SUMMARY

- **Osteogenesis imperfecta (OI) is a clinically and genetically heterogeneous disorder characterized by osseous fragility and fractures, accompanied by other connective tissue alterations, and thought to affect about 1 per 10,000 individuals in all its forms.**
- **The vast majority of affected individuals have mutations in one of the two genes, *COL1A1* and *COL1A2*, that encode the two chains of type I collagen, the major protein of bone. On clinical, genetic, and radiological grounds, now modified by biochemical and molecular genetic studies, four major types of OI have been delineated.**
- **OI type I, characterized by bone fragility, near-normal stature and blue sclerae, usually results from mutations in the *COL1A1* gene that lead to low or absent levels of the products of one allele, generally the result of premature termination codons.**
- **OI type II is lethal in the perinatal period and, like the other forms of OI, usually results from heterozygosity for mutations in either of the two type I collagen genes that perturb the normal sequence of the triple helix, particularly by mutation of single glycine codons or by mutations that lead to exon skipping.**
- **OI type III, the progressive deforming type, is characterized by severe growth retardation and bone deformity, accompanied by marked limitation of mobility, and life expectancy may be diminished.**
- **OI type IV is less severe, with adult stature ranging from about 4 feet (122 cm) to normal, and ambulation is generally independent although sometimes assisted.**
- **Although inheritance is generally autosomal dominant, recurrence in sibships with unaffected parents is seen with several types of OI and usually reflects parental mosaicism for the mutation.**
- **Confirmation of the diagnosis by analysis of collagens produced by cultured dermal fibroblasts or by direct gene analysis is readily available.**
- **Prenatal diagnosis is available for most forms of OI using a variety of strategies.**
- **Although treatment has been largely mechanical through assisted ambulation and internal fixation of bones, more recent studies suggest that additional medical strategies may hold promise.**

INTRODUCTION

The major clinical feature that defines osteogenesis imperfecta (OI) is bone fragility. Fractures may be rare or frequent (more than 200 prior to puberty), and bone fragility may be accompanied by reduced life span, short stature, bone deformities, dentinogenesis imperfecta, hearing loss, altered scleral hue, and other evidence of connective tissue abnormalities [1,2] (Table 1). In almost all individuals, OI results from mutations in one of the two genes (*COL1A1* and *COL1A2)* that encode the chains of type I collagen (Fig. 1, Tables 2 and 3).

History, Prevalence, and Classification

OI in all its forms probably affects more than 1 per 10,000 individuals, although precise accounting is difficult because of unfamiliarity with the disease among health care personnel, poor reporting of some forms, and, in some centers, evaluation of incidence at birth, which often misses the more mildly affected individuals. The condition is seen in all ethnic and racial groups, probably with equal frequency. There may be some forms of OI that are more common in isolated regions, presumably because of the accumulation of a rare recessive allele [3–5]. OI has been in existence for more than two millennia, and at least one skeleton from among those preserved in Egypt has the morphology compatible with a deforming variety of the disease [6]. A partial skeleton from the 7th century in Britain also has similar features [7]. Seedorf [8] cites the 11th century example of Ivar Benlos (Ivar the Boneless), the son of King Regnar Lodbrog, who was carried about on a shield and had little skeleton, as an example of OI in Denmark.

Lethal forms of osteogenesis imperfecta were recognized during the late 18th century and early 19th century by Lobstein [9] and by Vrolik (see discussion by Seedorf [8]), who lent their names to the syndrome [2]. By the middle of

Connective Tissue and Its Heritable Disorders, pages 385–430

TABLE 1. Classification of Types of Osteogenesis Imperfecta

Type	Clinical Manifestations	Inheritance	Molecular Defects
I (Mild)	Blue sclerae, bone fragility, normal or near-normal stature, no deformity, hearing loss in adolescence to adult years	AD	*COL1A1* Null
II (Perinatal lethal)	Short, deformed extremities, soft thoracic cage and skull with severe bone fragility, absent calvarial mineralization, bony compression, platyspondyly, and beaded ribs. Dark sclerae. Death in the perinatal period.	AD (New mutations) AR (Exceedingly rare)	*COL1A1* and *COL1A2* Substitutions for glycine Exon skipping Partial gene deletions C-terminal propeptide mutations that interfere with chain association
III (Deforming)	Bone fragility and progressive deformity, marked short stature, light sclerae, dentinogenesis imperfecta, hearing loss in early adult life and shortened survival, on average.	AD AR (Rare)	*COL1A1* and *COL1A2* Substitutions for glycine Exon skipping *COL1A2* mutations that prohibit chain association Homozygous by descent for point mutations in the triple helix
IV (Mild deforming)	Bone fragility, mild to moderate short stature, mild bone deformity, dentinogenesis imperfecta, light colored sclerae, hearing loss in early adulthood.	AD	*COL1A1* and *COL1A2* Substitutions for glycine Exon skipping Partial gene deletions
V*	Bone fragility, mild to moderate short stature, no dentinogenesis imperfecta, radio-ulnar synostosis. Hyperplastic callus formation	Probably autosomal dominant	Not known

*Details of recent studies that distinguish OI type IV and OI type V are discussed in Recent Developments.

the 18th century, the familial nature of OI was recognized and one family with autosomal dominant inheritance had been described by Ekman [10] (cited by Seedorf [8]). The association of OI with blue sclerae [11] and with hearing loss [12,13] was identified in the early part of the 20th century. The postulate that severe (congenita) forms differed from the milder varieties (tarda) based on the time at which fractures first occurred was proposed by Looser in 1906 [14]. Although often helpful in predicting long-term morbidity, this division frequently provided a false sense of security because it could be difficult, several years later, to distinguish some individuals initially classified in the tarda group from those in the congenita group. By the mid 1920s, Bell [15] was able to assemble a large number of families in Britain with OI and recognized that there was additional heterogeneity. Seedorf [8] realized that there were at least two milder phenotypes, one in which there was little deformity, generally normal height, and blue sclerae, and a second in which deformity was the rule. Ibsen [16], who recognized the heterogeneity described by Seedorf, was able to compile a substantial number of additional families.

Beginning in the late 1970s, Sillence and his colleagues [1,17], using radiographic, genetic, and clinical criteria, developed the classification currently in use. Although this division of OI into four major types (I–IV) was rapidly adopted by geneticists, it has not achieved similar popularity with orthopedic surgeons because of the difficulty in classifying many affected individuals. The Sillence modification of the Danish classification [8] has been used to categorize most of the patients who have been investigated at the biochemical and genetic levels. The biochemical studies themselves and recent linkage studies support the broad validity of the classification but confirm that it is incomplete. Although biochemical and genetic studies will provide the basis of the most rational classification, even such a detailed biochemical classification probably will never predict correctly the evolution of OI in every affected individual because of the still unexplained variability of expression seen in many families.

The value of a classification scheme and the criteria used to develop it depend on the use to which it is to be put. From a clinical point of view, classification is needed to provide information about natural history and recurrence risks and to determine whether therapies will change natural history. If these requirements can be met by clinical data alone, then no additional elements are necessary. At the present time, the clinical data alone do not provide some important information. For example, it is not possible to distinguish on clinical evaluation alone the apparently rare autosomal

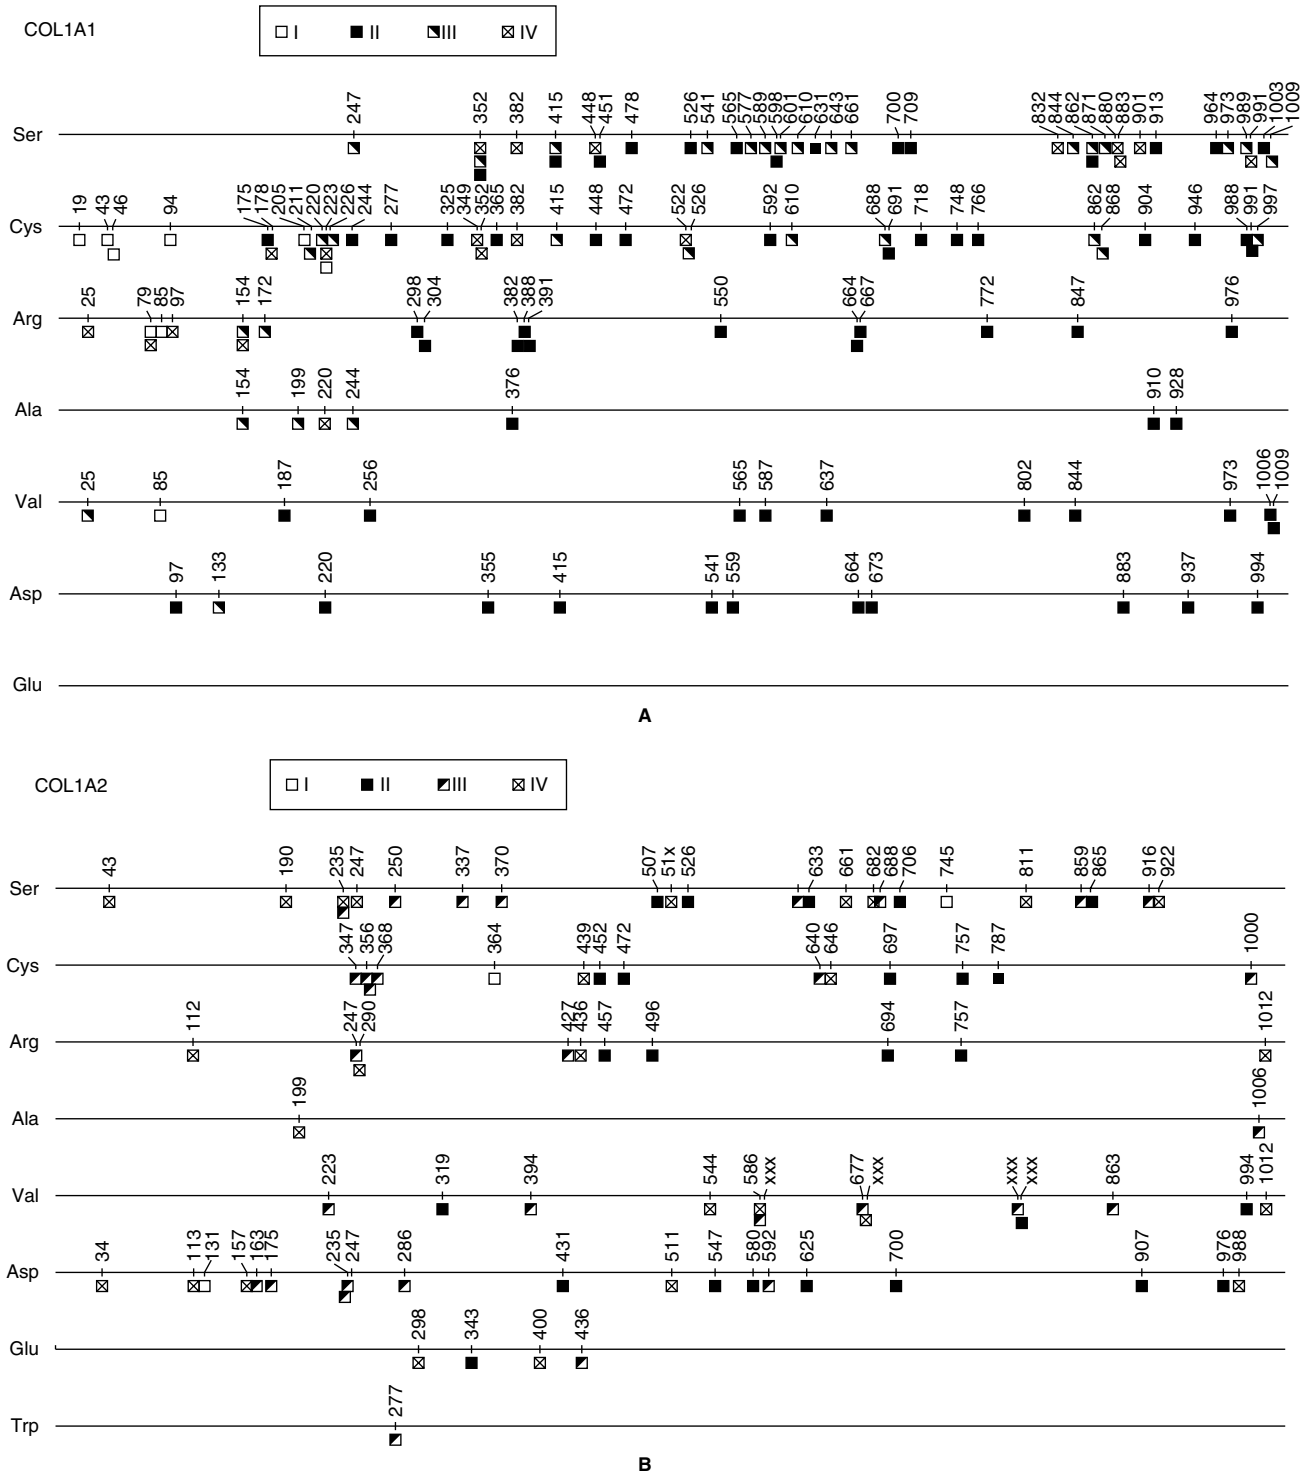

Figure 1. Point mutations in the triple-helical domains of the *COL1A1* (**A**) and *COL1A2* (**B**) genes that result in substitutions of glycine residues by other amino acids. The numbered residues are within the triple-helical domain of each chain; the first glycine of the triple helix is designated as residue number 1. There are 1,014 residues in the triple-helical domain of each chain. The substituting residue is listed at the left end of each line, the substituted glycine and its position are indicated by number, and the phenotype is indicated below the line. The source references for each published mutation can be found in the Database of Human Type I and Type III Collagen Mutations (*http://www.le.ac.uk/genetics/collagen/index.html*). All other mutations are from our own unpublished studies.

TABLE 2. Splice Site Mutations in the *COL1A1* Gene and Their Outcomes*

Phenotype	Mutation	Effect	Reference
OI type III	IVS8 + 1G → C IVS8 + 5G → A	Redefinition of exon 7 with skip of exon 8, skip of exon 8, retention of IVS 8; retention of IVS8 and IVS 7; use of cryptic acceptor in exon 8	[57] [59]
OI type IV	IVS9 − 1G → T	Skip exon 10	Unpublished
OI type I	IVS12 + 1G → A	Null allele, mechanism unknown	[19]
OI type I	IVS13 − 9G → A	Creates a new acceptor site, which is preferentially used, adds 7 nt to the mRNA and a frame shift in exon 14	Unpublished
OI type II	IVS14 + 5G → A	Exon skip in about half the products of the mutant allele	[133]
OI type II	IVS14 + 2T → A	Skip exon 14	Unpublished
OI type I	IVS16 − 2A → G	Low-abundance exon 17 skip; most of the products are rapidly degraded	Unpublished
OI type I	IVS17 + 1G → C	Rare skip of exon 17; most products are functionally null	[96]
OI type I	IVS18 + 1G → A	Use of cryptic donor site in exon 18 at G − 8 leads to frame shift and unstable mRNA	[56]
OI type I	IVS18 − 1G → A	Null allele, mechanism unknown	[19]
OI type II	IVS20 + 5G → C	Exon 20 skip	Unpublished
OI type I	IVS20 − 2delAG and del first 5 nt of exon 21	Use of downstream acceptor site in exon 21 results in frame shift	Unpublished
OI type II	IVS21 − 3C → N	Exon 22 skip	Unpublished
OI type I	IVS22 + 3A → G	Null allele; mechanism unknown	[19]
OI type I	IVS23 + 1G → C	Inclusion of 44 bp of intron 23 Inclusion of entire intron 23 Both contain stop codons	Unpublished
OI type I	IVS25 − 1G → A	Null allete, mechanism unknown	[19]
OI type I	IVS26 + 1G → A	Inclusion of intron 26	[322] [323]
OI type II	IVS26 − 2A → C	Exon 27 skip	[96]
OI type II	IVS29 − 2A → C	Exon 30 skip	Unpublished
OI type I	IVS36 + 1G → A	Use of cryptic donor site 44 bp upstream in exon 36; frame shift in exon 37	Unpublished
OI type II	IVS43 − 2A → G	Skip exon 44	[324]
OI type I	IVS44T + 2 → C	Use of alternative donor site in exon 44 8 nt upstream from usual site	Unpublished
OI type II	IVS47G + 1 → A	Exon 47 skip	Unpublished
OI type III	IVS47C − 3 → G	Low-abundance exon 48 skip; unclear whether some is spliced normally or is lost	Unpublished
OI type I	IVS48G + 1 → A	Unstable mRNA; mechanisms not identified. May use G − 17 in exon 48, G + 4 in intron 48, or include 91nt intron	[56]
OI type I	IVS49T + 2 → C	High-abundance mRNA that uses a nontraditional donor site GAG/GGC within the upstream exon; mRNA is abundant and stable, but frame shift occurs in product	Unpublished

*All unpublished mutations described in this table come from the laboratory of PH Byers.

recessive forms of OI that give rise to progressive bone deformity from those that result from dominant mutations. Furthermore, the hypothesis [1,18] that the severe lethal forms of OI were due to autosomal recessive mutations could not explain the unexpectedly low rate of recurrence of the condition among siblings, just as new dominant mutations could not explain what appeared to be an unexpectedly high recurrence rate.

