrant aids such as a walking stick, orthopedic shoes, adjustments to the home such as a raised toilet seat or a staircase with lowered steps, and a wheelchair.

ULLRICH DISEASE (SCLEROATONIC MUSCULAR DYSTROPHY; MIM 254090)

Clinical Features and Pathogenesis

The autosomal recessive disorder, Ullrich disease, a severe congenital muscular dystrophy, is allelic to Bethlem myopathy [30]. In 1930, Ullrich [31] described two unrelated patients with congenital muscular dystrophy (MCD). The disorder was defined as "scleroatonic muscular dystrophy". Peculiar clinical manifestations were proximal joint contractures and striking distal hyperextensibility, especially of wrists and ankles, leading to severe disability, while intelligence was normal. Since then, more than 20 patients with similar clinical manifestations have been reported worldwide [25,32], and thus recognized as having a distinct form of MCD. Some familial cases showed more than one sibling affected and a high incidence of consanguinity among unaffected parents, compatible with autosomal recessive inheritance [32]. Creatine phosphokinase is only moderately elevated [30,32]. Most patients die of respiratory failure with diaphragmatic paralysis in the first decade of life, and it is noteworthy that the diaphragm is particularly involved in *Col6a1* knockout animals (see below). De Paillette et al. [32] stated that diagnosis is easy and that the condition may not be as rare as suggested by the paucity of reports, as undiagnosed cases may be included in reported series of other congenital muscular dystrophies.

Vanegas et al. [30] described 4 patients from three families who all had homozygous or compound heterozygous mutations in the *COL6A2* gene. Patient A had a homozygous insertion of a C nucleotide leading to a premature termination codon (PTC) in exon 16 of the triple-helical domain; the healthy, consanguineous parents in their fifties were heterozygous carriers of the mutation. In patient B, there was an α2(VI) IVS17-2A>G substitution and, as a consequence,

activation of a cryptic acceptor site in exon 18, deletion of 28 nucleotides, and the introduction of a PTC due to a frame shift; the second mutation consisted of an α2(VI) IVS23-1G>A substitution with skipping of exon 24. Both mutations were present in a similarly affected brother. Again, the parents were healthy carriers. In patient C, only a mutation in one allele, the same α2(VI) IVS17-2A>G substitution as in patient B, could be detected and appeared to be a *de novo* mutation, as it was not found in her parents. A near total absence of collagen VI in the matrix of fibroblast cultures (patients A and B) and muscle sections (patients B and C) was demonstrated by immunofluorescence. A similar absence of collagen VI in muscle and skin was demonstrated in two further patients [33]. These results clearly demonstrate that Ullrich disease is caused by recessive mutations leading to a severe reduction of collagen VI. It is even more intriguing that, in Ullrich disease, a total lack of collagen VI should produce a muscle-specific disease rather than a more general phenotype consistent with its wide distribution, than it is that a haploinsufficiency should have the same effect in Bethlem myopathy.

It is somewhat surprising that both parents in family A and the mother in family B, all of whom carry heterozygous *COL6A2* mutations leading to premature termination codons, are clinically healthy and do not have Bethlem myopathy. It is noteworthy that no patients with Bethlem myopathy due to *COL6A2* haploinsufficiency have been reported to date, and that the *COL6A1* and *COL6A2* genes are regulated differently. Up-regulation of a normal *COL6A2* allele could compensate for the lack of expression of a mutant *COL6A2* allele and rescue the carriers from a Bethlem myopathy phenotype, whereas such a compensatory mechanism may not be operative for the *COL6A1* gene [30].

For differential diagnostic considerations, see Voit [25] and the kyphoscoliotic type of Ehlers-Danlos syndrome (EDS VI) (Chapter 9, this volume).

ANIMAL MODEL AND CELL EXPRESSION STUDIES

Bonaldo et al. [34] inactivated the mouse *Col6a1* gene by targeted gene disruption. As a consequence of the subsequent α1(VI) chain deficiency, homozygous mutants lacked collagen VI in all tissues, and neither could triple-helical molecules consisting of α2(VI) and α3(VI) chains be detected. Histological findings included fiber necrosis and phagocytosis and a pronounced variation in muscle fiber diameter. Muscles also showed signs of enhanced fiber regeneration. At all stages examined, necrotic fibers were particularly common in the diaphragm and auxiliary respiratory muscles. Similar, although milder, alterations were detected in heterozygous mutant mice, indicating haploinsufficiency of the *Col6a1* gene function. It seems that this is an animal model of both Bethlem myopathy and Ullrich disease, although the distribution of affected muscles is different. Amazingly, given the fact that collagen VI is widely distributed in the body, no other clinical signs were apparent, even in −/− mice. However, the corneal stroma especially of embryonic −/− mice does show disorganization of lamellae, fibril packing, and cells (D. Birk, personal communication 2001).

To explore further the consequences of collagen VI triple helical deletions on collagen VI biosynthesis, and to determine whether mutations in subunits other than the α1(VI) chain also affect intracellular multimer assembly, Lamandé et al. [21] transfected SaOS-2 human bone cells with an α3(VI) cDNA expression construct containing cDNA for a protein product containing a 202 amino acid deletion within the triple helical domain. Untransfected SaOS-2 cells produced α1(VI) and α2(VI) mRNAs at levels comparable to those of skin fibroblasts but were deficient in α3(VI) transcription and produced no stable collagen VI [35]. Normal collagen VI biosynthesis, however, could be restored in SaOS-2 cells by stable transfection with an α3(VI) cDNA expression construct, under which circumstances the α3(VI) chains produced rescued the α1(VI) and α2(VI) chains from intracellular degradation, and were incorporated into collagen VI trimers that were efficiently secreted. However, after transfection with mutant α3(VI) cDNA, collagen VI trimers containing truncated α3(VI) chains were almost entirely retained within the cells. The collagen VI patterns produced by fibroblasts expressing a naturally occurring truncated α1(VI) chain in Bethlem fibroblasts and SaOS-2 cells expressing a truncated α3(VI) chain were identical [21].

Chapter 26, Part VII

Knobloch Syndrome

Beat Steinmann and Peter M. Royce

Division of Metabolism and Molecular Pediatrics, Department of Pediatrics, University of Zurich, Switzerland

CLINICAL FEATURES, DIAGNOSIS, AND DIFFERENTIAL DIAGNOSIS

Knobloch syndrome (KNO; Retinal Detachment and Occipital Encephalocele; MIM 267750) is characterized by high myopia, vitreoretinal degeneration with retinal detachment, cataracts, atypical occipital encephalocele (or congenital occipital scalp defects rather than true encephalocele), and normal intelligence. The condition seems to be rare as only 24 families have been reviewed [1] since its first description in 1971 [2]. The clinical manifestations may also include lens subluxation, abnormal macular pigmentation, neovascular glaucoma, phthisis bulbi, a flat nasal bridge, midface hypoplasia, and mild generalized hypermobility of the joints. Sniderman et al. [1] reported a patient with a midline defect of the frontal region. It is noteworthy that one of the five affected siblings of the initial family [2] had only high myopia and vitreous syneresis but no history of occipital encephalocele, and that the size of the encephalocele may vary among affected individuals from the same family [3].

The encephalocele may be visualized by magnetic resonance imaging and computerized tomography. Histological examination of the scalp defect has demonstrated heterotopic neuronal tissue in most patients, but no true brain tissue, hence the designation "scalp defects" rather than true encephalocele [4]. A differential diagnosis for syndromes with encephaloceles is given by Cohen [5].