From the point of view of molecular genetic studies, it should be possible to distinguish mutations in the *COL1A1* gene from those in the *COL1A2* gene, to distinguish among various types of mutations, and to distinguish among mutations in different domains of the two genes. Although hypothesized [5], no mutations that cause OI have been identified in genes other than those of type I collagen. It has become practical, although still expensive, to identify

TABLE 3. Splice Site Mutations in the *COL1A2* Gene and Their Outcomes*

Phenotype	Mutation	Effect	Reference
OI type IV	IVS9 + 1G → T	Skip exon 9	Unpublished
OI type IV	IVS9 + 5G → A	Skip exon 9 (may be more complex)	Unpublished
OI type IV	IVS9 del + 4–7	Skip exon 9	Unpublished
OI type I/IV	IVS9 del + 3–13	Skip exon 9	[236]
OI type I/EDS	IVS9 + 5G → A	Skip exon 9	[325]
OI type IV	IVS12 + 2T → G	Skip exon 12	[237]
OI type IV	IVS12(+1) – (+19)del	Skip exon 12	Unpublished
OI type IV	IVS14 + 2T → C	Skip exon 14	Unpublished
OI type IV	IVS14 + 2T → A	Skip exon 14	Unpublished
OI type IV	IVS15 – 2A → G	Skip exon 16	Unpublished
OI type IV	IVS16 + 1G → A	Skip exon 16	[238]
OI type IV	IVS16 + 2T → C	Skip exon 16	[239]
OI type I	IVS19 – 1G → C	Skip exon 20	[240]
OI type IV	IVS21 + 5G → C	Skip exon 21 Normal splice of mutant allele	Unpublished
OI type IV	IVS21 + 5G → A	Skip exon 21 (only)	Unpublished
OI type I/DI	IVS21 + 5G → A	Skip exon 21	[241]
OI type IV	IVS26 + 3A → G	Skip exon 26	[242]
OI type II	IVS27 – 2A → G (Other allele is null)	Skip exon 27	[97]
OI type II	IVS30 + 1G → A	Skip exon 30	Unpublished
OI type II	IVS32 + 1G → A	Skip exon 32	Unpublished
OI type IV	IVS33 + 4G → A	Skip exon 33 Use of cryptic donor site in intron 33 that results in insertion of 18 nt and 6 amino acid residues	[243]
OI type II	IVS33 + 5G → A	Skip exon 33	[135]
OI type II	IVS37 + G → T	Skip exon 37	Unpublished
OI type IV	IVS37 – 2A → G	Skip exon 38 Probably minor outcome; major use of cryptic site and frame shift	Unpublished
OI type II	IVS41 – 3T → G	Skip exon 42	Unpublished
OI type IV	IVS43 + G → A	Skip exon 43, include intron 43	Unpublished

*All unpublished mutations described in this table come from the laboratory of PH Byers.
EDS, Ehlers Danlos Syndrome; DI, Dentinogenesis Imperfecta.

mutations in the *COL1A1* and *COL1A2* genes with sufficient speed to make them clinically useful [19]. This strategy can be particularly useful for prenatal diagnosis early in pregnancies at risk and to identify individuals who are mosaic for mutations and thus at risk of having infants with much more severe phenotypes than those with which they themselves are affected. From a clinical point of view, it is often not significant whether the mutation occurs in *COL1A1* or *COL1A2*; it is the mode of inheritance and the ability to determine whether the next child is affected that are important.

Most geneticists continue to use the Sillence classification as it has been modified by the use of molecular genetic and biochemical studies during the last two decades. The Sillence classification is used here, while trying to point out both its limitations and its advantages. Thus, as now construed, osteogenesis imperfecta can be divided into four major groups — types I, II, III, and IV — that differ in clinical presentation, radiographic picture, mode of inheritance, and, for the most part, biochemical basis of the connective tissue disorder (see Tables 1–3 and Figs. 1 and 2). It is likely that biochemical, morphologic, and molecular genetic studies will add additional types of OI in future years [20], but there are not yet sufficient published criteria to warrant their addition in this chapter.

The greatest limitation of the Sillence classification, even as modified from the original here (and of any other classification, for that matter), is that it attempts to convert what is essentially a continual variable of clinical phenotypes into discrete variants. In this situation, a "stereotyped" or idealized prototype is taken as the model. As will be clear, the linear nature of the type I collagen molecule and the possibility of literally thousands of discrete causative mutations in each of two genes (*COL1A1* and *COL1A2*) are more compatible with a continuously variable range of phenotypes than with discrete entities. Nonetheless, to the extent that phenotypes vary around a few discrete nodes, classification in this manner can be useful for the clinician and for the family.

From the perspective of a classification of OI based on gene of origin and nature of the mutation, several different elements emerge. There are four general classes of mutation: (1) those that alter the amount of type I procollagen produced; (2) those that alter the structure of the triple-helical domain of type I procollagen by virtue of substitutions of the canonical third position glycine residue, small deletions or duplications, or exon skipping; (3) those that alter residues in the carboxyl-terminal propeptide and influence chain association; and (4) those that alter the chain composition of

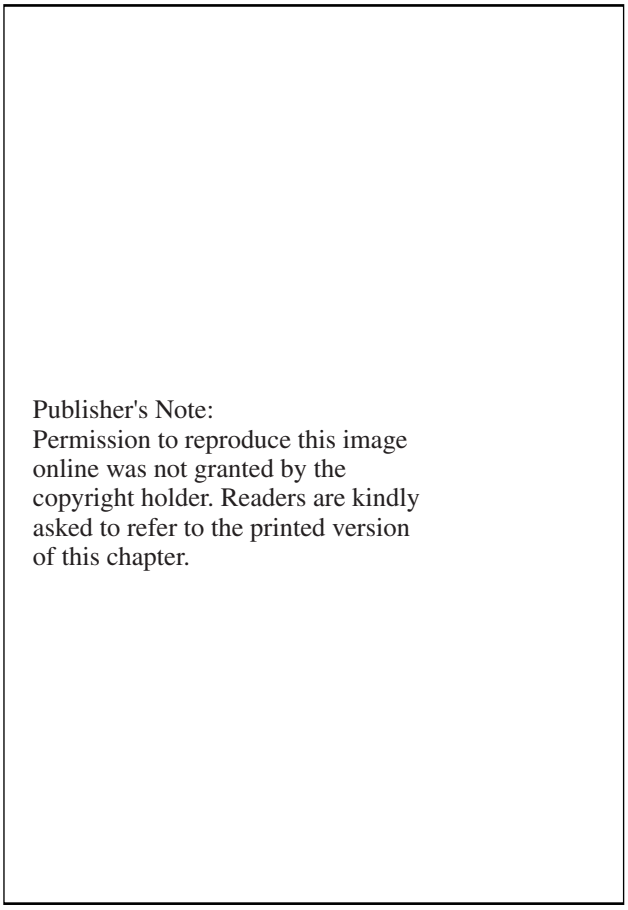

Figure 2. Molecular mechanisms of osteogenesis imperfecta. Virtually all individuals with OI have mutations that affect either the amount of type I procollagen synthesized (Group A) or the structure of the chains of type I procollagen (Group B). In the first group (**A**), ''excluded'' mutations, the decreased synthesis of type I procollagen usually results from a decrease in the amount of steady-state mRNA for the proα1(I) chain. Because type I procollagen molecules must contain at least two proα1(I) chains, that chain becomes the limiting molecule in procollagen production. Almost all the mutations that result in decreased *COL1A1* mRNA are those that lead to premature termination codons in the mRNA, although a mutation in a *COL1A2* allele that resulted in the destruction of all procollagen molecules into which the abnormal chain was incorporated could produce the same end result. In the second group (**B**), ''included'' mutations, mutations may occur in either the *COL1A1* or the *COL1A2* gene to alter the structure of proα chains. The gene in which the mutation occurs affects the proportion of abnormal molecules and is probably reflected in the phenotype. (Reprinted from [71].

type I procollagen by diminishing the production of proα2(I) chains. The clearest distinction in phenotype is between those mutations that decrease the production of type I procollagen and those that produce abnormal molecules. The former result in the mild OI type I phenotype, whereas the latter produce the more severe deforming and lethal varieties. For mutations within the triple-helical domain, the nature of the substituting amino acid, the chain in which it occurs, and the position in the chain are all factors that contribute to the severity of the phenotype (see extended discussions below). It is clear, however, that not all the determinants of the phenotype are known. The lack of complete understanding of the variables in this pathway may be best understood if it is remembered that OI represents the physiological response of an organism to mutations in a major structural element of body form, type I collagen. Such a concept emphasizes the role of evolution in defining the complexity of interactions of these molecules and the role that variations in other molecules play in determining body form.

OSTEOGENESIS IMPERFECTA TYPE I

Clinical Features of Osteogenesis Imperfecta Type I

OI type I (MIM 166200) is inherited in an autosomal dominant fashion and, typically, affected individuals have blue sclerae, normal teeth, normal or near-normal stature, and may experience a few or more than fifty fractures (usually of long bones) before puberty [1,21].

Individuals with OI type I rarely have fractures *in utero* or in the perinatal period, although femoral bowing can lead to early prenatal diagnosis. Occasionally, fractures occur during diaper changing, but their usual onset is when children begin to stand and walk. Fractures may affect any bone, but it is common to see involvement of long bones, the ribs, and the small bones of the hands and feet. Avulsion fractures of the olecranon and transverse fractures of the patella, which are seen in people with OI type I, result from sudden contractions of the triceps and quadriceps, respectively [22]. Fracture frequency remains roughly constant through childhood and then decreases dramatically after puberty. Although many hormonal changes occur in the peripubertal period and no doubt contribute to the change in fracture rate, animal models suggest that bone thickness increases to compensate for fragility [23]. Fractures heal normally and without deformity, given good orthopedic care.

The incidence of OI type I has been estimated at between 1 in 15,000 and 1 in 20,000 but, because of the relatively mild presentation, the incidence may be underestimated. There appears to be no decrease in fertility and little, if any, change in the longevity of affected individuals (that is, genetic fitness approaches 1). At birth, blue sclerae are readily apparent and may be darkly colored, lightening gradually to the blue-gray present in affected adults. Radiographic bone morphology is generally normal at birth, although mild osteopenia or femoral bowing may occur in some newborns. Affected individuals are usually within the normal range for height although often shorter than their unaffected family members. Vertebral body morphology in the adult is normal initially but often develops the classic ''cod-fish'' appearance, which is accompanied by loss of height in later decades (Fig. 3). Fracture frequency may increase following the menopause in women and in the sixth to eighth decades for men. In about half the families with OI type I, affected individuals have early-onset hearing loss, beginning in the late teens and leading gradually to profound loss by the end of the fourth to fifth decades [24–29]. Early hearing loss is generally conductive and may be readily treated by surgical techniques. Later, a sensorineural component appears to emerge [28]. Despite advances in prosthesis design and in the technique of replacement of the fractured and fused bones of the middle ear, which provide significant restoration of hearing for many affected individuals [27,30–35], hearing loss may continue following a period of improvement after surgery. Early hearing loss is typically high-frequency in type, and tympanometry identifies a characteristic bifid compliance curve [24].

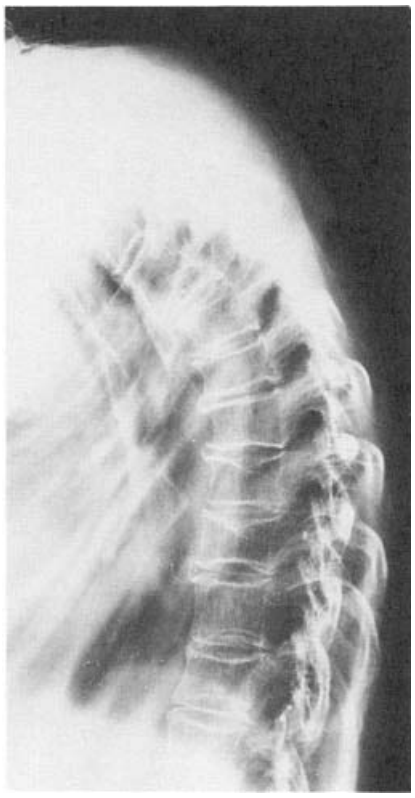

Figure 3. Vertebral body deformity (''cod-fish'' vertebrae) in a 48-year-old woman with OI type I. The lateral spine X-ray demonstrates marked osteopenia, kyphosis, and deformation of the vertebral bodies by the intervertebral discs. The radiograph is courtesy of Drs. David Rowe and Jay R. Shapiro.

Additional clinical findings in people with OI type I may include mild joint hypermobility and increased bruising. Mitral valve prolapse and aortic valvular insufficiency have been identified in some individuals with OI type I, but it is not clear that these disorders are significantly more frequent than in the general population [36]. A small group of people who have OI type I have been found to have slightly larger than normal aortic root diameters, apparently without significant risk of progression or dissection [36,37]. Rare individuals with OI type I may have vascular dissection [38]. Although type I collagen is a major structural element of arterial walls, the effect of diminished amounts of it is not a universal predisposition to aneurysm formation or dissection, both of which appear to be uncommon.

In some classifications, OI type I is subdivided on the basis of the absence (IA) or presence (IB) of dentinogenesis imperfecta (DI) [39]. Even mild dentinogenesis imperfecta is very uncommon when OI type I is defined by the biochemical finding of diminished type I collagen production and no evidence of abnormal molecules [40]. Most individuals with DI make abnormal type I procollagen molecules, and some with relatively mild forms of OI may also have blue or blue-gray sclerae [40]. Blue sclerae are not the sole clinical criterion for OI type I, and the inclusion of a form of OI type I with DI may reflect an undue reliance on scleral hue as a distinguishing feature of OI types.

Biochemical and Molecular Bases of OI Type I

Null Alleles (Silent Alleles or Mutations Leading to Excluded Proteins) are Most Common

Several forms of OI were among the earliest of the inherited disorders of collagen biosynthesis and structure to be studied using cultured dermal fibroblasts from affected individuals [41,42] (for detailed reviews of collagen protein and gene structure, see Chapter 2, this volume). Cells cultured from patients who, in retrospect, would be considered to have OI type I synthesized less type I procollagen than did those from controls, but the mechanism by which production was decreased was not determined. Concordant with these studies, skin from many individuals with OI, including those with mild, dominantly inherited OI and blue sclerae, had a low ratio of type I to type III collagen [43]. It soon became clear that the synthesis of type I procollagen by cells cultured from individuals with OI type I was about half the normal level, while that of type III procollagen was normal [44] (see Fig. 4 as an example). The structure of the secreted type I procollagen was normal, and the decrease in type I procollagen production resulted from the synthesis of only half the usual amount of the proα1(I) chains of type I procollagen (see Fig. 2).

The mechanism by which the synthesis of proα1(I) chains is decreased has come under increasing scrutiny. In the vast majority of instances, the mechanism reflects about half normal steady-state levels of *COL1A1* mRNA in cells. A variety of mutations that result in decreased synthesis of proα1(I) chains — deletion of an allele, promoter and enhancer mutations, splicing mutations that lead to frame shifts and premature termination codons, as well as point mutations that change codons to termination codons, all have the potential to reduce amounts of steady-state *COL1A1* mRNA, although deletion of the entire allele and promoter/enhancer mutations have yet to be described [45]. Mutations that prohibit proα1(I) chain assembly into molecules also result in the same biochemical picture and similar clinical phenotypes.

Examination of genomic DNA from fifteen individuals with OI type I demonstrated no evidence of change in copy number of the *COL1A1* gene in individuals [46]. Furthermore, linkage studies in 38 additional families have

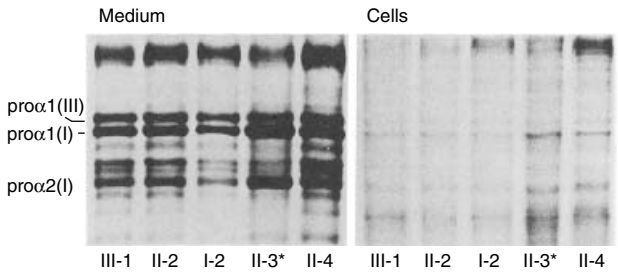

Figure 4. Decreased synthesis of type I procollagen by dermal fibroblasts from individuals with OI type I. Cells were incubated with [^{3}H]proline overnight in the presence of ascorbic acid. The medium and cell-layer proteins were harvested separately and examined under reducing conditions by SDS-polyacrylamide gel electrophoresis. Individual II-3 is not affected; all the others have OI type I. The pedigree is presented in Fig. 5A. In the cells from affected individuals, a mutation in one allele of the *COL1A1* gene prevents the protein product of the mutant allele from associating with other molecules (see Fig. 5). (Reproduced from Willing et al. [60].)

demonstrated no evidence of deletion of those regions of the *COL1A1* gene used for linkage analysis [47] and confirmed that most individuals with the OI type I phenotype have mutations linked to the *COL1A1* gene. There are three common types of mutation that result in a reduced level of cytoplasmic *COL1A1* mRNA. These are single base substitutions that create a premature termination codon, insertion or deletion of nucleotides in numbers not whole integer multiples of three so that frame shifts and downstream stop codons are produced, and splice site mutations that result in insertions or deletions that produce frame shifts or intron inclusions with internal stop codons [19,48–52] (Table 4). It appears, on the basis of quite limited data, that single codon mutations to nonsense codons, small insertion/deletions (perhaps at "hot spots" characterized by runs of single nucleotides [19]), and splice site mutations are probably equally represented as the causative mutations. Although such mutations are often referred to as "truncation" mutations, with the expectation that they encode shortened proteins, the major impact is instead very marked reduction in stability of the mRNA due to a process known as "nonsense-mediated decay." Although a small amount of this mRNA can often be amplified from cells [53], more detailed studies demonstrate that the majority of it is retained within the nucleus, where translation does not occur. If the new stop codon is separated from the normal termination codon by one or more introns, the mRNA is usually very unstable, although the precise mechanism of decay is unclear [54,55].

Splice site mutations constitute a special category because similar mutations at other intron/exon boundaries can result in exon skipping and very different phenotypes. For example, the same mutation in adjacent introns 47 and 48 (IVS + 1G → A) results in OI type I (intron 48) [56] or lethal OI type II (intron 47) (PH Byers, unpublished). The intron 48 mutation results in the use of alternative donor sites that produce frame shifts, premature termination codons, and unstable mRNA. In contrast, the intron 47 mutation results in exon skipping and deletion of an in-frame cassette (see below for discussion of disease mechanism). Although this pattern of mutation outcome has been seen in many genes, the explanation has been elusive. It now appears that the most likely reason for differences in outcome of these mutations is related to the order in which the intron is normally removed with respect to the surrounding introns [57,58]. It appears now that mutations in rapidly removed introns generally result in skipping of the adjacent exon, whereas mutations in slowly removed introns result in the choice of alternative acceptor or donor sites, or intron inclusion, most of which lead to frame shifts and mRNA instability [57,58]. In some instances, an intron can be removed in a different order in different splicing pathways. When this occurs, multiple outcomes may appear and change the expected phenotype [57,59].

Mutations that Abolish Proα1(I) Chain Association can Produce OI Type I

The most completely characterized mutation in the *COL1A1* gene that results in the defective production of type I procollagen as a result of a defect in chain association is a 5 bp deletion near the 3′ end of one *COL1A1* allele [60]. The mutation results in a reading frame shift 12 amino acid residues from the normal terminus of the chain and predicts an extension of 84 amino acids beyond the normal termination site (Fig. 5). Although the abnormal mRNA can be translated *in vitro*, it is very unstable in the intact cell. A similar mutation in the murine *Col1A1* gene also results in the synthesis of a very unstable chain that can be stabilized by the addition of proteosome inhibitors, suggesting that these chains are synthesized and rapidly degraded in the proteosome, a cytoplasmic entity responsible for turnover of many proteins [61]. Because the proα chains are normally synthesized within the rough endoplasmic reticulum, proteosomal degradation would require retrograde transport, something seen with several other defective proteins. The possibility that a protease residing in the endoplasmic reticulum, rather than the 26S cytoplasmic proteosome, is responsible for degradation has not been entirely excluded because the inhibitors of proteosomal degradation are not entirely specific. Although the end effect of this mutation, a lack of adequate proα1(I) chains, is the same as if the mRNA were unstable, it makes clear that many different mutations in the *COL1A1* gene could produce the OI type I phenotype by resulting in the

C

Figure 5. Molecular basis of OI type I in one family (pedigree at top). **A**, **B**: Southern blots of genomic DNA from family members. DNA was digested with *Eco*R1 and separated by electrophoresis in agarose before transfer to nitrocellulose. The filter was hybridized with a partial cDNA from the 3′ end of the *COL1A1* gene (A in map below) (**A**) or with a short fragment of the cDNA (B in map below) from the 3′-untranslated region (**B**). There are two *Eco*R1 sites 22.6 kb apart that encompass virtually the entire coding region of the gene (see map below **B**). The 3′ site is located approximately 30 bp from the 3′ end of the coding sequence (**B**), and a third *Eco*R1 site is located 5.7 kb further 3′ in the DNA. In this family, affected members have two distinct alleles: one is normal, and the other is about 6 kb larger than normal (**A**). The mutation in this family is the deletion of 5 bp within the 3′ intragenic *Eco*R1 site that fuses the 22.6 kb and 5.7 kb fragments (**B**). This mutation results in a frame shift and the synthesis of a chain predicted to be 84 amino acids longer than normal because of the carboxyl-terminal extension (**C**). The abnormal chains appear to be highly unstable and rapidly degraded within the cell (**D**). Figures **A**–**C** reproduced from Willing et al. [60].

synthesis of half the normal amount of a functional proα1(I) chain. In each instance, the synthesis of proα2(I) chains would be expected to be normal, but about half of them would not be incorporated into intact molecules (because proα2(I) chains alone cannot associate into trimers) and thus would be degraded.

Structural Mutations in COL1A1 and COL1A2 can also Produce OI Type I

In some families, a phenotype similar to OI type I is thought to result from mutations in the *COL1A2* gene, but the clinical criteria by which the diagnosis of OI type I is made are not always clear. Although less common than "null" allele mutations, there are several examples in which the synthesis of abnormal type I procollagen molecules can produce the OI type I phenotype (see Fig. 1 and 2). In one family, cells cultured from the affected mother and son, but not the normal daughter, synthesized α1(I) chains bearing a cysteine residue within the protease-resistant domain of the collagen molecule, a region from which that residue is normally absent [62]. Although it was initially thought that the substitution could be for a nonglycine residue in the triple helix, peptide sequence analysis and the sequence of the cDNA demonstrated that the mutation resulted in the substitution of a glycine by cysteine three amino acid residues carboxyl terminal to the end of the triple helix [63,64]. This mutation did not lead to overmodification of the triple helix, in contrast to mutations that produced substitutions for glycine within the triple-helical domain. The mechanism by which bone fragility was produced is not clear but could reflect the presence of a free sulfhydryl group in about half the type I collagen molecules (those that contain only a single abnormal chain). Other substitutions of cysteine for glycine within the triple-helical domain of the α1(I) chain at residues 94 [65], 46 [66], 43 [67], and 19 [40] also produce very mild forms of OI, perhaps compatible with OI type I.

One patient, with blue sclerae, a height of 4′ 10″ (147 cm), deformity as a result of a poor orthopedic result, and hearing loss, was the only affected member of her family. Her cultured dermal fibroblasts synthesized a proα2(I) chain in which 18 amino acid residues were deleted from the triple-helical domain [68]. Subsequent studies indicated that a point mutation resulted in the excision of the sequence of exon 12 (amino acids 91–108) from about half the *COL1A2* transcripts as a result of a point mutation at the consensus splice donor site. These findings suggest that other point mutations in the *COL1A1* gene, and perhaps in the *COL1A2* gene (as suggested also by linkage studies [47,69,70]), could produce similar phenotypes (see Fig. 1 and 2 and Tables 2 and 3).

Diagnosis, Management, and Treatment of OI Type I

OI type I is first suspected because of a family history or the finding of blue sclerae in the patient with fractures but normal body habitus. In the absence of a family history, the diagnosis is generally confirmed by studies of collagen synthesis by dermal fibroblasts [71] or by direct analysis of the type I collagen genes [19]. It is important to establish, or confirm, the diagnosis in infants for whom there is no family history because the biochemical or molecular genetic studies provide reassurance as to the relatively mild natural history, provide a way to determine the recurrence risk (small), and, in large part, eliminate concern that fractures arise from abuse [66] (and see below). A letter to the family and another to the referring physician are often vital forms of protection against harassment of the family. When first seen, each affected individual should have formal hearing evaluation, which should be repeated at approximately three-year intervals after adolescence. There are probably not increased risks of other disorders, and routine health care and preventive medicine protocols should be followed.

Currently, no treatment is known for OI type I that decreases the frequency of bone fracture or increases bone density [72,73]. An effective agent could increase the production of type I procollagen if the mutation that produced the phenotype resulted in diminished synthesis and secretion. Although a number of agents, such as ascorbate, can increase the production of collagens by cells in culture, none has been tested clinically. Alternatively, an agent that decreased bone turnover could be effective. Bisphosphonates, which alter bone resorption and alter the rate of fracture in osteoporosis, are potentially effective agents that need to be studied in a controlled format. Preliminary data presented at the Sixth International Symposium on Osteogenesis Imperfecta (Montreal, September 1999) by Sillence and others suggest that as children with OI type I go through puberty, usually they do not have the increase in bone mass and bone density that occurs in unaffected children. Use of intravenous pamidronate may increase bone density in this period. Only a small group of people have been studied in this context, and it cannot be emphasized too strongly that carefully controlled studies are needed to assess the efficacy of such agents. Further use of the drug in other forms of OI is discussed below.

The orthopedic management of individuals with OI type I is generally straightforward [74]. Families are instructed in the emergency care of fractures. The methods of fracture treatment are the same as in normal children. Immobilization is kept to a minimum, and lightweight casts are used routinely. Avulsion fractures of the olecranon and patella are fixed with biodegradable devices, thereby avoiding further surgery for removal of metallic implants [75]. Progressive scoliosis is treated by spinal fusion with instrumentation using methods similar to those used in treating idiopathic adolescent scoliosis [76,77]. Brace treatment is less effective than in children without OI because of the osteopenia of the rib cage. However, the prevalence of scoliosis and various aspects of its management will need to be re-evaluated once the outcomes of bisphosphonate treatment are established. Delivery of an affected infant by Cesarean section does not appear to diminish fracture rate and thus such intervention should be reserved for the usual obstetric reasons.

OSTEOGENESIS IMPERFECTA TYPE II (PERINATAL LETHAL FORM)

Genetics, Natural History, and Management

OI type II (MIM 166210), the perinatally lethal form of OI, affects between 1 in 20,000 and 1 in 60,000 newborn infants [1,78,79]. Prematurity and low birth weight are common. Affected infants have a characteristic facial appearance with dark sclerae, a beaked nose, and an extremely soft calvarium. The extremities are short, the legs are bowed, and the hips are usually flexed and abducted (frog-leg position); the thoracic cavity is generally very small. The radiological picture is heterogeneous [18,80], but all infants have markedly telescoped femurs, bowed tibias, and a virtual absence of calvarial mineralization. The ribs are generally beaded, although they may be broad throughout,

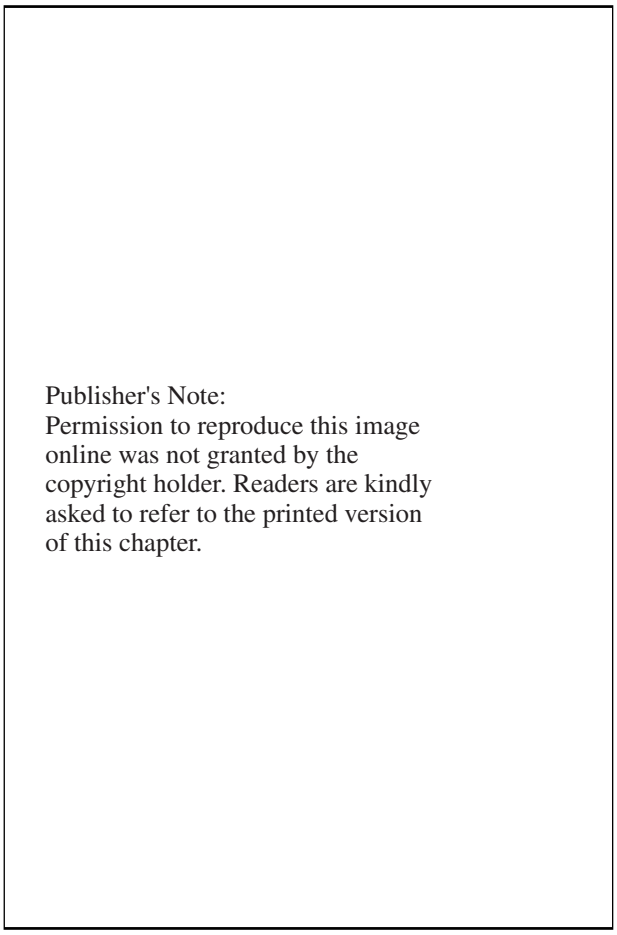

Figure 6. Radiographs of infants with OI type II. There is moderate variation in the radiographic features of infants with perinatal lethal OI. All have shortened femurs, ''beaded'' ribs, and decreased calvarial mineralization. Many also have platyspondyly. The identification of five ''groups'' by Byers et al. [80] and three types of OI type II by Sillence et al. [18] reflects the variation in radiographic presentation. There is little evidence that there are different genetic mechanisms. Only the extent of rib involvement appears to hint at prognosis, with survival longer in the presence of a larger rib cage and fewer fractures. (Figure reproduced from Byers et al. [80]).

and the vertebral bodies may be flattened (Fig. 6). Obvious fractures of the long bones with displacement are rare in the newborn period (probably because the bone is soft and compressed). More than 60% of infants with OI type II die during the first day, 80% die within the first month, and survival beyond a year must be extremely rare (Fig. 7) [80]. The only role for Cesarean section in the delivery of infants with OI type II is if any of the usual obstetric complications intervene.

Survival for infants with OI type II ranges from minutes to months [80]. Death usually results from pulmonary insufficiency, congestive heart failure, or pneumonia. The most difficult management decisions occur at the birth of an affected infant if the diagnosis is not clear. If the diagnosis is known, infants are offered supportive care and parental bonding is encouraged. Some affected infants can leave the hospital, and supportive care in the home is essential.

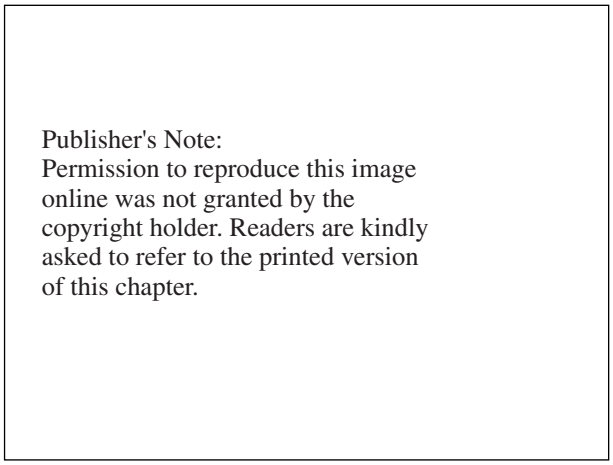

Figure 7. Survival curve for 45 infants with OI type II. More than 50% of infants with OI type II die within 24 hours of delivery. Very few survive beyond 2 months. Routine obstetric ultrasound examination leads to early second-trimester identification of affected fetuses in many instances. (Figure reproduced from Byers et al. [80].)

Bedding that contains soft foam can decrease the fracture frequency. Respiratory insufficiency may limit the ability of many affected infants to maintain adequate caloric intake.

With the increasing use of routine early second trimester ultrasound to assess fetal development, affected infants are being detected early in pregnancy, often leading to its termination [79,81–91]. If, however, no early-pregnancy studies have been done and the diagnosis is suspected only late in pregnancy, there has been some controversy about the mode of delivery. Most recently, it appears that an informal consensus is building against the use of Cesarean delivery. Such a move is supported by data indicating that Cesarean delivery does not prolong survival or change the number of fractures in infants thought to have OI type II.

There has been some uncertainty about the mode of inheritance of OI type II. Seedorf [8] identified some instances of sibling recurrence of OI type II in which parents were not related. Sillence et al. [1,18] identified one family with multiple affected children born to normal but consanguineous parents. Using the formula of multiple, independent ascertainment, they calculated a segregation ratio of close to 0.25, consistent with autosomal recessive inheritance. Furthermore, they cited several instances of sibling recurrence in consanguineous families to support the hypothesis of autosomal recessive inheritance of OI type II.

It now appears that the initial assessment of the mode of inheritance of OI type II was either incorrect or incomplete. Analysis of more than 200 families into which a proband with OI type II was born [80,91–96] has indicated that new dominant mutation is the usual explanation for the phenotype. Although there were no instances in most families, the small rate of recurrence was most consistent with parental mosaicism (either isolated gonadal mosaicism or combined somatic and gonadal mosaicism) (see below). Autosomal recessive inheritance could not be excluded as an explanation for recurrence in one family [80], and biochemical and molecular genetic evidence is consistent with that conclusion in at least one other family [97] and

also consistent with compound heterozygosity for mutations in type I collagen genes.

The largest study of OI type II found a recurrence risk of 6–7% among siblings [80]. A more recent study [96], in which recurrence following the birth of a first or second affected infant was analyzed, found a 2% recurrence risk after the first and a 22% recurrence risk after the second affected infant. The recurrence results from parental mosaicism for the mutation that is lethal in the infant who is heterozygous for the same mutation. We are aware of more than 20 families in which one parent is mosaic for a causative mutation, and several more have been detailed in the literature [80,98–107]. In almost all the families in which the mutation was identified, one parent was mosaic in both germline and somatic cells, indicating that the mutation occurred early in embryogenesis, before the allocation of cells to different lineages. On the basis of results to date, it appears that mutations occur equally in male and female embryos. In some instances, the extent of mosaicism is sufficient to result in mild features of OI (often compatible with OI type IV, see below) in the mosaic parent [103,104,106,107].

The hypothesis that OI type II was inherited in an autosomal recessive fashion reflected the attempt to explain recurrence of severe OI phenotypes among siblings and the presence of consanguinity in some of the families. It is worth noting that the subdivision of OI type II into A, B, and C [18] and the identification of four groups with OI type II [80] demand too much of the supporting data. In short, virtually all instances of OI type II represent the results of dominant mutations in the genes of type I collagen, and recurrence of the phenotype among siblings is accounted for by parental mosaicism for the mutation. Several options for prenatal diagnosis in subsequent pregnancies can now be offered to all families who have had a child with OI type II (see below).