INHERITANCE

The disorder is inherited as an autosomal recessive trait because of the occurrence of affected sibs of both sexes born to healthy parents who have often been consanguineous. The gene for the disorder was mapped to chromosome 21q22.3 [6] on the basis of homozygosity mapping in the largest kindred described [3]. The disorder in this family is due to a homozygous mutation at the AG consensus acceptor splice site, IVS1-2A>T, of the *COL18A1* gene coding for the α1(XVIII) chain of collagen XVIII [7]. In three of five unrelated families, Sertié et al. [7] identified different frameshift changes, each predicting a premature stop codon, in exons 10, 36, and 41, respectively. Menzel et al. [8] excluded chromosome 21q22.3 as the locus for Knobloch syndrome in a small New-Zealand family [9], and proposed that the condition be subdivided into KNO1 and KNO2 for the two variants, linked and unlinked to chromosome 21q22.3, respectively.

PATHOGENESIS

Collagen XVIII is expressed in three variant forms, with large differences between them in the size and sequence of their N-terminal regions (see also Chapter 2, Part I, this volume). The short isoform of collagen XVIII is expressed in brain, retina, and vascular and epithelial basement membranes throughout the body, whereas the long isoforms are not expressed in retina or brain. Collagen XVIII exists as a heparan sulfate proteoglycan, and proteolytic cleavage within its hinge region results in release of the last 184 carboxyl terminal amino acid residues, which correspond to a 20 kDa fragment, endostatin, that can be detected in plasma and tissue extracts, and that inhibits angiogenesis and tumor growth.

It has been proposed that collagen XVIII acts as a local, basement membrane-associated regulator of angiogenesis. It is also likely that the triple-helical, heparan sulfate-containing portion plays a role in the assembly and maintenance of the structural integrity of the basement membranes in which it is found, or in their cell-binding properties. Since collagen XVIII is expressed in the developing and postnatal eye, along with collagens II and XI, it is possible that it is part of a connective tissue scaffold that is essential for maintaining a normal vitreous structure and functional retina.

The pathogenetic mechanism leading to Knobloch syndrome seems to be haploinsufficiency. The α1(XVIII) IVS1-2A > T mutation described by Sertié et al. [7] predicts the creation of a stop codon in exon 4 and, therefore, truncation of the α1(XVIII) collagen short isoform which indicates that the short isoform has a major role in determining retinal structure as well as in the closure of the neural tube, and that its absence impairs embryonic cell proliferation and/or migration as a primary or secondary effect. It is intriguing that ocular anomalies and occipital encephalocele are the only major clinical alterations observed in patients in spite of the ubiquitous presence of the collagen XVIII short isoform throughout the body.

ANIMAL MODEL

In mice with inactivated *Col18a1* alleles, the normal postnatal regression of hyaloid vessels along the inner limiting

Connective Tissue and Its Heritable Disorders, pages 1129–1130

membrane of the retina is greatly delayed, and the outgrowth of the retinal vasculature is abnormal. The results are consistent with the hypothesis that collagen XVIII/endostatin plays a negative role in the regulation of angiogenesis in specific anatomical locations, and this is further supported by enhanced vessel outgrowth in aortic explants from homozygous mutants. The lack of collagen/endostatin also causes alterations in the matrix of the vitreous. All these alterations provide an explanation for the high myopia, vitreoretinal degeneration, and retinal detachment seen in patients with Knobloch syndrome [10].

Appendix II

Extracellular Collagen Metabolites in Body Fluids

Leila Risteli and Juha Risteli

Department of Clinical Chemistry, FIN-90014 University of Oulu, Oulu, Finland

INTRODUCTION

In recent years, several methods have been developed and subsequently validated for use in clinical laboratories that allow the quantitative measurement of various structural domains of procollagens and collagens in body fluids, in particular in blood samples. As such assays are based on immunological detection, they offer superior sensitivity and specificity to traditional biochemical methods. Although the typical samples used in the clinic are serum or urine, measurements can also be carried out in relevant tissue fluids and thus allow the assessment of metabolite concentrations *in situ*. In fact, the development of assay technology has made it possible to attain better insight into the physiology of fibrillar collagens and their precursors, procollagens, in the human organism. This methodology has mostly been used in research into, and clinical management of, acquired diseases, whereas its application to genetic disorders of connective tissue has so far been relatively rare [1–3]. Table 1 summarizes the advantages of the immunoassay approach in the quantitative assessment of the synthesis and degradation of connective tissue proteins.

To interpret correctly the results of a quantitative immunoassay, it is necessary to understand the chemical nature of the antigenic determinant recognised by the assay. This is particularly important in the case of genetic diseases in which not only the amount but also the structure of a connective tissue protein may be altered. For fibrillar collagens, the varying degrees of the posttranslational modifications and differing extents of the cross-linking process provide additional sources of variation.

TABLE 1. Advantages of Quantitative Immunoassays for Connective Tissue Metabolites

- Noninvasiveness: sample usually serum or urine
- Quantitative results in absolute terms, transferable from one laboratory to another
- Generally available, if commercialized, and relatively inexpensive
- Can be performed in ordinary hospital laboratories: regular and professional quality control
- Applicable to cell cultures [4] and tissue studies (e.g., suction blisters of the skin [5])

Connective Tissue and Its Heritable Disorders, pages 1141–1160

Here we first briefly describe the collagen metabolites and the assays that are generally available for them, and comment on some other assays that have also been described in the literature. This section is followed by tables listing the reference intervals for the metabolites of types I and III collagens in different kinds of biological samples. In this part, we concentrate on those metabolites for which commercial assays are generally available and for which adequate reference materials have been published. Because the immunoassays, when carried out in a hospital laboratory, are reliable, reproducible, relatively simple, and inexpensive, it seems justifiable to include some of them in the basic evaluation of patients with suspected osteogenesis imperfecta or other heritable disorders which affect type I or type III collagen.

BY-PRODUCTS OF COLLAGEN SYNTHESIS

Assay Principles

There is an elegant possibility of noninvasively assessing the ongoing synthesis of the fiber-forming interstitial collagen types I to III in humans, because these proteins are synthesized as procollagens, which lose their propeptide domains *en bloc*. The free propeptides, in principle, reflect the amount of the respective collagen that is being deposited in the tissue at any one time in a stoichiometric 1 : 1 fashion. The propeptides are measurable by immunological techniques, and a number of biological fluids can be used as samples. However, it has turned out that when applying such a method to a new type of sample it is essential to characterize the antigen measured, at least with respect to its size and the shape of the inhibition curve it produces in comparison with the standard antigen [1].

The locations of the antigenic determinants and the conformational requirements of the propeptide immunoreactions have been relatively well characterized. As procollagens contain three polypeptide chains, the intact propeptides are also trimeric structures. In this chapter, the term "propeptide" and the abbreviations for the individual propeptides denote such trimeric protein fragments. The molecular properties of the intact propeptides of human type I procollagen are given in Table 2, together with the main characteristics of the circulating antigens related to these protein fragments. The primary structures of the amino terminal and carboxyl terminal propeptide domains of other fibrillar procollagens are homologous to the respective domains of type I procollagen,

TABLE 2. Properties of the Propeptides of Type I Procollagen and Corresponding Circulating Antigens

	PICP	PINP
Chemical nature	Glycoprotein, contains oligosaccharides of the high-mannose type	Partly collagenous, phosphorylated at serine residues
Molecular mass	100,000	35,000
Molecular shape	Globular	Elongated
Related circulating antigens		
Homogeneity	Homogeneous	Heterogeneous
Size	As intact PICP	Major antigen as intact PINP, minor antigen smaller
Clearance by	Liver endothelial cells	Liver endothelial cells, smaller antigen by the kidneys
Clearance receptor	Mannose receptor	Scavenger receptor

PICP = carboxyl terminal propeptide of type I procollagen; PINP = amino terminal propeptide of type I procollagen;
The data relate to the intact, trimeric propeptides as they are released from the native procollagen molecule, not to the corresponding domains in the individual polypeptide chains. Although not directly studied, the half-lives of the propeptides in human serum can be estimated to be about one hour. This conclusion is based on their rates of response after glucocorticoid treatment in humans [6] and on comparison of PINP with *in vivo* clearance studies of the amino terminal propeptide of type III procollagen (PIIINP), which is removed from the circulation by the same receptors as PINP [7].

but at the protein level only the amino terminal propeptide of type III procollagen (PIIINP) has so far been available for protein chemical studies and commercial immunoassay. PIIINP resembles the amino terminal propeptide of type I procollagen, PINP, in its molecular shape, charge and metabolic properties. However, the metabolism of PIIINP is more complex, in particular because of its transglutaminase-mediated cross-linking [8]. On the other hand, PINP is less stable than PIIINP because of its lack of interchain disulfide bridges. An assay for the carboxyl terminal propeptide of type II procollagen, also known as chondrocalcin, is being used in studies on acquired cartilage diseases, but this assay is not commercially available (see below).