OI type II needs to be differentiated from other lethal skeletal dysplasias — especially thanatophoric dysplasia (MIM 187600) and achondrogenesis (MIM 200600) — and the autosomal recessive form of hypophosphatasia (MIM 241500). Although the radiographic picture of OI type II is characteristic, the ultrasound features early in pregnancy may be difficult to distinguish from other lethal forms of skeletal dysplasia. The characteristic rib abnormalities and markedly decreased calvarial mineralization are the most helpful features. Experienced pediatric radiologists generally have little trouble with the diagnosis in newborns, although evaluation of X-rays of early fetuses may present problems. Nonetheless, many referral centers can provide diagnostic assistance. If there is any doubt, the diagnosis of OI type II can be confirmed by examination of the collagens synthesized by cultured fibroblastic cells from any of several tissues or by direct analysis of type I collagen genes. Alternatively, if no fibroblasts are available to study, pathological examination with the finding of undermineralized bone, osteoblastic cells with dilated rough endoplasmic reticulum, and increased osteoid can help to confirm the diagnosis [108].

Biochemical and Molecular Bases of OI Type II

OI type II is the most extensively studied form of OI and the best characterized at both the biochemical and molecular genetic levels. Cells from several hundred affected infants have been studied in culture (see below), and the molecular basis of OI type II has now been established in more than 100 infants (Fig. 1). A surprisingly wide array of mutations in type I collagen genes produce the OI type II phenotype. These include point mutations in both genes in the domains that encode the triple-helical regions and result in substitutions for glycine, multiexon rearrangements, small deletions or duplications, and single-exon skips in the triple-helical-encoding domains. Mutations in the *COL1A1* gene in the domain that encodes the carboxyl-terminal propeptide, which produce sequence changes that interfere with molecular assembly, can also produce the phenotype [109,110]. In almost all instances, the affected individual is heterozygous for the lethal mutations.

Rearrangements

All multiexon rearrangements within the *COL1A1* gene and most in the *COL1A2* gene have proved to be lethal. Among the cells initially studied by Pentinnen and his colleagues [41] was one from an infant that had the lethal form of OI [111]. Although it was recognized that the cells did not produce type I procollagen efficiently, the nature of the defect was unclear. Studies by others of the same cell strain led to the recognition that decreased production was a consequence of inefficient secretion of molecules that contained one or more proα1(I) chains from which the 84 amino acids from 327 to 411 of the triple-helical domain (encoded by exons 23–25) had been deleted [112–114]. Because the deletion endpoints were within introns, the resulting proα1(I) chain was predicted to have an intact Gly–X–Y triplet structure, 84 residues shorter than the product of the normal allele. Cells from this infant synthesized three populations of type I procollagen molecules: normal molecules and those that contained either one or two of the short chains. Molecules that contained the shortened chain had a decreased thermal stability (about 32 °C compared to the normal of 42 °C) and virtually none of these molecules was secreted [112,115].

Identification of a multiexon deletion among the first few cell strains from infants with OI type II to be studied created the expectation that such mutations would be encountered frequently. However, only two additional published examples of multiexon rearrangements within the type I collagen genes that cause OI type II have emerged. In the first, a 600 bp duplication within one *COL1A1* allele [113,114] that resulted from a recombinational event involving exons 17 and 14 produced proα1(I) chains in which 60 amino acids were duplicated [116]. The abnormal molecules synthesized by these cells were secreted only slightly less efficiently than the normal molecules, so that the lethal effect was probably the consequence of the presence of molecules in the matrix that could not copolymerize with the normal molecules to form fibrils. The other rearrangement identified was a 4.5 kb, seven-exon deletion from one *COL1A2* allele. About half the proα2(I) chains synthesized lacked 180 amino acids of the triple helix, residues 586–765 [117]. Molecules that contained the shortened chain were not secreted but remained in the lumen of the rough endoplasmic reticulum (Fig. 8), where they remained bound to prolyl hydroxylase for an extended period [118]. This cell strain provided a surprising insight into the manner in which the behavior of molecules synthesized by cells from individuals with OI might be altered. Although the deletion resulted in maintenance of the triplet motif of the triple helix (Gly–X–Y), molecules that contained the abnormal chain had undergone a marked increase in post-translational modification but only amino-terminal to the deletion junction. Thus, although the triple-helical structure was maintained, the stability of the triple helix amino-terminal to the junction was compromised. This demonstrated clearly

that even minor shifts in triple helix registration among chains are destabilizing and indicated that interactions in addition to hydrogen bonding involving hydroxyproline residues must contribute to helix stabilization (Fig. 9). It was further surprising that the secretion of, at best, very small amounts of the abnormal molecule was sufficient to result in the OI type II phenotype. If the block to secretion were complete, the phenotype would be expected to be OI type I (see above), suggesting that other factors may play a role in the generation of phenotype or that very small amounts of abnormal molecules in the matrix may be sufficient.

Point Mutations

The majority of cells from infants with OI type II are heterozygous for point mutations that result in the substitution of single glycine residues within the triple-helical domain of either the proα1(I) or proα2(I) chains (see Fig. 1). These mutations lead to increased post-translational modification (Fig. 10) as a result of decreased triple helix stability (Fig. 11), interfere with secretion (like those with more complex mutations illustrated in Fig. 8), and affect the formation of fibrils in the extracellular matrix.

The first demonstration that point mutations in the triple helix of the proα1(I) chain might be significant came with the recognition that cells from an infant with OI type II contained a cysteine residue (normally excluded) within the triple-helical domain of the α1(I) chain [119]. In this cell strain, one allele contained a single nucleotide substitution that changed the glycine codon at position 988 in the triple helix to that for cysteine [120]. All molecules that contained either one or two copies of the abnormal chain were less efficiently secreted than normal molecules, had undergone increased post-translational modification (lysyl hydroxylation and hydroxylysyl glycosylation) along the entire length of the molecule, and were less stable to thermal denaturation (they melted at 38 °C instead of the normal 42 °C). A similar pattern of behavior of abnormal molecules has now been noted in cell strains from many other infants with OI type II.

Because of the importance of glycine in every third position for the propagation and stability of the triple helix (see also Chapter 2, part I, this volume), it was postulated (as a result of these studies) that substitutions of most glycyl residues in the triple-helical domain of the α1(I) chain would most likely result in the same phenotype, provided they interfered sufficiently with stability. It is now clear that most substitutions for glycine within the triple-helical domain of either proα1(I) or proα2(I) chains result in the clinical picture of osteogenesis imperfecta. However, the severity of the phenotype is a reflection of the chain in which the mutation appears, the location of the mutation in that chain, and the nature of the substituting residue (see Fig. 1).

Almost 100 point mutations have now been characterized from infants with the lethal OI phenotype (Fig. 1). Single nucleotide substitutions in the glycine codon (GGN) give

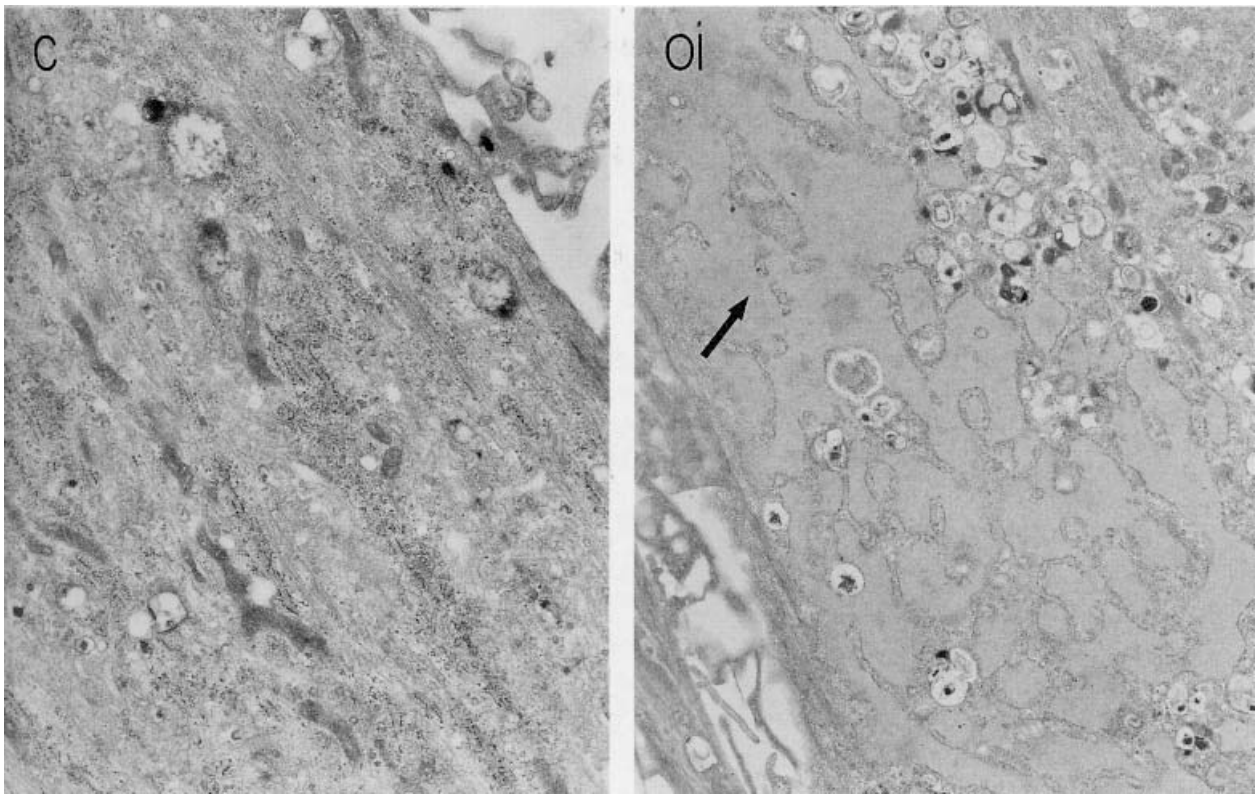

Figure 8. Electron micrograph of rough endoplasmic reticulum (RER) in cultured fibroblasts from an infant with OI type II. The RER (arrow) is engorged with abnormal type I procollagen. This infant had a 4.5 kb deletion from one *COL1A2* allele (see Fig. 9), and all type I procollagen molecules that contained the abnormal chain were not transported beyond the RER. Although this degree of RER engorgement is greater than that seen in cells from most infants with OI type II, cells from virtually all affected infants have defects in the secretion of type I procollagen. C, control, OI, osteogenesis imperfecta. (Figure reprinted from Willing et al. [117].)

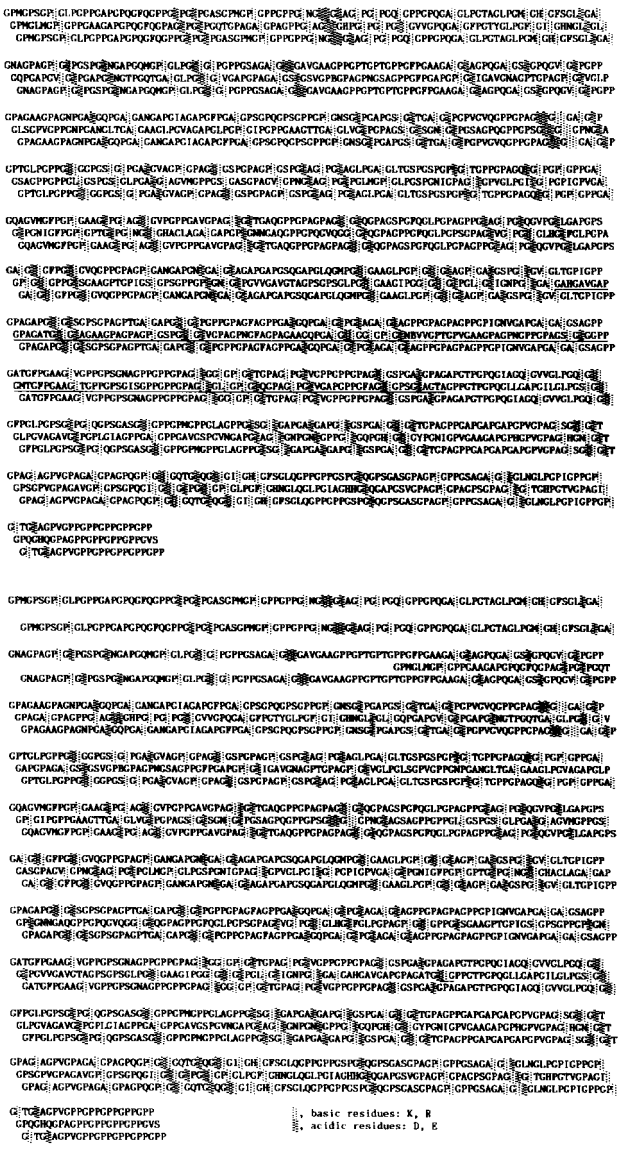

Figure 9. Alignment of the three chains and charge distribution in the triple helix of normal type I collagen (**top**) and when a shortened proα2(I) chain is included (**bottom**). The sequence of the α2(I) chain is the middle line in each row, and that of α1(I) is on the top and bottom lines. The amino acid residues in both chains are represented by the single-letter code. Every Y-position (Gly–X–Y) proline is ordinarily hydroxylated to hydroxyproline, and several Y-position lysyl residues are usually hydroxylated. All are shown as unmodified residues. The chains are staggered by one position, with α1(I) occupying the first and third positions and α2(I) the second (this conforms to most models of the triple helix). The portion of the α2(I) chain that is deleted from the bottom figure is underlined in the top (residues 587–765); the two residues that mark the deletion junction are underlined in the bottom figure. The first glycine of the triple helix is designated as position 1 in this figure, although both chains have additional residues in their precursor forms. The charged residues have been replaced by symbols, as indicated in the key. The alteration in relative position of charged residues in the abnormal molecule, as well as alterations in the relative content of tightly wound and loosely wound helix, probably accounts for the striking alterations in molecular behavior. Similar alterations with small deletions or insertions or exon skips would be expected. (Figure reproduced from Willing et al. [117].)

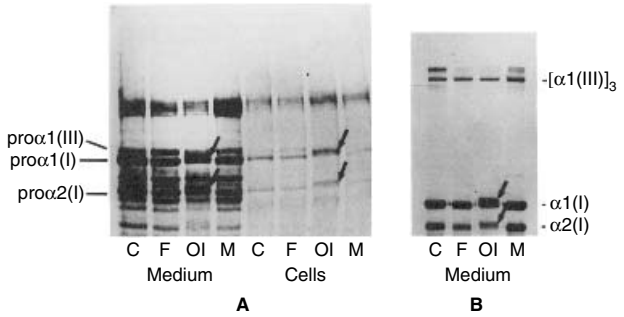

Figure 10. Collagens synthesized by dermal fibroblasts from an infant with OI type II (OI), the unaffected father (F) and mother (M), and a control (C). Cells were incubated with [^{3}H]proline overnight in the presence of ascorbic acid. The medium and cell-layer proteins were harvested and separated under reducing conditions on SDS-polyacrylamide gels (**A**). Cells from the affected infant synthesized some normal type I procollagen molecules and a second species that is inefficiently secreted and accumulates in the cells (arrow). The slower mobilities of the chains from the abnormal molecules (arrows) are best seen following digestion of the procollagens with pepsin (which removes the amino- and carboxyl-terminal propeptides) (**B**). The altered mobilities are the consequence of post-translational hydroxylation of additional lysyl residues within the triple helix and of subsequent glycosylation of the hydroxylysyl residues. The mutation in this cell strain is substitution of glycine at position 580 of the triple-helical domain of the α2(I) chain by aspartic acid as a result of heterozygosity for a point mutation [319]. (Figure reproduced from Bonadio et al. [321].)

rise to codons for serine, arginine, cysteine, tryptophan, and a stop codon (first-position substitutions), or aspartic acid, glutamic acid, valine, and alanine (second-position substitutions). If substitution were a random event, then the proportions of the substitutions should reflect glycine codon usage. In both genes, triple helix glycine codons occur as GGT, GGC, GGA, and GGG (in order of frequency from most to least common). Of possible substitutions, tryptophan (GGG→TGG) and glutamic acid (GGA→GAA or GGG→GAG) would be expected infrequently, and a stop codon would be expected to produce a "null" allele effect and thus an OI type I phenotype. To date, substitution of glycine in the α1(I) chain by glutamic acid has not been observed in OI type II, and only a single instance of glutamic acid for glycine has been seen in the α2(I) chain (Gly343Glu) [121]. It is not clear whether substitutions for glycine residues within the triple-helical domains of the two chains occur with the frequency expected on the basis of codon frequency, but it is clear that there has been some ascertainment bias. For example, the abundance of cysteine mutations in the α1(I) chain represents an ascertainment bias as a result of screening for identifiable protein abnormalities. About twice as many mutations have been identified in the *COL1A1* gene as in the *COL1A2* gene. The reason for this discrepancy is not clear but may reflect a different role for the α2(I) chain than the α1(I) in the triple helix.