Although the two propeptides, amino terminal propeptide (PINP) and carboxyl terminal propeptide (PICP) of type I procollagen originate from the two ends of the same procollagen molecule and are thus produced and released in equimolar amounts, in reality their relative quantities as measured in serum show some variation. Initially, the cleavage of PINP may be delayed and, indeed, some amino terminal propeptide can be found on the surface of growing fibrils in, e.g., the osteoid of mineralizing bone. Also their clearance differs. In particular, in infants and children there is an excess of PINP, in comparison with PICP (Fig. 1). After puberty the equimolar ratio typical of the sera of adults is reached. A disproportionate increase in the circulating PINP concentration also takes place in active Paget's disease of bone [10] and aggressive breast carcinoma [11]. An inherited disorder, Camurati-Engelmann disease (MIM 131300) that resembles Paget's disease (MIM 167250 and 602080) in some of its pathophysiological features, may also display such a characteristic [12].

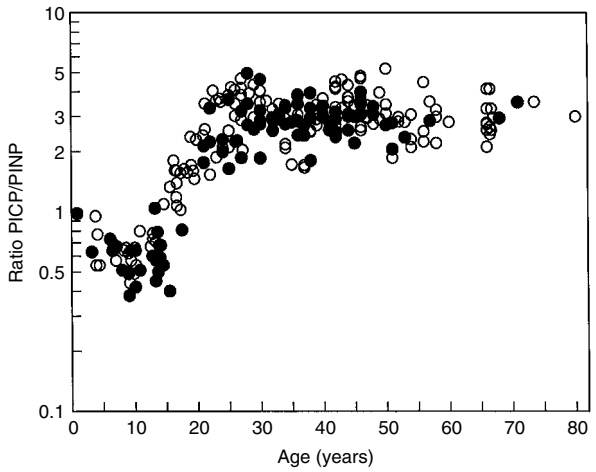

Figure 1. Ratio of the concentrations (in μg/L) of the carboxyl terminal (PICP) and amino terminal (PINP) propeptides of type I procollagen in human serum as a function of age of the individual. The open symbols denote females and the closed symbols males. (Redrawn from [9], with permission.)

Metabolic Fates of the Propeptides

Once the propeptides have been cleaved from a procollagen molecule, they do not seem to be significantly further metabolized *in situ*, but find their way into the circulation. For the propeptides set free in soft tissue, this route involves passage via the lymphatic system, whereas those originating in the skeleton obviously have direct access to the blood. Consequently, the relative concentration of the amino terminal propeptide of type III procollagen, PIIINP, is about ten times higher in lymph than in serum, whereas for the carboxyl terminal propeptide of type I procollagen, PICP, both concentrations are equal [13].

The half-lives of the circulating propeptides are of the order of minutes when studied in the rat [14,15] or up to an hour in the pig [7]. Their own metabolism takes place in the liver, where they are taken up by two different receptor-mediated systems (Table 2). These data from experimental and domestic animals and cultured liver endothelial cells have been substantiated by measurements in different vascular beds in man [16]. The scavenger function of the sinusoidal endothelial cells must be distinguished from the metabolic functions of the hepatocyte. In the case of the most common liver damage, the former is rarely affected, and thus a mild to moderate increase in the serum concentrations of transaminases is not usually accompanied by impaired

propeptide clearance. However, the deterioration of the scavenger function of the sinusoidal endothelial cells, e.g., in primary biliary cirrhosis, as indicated by an increased PIIINP concentration in the serum, predicts poor survival [17].

The propeptides can be measured in a number of tissue fluids, such as wound fluid [18] or suction blister fluid [5] of the skin, where they reflect the local collagen synthesis rate. The production of suction blisters is a relatively noninvasive method that has been used, for example, to demonstrate the effect of glucocorticoids on skin collagen synthesis [5] and in the diagnosis of sporadic cases of Ehlers-Danlos syndrome type IV [19]. The latter (see Chapter 9, this volume) is associated with a decreased production of type III procollagen as measured by PIIINP. In these fluids the propeptide antigens resemble, with respect to both homogeneity and molecular size, the authentic propeptides as they are released *en bloc* from the procollagen molecule. The amniotic fluid, at least close to the term of a pregnancy, can be regarded as an *in situ* system in this respect, as most of the intact propeptides in it must have originated from the fetal membranes (Fig. 2). However, these membranes have the same genotype as the other fetal tissues; i.e., they will produce genetically defective collagens in the case of an inherited collagen disorder.

In contrast to the propeptides at their sites of origin, in the blood the antigens related to the amino terminal propeptides of the fibrillar procollagens are heterogeneous in size and metabolic behavior (Fig. 3). The smallest antigenic forms are eliminated via the kidneys [16]. The origin of these is at least partially the degradation of the corresponding pN-collagen in tissues, in addition to the possibility that the propeptide itself is partially digested or denatured [21]. For PINP, the different assays described in the literature differ with respect to their sensitivities to such degradation products [21,22]. In the case of PIIINP the situation is even more complex, as the additional circulating antigen forms partially appear even larger than the intact, trimeric propeptide. One explanation for this could be that PIIINP contains a transglutaminase cross-linking site [8] allowing the formation of higher aggregates of PIIINP itself or with other proteins. Another reason could be the fact that a substantial proportion of PIIINP is still found as tissue type III pN-collagen, the degradation of which could also produce large antigenic fragments. In fact, the most abundant form of PIIINP in the blood of healthy adults is form B (Fig. 3). Such complexity is not a problem for PICP as it is always present as one form with properties identical to those of the intact PICP.

Tables 3 and 4 list the assays for the propeptides of type I and type III procollagens, respectively, that have been described in the literature and that have been or are available commercially.

Stability of the Propeptide Antigens

All the propeptide antigens are very stable in serum if samples are taken, handled and stored according to good clinical laboratory practice. There are a number of reports in the literature on the analysis of PINP, PICP or PIIINP in frozen samples that were collected several years previously; the antigens also resist repeated freezing and thawing cycles.

The thermal stability of PIIINP is clearly higher than that of PINP because there are interchain disulfide bridges within the collagenous domain of the former but not within that of the latter. Their *in vitro* stabilities are comparable to each other, i.e., there is no change in the serum concentration of either if samples are kept for 7 days at room temperature. However, denaturation of the PINP antigen may occur if samples are handled improperly, e.g., by keeping them for days at +37°C [21]. As an antigen, PICP is more sensitive to extreme conditions, such as acidic pH, but if samples are handled according to the normal practices of clinical laboratories, antigen stability is not a problem.

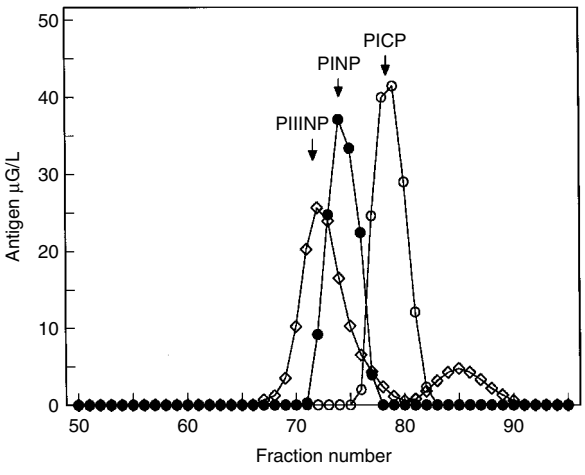

Figure 2. Sizes of the propeptide antigens of type I and III procollagens in amniotic fluid at term. Gel filtration on Sephacryl S-300 of amniotic fluid from full-term labor. The elution positions of standard PIIINP, PINP, and PICP are indicated by arrows. PIIINP and PINP elute earlier than PICP, because the former are elongated, partially collagenous structures, whereas PICP has a compact, globular conformation. Open circles = PICP; closed circles = PINP; open squares = PIIINP. (Reproduced from [20], with permission).

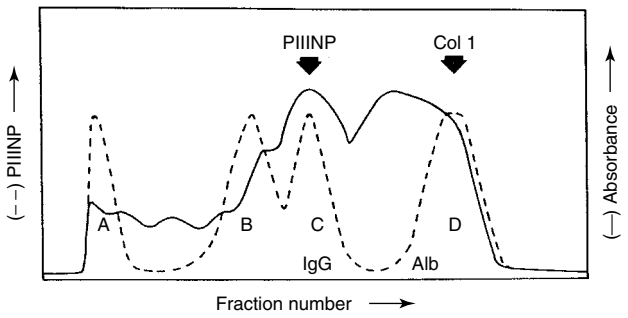

Figure 3. Schematic representation of a gel filtration analysis of different antigenic forms of the amino terminal propeptide of type III procollagen (PIIINP) in serum, in which up to four antigenic peaks (A–D) can be detected [1]. Form C has the size of the authentic PIIINP. In normal adult serum, form B, a possible dimer of C, is the most abundant. Form A is possibly a conjugate with LDL or some other large plasma protein. Depending on the assay used, a considerable amount of form D can be measured, which behaves similarly to the monomeric degradation product of the propeptide after bacterial collagenase digestion, the elution position of which is indicated by Col 1. IgG and Alb denote the elution positions of immunoglobulin G and serum albumin, and indicate that the intact PIIINP (form C) elutes in the position of a protein as large as 150,000 kDa, in spite of the fact that its molecular mass is only 42,000. This is due to its elongated, partially collagenous structure.

TABLE 3. Assays for the Propeptides of Type I Procollagen

Assays Commercially Available		
Assay/Supplier	Antigenic Determinant/Assay Principle	Reference
PICP/Orion Diagnostica (previously Farmos Diagnostica) +DiaSorin (previously Incstar) +Chugai Diagnostic Science	Conformational, requires three polypeptide chains/RIA, polyclonal antiserum	[23]
PICP/Metra Biosystems (Prolagen-C®)	Conformational, requires three polypeptide chains/IEMA, monoclonal and polyclonal antibodies	[24]
PINP/Orion Diagnostica	Antigenic determinant in the most aminoterminal part of PINP, specific, detects the major circulating antigen in serum/RIA, polyclonal antiserum	[22]
"In-house" Methods That Have Been Described in the Literature		
Reference	Comment	
[25]	PINP assay based on a synthetic peptide; antiserum most likely nonspecific and detects unrelated material in serum, since concentrations 100 times too high	
[26]	PINP assay based on a synthetic peptide; specific; probably detects both circulating forms of PINP	
[27]	PINP assay based on PINP derived from a single proα1 chain; antigen isolated from amniotic fluid; specific; detects both circulating forms of PINP	

RIA = radioimmunoassay; IEMA = immunoenzymometric assay.

TABLE 4. Assays for the Aminoterminal Propeptide of Type III Procollagen

Assay/Supplier	Antigenic Specificity/Assay Principle[a]	Reference
P-III-P		
Hoechst-Behringwerke RIA-Gnost P-III-P (no longer available)	Antigenic determinant in the most aminoterminal part of the propeptide; specificity D = B,C/RIA, polyclonal antiserum	[28]
Fab-assay (no longer available)	Specificity D ≫ B,C/RIA with Fab-fragments of a polyclonal antiserum	[29]
IRMA (now from CIS International)	Specificity D ≫ B,C/IRMA, two monoclonal antibodies	Not published
PIIINP/Orion Diagnostica	Specificity B,C ≫ D/RIA, polyclonal antiserum	[30]

RIA = radioimmunoassay; IRMA = immunoradiometric assay.

Effects of Physiological Changes and Acquired Diseases

The rate of collagen metabolism changes in many physiological situations and is affected by many kinds of treatment. Normal growth is associated with rapid collagen turnover, and the catch-up growth during the recovery of a child from a debilitating disease enhances collagen synthesis and turnover even further. Circulating propeptide concentrations are at their highest in infants, decrease rapidly thereafter and then remain almost constant until puberty. Large changes can be seen during puberty, coinciding with the pubertal growth spurt, the age at which the maximal increase in propeptide markers occurs in girls preceding that in boys by 2 years. In children up to puberty there is also a still unexplained difference between the two type I

procollagen propeptides, PICP and PINP. Before puberty the ratio PICP/PINP, when expressed in μg/L, is around 1, but after puberty it increases close to the ratio of 3–4 : 1. Since the molecular mass of PICP is about three times that of PINP (Table 2), the latter ratio is close to the equimolar concentrations expected (Fig. 1). Glucocorticoid treatment decreases the rates of type I and III collagen synthesis rapidly and specifically. Other drugs that slow down bone turnover, even though their primary effect would be toward matrix degradation, such as the bisphosphonates, decrease the circulating concentrations of PICP and, in particular, of PINP, because of the coupling of bone formation with bone resorption [3].

Propeptides in Genetic Diseases

At present, several hundred different genetic alterations have been described in the *COL1A1*, *COL1A2*, and *COL3A1* genes, leading to different biochemical defects (see Chapters 8 and 9, this volume). Although there are already some reports on the use of biochemical markers, in osteogenesis imperfecta, for example, clearly more work is needed before it is possible to generally predict what changes different defects can be expected to cause in the circulating concentrations of the procollagen propeptides. However, there is already some information suggesting that these noninvasive tests can aid in the diagnosis of certain heritable disorders of type I and III collagens.

Osteogenesis Imperfecta

Several reports have shown that in osteogenesis imperfecta (see Chapter 8, this volume) the serum concentration of PICP is low or within the lower part of the reference interval, indicating that the rate of synthesis of type I procollagen is low in this disorder (Table 5). Fewer studies have included the use of PINP and published studies have, unfortunately, been carried out with two assays that differ with respect to their antigen specificity. The assay for intact PINP was more sensitive in distinguishing an abnormality than that for intact PICP in one study in which the same patient was tested *in utero* (Fig. 4) and after birth at the age of 1–2 years [20]. In another study, an assay for PINP was used which measures both the intact propeptide and its monomeric form [34]. The latter may be derived either from the denaturation of the propeptide itself [21] or from the degradation of tissue type I pN-collagen — this may explain why the total PINP assay was less sensitive than that for PICP in distinguishing osteogenesis imperfecta patients from controls. The lower than normal circulating concentration of PICP in type I osteogenesis imperfecta has been a general finding, and is excellently demonstrated by a study in a large Italian kindred [32] (Fig. 5).