Substitutions of glycine by residues with bulky side chains along the carboxyl terminal three-quarters of the length of the triple-helical domain of the α1(I) chain tend to have very severe or lethal consequences, but less predictably so in the α2(I) chain. Thus, in the α1(I) chain it is the rare substitution of glycine by arginine, alanine, aspartic acid, glutamic acid, valine, or tryptophan carboxyl terminal to residue 250 of

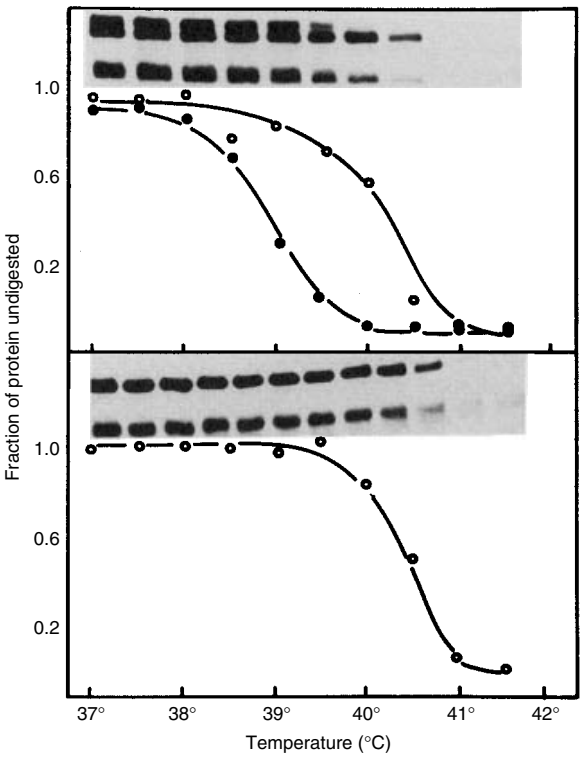

Figure 11. Thermal stability of collagens synthesized by dermal fibroblasts from an infant with OI type II. The infant is the same as that described in Fig. 10. Cells were incubated with [^{3}H]proline for 16 hours and the collagens secreted into the medium were harvested and treated with pepsin. Following dialysis and transfer to a neutral pH buffer, the sample was warmed at a rate of 5 °C/hour. At 0.5 °C increments, aliquots were removed and digested with trypsin. The proteins were separated by SDS-polyacrylamide gel electrophoresis, and the radioactivity in the bands was quantified by scanning densitometry. These data were used to generate the melting temperature curves in the top and bottom panels. The top panel shows results for the normal collagens (open circles) and the abnormal collagens (closed circles) made by the OI type II cells; the bottom panel shows results obtained with control cell collagens. The temperature at which half the collagen was digested (Tm) was 40.5 °C for the control collagen and the normal collagen produced by the OI type II cells but was 39.5 °C for the abnormal collagen molecules. (Reprinted from Bonadio et al. [321], with permission of the publisher.)

the triple-helical domain that would be expected to be nonlethal. If such mutations are found in nonlethal forms of OI, the possibility of mosaicism for the mutation needs to be considered.

One of the most striking features of point-mutation distribution is the nonlinear effect of substitutions of glycine by serine and cysteine in both the α1(I) and α2(I) chains. These substitutions result in alternating lethal and nonlethal zones or domains [122] along the chains from the carboxyl-terminal ends of the triple-helical domains up to residues 200 of the same domains. The explanation for these findings has not been readily forthcoming but probably reflects regional sequence variations in the chains. It has been postulated for more than 20 years that there are domains that can be recognized by their effects on folding and melting [123]. Bächinger and colleagues [124] examined sequence variation along the length of the triple helix of type I collagen and tried to correlate the position of mutations and their relation to regions of peak stability but were unable to create a coherent model. In the α1(I) chain, substitutions of cysteine for glycine can result in significant conformational changes that are seen as "kinks" in the molecules when they are examined by electron microscopy after rotary shadowing or when models are constructed [125–128]. Other substitutions appear not to create such structural changes when they occur in the α1(I) chain [128] but may do so if they affect the α2(I) chain [129], although too few examples have been examined to be sure. Modeling these substitutions with space-filling tools suggests that one form the molecule could take to create the bend is a loop-out of a single tripeptide [127]. Crystal structure of a model peptide in which alanine is substituted for glycine in the center of a repeating Gly–Pro–Hyp polypeptide suggests that with other residues a phase shift in the molecule can occur and be propagated toward the amino-terminal end of the molecule [130]. Examination of the structure of different α1(I) trimers that contain substitutions of glycine by serine that correspond to lethal or nonlethal positions suggests that the intrinsic pitch of the triple helix is an important factor in determining the clinical outcome of the mutation [131,132]. Although such studies are instructive, the use of single peptides limits their relevance to the molecular pathogenesis of OI because most type I collagen molecules are heterotrimers. The importance of these models for disorders in which the abnormal molecules form homotrimers is clear, but for abnormalities of type I collagen they need to be refined.

Exon-Skipping Mutations and Small Deletions

Heterozygosity for exon-skipping defects within the triple-helical domains of both type I collagen genes comprises the second-largest group of mutations that produce the OI type II phenotype (see Tables 2 and 3). Within the regions of both *COL1A1* and *COL1A2* that encode triple-helical domains, the exons are cassettes that begin with a glycine codon and end with a Y-position codon. Thus, mutations that lead to skipping of an entire exon result in the deletion of an integral number of Gly–X–Y triplets from the products of one allele. In general, they occur as a result of point mutations in the splice donor or splice acceptor sequences. In the *COL1A1* gene, mutations that result in skipping exons 14 [133], 20, 27, 30, 44, and 47 produce the OI type II phenotype (Table 2). In the *COL1A2* gene, there are no lethal exon-skipping mutations 5′ of exon 27 (Table 3). Skipping of exon 28 in *COL1A2* as a result of an acceptor site mutation resulted in the OI type II phenotype but may have been accompanied by a *COL1A2* null in the other allele [97,134]. Skipping of exons 30, 32, 33 [135], 37, and 42 in the *COL1A2* gene have all proved to be lethal (Table 3). One of the infants whose cells skip exon 14 of the *COL1A1* mRNA is homozygous for the IVS14 + 5G → A mutation for which its father was mosaic [133]. These data suggest that the infant had uniparental isodisomy for all or part of chromosome 17 and further, because some normal molecules were also made, that the mutation produced a leaky effect on splicing. Heterozygosity for a mutation at the canonical splice donor site in *COL1A1* intron 14 (IVS14 + 2T → A) produced the lethal OI phenotype, confirming the effect of skipping exon 14 in half the mRNA species (see Table 2).

Deletions of single Gly–X–Y triplets in the proα1(I) chain, residues 732–734 (unpublished results), 868–870 [136], or 874–876 [137], have also been identified in infants with the perinatally lethal form of OI. Similar mutations that result

in the deletion of triplets in the proα2(I) chain can have a similar effect, as can duplications of triplets or sextets within the proα1(I) chain [96,138]. Like the other mutations, they alter the extent of post-translational modification of the triple helix amino-terminal to the site of the mutation and thermal stability, and they interfere with secretion.

Mutations Outside the Triple-Helical Domain

Although less common than the other mutations, alterations in the sequence of the carboxyl-terminal propeptide of the proα1(I) chain can cause OI type II. Most such mutations interfere with the ability of proα1(I) chains to associate correctly with other proα1(I) chains or proα2(I) chains. Several single amino acid substitutions in the carboxyl-terminal propeptide have been identified [109,110] as well as a two amino acid deletion [109]. In addition, frame shifts that alter the sequence within the large terminal disulfide-bonded loop of the propeptide and alter the ability of the propeptide to fold normally are also associated with the OI type II phenotype [139]. These differ from premature termination codons that appear earlier or frame shift mutations that predict the loss of the entire carboxyl-terminal propeptide. This latter group may result in very unstable mRNA species (most likely) or, in some instances, result in chains that are unable to associate at all with their partners and usually result in the OI type I phenotype (see above). The mutations in the C-propeptide domain in the proα1(I) chain that result in the lethal OI phenotype are often associated with the induction of BiP, a chaperone resident in endoplasmic reticulum that recognizes unfolded proteins. In addition, such proteins are often very unstable and may be degraded by the cytoplasmic 26S proteosome [61]. In some cells, the secretion of normal type I procollagen is reduced to about 25% of the normal amount, which is apparently insufficient to sustain normal bone formation [139].

Homozygosity or Compound Heterozygosity is Rare

The vast majority of infants with OI type II appear to be heterozygous for mutations in one of the genes that encode the chains of type I procollagen, a concept that is reinforced by the finding of parental mosaicism in a small proportion of them. There are, nonetheless, a small number of infants in whom two mutant alleles appear necessary to produce the OI type II phenotype. In one, a *COL1A2* intron 27 splice acceptor mutation (IVS27 − 2A →G) resulted in skipping of exon 28 and deletion of the amino acids encoded by exon 28 [97]. In addition, the infant apparently received a *COL1A2* allele from one parent that had reduced mRNA synthesis capacity so that less than normal amounts were made [97]. As a result, all the proα2(I) chains synthesized (half the normal amount) were abnormal and the cells secreted a trimer of proα1(I) chains [134]. The second mutation has not yet been identified and parental studies are incomplete, so that a final evaluation of the need for two mutations remains to be confirmed.

A further example of homozygosity for a mutation provides additional insight into the mechanisms that may produce OI type II [133]. The infant described bore two copies of an allele in which there was a *COL1A1* donor site mutation in intron 14 (IVS14 + 5G → A). In cultured dermal fibroblasts, there appears to be alternative splicing in both alleles. As a consequence, normal mRNA and mRNA in which exon 14 had been skipped were present in equal abundance. Although homozygous for the mutant allele, this mutation mimics the effect of an intron 14 splice donor mutation (IVS14 + 2T → A) in which all the products of the allele result in exon skipping. Because the father of the infant with the leaky splice donor mutation (IVS14 + 5G → A) was mosaic for the mutation, it is not clear what the phenotype of the heterozygote would be, although it is likely that it would be mildly to moderately severe.

The clinical phenotype of OI type II produced by exon-skipping mutations or small genomic deletions is indistinguishable from that resulting from multiexon deletions, substitutions for single glycine residues in the triple-helical domain of either chain, or carboxyl-terminal propeptide mutations.

OSTEOGENESIS IMPERFECTA TYPE III

Natural History

The progressive deforming variety of osteogenesis imperfecta, OI type III (MIM 259420—note that although the MIM identification number would indicate that inheritance is recessive, the data suggest heterogeneity), is probably genetically heterogeneous (see below), although the majority of cases appear to result from dominant mutations in either of the two type I collagen genes. The phenotypes are usually recognized at birth or prenatally because of short stature and deformities resulting from *in utero* fractures. Radiographs at birth generally demonstrate an undermineralized calvarium with a large anterior fontanelle and Wormian bones; thin gracile ribs, which may have fractures, thin, gracile long bones, which frequently show evidence of intrauterine fracture with healing and of bowing, especially of the tibias; short and deformed (but generally not crumpled, "accordion") femurs; and generalized osteopenia (Fig. 12). If no fractures are present at birth, they usually appear during the first year of life, frequently with minimal trauma. If not evident at birth, long bone deformity generally becomes apparent during the first two years of life (Fig. 13). Between two and five years of age, "cystic" structures form in the distal metaphyses of many of the long bones ("popcorn epiphyses") (Fig. 14) but especially in the distal femurs [140]. These are areas in which the growth plate is disrupted, probably by recurrent microfractures, and herald the loss of long bone growth. The thin cortex of the long bones predisposes to angulation deformities and, as a result of the deformities, to fracture. Individuals with OI type III have the highest fracture frequency of all those with OI, and 200 fractures during a lifetime is not uncommon.

In a very small proportion of children with progressive deforming varieties of OI, exuberant, hyperplastic callus formation may be observed at the site of fractures, with gradual resolution over time [141–143]. It has been proposed that the presence of hyperplastic callus defines a different type of OI, OI type V [20], although the criteria for this diagnosis are not clear. These regions of hyperplastic callus raise concern about the presence of osteosarcoma [144,145] and, rarely, osteosarcoma may develop in individuals with OI [146–149].

Bone deformation at the base of the skull in individuals with OI type III is of concern because it leads to basilar impression or progressive incursion of the spinal column into the cranium with compression of the brain stem. Involvement of the cranial base is not limited to individuals with OI type III, and some with OI type IV may also be at risk [150,151]. Because of its higher incidence in this group, more aggressive screening may be needed to identify affected individuals. The diagnosis of basilar invagination is best made by MRI or computerized axial tomography because lateral films of the skull may not be informative in the early stages [152]. These

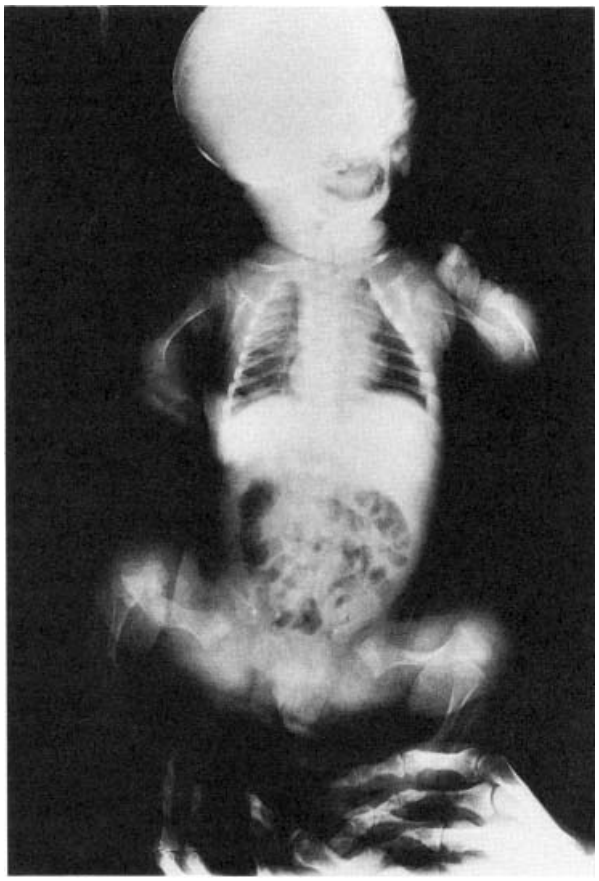

Figure 12. Radiograph taken shortly after birth of an infant with OI type III. Calvarial mineralization is decreased, the ribs have a near-normal size and configuration, and there is marked deformity of the long bones of the lower limbs. This infant is heterozygous for a mutation that results in the substitution of the glycine residue at position 526 of the α1(I) chain by cysteine. (Reprinted from Starman et al. [65] by copyright permission of the American Society for Clinical Investigation.)

findings may be evident in childhood and are occasionally associated with symptoms that can include headache, cranial nerve dysfunction [153], long tract signs, and respiratory depression with sleep apnea [154–157]. Death from respiratory compromise or brain stem compression may be one of the consequences [158,159]. Treatment for basilar invagination and the associated neurological impairment is currently surgical, and it is often suggested that both decompression of neuronal components and stabilization of the spatial relationship between the spine and the lower cranium are needed to prevent progression [152,153,157,160–163]. After surgery, prognosis remains uncertain, and further follow-up of those who have had surgery is needed. If medical therapy with bisphosphonates were successful in changing the mineral content of bone and protecting against deformation of the lower skull, it could be a valuable therapy, even if the effect on long bone morphology and fracture were more limited.

Another consequence of loss of bone rigidity is that some children and adults with OI type III are at risk of significant bowel obstruction as a result of protrusio acetabuli [164].

Children with OI type III, and some other forms of OI, are frequently described by their parents as having increased sweating, heat intolerance, and a preference for cooler environments. The metabolic basis of these observations is unclear, although increased bone turnover may be one factor as bisphosphonate treatment may reduce sweating in some children. As a result, however, concern has been raised about hyperpyrexia during surgery, and at least some instances of such a complication have been observed [165–167]. It is unclear, however, whether hyperpyrexia during surgery is a reflection of OI itself or of the concomitant presence of one or more predisposing mutations for malignant hyperthermia that is independent of OI. In general, this seems to be a rare complication of anesthesia in children or adults with OI, although the use of nonprovocative anesthetic agents may be the reason it is seen so infrequently.

Although head size may be large, with resultant ventricular enlargement, there does not seem to be a significant risk of loss of intellectual function. Instead, the large head size appears to reflect the lack of containment by the soft calvarium and may be present in 15–20% of children with OI type III [155,168]. Over time, a characteristic "triangular" facies develops, with a broad and bossed forehead and small chin.

Dentinogenesis imperfecta is common and involves both the primary and secondary teeth, although the earliest erupted teeth are often the most affected. Sclerae are often pale blue at birth and generally become of normal hue by puberty.

Short stature is the rule in OI type III and is one of the diagnostic features. An adult height between 90 cm and 110 cm is characteristic. Many children with OI type III develop significant kyphoscoliosis, which may progress to cause cardiopulmonary insufficiency, probably the major cause of early death in these individuals [159].

Life expectancy is not well-documented in OI type III but, to the extent that it is, premature death is the rule rather than the exception. There appear to be two major peaks of mortality, one in late childhood or adolescence, in which acute respiratory compromise is the cause of death, and a second in the third or fourth decade, in which cardiac decompensation is the rule [159]. On the other hand, long-term survival is also known.