In principle, the diagnosis of osteogenesis imperfecta could be made by serum propeptide analysis in those cases (mostly type I) in whom there is a quantitative decrease in the rate of synthesis of type I procollagen as a result of a regulatory defect. Similarly, a qualitative change in the structure of the procollagen that leads to a decreased rate of synthesis, but does not affect the structure of the propeptides, can be detected by either the PICP or the PINP analysis. However, if the structure of one propeptide is altered, both propeptides of type I procollagen should be measured to detect any discrepancy in the ratio of PICP/PINP. It would also be interesting to know how lack of the proα2(I) chain is reflected in the apparent concentrations of the circulating propeptides, since this occurs in certain patients with osteogenesis imperfecta. At present it is not known how well

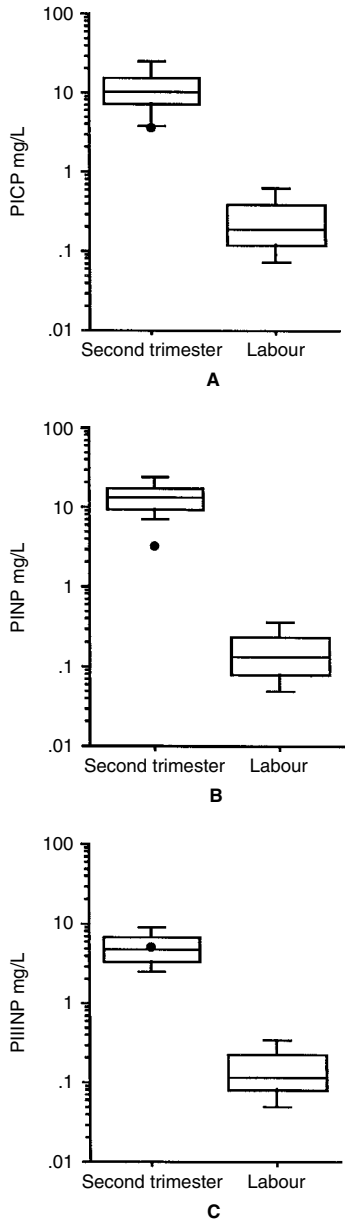

Figure 4. Concentrations of the intact trimeric propeptides of type I (PINP and PICP) and type III procollagens (PIIINP) in amniotic fluid. The reference intervals in the second trimester ($n = 105$) and at term ($n = 40$) are indicated in the form of box-and-whiskers diagrams. The box indicates the lower and upper quartiles and the central line is the median. The ends of the "whiskers" are the 2.5% and 97.5% values. The black dots indicate the normal PIIINP, decreased PICP, and particularly low PINP values in the amniotic fluid of a mother carrying a fetus with mild osteogenesis imperfecta. (Reproduced from [20], with permission.)

the immunoassay for PICP is able to detect the corresponding propeptide derived from the α1-homotrimer variant of type I collagen, although the assay for PINP equally recognizes both the normal and the homotrimer variant. In this respect, it is interesting that a polymorphism in an SP1 binding site in the *COL1A1* gene has been suggested to lead to some synthesis

TABLE 5. Propeptides of Type I Procollagen in Osteogenesis Imperfecta (OI)

Finding	Reference	Comment
Diagnostic potential		
PICP lower than −2 SD of the controls in type I OI, less low in types III and IV OI	[31]	Assay from [23], suggested for pedigree screening in type I OI
PICP decreased in type I OI	[32]	Assay from [23]
PICP decreased in types I, III and IV OI	[33]	Assay from [23]
PICP decreased in type I OI and less so in types III and IV; total PINP low in children with OI, not in adults with OI	[34]	Both PICP [23] and PINP [27] generally lower in mild OI with a quantitative defect than in severe OI with a qualitative defect
Effects of treatment		
PICP decreased in type I OI, some increase in response to growth hormone treatment	[35]	Assay from [23]
PICP probably decreases during bisphosphonate treatment of OI	[36]	Assay from [23]
Potential for prenatal diagnosis		
PICP and PINP decreased in amniotic fluid of a fetus with type I OI (mild phenotype)	[20]	PICP [23], PINP assay [22]

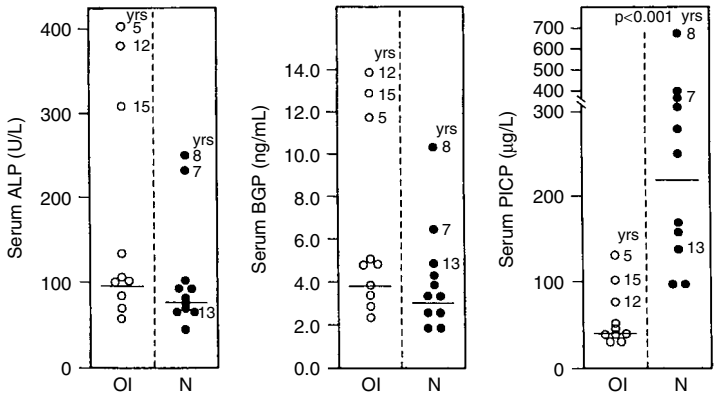

Figure 5. Concentrations of the carboxyl terminal propeptide of type I procollagen (PICP) and osteocalcin/bone Gla-protein (BGP) and the activity of alkaline phosphatase (ALP) in affected (open circles) and unaffected (closed circles) members of a family with type I osteogenesis imperfecta. The three markers measured represent different aspects of bone formation, matrix formation (PICP), matrix maturation (ALP), and matrix mineralization (BGP). Only the concentration of PICP is decreased due to a deficiency in the rate of synthesis of type I collagen, whereas the other aspects of bone formation appear normal. (Reproduced from [32], with permission.)

of the α1-homotrimer type I collagen in bone in apparently healthy people, increasing its fragility [37].

Propeptide measurements could be used as the first tests to distinguish overt osteogenesis imperfecta from suspected child abuse. An ordinary serum sample is sufficient and the results are obtained quickly and inexpensively. However, because healing of recent fractures increases the concentrations of the propeptides, the patient should be tested also later. In any case, a follow-up of suspected cases is otherwise recommendable and the simplicity of the biochemical procedure could justify it. Until recently, cell culture studies requiring a skin biopsy sample and taking a long time to perform have been the only biochemical tools to be used in this differentiation [38].

The Ehlers-Danlos Syndrome

The defective production of type III collagen in Ehlers-Danlos syndrome type IV (see Chapter 9, this volume) leads to a lower than normal circulating concentration of the amino terminal propeptide of type III procollagen, PIIINP (Table 6). The general view is complicated by the fact that several different PIIINP assays have been used in the literature that differ with respect to whether they detect exclusively the intact propeptide, as would be desirable here. There is also one example of a measurement in skin suction blister fluid verifying diagnosis [19].

In Ehlers-Danlos syndrome type VII, the various forms of which lead to impaired release of the amino terminal propeptide of type I procollagen by several mechanisms, the concentration of intact PINP in the serum should, in principle, be decreased, in the presence of a normal PICP concentration. However, in one adult patient with EDS VIIB studied in our laboratory (case 1 in [41]), the serum concentration of PINP was 32 µg/L and that of PICP 160 µg/L, with a PICP/PINP ratio of 5.0. Thus, the lack of a cleavage site in the α2 chain of type I procollagen in this condition does not seem completely

TABLE 6. Aminoterminal Propeptide of Type III Procollagen in Ehlers-Danlos Syndrome Type IV (EDS IV)

Finding	Reference	Comment
Low in serum in atypical case of EDS IV	[39]	Assay from [28], no longer available
Low in serum in some patients with EDS IV	[40]	As above
Decreased concentration in suction blister fluid in the skin, with normal PINP concentration, and low in serum (sporadic case of EDS IV)	[19]	Assay from [30]

to prevent the *in vivo* liberation of the amino terminal propeptide. However, the possibility still remains that such a defect could have a more pronounced effect on the PICP/PINP ratio in children.