Genetics of OI Type III

The mode of inheritance of the progressively deforming varieties of OI has been uncertain and, as a result, genetic counselling in families with affected individuals has been confusing. Initially described as a usually autosomal recessive condition [1,169], it is now clear that the major reason for the confusion is that the OI type III phenotype is genetically heterogeneous. Furthermore, parental mosaicism leading to recurrence of the phenotype among their children has added to the uncertainty about inheritance [170]. There are now well-documented instances of autosomal recessive inheritance [171–176], of parental mosaicism leading to sibling recurrence [170], and of autosomal dominant forms of OI type III [170,177].

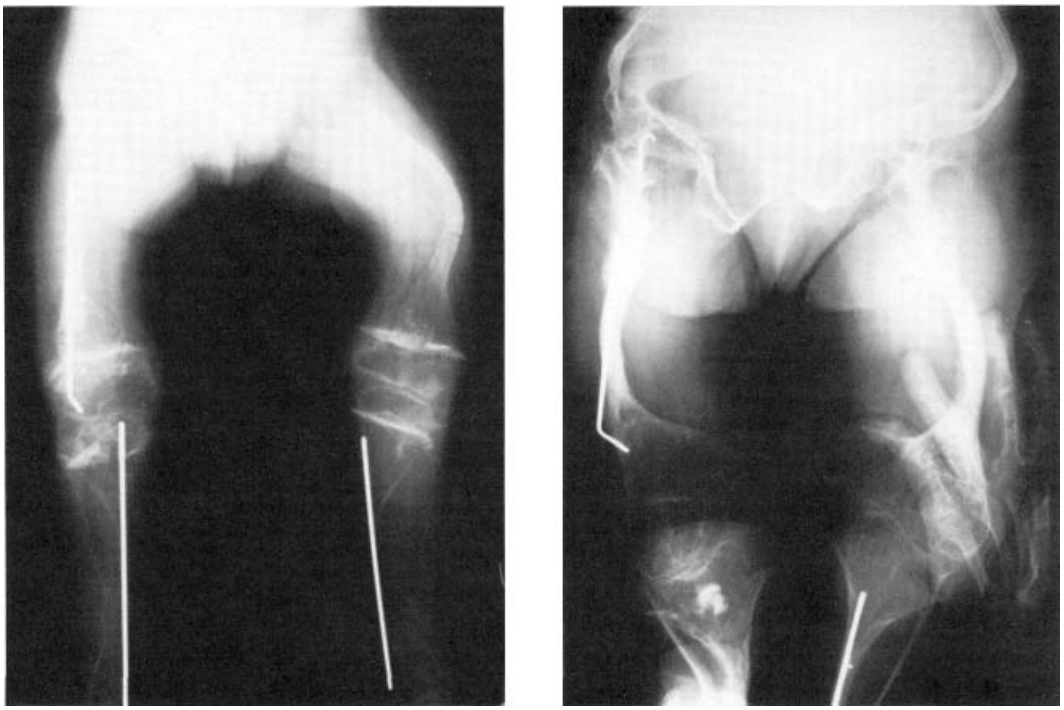
Although autosomal recessive inheritance of the progressive deforming phenotype is probably rare in most populations [169], it may be the most common form of OI in the South African Black population [3]. Among the South African families, there is evidence of consanguinity and a relatively high frequency of affected siblings. Furthermore, biochemical studies have failed to demonstrate evidence of abnormalities in the structure or synthesis of collagen [5]. In this population, linkage studies using *COL1A1* and *COL1A2*

polymorphic markers have excluded these as candidate genes for mutations that produce the phenotype [5]. In most families in other populations, only a single child is affected with OI type III, compatible with the phenotype usually resulting from a new dominant mutation. This hypothesis has been amply confirmed by the birth of affected children to affected individuals in some families, and by biochemical findings in the majority of affected individuals [71].

Management and Treatment of OI Type III

Following the birth of a baby with OI type III, families need support to gain confidence in caring for their child [178]. Pain care is essential. Parents need advice concerning the emergency treatment of fractures. Lightweight, flexible splints are provided for the families to support new fractures.

Figure 13. Progressively deforming nature of OI type III. The radiographs of the arms were taken at ages 2 years (**A**), 9 years (**B**), and 22 years (**C**), and those of the legs were taken at 3 years (**D**), 5 years (**E**), and 28 years (**F**). **A** and **B** are of the left arm, and **C** is of the right arm. The magnification of each radiograph is the same, indicating the paucity of growth of the long bones over many years.



E F

Figure 13. (*Continued*)

The prognosis for infants with OI type III, in the absence of treatment to improve bone mass, is poor because of severe bone fragility with progressive deformities of the long bones and spine, muscle weakness, and joint contractures [179–182]. The progressive deformities result from malunion of fractures, deformation of bones, and abnormal function of the growth plates. Progressive scoliosis is usual and may result in even more pronounced short stature and life-threatening cardiopulmonary decompensation [76,156,183]. Many, if not most, children do not walk because of the severity of their bone fragility, anatomic deformities, and muscle weakness. Consequently, most of these children use mobility devices such as wheelchairs. Increasing musculoskeletal and respiratory symptoms occur in adulthood along with the complications of basilar invagination (see above).

Until recently, any enthusiasm for medical therapy for children with OI type III was limited because of the absence of convincing demonstration of efficacy. Agents studied included anabolic steroids, sodium fluoride, magnesium oxide, and calcitonin, all of which failed to provide evidence of therapeutic value [184]. Growth hormone therapy over an extended period has enjoyed its enthusiasts, but prolonged increase in growth, increased bone mineralization, and decreased fractures have not been easy to detect in longitudinal studies in a relatively small population [185,186].

There has been an upswing of interest in the use of bisphosphonates, agents that interfere with bone resorption and decrease bone loss in postmenopausal women with osteoporosis and children with osteoporosis of unknown origin [187]. Beginning in the early 1990s, single patients with severe OI [188,189] or small groups of children [190–193] have been treated with these drugs. As with many small, uncontrolled trials, the enthusiasm for these drugs has been high. The small observational studies are of limited value, however, because, although they report apparent improvement in bone mass, they are compromised by the absence of controls, uncertainty about the endpoints, the use of internal longitudinal controls with, in some instances, very high starting values for fracture rates, and uncertainty about appropriate measures for success. In the largest and most comprehensive of these studies [73], 30 children aged between 3 and 16 years were studied for up to 5 years. They received intravenous pamidronate at intervals from 4 to 6 months, or, in some instances, more frequently. Bone mineral density, vertebral area, metacarpal cortical width, height, several biochemical measures of bone synthesis and turnover, and aspects of mobility and general well-being were examined. In this study, there was an increase in the bone mineral density of the lumbar spine in all groups, although absolute changes were difficult to assess because they were reported as Z scores and measured against pretreatment values. Vertebral area also increased. Fracture rates appeared to decrease slightly, but neither they nor growth rates appeared to change significantly. The authors reported quite remarkable changes in the sense of well-being among the children with decreased bone pain and an increased willingness to walk. Anecdotal descriptions of changes in the character of bone in some children being operated on suggest that alterations in bone composition could be beneficial. Like all the other studies reported, this one is observational, although it uses well-defined measures of change in bone and behavior. Currently, there is a large multicenter controlled trial in progress using the same type of protocol at the Shriners Hospitals in the United States,

Figure 14. ''Popcorn'' epiphyses at the ends of long bones in a child with OI type III (Courtesy Dr.B. Steinmann).

with hopes of completion by the beginning of 2002. The outcome of these studies will be particularly important in determining the extent to which bisphosphonates can be valuable adjuncts to sustained physical therapy, traditional surgical intervention, and other supportive measures.

Physical therapy and the use of internal rodding or external bracing will continue to be mainstays of therapy to improve strength and joint mobility and to create confidence in standing, walking, and other physical activities [73,180]. The studies on bisphosphonates have generated considerable enthusiasm for their use, even in the absence of controlled studies. It is important that well-designed studies be done in the near future to determine whether many of the early problems with recurrent fractures and pain can be alleviated by the early administration of bisphosphonates, whether continuous or intermittent oral dosing can be used, and whether outcome is improved with treatment within the first few months of life. If the apparent improvement can be further documented in controlled studies, and studies of bone morphology and strength provide supportive data, then the roles of lower-limb bracing and intramedullary rodding of long bones of the upper and lower limbs will need to be re-evaluated. For example, could bracing or surgery be avoided in many children with OI type III, or could external bracing substitute for rodding, particularly in young children? If intramedullary rods are used, should they be nonextending or extending? [74,194–197] Should the rods be inserted before the commencement of bisphosphonate treatment or after treatment has improved the bone quality to a particular level? The prevalence of scoliosis will also need to be determined, and the brace and surgical management will also need to be re-evaluated. The influence of treatment with bisphosphonates on the incidence and progression of basilar invagination of the skull will need to be assessed. Further, the effect on hearing loss should be determined. Finally, although the action of the current forms of bisphosphonates appears to be limited to bone because of tissue-specific distribution of the drug and cell-specific limitations in uptake, some of these drugs appear to be potent inhibitors of protein prenylation [198,199] (see also Chapter 1, Part III, this volume) and thus their side effects need to be monitored closely.

Bone marrow transplantation, with the objective of transferring marrow stromal cells, has been proposed as a therapeutic strategy in children with severe forms of OI [138]. Initial studies to test the feasibility of whole bone marrow transplantation [138] have been met with both high enthusiasm [200] and considerable concern [201,202]. In the initial studies reported [138], three children with severe OI, each with a different *de novo* mutation in a type I collagen gene, had partial marrow ablation using cytotoxic drugs and then had a bone marrow transplantation from a compatible unaffected sibling donor. Two infants had relatively uncomplicated courses, whereas the third had significant complications, possibly related to the procedure. The authors reported some improvement in height/length and bone density, but the basis of these differences has been called into question [202]. At this point, although some cells may be directed to bone, the extent of engraftment using whole marrow seems far too small to support significant bone changes. The prudent course at this point seems to be to provide far better animal studies as a prelude to further studies in humans. At least one person with a form of OI has survived bone marrow transplantation for hematopoietic malignancy, indicating that OI itself is not a contra-indication to the procedure; however, no details of subsequent changes in bone are included in that report [203].

The concept behind the use of stromal cells is that they appear to contain multipotent stem cells that have the capacity to produce bone cells [204,205]. These osteoblastic precursor cells, the idea continues, could repopulate the marrow and may have a replicative advantage over the endogenous cells. The first human studies, done to test feasibility rather than efficacy [138], were carried out after very preliminary experiments in mice. In those studies in mice, biologically marked marrow cells were shown to be present in many tissues after intravenous administration of cultured adherent cells from marrow [206], but no attempt was made to determine whether bone could be repopulated

to a sufficient extent to change its character. In subsequent studies, mice that constitutively carried multiple copies of a shortened human *COL1A1* transgene were injected with stromal cells from normal mice, and bone and other tissues were assayed for the mouse *Col1a1* and the human *COL1A1* genes. These assays were difficult and nonlinear so that precise measurement of the effect was uncertain. The amounts of collagen and mineral in bone were measured, and the treated mice appeared to have slightly greater amounts of each [207]. The intrinsic variation within the target strain makes these results very difficult to interpret, however [208–210]. It is clear that cells derived from marrow that have the capacity to make bone can home to bone, but the efficiency of uptake, the extent to which they can be used to make new bone, and the age at which they show the greatest efficacy all need to be determined.

Biochemical and Molecular Genetic Defects in OI Type III

The issues of the mode of inheritance, the molecular basis of OI type III, and the number of genes in which mutations could produce OI type III remain incompletely resolved. It is clear that many individuals with OI type III have dominantly inherited disorders that result from mutations in the genes of type I collagen (see Fig. 1) [71,99,170,177,211–218]. In many instances, cultured cells appear to synthesize only normal type I procollagen molecules, although in some cases this reflects the position of the substitution in the chains of type I collagen (Fig. 15). Nonetheless, although the effects of mutations in type I collagen genes may be difficult to detect by the protein screening techniques normally used, the primary mutations may occur in genes other than those that encode the chains of type I procollagen. For example, the studies in Southern Africa (cited above [4,5]) could be consistent with a localized noncollagen mutation that results in OI type III. The intermediate form of hypophosphatasia, particularly with marked elevations of alkaline phosphatase in plasma, mimics some of the features of OI type III.

Autosomal Recessive OI Type III

The molecular basis of recessively inherited OI type III due to a mutation in a type I collagen gene has been determined in two families. In the first, the proband was born to phenotypically normal, first-cousin parents and was recognized to have OI at birth. He had bone fragility, short stature, decreased calvarial mineralization, and moderate bone deformity, which increased during childhood [171,172]. Type I collagen isolated from the proband's skin contained only α1(I) chains. Dermal fibroblasts cultured from the child secreted type I procollagen molecules that contained only proα1(I) chains because proα2(I) chains synthesized by the cells were not incorporated into procollagen molecules [173,174]. Both *COL1A2* alleles contained the same 4 bp deletion near the end of the exon that encodes the carboxyl-terminal end of the proα2(I) chain that changed the sequence of the final 33 residues of the chain [175]. The frame shift deleted the cysteine residue in carboxyl-terminal propeptide position 245 that normally bonds with a cysteine residue at position 80 of the propeptide to stabilize its structure. Other studies support the concept that alterations in this domain and, more specifically, loss of the cysteine residue near the end of the chain, alter the ability of such abnormal proα2(I) chains to be incorporated into type I procollagen molecules [219,220]. In the absence

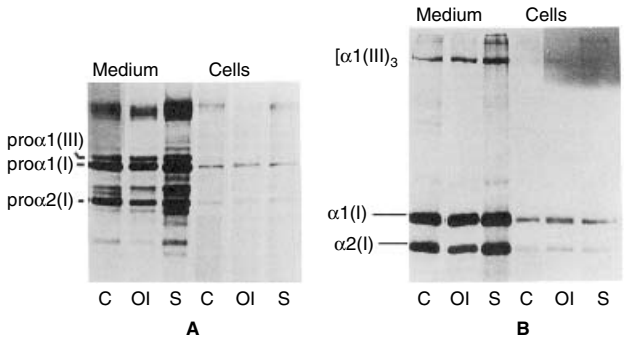


Figure 15. Collagens synthesized by cells from an individual with OI type III due to a point mutation that results in the substitution of the glycine residue at position 154 in the α1(I) chain by arginine. Cells were incubated with [^{3}H]proline overnight in the presence of ascorbic acid, and the medium and cell-layer proteins were harvested separately and analyzed by electrophoresis on SDS-polyacrylamide gels under reducing conditions (**A**) or under nonreducing conditions following partial proteolysis with pepsin (**B**). The proα chains of type I and type III procollagens have essentially normal electrophoretic mobilities (**A**). When the procollagens are treated with pepsin and the resulting α chains are analyzed, a subtle difference in the intensity of bands in the cell layer becomes apparent, compatible with the accumulation of a small amount of type I procollagen within the cells (**B**). These findings indicate that not all mutations in the genes that encode the chains of type I procollagen are readily identified at the protein level. C, control cells; OI, cells from the proband with osteogenesis imperfecta; S, cells from an unaffected sibling. (Reprinted from Pruchno et al. [245], with permission of the publisher.)

of normal proα2(I) chains, proα1(I) homotrimers formed. The chains in these molecules were overmodified along the length of the triple helix (although its thermal stability was normal [221]), and the molecules were secreted more slowly than the normal type I procollagen. About two-thirds of the normal amount of type I procollagen would be expected to be synthesized and secreted (the stability of the molecules being normal). It is not clear whether the relatively severe phenotype resulted from the presence in the matrix of only homotrimeric molecules that were overmodified or from the absence of the α2(I) chain. This mutation demonstrated, to the surprise of many, that the absence of α2(I) chains in type I collagen can be tolerated, albeit with consequences. Interestingly, an Ehlers-Danlos phenotype also results from homozygosity (or compound heterozygosity) for mutations in the *COL1A2* gene that lead to little or no mRNA from those alleles [222,223] (see also Chapter 9, this volume). The reason for the different phenotypes is yet to be resolved but could be a consequence of the synthesis of some abnormal proα2(I) chains in the OI instance.

In a second consanguineous family, two siblings with OI type III are homozygous by descent for a *COL1A2* mutation that results in substitution of the glycine residue at position 751 of the triple helix by serine (Gly751Ser). Heterozygosity for the same mutation results in mild features of OI in the parents, who have mild short stature, a triangular face, mild bowing of the lower legs, and generalized osteopenia with mild platyspondyly of the lower spine.

No noncollagen genes that could result in the OI type III phenotype, if mutated, have been identified.

OSTEOGENESIS IMPERFECTA TYPE IV

Natural History and Genetics

OI type IV (MIM 166220) is a dominantly inherited disorder characterized by normal or greyish sclerae, mild to moderate deformity, and stature that is generally short for the family and often below the 5th percentile for age [1,224]. Dentinogenesis imperfecta is common. Estimates of the prevalence of hearing loss among individuals with OI type IV are scanty. Analysis of dominant pedigrees identified through linkage studies suggests that hearing loss is a more constant feature of families in which linkage to polymorphic markers at the *COL1A1* locus is demonstrated, most of whom are likely to have OI type I as a result of *COL1A1* null alleles [47,50,56].

The majority of infants with OI type IV can be identified in the perinatal period. The presenting features at birth can include fractures that occurred either *in utero*, during labor and delivery, or in the newborn period. Occasionally, these fractures go unrecognized because of adequate healing and a failure to take X-rays. Lack of early recognition of these fractures puts these children and their families in jeopardy of accusation of child abuse when the "first" fracture occurs and the previous, now healed, fracture is detected by routine skeletal survey. Thus, early ascertainment of affected infants is important and can protect some families from suspicion of having abused their child. Not all infants with OI type IV have fractures or deformity at birth, and some may have only mild femoral bowing.

Although birth length is frequently normal, by two years of age height is generally below the 25th percentile and frequently below the 5th percentile, and growth follows the lower percentile tracks thereafter. It can be particularly distressing for families to see their children drop from the 50th percentile to the 5th or below before resuming a growth velocity appropriate for that size. Concerns about other causes of growth retardation are common at that time, for both family and physician, but in these families OI is generally the sole cause.

The fracture rate in individuals with OI type IV may be quite variable. Fractures during the first few months following birth are common and then frequently cease until the child begins to walk. Significant bowing of the femurs, which may have been present in the newborn, may gradually diminish as the child begins to bear weight, and the deformity present in the lower legs may also lessen. Fracture frequency may increase with ambulation and then, as in the other forms of OI, decrease following the onset of puberty. Fractures rarely cease altogether during adult life but are generally uncommon from 20 to 40 years of age, only to increase in the older age group, especially among postmenopausal women. In some individuals, the phenotype may be very mild, with minimal effect on stature, dentin formation, and hearing, such that the onset of fractures in the near postmenopausal period raises the issue of osteoporosis. Family studies in this group of women may be particularly useful.

Scoliosis occurs in perhaps as many as one-third of individuals with OI type IV and ranges from mild to severe [76,156,183,225,226]. As in OI type III, kyphoscoliosis may compromise cardiopulmonary function if severe. In individuals with OI type IV who have scoliosis, both bracing and placement of rods to prevent progression may be valuable in preventing later cardiovascular disease. Because the bones of the ribs are better able to resist deformation from external compression, and because the quality of the ligaments and bones in the spine appears better than in OI type III, the prognosis following bracing or surgery appears to be significantly better.

Although thought to be rare when initially segregated from other forms of OI by Sillence et al. [1], OI type IV is probably one of the more common varieties of OI. The family described by Ekman in 1788 [10] (cited by Seedorf [8]) probably had OI type IV. Many of the families described by Seedorf [8] with dominantly inherited OI characterized by mild deformity and short stature also fit into this group. A significant number of the individuals with dominantly inherited OI described by Bauze and colleagues [42] also had this form of OI.

Considerable confusion concerning the classification of individuals with this form of OI has periodically created havoc with the clinical literature and with biochemical studies. At the time Sillence and colleagues extended the OI classification, they limited OI type IV to those with white sclerae [1]. Subsequently, those with blue sclerae and almost any degree of deformity were often considered to have OI type I, no matter how illogical such a classification might have seemed on the surface. As more extensive biochemical and clinical studies have been completed, it has become clear that the criteria for inclusion within OI type IV should be extended so that scleral hue (probably one of the least helpful clinical signs for classification) does not assume such a large role [71].

In the absence of severe cardiopulmonary complications, the life span of individuals with OI type IV is probably near normal [159]. As a result, both sporadically affected individuals and large families with affected members having OI type IV are seen, raising, for some, the concern that there are both dominantly inherited and autosomal recessive forms of OI type IV. As pointed out by Sykes et al. [47], there is little evidence that there are any families with mutations in the genes of type I collagen in which OI type IV is inherited in other than an autosomal dominant fashion. Detailed biochemical and molecular genetic studies also support this hypothesis, and there is now evidence that the occasional event of sibship recurrence of OI type IV with normal parents reflects parental mosaicism for the mutation [227] (PH Byers et al. unpublished results).

The OI type IV phenotype covers a wide range, from the OI type III picture on the one hand to that of OI type I on the other. Intrafamilial variability can be dramatic [228,229]. There are at least two explanations for intrafamilial variation in expression: the genetic background on which the primary mutation is expressed (the other genes that account for variability have yet to be identified) and mosaicism. When mosaicism for a mutation that results in a severe or lethal phenotype in the heterozygote occurs in the proband with OI type IV, counselling will differ from circumstances in which the condition is inherited in an autosomal dominant fashion. The frequency of mosaicism is uncertain but needs to be considered in all instances in which the proband with a nonlethal form of OI is the first affected individual in the family [96,230].

Management of Individuals with OI Type IV

The objectives of treatment and management of individuals with OI type IV are to minimize the long-term complications of kyphoscoliosis and to assure independence and mobility [180,231,232]. As indicated above, the scoliosis that is often associated with OI type IV is generally

amenable to bracing, and progression can often be minimized. In the event that scoliosis progresses beyond 50–60°, surgical intervention is often a valuable adjunct to therapy.

In general, fractures are treated in the usual orthopedic manner. It is important to minimize the duration of immobility, to start physical therapy immediately upon removal of casts, to use lightweight casts whenever feasible, and to maintain as aggressive a program of physical activity as possible. On occasion, either recurrent fracture in the same location or angulation deformity of a long bone will necessitate surgical repair and stabilization, usually by placement of intramedullary rods. Fixation with screws and plates appears to offer few advantages and several disadvantages when compared with rod placement.

There is consensus that aggressive physical therapy directed at muscle strengthening and a program of early and assisted ambulation will provide the greatest likelihood of independent ambulation for individuals with OI type IV. The program is similar to that used for children with OI type III and relies on a regimen of physical therapy, graded activity, and external support for limbs at risk of fracture. The most common braces use a lightweight plastic "clam-shell" anterior and posterior support with hinged hip, knee, and ankle joints.

Dentinogenesis imperfecta often leads to fracture and excessive wear of fragile teeth. Advances in the design and application of plastic polymers to coat and shape teeth have provided some measure of therapy for individuals with dentinogenesis imperfecta. The early application of bonding agents appears to slow the rate of fracture of teeth and to impede the loss of tooth structure for children and probably offers some of the same advantages for secondary teeth.

Hearing loss is a feature of OI type IV, but profound loss of function in childhood is rare and should prompt the search for other causes. Children should be tested at least once prior to puberty, and adults warrant formal testing about every three to five years unless there is a clinical reason to suspect that hearing loss is progressing at a more rapid rate. As indicated above (see OI type III), the early phases of hearing loss can be managed with amplification devices, but the more profound loss encountered in later life usually requires surgical intervention to repair stapes fixation, the most common cause of deafness.

The role of bisphosphonates in the management of children with OI type IV is still undecided (see detailed discussion above) and awaits the outcome of controlled trials currently under way.

Biochemical and Molecular Genetic Bases of OI Type IV

Individuals with OI type IV were included in the studies of collagen content of skin [42,43] and collagen synthesis by cells from individuals with OI [41]. These studies suggested that there were alterations in the amount of type I collagen synthesized by cells or present in tissues. However, it was linkage analysis, using polymorphic markers within the *COL1A2* gene, that demonstrated definitively that the phenotype could result from mutations in or near the *COL1A2* locus [233]. Linkage heterogeneity was subsequently recognized among families with dominantly inherited forms of OI [47,69,70,234]. In these families, OI type IV was most often linked to polymorphic markers at the *COL1A2* locus, but in some families linkage to *COL1A1* was identified. The clinical criteria by which many of these families were classified were often not clearly defined. As a result, minor features such as scleral hue, rather than major features of bone deformity and stature, may have been used, with the resultant classification of families with OI type IV into the OI type I subset. The significant point from these studies is that mutations in either *COL1A1* or *COL1A2* can lead to the OI type IV phenotype.

As is true in other forms of OI, point mutations that result in substitutions for glycine residues in the triple-helical domains of the proα1(I) and proα2(I) chains, exon-skipping mutations, and a variety of other mutations that disrupt the normal sequence of the proα chains can all result in the OI type IV phenotype (Fig. 1 and Tables 2 and 3).

Point Mutations in Type I Collagen Genes

As discussed above with reference to substitutions of glycine residues that result in the OI type II and type III phenotypes, mutations that give rise to the OI type IV phenotype are scattered along the chains if they produce substitutions of glycine by serine or cysteine, but in the proα1(I) chain other substitutions are clustered close to

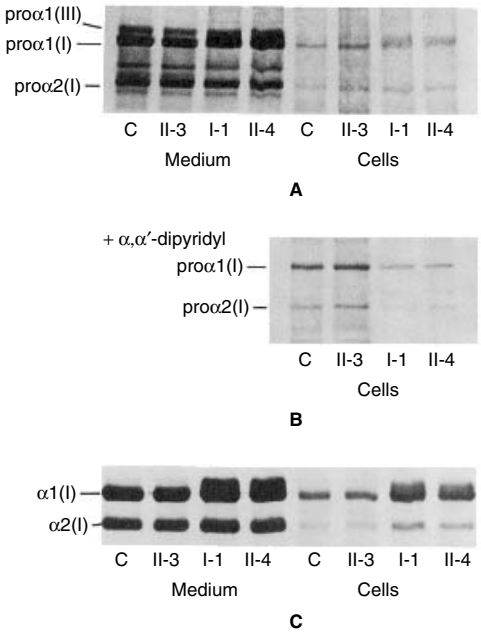

Figure 16. Collagenous proteins synthesized by dermal fibroblasts from individuals with OI type IV due to the substitution by arginine of glycine at position 1012 in the α2(I) chain. Cells were labeled with [^{3}H]proline for 16 hours in the presence of ascorbic acid. Medium and cell-layer proteins were harvested separately and analyzed by SDS-polyacrylamide gel electrophoresis under reducing conditions (**A**) or were digested with pepsin and the proteinase-resistant chains of the collagen triple helices examined under nonreducing conditions (**C**). Additional cells were incubated with [^{3}H]proline in the presence of α,α′-dipyridyl, which inhibits post-translational modification of procollagen molecules (**B**). In the presence of the inhibitor, the reversion to normal electrophoretic migration indicates that the altered mobilities seen in **A** and **C** do not reflect the insertion of peptidyl sequence. Cells from affected individuals I-1 and II-4 (parent and child) synthesize some normal molecules and some molecules that contain chains with slower than normal electrophoretic mobilities. The secretion of the abnormal molecules is delayed, as evidenced by the accumulation of molecules in the cell-layer compartments. (Reprinted from Wenstrup et al. [235], with permission of the publishers.)

the amino terminus (Fig. 1). The variability in the proα2(I) chain is a little greater, and one of the first point mutations identified in the *COL1A2* gene to produce OI type IV was shown to result in substitution of the glycine residue at position 1012 by arginine (Gly1012Arg) [235] (Figure 16).

Exon-Skipping Mutations that Result in OI Type IV

In the *COL1A1* gene, only the skipping of exon 10 has been shown to produce the OI type IV phenotype (Table 2). In the *COL1A2* gene, skipping of exons 9 [236] (PH Byers et al. unpublished results), 12 [237], 16 [238,239], 20 [240], 21 [241], and 26 [242] all result in the OI type IV phenotype (Table 3). This spread of mutations more 3′ in the gene and carboxyl terminal in the protein suggests that the type I procollagen molecule is more tolerant of changes in the proα2(I) chain than in the proα1(I) chain. Most of these exon-skipping events are the consequence of mutations in the canonical splice junction sequences. We (C Kuslich and PH Byers, unpublished results) have also observed splice site mutations that result, in part, in exon-skipping in more 3′ positions in the gene, but often the major product is unstable and only a small proportion of the transcripts contain the exon-skipped product. In these situations, the clinical phenotype reflects a complex mix of factors.

Other Mutations that Produce the OI Type IV Phenotype

As is true of the OI type II phenotype, it is likely that as the number of mutations characterized increases, variations on the more common themes will be identified. For example, an intron 33 point mutation that results in the use of a cryptic donor site 18 nucleotides into the intron results in the insertion of six additional amino acids in the triple helix, between residues 585 and 586 of the α2(I) chain, and produces the OI type IV phenotype [233,243]. In a second family, deletion of 9 bp removes a Gly–Pro–Hyp triplet at residues 1009–1011 of the α2(I) chain and produces a mild phenotype (GA Wallis, PH Byers, unpublished results).

MECHANISMS OF MUTATION IN COLLAGEN GENES THAT RESULT IN OSTEOGENESIS IMPERFECTA

For several reasons, collagen genes are good reporters of mutations. First, there is a high density of invariant and required glycine residues in the triple-helical domain (one-third of all amino acids). Substitution of either of the first two nucleotides of the glycine codon (GGN) changes the encoded amino acid to one that has a side chain that does not fit in the central core of the triple helix. Thus, the alteration of any of 22% (2 out of 9) of the nucleotides encoding the triple-helical domain will probably give rise to a phenotypic change in the heterozygote. Second, the large exon number, and sensitivity to exon loss regardless of position in the protein, provides more than 200 additional mutation-sensitive sites in each gene. Third, the need to maintain structure in the globular carboxyl-terminal domain to allow for interactions that generate a triple-chain molecule provides an unknown number of additional targets. Finally, because type I collagen forms fibrils from identical subunits, the presence of any sequence alteration in the externally facing residues of the triple-helical domain could interfere with the production of a normal fibrillar structure. In the 18 kb *COL1A1* gene, this means that mutation at 8–10% of the nucleotides has the potential to produce an OI phenotype. The *COL1A2* gene, which is about twice that size, would have correspondingly fewer reporter nucleotides.

Most characterized mutations that produce recognizable forms of OI are single nucleotide substitutions that alter a glycine codon. Some of the cataloged mutations have occurred independently in unrelated individuals. Some of the recurrent mutations appeared at CpG dinucleotides in the *COL1A1* gene, such as Gly79Arg [53,244] Gly154Arg [245,246], Gly352Ser [122,211,247], Gly415Ser [105,211], Gly589Ser [212,248,249], Gly688Ser [138,250], Gly862Ser [170,215,248,251], and Gly1003Ser [245]. In the *COL1A2* gene, recurrent mutations at CpG sites have been identified at Gly238Ser [40,96,217,252], Gly247Cys [250], Gly502Ser [253], and Gly859Ser [216,252]. Substitutions of alanine for glycine are markedly underrepresented in both genes (Fig. 1). Only a single substitution by tryptophan has been identified in either gene (Gly227Trp in *COL1A2*) (Fig. 1), which is probably consistent with glycine codon usage. With the exception of mutations that give rise to substitutions of glycine by cysteine in the proα1(I) chain, there is a paucity of mutations in the domains of both chains amino-terminal to residue 200 of the triple helix. This either represents different phenotypes that result from these mutations or, more likely, a lesser effect on protein electrophoretic mobility, which is used to screen cells prior to mutation analysis. With directed DNA analysis in the absence of protein studies, these gaps may be filled.

Translation of Mutation to Phenotype

The most complex task in the study of OI is to understand the relationship between the genotype (the specific mutation in a single host) and phenotype in a single person. The difficulty of this task is best recognized when we remember that the OI phenotype is the physiologic response to a mutation in a single collagen allele (most of the time). This response is mounted on the background of the entire genetic background, which is the product of millions of years of evolution in the context of normal collagen alleles. Thus, it should not be surprising that the molecular correlates of clinical severity may not emerge solely from identification of the nature and site of individual mutations.

At the molecular level, OI falls into two groups that have fundamentally different mechanisms of action — the production of structurally normal but diminished amounts of type I procollagen in one, and the production of abnormal molecules in the other. At the clinical level, this distinction marks the divide between OI type I and other types of OI. Yet, even among those with OI type I, there can be considerable differences in the clinical picture. OI type I almost always results from mutations in the *COL1A1* gene that lead to premature termination codons within the mRNA from one allele. There are several mutational events that can give rise to these premature termination codons. They include single nucleotide substitutions within codons, the insertion or deletion of nucleotides in amounts not divisible by 3 in coding sequences, and the creation of frame shifts as a consequence of splice site mutations. The several mechanisms by which these alleles are produced may explain some of the clinical variability between families and, in some instances, even among members of the same family. The stability of the mRNA produced by these different mechanisms has not been extensively explored, and it is possible that some protein product could be produced that does not become incorporated into molecules but could interfere with fibrillogenesis. With splice site mutations, it is not uncommon for several mRNA species to be produced. In some instances, these low-level transcripts may be stable, have intact association

domains, and, say, skip an exon. Although these products may be present at only the 2–5% level, they may be sufficient to modify the expected phenotype of the *COL1A1* null.

Although the expression of the two type I collagen genes is coordinated, mutations in the *COL1A1* gene that lead to low levels of mRNA do not appear to up-regulate the other allele, down-regulate *COL1A2* expression, or alter the expression of many other genes expressed in bone and other connective tissues. The effects of these mutations should be felt directly in the extracellular matrix, where about half the normal amount of normal type I procollagen molecules is secreted into an environment in which all other interacting molecules, including proteoglycans and other collagens, are made in their usual amounts. The use of emerging "chip" technology to identify genes, the expression of which is altered in cells from individuals with different forms of OI, may provide clues to the mechanisms of complex tissue alterations. Fibrillogenesis is a complex process [254,255] (see also Chapter 2, Part I, this volume) that is strongly influenced by multiple components in the matrix. In addition, mineralization is expected to occur on a highly organized substrate that must be altered when the amounts of the different components vary. The effects on tissue strength of decreased production of type I procollagen are not well-understood. Bonadio et al. [23] demonstrated that in the OI type I mouse model there is a marked decrease in bone strength, compatible with a tissue that has decreased amounts of type I collagen. It is not clear, however, that a decreased amount of collagen is the only effect. The striking morphology of collagen fibrils in the skin of individuals with OI type I, similar to that seen in skin from people with Ehlers-Danlos syndrome type I [256], suggests that altered ratios of the major components of the matrix may contribute to abnormal tensile strength. Thus, even the simplest of mutations is likely to have complex effects on the extracellular matrix, forcing us to recognize the interrelationships of the numerous macromolecules in the tissue. Although the pathway from mutations that result in decreased amounts of type I procollagen production to the end product of brittle but normally formed bones is not yet completed, the major factors have probably been identified and warrant further study.