A Genetic Trait Increasing the Circulating PICP Concentration

Individuals with surprisingly high circulating concentrations of PICP have sporadically been found in several populations. Values in such individuals typically exceed the upper limits of the age-adjusted reference intervals by two standard deviations or more and are seen in persons with no known pathology of bone or other specific tissues. This trait is inherited in an autosomal dominant fashion [42], and is not related to any abnormality in the structure or metabolism of type I procollagen itself. The molecular explanation of this finding is not yet known, but it is probably related to the further metabolism of the PICP fragment via the mannose receptor, as the circulating PINP is always normal (Fig. 6). It is worth noting that such grossly elevated values change in response to the known modifiers of type I collagen metabolism, e.g., growth, pregnancy [43], or medical treatment. In the rare case that a person with type I osteogenesis imperfecta had also this genetic trait, the circulating PICP concentration might be considered normal. However, defective type I collagen synthesis should then be detectable by PINP measurement.

Nonfibrillar Collagens

The possibility of specific measurement of the synthesis of any nonfibrillar collagen is very limited at present. Most such collagens are known not to be derived from procollagens that would also give rise to by-products allowing direct quantification of the synthesis rate. Specific immunoassays have been described for the 7S [44] and NC1 [45] domains of type IV collagen and for type VI collagen [46]. However, the composition of the antigens used is not completely clarified with respect to what is at present known about the chain composition of these collagens. Furthermore, changes in the antigen concentrations measured with such assays are not simple to interpret. They may reflect different metabolic phases; for example, newly synthesized molecules that have leaked into the circulation before their deposition into the tissues, antigenic fragments originating from the breakdown of tissue forms, or both.

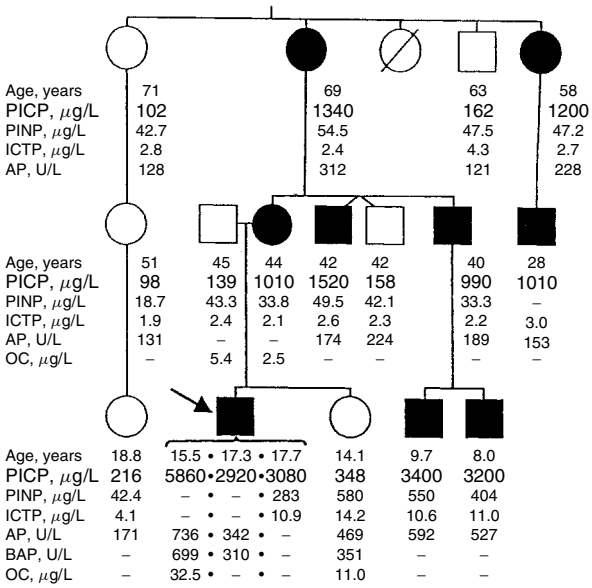

Figure 6. Elevated circulating concentration of the carboxyl terminal propeptide of type I procollagen (PICP) as a hereditary trait in a Finnish family. Members having the trait are represented by closed symbols. The arrow indicates the proband, whose high circulating PICP concentration was noticed when he participated in a study concerning the possible effects of glucocorticoid medication for asthma on the skeleton of growing individuals. PINP = amino terminal propeptide of type I procollagen, ICTP = cross-linked carboxyl terminal telopeptide of type I collagen, AP = alkaline phosphatase, BAP = bone-specific alkaline phosphatase, OC = osteocalcin. (Reproduced from [42], with permission.)

Markers of Cartilage Metabolism

Cartilage matrix contains several collagens, the most abundant of these being type II collagen which, as a fibre-forming collagen, closely resembles type I and III collagens in its structure, biosynthesis and cross-linking, together with large amounts of proteoglycans and several other proteins (see Chapters 1, Part II, and 4, this volume). Quantitative assays for a number of these components have been reported, but they are mostly still so-called "in-house" methods, i.e., they are not commercially available [47]. Their possible utility in the diagnosis and follow-up of hereditary cartilage disorders has not been systematically tested, although the information provided by them in investigating the courses of rheumatoid arthritis and osteoarthritis has been documented on several occasions [48]. The methods have mostly been applied to *in situ* measurements in synovial fluid, but often also to serum studies [48].

The carboxyl terminal propeptide of type II procollagen — PIICP according to the nomenclature used here, but originally known as chondrocalcin — can be measured in both synovial fluid and serum [49,50]. In a study of severe osteoarthritis due to a point mutation in the type II collagen gene, the concentration of the propeptide in the serum of affected family members did not differ from that in their healthy relatives [51]. Reference intervals for Canadian children and adults have been reported [50]; the serum content of the propeptide is higher in infants and children than in older age groups and also reflects the pubertal growth spurt. The mean concentration in adults, 5.7 μg/L, is about

5% of the corresponding concentration of the carboxyl terminal propeptide of type I procollagen, PICP. Several antibodies that recognize precisely defined structures in partially degraded type II collagen have also been characterized [47].

Aggrecan is the most abundant proteoglycan in cartilage, and a number of monospecific antibodies have been described that recognize well-characterized epitopes in the core protein and in the glycosaminoglycan side chains [47]. Some of these antibodies can be used for quantitative measurement of the corresponding antigens in synovial fluid and serum. There is a lot of structural and metabolic complexity as the differing extents of the various posttranslational modifications make the glycosaminoglycan side chains heterogeneous, and because several proteolytic enzymes are involved in the degradation of aggrecan. The chondroitin sulfate epitope, 846, is considered a marker of newly synthesized aggrecan, while another chondroitin sulfate epitope, 3-B-3, may indicate irreparable cartilage destruction [47]. Methods also exist for keratan sulfate which detect this glycosaminoglycan in serum.

Hyaluronan is present in cartilage, synovial tissue and other connective tissues; increased circulating concentrations have been associated with inflammatory joint disease and liver disease [52]. Hyaluronan that enters the circulation from the joints is partially taken up and degraded by lymph nodes and partially enters the liver endothelial cells by a receptor-mediated mechanism [52].

Cartilage oligomeric matrix protein, COMP, can be detected in synovial fluid and serum, where its presence in increased amounts in early rheumatoid arthritis indicates a poor prognosis [53]. This protein is also present in other connective tissues than cartilage.

The protein known previously as YKL-40 or human cartilage gp-39, for which there is a new immunoassay kit [54] available under the trademark Chondrex (Quidel), is produced by chondrocytes and synovial cells [55], and also by other tissues including the liver and malignant tumors. The protein belongs to the chitinase family, but its assumed role in the cartilage matrix has not been as thoroughly investigated as those of aggrecan, hyaluronan, and cartilage oligomeric matrix protein.

PRODUCTS OF COLLAGEN DEGRADATION

The assessment of collagen degradation has progressed from assays of hydroxyproline and other low molecular weight compounds that can be derived from any collagenous protein to the measurement of specific, often complex, telopeptide sequences derived from a known collagen type. Samples most frequently used include urine and, more recently, mainly due to unsatisfactorily large variations in urinary excretion, serum. Collagen degradation products have only rarely been measured in tissue fluids or extracts, but the peptide-related methods lend themselves well to such an approach, if it is reasonable to assume that such degradation products are set free in the tissue concerned.

In principle, mutations involved in heritable disorders of connective tissue may affect the structure of either an extracellular matrix protein, i.e., a substrate, or an enzyme involved in the degradation of various components of the matrix. An example of the former, in addition to the mutations in collagens themselves, is homocystinuria (see Chapter 13, this volume), in which the cross-linking of type I collagen seems to be impaired to the extent that the circulating concentration of one of its degradation products, the ICTP antigen (Table 7; see below) [56], is decreased to one third of that in healthy individuals [57]. An example of the latter is pycnodysostosis, a disease in which the osteoclastic enzyme cathepsin K is deficient [58] (see also Chapter 22, this volume). This disease leads to impaired release of the degradation products of bone type I collagen that normally contain epitopes produced by cathepsin K, such as those detected by the CrossLaps™ and NTx assays (see below) [59]. However, the serum ICTP concentration is paradoxically increased [59], indicating that the degradation of bone collagen is performed under such circumstances by other enzymes, most likely those belonging to the family of matrix metalloproteinases [60].

Collagen-Derived Amino Acids, Cross-Links, and Peptides

Urinary excretion of hydroxyproline (more specifically 4-hydroxyproline) has been widely used in assessing the degradation of collagen in spite of its limitations: only around 10% of hydroxyproline is excreted, a proportion is derived from the synthesis of fibrillar collagens (amino-terminal propeptides), other proteins may contain it (e.g., the C1q component of complement), and it can be absorbed from the diet.

To overcome the fact that hydroxyproline excretion can also be affected by the degradation of newly synthesized collagen before it is even deposited into fibers, the next development was to measure stable cross-links, which can only be derived from the degradation of collagen fibers. The two cross-links usually measured have a pyridinium structure and are generally known as pyridinoline (correctly, hydroxylysyl pyridinoline) and deoxypyridinoline (lysyl pyridinoline) (see Chapter 2, this volume). They differ in their extent of lysyl hydroxylation, which is one of the post-translational modifications of the collagens. Although these cross-links are found in all fibrillar collagens, there is a relative abundance of lysyl pyridinoline in bone collagen. However, there is also a lot of lysyl pyridinoline in the type I collagen of muscle and many internal organs, although not in that of skin. Since the type III collagen of soft tissues contains a significant quantity of hydroxylysyl pyridinoline at the amino terminus, the overall ratio of hydroxylysyl pyridinoline to lysyl pyridinoline is also for this reason lower in bone, which lacks type III collagen, than generally in soft connective tissues. In any case, the fully hydroxylated variant normally predominates in bone, most soft tissues and urine. Despite the fact that only pyridinolines are usually measured, other mature cross-links are also known to exist, some with pyrrolic [61] and others with still uncharacterized structures [62].

Initially, the total excretion of pyridinoline cross-links was measured by high performance liquid chromatography with fluorescence detection, but more recently it has also been possible to quantify the cross-links by specific immunoassays. In principle, either of these methods can be used to detect total (including free and peptide-bound) or free cross-links, depending, respectively, on whether the sample is first hydrolyzed or not. It should also be noted that acid hydrolysis destroys the glycosylation of the cross-links, whereas the immunoassays for the free forms may also detect cross-links that still carry carbohydrates. Some reaction also by small cross-linked peptides cannot be excluded. Specific assays have also been developed for measuring the urinary excretion of

TABLE 7. Assays for Degradation Products of Type I Collagen Fibers

Assay/Supplier/Sample	Antigenic Determinant/Assay Principle	Reference
ICTP/Orion Diagnostica +DiaSorin (previously Incstar) +Chugai Diagnostic Science/serum	Phenylalanine-rich domain in the carboxyl terminal telopeptide of type I collagen; trivalent cross-link necessary/RIA, polyclonal antiserum	[56,60]
CrossLaps™/Osteometer/serum	Two β-isomerized EKAHDGGR-peptides from the carboxyl terminal telopeptide; a trivalent cross-link must be present/ELISA, two monoclonal antibodies; automated version also available (Roche Diagnostics)	[65]
Urine (β assay)	Linear EKAHDGGR-peptide, β-isomerization of Asp residue necessary (?)/ELISA, polyclonal antiserum	[66]
Urine (α assay)	Linear EKAHDGGR-peptide, no β-isomerization of Asp residue/RIA, monoclonal antibody	[67]

ICTP = cross-linked carboxyl terminal telopeptide of type I collagen (see Fig. 7); NTx = trademark for assay of cross-linked aminoterminal telopeptide of type I collagen; RIA = radioimmunoassay; ELISA = enzyme-linked immunosorbent assay; CLIA = chemiluminescence immunoassay; EIA = enzyme immunoassay; HPLC = high-performance liquid chromatography

glycosylated hydroxylysines [63] that could be helpful in cases of defective lysyl hydroxylation or glycosylation.

Since a proportion of the urinary cross-links were known to be in peptides, the next phase was to develop immunoassays for the telopeptide regions of the collagen molecules where the cross-links are located. An in-house assay has also been described that measures a degradation product of type I collagen originating in its central, triple-helical domain and detects similar antigens in human serum [64].

Cross-Linked Telopeptides

At present, assays based on three kinds of antigenic determinant in the cross-linked telopeptides of type I collagen are commercially produced and generally available (Table 7), two of these being for the carboxyl terminal and one for the amino terminal telopeptide. The structures of the antigenic determinants required by the assays are depicted in Fig. 7. The size of the type I collagen fragments released depends on the nature of the degradative enzymes involved. The CrossLaps and NTx assays reflect cathepsin K-mediated bone resorption, whereas the ICTP is most likely derived via the matrix metalloproteinase route [60]. A further complication is caused by the fact that some aspartyl residues in the telopeptides are subject to L → D racemization and β isomerization of the subsequent peptide bond. Such aspartic acid residues are located within the epitope of the CrossLaps™ assay (Table 7). Recently, β-isomerization has been described also in the amino terminal telopeptide of type I collagen [73]. As the extents of these spontaneous modification reactions increase with time, the relative proportions of the different variants will vary, depending on the age of the collagen fiber being degraded. At the carboxyl terminus of type I collagen only the α1 chains take part in cross-link formation, whereas at the amino terminus the α2 chain also has an important role. The NTx assay is specific for such variants of the cross-linked N-telopeptides that involve the amino terminal telopeptide part of the α2-chain.

Collagen Degradation and Inherited Diseases

Conflicting results have been obtained with the type I collagen telopeptide assays in osteogenesis imperfecta [74]. The NTx assay has been reported to show increased type I collagen degradation in types I, III, and IV of this disease [75], whereas the ICTP assay [34] sometimes shows normal or decreased levels, as might be expected from

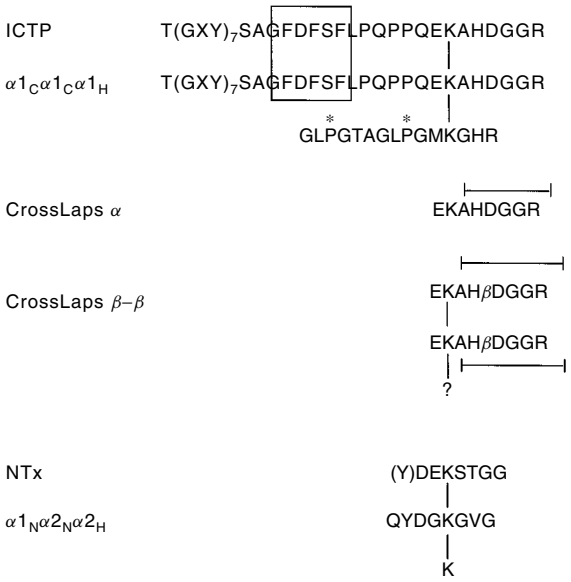

Figure 7. Antigenic determinants of different immunoassays recognizing the telopeptides of type I collagen. The CrossLaps and NTx assays reflect cathepsin K-mediated bone resorption, whereas the ICTP is most likely derived via the matrix metalloproteinase route [60]. In pycnodysostosis due to cathepsin K deficiency, the urinary excretion of the CrossLaps and NTx antigens is low, whereas the serum ICTP concentration is increased [59]. The ICTP assay detects only fragments having two phenylalanine-rich domains (box in the figure): to bring them together, a trivalent cross-link must be present. The asterisks denote proline residues (deduced from the DNA sequence) that in the protein are usually posttranslationally hydroxylated to 4-hydroxyproline. The CrossLaps assays detect linear, eight amino acid-long sequences, in which the aspartic acid residue (D) is in either α-or β-configuration, and can also racemize from an L- to a D-amino acid. The NTx assay requires the sequence QYDGKGVG, in which K is incorporated in a trivalent cross-link. The $\alpha1_C$ denotes the carboxyl terminal telopeptide, the $\alpha1_N$ and $\alpha2_N$ the aminoterminal telopeptide, and $\alpha1_H$ the peptide derived from the helical region of another collagen molecule. (Reproduced from [3], with permission.)

the decreased rate of synthesis of type I procollagen and, presumably, the smaller total amount of type I collagen in the body. There is some indication that qualitative defects in type I collagen are associated with more active collagen degradation [34,75] — in addition to NTx and ICTP, such a trend can also be seen in the excretion of the pyridinoline cross-links [34]. On the other hand, if the rate of type I collagen turnover is increased, the degradation of immaturely cross-linked collagen is not detected by the ICTP assay [60]. In addition, structures that are recognized by these assays can be derived from poorly mineralized bone matrix, which may be turned over at a high rate, as well as from the soft tissues.

Ehlers-Danlos Syndrome

An interesting, simple way to diagnose Ehlers-Danlos syndrome type VI has been suggested that can be carried out by determining the urinary excretion of hydroxylysyl pyridinoline and lysyl pyridinoline. Because the enzyme lysyl hydroxylase is defective, the amount of hydroxylysine is lower than normal. Three hydroxylysine residues are needed for the adequate formation of the hydroxylysyl pyridinoline. Consequently, the ratio of the less hydroxylated (lysyl pyridinoline or deoxypyridinoline) to the fully hydroxylated pyridinoline (hydroxylysyl pyridinoline or pyridinoline) cross-link has been found to differ dramatically between healthy individuals and patients with Ehlers-Danlos syndrome type VI [76,77] (see also Chapter 9, this volume).

Bruck Syndrome

Bruck syndrome (MIM 259450) (see also Chapter 26, Part IV, this volume) is characterized by the underhydroxylation of the telopeptides of type I collagen in bone, but not in that of ligaments, and not in those of type II collagen in cartilage [78]. Because telopeptidyl hydroxylysine is necessary for the formation of mature pyridinoline cross-links, the contents of hydroxylysyl and lysyl pyridinolines are low in bone collagen. Accordingly, the urinary excretion of lysyl pyridinoline is decreased and the ratio hydroxylysyl pyridinoline/lysyl pyridinoline is increased. However, hydroxyproline excretion is also increased, indicating an increased turnover of bone collagen (Ruud A. Bank, personal communication).

REMARKS ON THE USE OF THE REFERENCE INTERVAL TABLES (8–12)

The reference interval (previously known as normal range) of an analyte is generally defined as the range of concentrations that includes the central 95% of the values obtained in a given healthy population. For variables that show a Gaussian (normal) distribution, this is the same as the range defined as two (exactly 1.96) standard deviations to each side of the mean value. If the distribution is skewed, it can often be normalized by substituting the primary values by their logarithms, a procedure known as logarithmic transformation. If this is carried out, the limits of the reference interval are calculated using the logarithms and these are then changed back to the primary values.

Although a number of age groups from different countries have been studied with the collagen/procollagen assays, the quality and thus the usefulness of the reference values published is variable. Unfortunately, authors often do not disclose whether the distributions of the variables were found to be normal or not. Without this information it is impossible to know if it is legitimate to use, for example, the mean and standard deviation given to calculate the reference interval. Because of this diversity, we always indicate what parameter has been reported. Despite the lack of uniform reference intervals we felt justified in giving the information in the Tables as it was reported by the respective authors.

For the analytes measured in urine, there is an additional problem due to the great variation in urinary volume [79]. It is common practice to express the excretion of urinary collagen metabolites in relation to the amount of creatinine excreted in the sample. This is based on the assumption that creatinine excretion is relatively stable both within an individual and between individuals. However, when dealing with handicapped patients, often with decreased mobility, it is worth noting that creatinine excretion is related to muscle mass. A 24-hour collection of urine is generally considered ideal, but in practice a spot urine is mostly used, in particular for children. For such reasons, serum assays are generally preferred in modern clinical chemistry and these have also recently been developed for the collagen telopeptide variants. However, the kidneys concentrate the small excreted molecules and most likely also further catabolize the cross-linked peptides. Thus, free lysyl pyridinoline is practically unmeasurable in the blood, and urine should be used.

TABLE 8. Reference Intervals for Concentration of the Carboxyl Terminal Propeptide of Type I Procollagen (PICP)

Sample, Sex, Age	Concentration (μg/L)	Comment
Systemic Monitoring of Connective Tissue Metabolism		
Amniotic fluid		
Second trimester	3790–25,440 (2.5th and 97.5th centiles)	Finnish [20]
Labor at full term	70–630	
14 to 40 weeks of gestation	556–706[1] (95% confidence interval of adjusted mean in the appropriate-for- gestational-age group)	Caucasian and African American [80]
Cord blood serum (full-term)	1408 ± 419	American [81]
Serum		
Infants, 1 month	1408–5201 (95% confidence interval)	American [82]
3 months	998–3999	
6 months	961–2462	
9 months	763–1721	
12 months	829–1649	
18 months	710–1648	
Children, 1–5 years	294–402 (95% confidence interval)	Nigerian[83]
Boys, 0–2 years	784 ± 329	Chinese [84]
3–9 years	223 ± 118	
10–14 years	268 ± 113	
15–18 years	155 ± 20	
Girls, 0–2 years	557 ± 260	
3–8 years	216 ± 93	
9–12 years	243 ± 65	
13–17 years	129 ± 29	
Boys, 0.1–1.0 years	950 ± 86	Italian [85]
1.1–2.0 years	680 ± 87	
2.1–4.0 years	433 ± 58	
4.1–6.0 years	350 ± 57	
6.1–8.0 years	219 ± 40	
8.1–10.0 years	278 ± 35	
10.1–12.0 years	355 ± 25	
12.1–14.0 years	446 ± 37	
14.1–16.0 years	525 ± 46	
16.1–18.0 years	282 ± 29	
Girls 0.1–1.0 years	905 ± 82	
1.0–2.0 years	674 ± 90	
2.1–4.0 years	419 ± 50	
4.1–6.0 years	340 ± 42	
6.1–8.0 years	229 ± 21	
8.1–10.0 years	359 ± 24	
10.1–12.0 years	447 ± 36	
12.1–14.0 years	397 ± 32	
14.1–16.0 years	272 ± 24	
16.1–18.0 years	218 ± 27	
Boys, 2–14 years	52–544 (mean ± 2SD, normalized to body surface)	Italian [86]
Girls, 2–12 years	18–546	
Boys, 4–16 years	193–716 (95% reference interval)	Irish [87]
17–18 years	105–452	
Girls, 4–12 years	225–676	
13–14 years	108–567	
15–18 years	82–285