The phenotypic effects of mutations that result in the generation of abnormal type I procollagen molecules are more deleterious than those of "null" mutations. There is, however, an enormous range in the clinical presentation of these mutations, which appears to reflect the gene (chain) in which the mutation occurs, the nature of the mutation, the location of the abnormal sequence in the protein, and the effects of the mutation on the behavior of the chain and the mature molecule into which it is incorporated.

In contrast to the gradient of effect of large residue substitutions, substitutions of glycine by serine and cysteine, residues with smaller, hydrophilic side chains, have a nonlinear effect on phenotype. These two substitutions have different effects within the molecule. There are no cysteine residues within the triple-helical domain of either proα1(I) or proα2(I) chains. Substitution of cysteine for glycine within proα1(I) chains leads to interchain, intramolecular disulfide bonds when two abnormal chains are in the same molecule. The disulfide bond can introduce a "kink" in the triple helix of some molecules and may partially stabilize an otherwise unstable molecule and provide a new site of nucleation for triple helix formation. In contrast, serine appears to disturb triple helix shape, the rate at which helix forms, or both, without introducing a stable shape change. Within both proα1(I) and proα2(I) chains, both substitutions result in alternating regions of lethal and nonlethal phenotypes. The density of mutations is not yet sufficient to determine whether two types of substitution in the same region have the same phenotypic effect because there are few examples of different substitutions at the same residue within the triple helix.

Substitutions for glycine residues alter the triple-helical structure [257] and delay triple helix formation. In molecules where the progress of helix formation can be monitored, triple helix appears to propagate normally from the carboxyl-terminal end to the site of the mutation, where it either ceases or slows at 37 °C [258]. The effect on helical structure has been suggested by both modeling studies and the analysis of peptides with substitutions [127,130,257]. In both situations, there is a change in the pitch of the helix in the region of the substitution that propagates an altered relationship among the chains to their amino-terminal ends.

Both the delay in helix formation [258] and the change in relationship among residues in the three chains help to explain why overmodification of lysyl residues occurs largely amino-terminal to the site of mutations, although there is evidence of a minor extent of retrograde destabilization. In the normal molecule, post-translational modification continues until the triple helix is formed and stable. In the presence of mutations in the triple helix, the disruption of the helical motif does not allow the chains to come into proximity. A new site of nucleation must be found amino-terminal to the disruption and, while this occurs, post-translational modification continues. The association of molecules that contain abnormal chains with the modifying enzymes is one factor that accounts for the delay in secretion.

The key to the transport of type I procollagen molecules from the endoplasmic reticulum is folded status [259]. The effects of mutations vary from the complete inhibition of transport to a virtually undetectable delay in secretion. Substitutions for glycine, and other mutations that alter helix integrity, are most likely to result in intracellular retention if they occur near the carboxyl-terminal end of the triple helix. Furthermore, the more bulky residues, such as valine, aspartic acid, glutamic acid, and arginine, generally have a greater effect. Substitutions of glycine by serine often result in little impairment of secretion despite their relatively carboxyl-terminal locations and extensive overmodification [260]. The reasons for the disparities in effect are not clear. Possibly, the larger residues exert a greater effect on folding and impair chain alignment more than the smaller ones, as might be expected. Alternatively, there may be a greater effect on changes in helical pitch with larger residues. The abnormal molecules are retained by association with modifying enzymes in the rough endoplasmic reticulum, prolyl and lysyl hydroxylases and protein disulfide isomerase being the best candidates [118,261].

Mutations that result in exon skipping, or the insertion or deletion of small multiples of triplets, also delay secretion, largely as a result of the retention of procollagen molecules in the rough endoplasmic reticulum. This has always been a finding that is difficult to explain because triplet integrity is maintained throughout the majority of the molecule. More recent studies suggest that the pitch of the helix differs along the extent of the molecule [257]. The logical interpretation of these data suggests that there is too little flexibility in these different helical motifs to allow propagation to occur efficiently. Thus, regardless of the size of any discontinuity (single triplet, single exon, or multiple exon), the failure

to propagate helix reflects variations in pitch. This appears to provide a unifying model for these different extents of deletion or insertion.

Studies of cells that synthesize abnormal collagens, and of bone from affected individuals, suggest that some abnormal molecules are incorporated into the matrix, although not into the most highly cross-linked, stable portion [262]. An *in vitro* study of purified molecules demonstrates that the inclusion of even a small proportion of molecules that harbor abnormal chains readily leads to the failure of fibril formation or the formation of abnormal fibrils [263]. These two different studies have not been readily reconciled because there are abundant fibrils formed in both tissues and cultured cells, even in the presence of known mutations. Thus, the precise manner in which these mutations produce a phenotype remains to be examined.

PRENATAL DIAGNOSIS OF OSTEOGENESIS IMPERFECTA

Several approaches to prenatal identification of fetuses affected with OI are available. These include mutation detection in fetal tissue (in some instances, regardless of whether previous affected individuals in the family have been studied) [88,96], analysis of linked *COL1A1* or *COL1A2* markers in at-risk families [96,264,265], analysis of proteins synthesized by chorionic villi [107], and analysis of proteins synthesized by cells grown from chorionic villi [96]. Ultrasonography or other radiographic approaches can provide specific diagnoses as well [84,86,87,91,111,266–268] and, because they are more general, could identify other abnormal conditions. The technique used for prenatal diagnosis depends on the information available in the family, the type of OI for which the pregnancy is at risk, and the gestational age by which the diagnosis must be established (Fig. 17).

Linkage analysis in appropriate families provides diagnosis at 11–12 weeks gestation if DNA is prepared from chorionic villus samples, or 16–17 weeks if amniocytes are used. Linkage studies, using linked markers in *COL1A1* and *COL1A2*, require that the family be sufficiently large to exclude one locus and that the couple for whom the studies are proposed be informative. With an increasing number of polymorphisms available at both loci, the proportion of families that is informative is high. In some instances, it may be sufficient to exclude one locus because the data now indicate that there is very little likelihood of genes other than *COL1A1* and *COL1A2* harboring mutations that produce the dominant OI phenotypes.

An alternative to linkage studies in small families in which it has not been possible to exclude a locus is analysis of the collagens synthesized by cells cultured from chorionic villus samples taken at 10 weeks gestation. Sufficient cells are available within 10 days after the biopsy in most instances, and the biochemical studies can be completed within an additional 10 days [96]. Successful use of such studies requires that an affected individual in the family has been studied previously and that any alteration in electrophoretic mobility of the abnormal collagens can be identified in the molecules synthesized by chorionic villus cells. Some families with a previously affected child with OI type III, or a parent with OI type III, representing a significant group of families by which prenatal diagnosis might be requested, may not be amenable to prenatal diagnosis because no abnormality can be identified. Further, there is significant variation in the relative amounts of type I and III procollagens synthesized by different chorionic villus cell strains, making the diagnosis of OI type I difficult unless other measures to determine that one *COL1A1* allele is transcribed at low levels can be used [96]. Amniotic fluid cells do not synthesize regular type I procollagen and so cannot be used for prenatal diagnosis by analysis of proteins.

Transabdominal ultrasound examination can identify fetuses with OI type II by 15–17 weeks gestation [266,269–271] and most fetuses with OI type III by 20 weeks gestation [91,94,272]. By 14–16 weeks, fetuses with OI type II have short femurs, a small thoracic cage with evidence of rib irregularity, and diminished calvarial mineralization. Increasingly, with the use of routine ultrasound screening of pregnancies, fetuses with OI type II are recognized prior to 20 weeks gestation. The findings in OI type III are limited to deformity and shortening of the long bones and decreased mineralization but do not become definitive until about 20 weeks gestation. In the absence of fractures or deformities, neither OI type IV nor OI type I can be identified prenatally by ultrasound examination.

DIFFERENTIAL DIAGNOSIS OF OTHER CAUSES OF OSTEOPENIA AND FRACTURE

The diagnosis of OI must be considered whenever osteopenia or pathological fracture is encountered clinically. Although osteopenia is commonly associated with bone

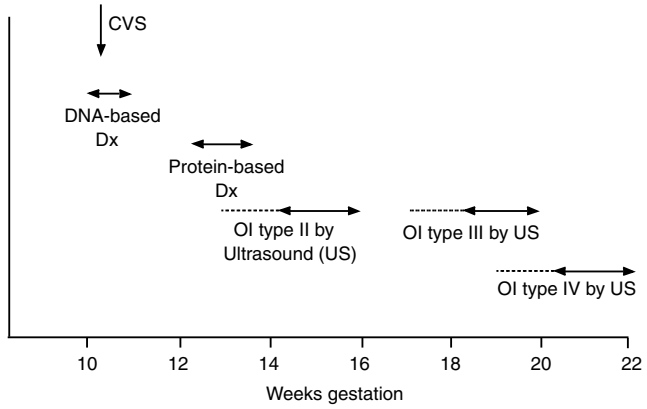

Figure 17. Options for prenatal diagnosis of different forms of OI and the gestational age at which they can be accomplished. CVS, chorionic villus sampling; Dx, diagnosis; US, ultrasound. (Reprinted from Pepin et al. [96], with permission of the publisher.)

fragility, not all bone fragility is characterized by osteopenia as various hyperostotic syndromes are also characterized by bone fragility.

The differential diagnosis to be considered depends, to some extent, on the age at which diagnosis is pursued. Early in gestation, for abnormal bone length identified at the time of routine ultrasound examination (e.g., 16–18 weeks), it would include the major forms of dwarfing: OI type II, OI type III in some instances, autosomal recessive hypophosphatasia (MIM 241500), achondrogenesis (MIM 200600,200610,200700), thanatophoric dysplasia (MIM 187600), and some forms of other lethal dwarfing conditions. By the time of the late mid-trimester and early third trimester, additional conditions, including OI type IV, occasionally OI type I, campomelic dysplasia (MIM 211970), and achondroplasia (MIM100800) become concerns because of limb-length abnormalities and deformity. At the time of birth, the radiographic picture of OI type II usually does not create difficulty, although on rare occasions the nature of the bone abnormality may not be so easily distinguished from hypophosphatasia. The complete absence of mineralization of some vertebral bodies in hypophosphatasia is a helpful clue. At birth, the milder forms of OI may be confused with campomelic dysplasia (in part because some disorders called campomelic dysplasia are, in fact, forms of OI), and the presence of bowing of the long bones should alert the physician to the possibility of OI. Fractures in the newborn period and during childhood often raise the question of nonaccidental injury (see below). At slightly older ages, fractures may raise the question of osteopetrosis (MIM 166600,259700), pycnodysostosis (MIM 265800), and other disorders of increased bone density. During childhood and adolescence, osteopenia may raise the question of juvenile osteoporosis (MIM 259750), which is characterized by decreased bone density, especially of the vertebral bodies, perhaps as a consequence of decreased collagen production. In adult life, familial varieties of "osteoporosis" may represent mild forms of OI.

The extensive range of connective tissue involvement that accompanies bone fragility in some individuals with OI sometimes leads to confusion about the diagnosis. For example, in one family, affected individuals presented with clinical findings that represented a combination of features of OI and the Ehlers-Danlos syndrome (see above, with discussion of OI type IV due to skipping of exon 11). The demonstration of the deletion of amino acid residues encoded by exon 11 from about half the proα2(I) chains synthesized, as a result of a 19 bp deletion that removed a splice junction, appears to account for some of the phenotypic findings. The deletion removes one of the lysyl residues involved in intermolecular cross-link formation, affects the structure of the amino-terminal end of the triple helix, where interaction with matrix mineralizing elements may occur, and changes the organization of the amino-terminal propeptidase cleavage site. Thus, a small deletion may alter many functional domains of the type I procollagen molecule with reflection in a complex phenotype (see Chapter 9, this volume).

Osteoporosis-pseudoglioma (MIM 259770) [273–275] (see also Chapter 26, Part V, this volume) and a separate syndrome of osteopenia, fractures, blue sclerae, and craniosynostosis (MIM 112240) [276] share some features of OI, but no molecular basis of either disorder has been established and no evidence of abnormal collagen synthesis or structure has been identified in either. Osteoporosis-pseudoglioma, a rare recessive disorder, has been localized to 11q12–13 [277], a region that has been extensively mapped [278], so the gene should be identifiable in the near future. Studies of collagens synthesized by cells grown from individuals with other connective tissue disorders in which bone fragility occurs, geroderma osteodysplastica (MIM 231070) and Hajdu-Cheney syndrome (MIM 102500), and in the syndrome of blue sclerotics with fragile corneas, have been normal (PH Byers, unpublished results, and B Steinmann, unpublished results).

Bruck syndrome (MIM 259450) (see also Chapter 26, Part IV, this volume), a rare disorder characterized by bone fragility and joint contractures [279–281], has many characteristics of a mild form of osteogenesis imperfecta. The results of analyses of bone-derived cross-linked collagen peptides in bone and urine are consistent with the absence of a lysyl hydroxylase specific for the lysyl residue in the N-terminal telopeptide of type I collagen. This disorder has been mapped to 17p12 [282], but none of the known lysyl hydroxylases map to that domain.

A form of neonatal hyperparathyroidism that results from heterozygosity for mutations in the calcium-sensing receptor gene has some features of OI [283], as does the syndrome of the calvarial "doughnut lesions" (MIM 126550) [284].

DENTINOGENESIS IMPERFECTA

Dentinogenesis imperfecta (DI) is a form of hereditary dentin abnormality [285,286] and may accompany most forms of osteogenesis imperfecta (DI type I), although it is uncommon in OI type I. In addition, isolated DI may be inherited in an autosomal dominant manner as a distinct entity (DI type II). The clinical manifestations of DI type I include discoloration of the teeth with a characteristic brown or blue-grey color. The primary teeth often appear opalescent when first emerging. Radiographically, a variety of findings characterize DI, including, most commonly, narrow pulp chambers and thin enamel with constricted necks of the teeth (for a review, see [285]).

DI type II (MIM 125490) is a dominantly inherited form of dentinogenesis imperfecta, genetically distinct from that which accompanies OI. Linkage studies have confirmed that the mutant gene is in close proximity to the *Gc* locus on the long arm of chromosome 4 [287] within a 2cM region at 4q21 [288], a region devoid of fibrillar collagen genes. Several genes that map to this locale have been excluded as harboring mutations, including dentin phosphoprotein [289] and osteopontin [290]. Teeth from individuals with isolated DI have been shown to lack phosphophoryn [291,292], a glycoprotein that appears to play a critical role in mineralization of the dentin matrix. However, no genetic studies have either excluded it as a candidate or confirmed mutations in the structure of the gene.

Treatment of the effects of DI type I is largely symptomatic, although there is increasing support for the early application of surface polymer coats to affected teeth to preserve surface as long as possible. For teeth that are rapidly ground to gum level, dental implants could be considered if the mandible and maxilla have sufficient bone matrix to provide adequate support.

OSTEOGENESIS IMPERFECTA AND ABUSE

Since the early 1980s, there has been increasing concern about nonaccidental injury to infants and children and awareness that such injury may lead to death. Physicians and social service agencies have been galvanized in efforts to minimize the possibility of injury to children and to intervene quickly in instances where it seems likely. In

the same period, there has been concern that the number of children with OI who have been removed from their homes because of mistaken accusations of parental abuse has increased. These concerns, in the absence of stringent data, represent a dilemma for the physician, the family, the social agencies, and those who offer diagnostic testing on a service basis. Paterson and McAllion [293] surveyed more than 800 individuals with OI in Britain and found that diagnosis had been reached only with some difficulty in about 15% of them and that, of these, in 15 families there had been accusations of abuse with the institution of formal proceedings. No similar data are available in the United States. In the majority of the 15 cases in Britain that advanced to the stage of hearings, the diagnosis of OI was clearly overlooked, but in a few, even physicians familiar with OI might have had difficulty because of normal teeth, normal bone densitometry, and normal sclerae. Paterson and colleagues [294] considered this group of children and proposed that they have an entity that they termed "temporary brittle bone disease." These are children in whom abuse cannot be directly demonstrated but who have a pattern of fractures that is similar to that seen in abused children. They do not have biochemical findings consistent with OI but may have other characteristics, such as prematurity, that may predispose to fractures. Miller and Hangartner [295] examined 33 infants whom they thought fit into this group because they had multiple fractures, parental denial of abuse, no bruising, and no further fractures following evaluation. They thought that prematurity, decreased fetal movement, and uterine constraint were correlated with this phenotype. In addition, they used radiographic absorptiometry or computed tomography to evaluate bone density in a subset and found it to be diminished, although relatively few controls were studied and the values were compared with adult controls. The concept as a whole has few supporters, and most investigators who are concerned about abuse find no evidence for the existence of such a distinct entity [296,297]. For the concept of transient brittle bone disease to gain credibility, positive diagnostic criteria will have to be developed.

There is continuing controversy over the best way to identify the child with OI in these circumstances. On the one hand, some students of the area [293,298] indicate that virtually any type of fracture can be seen in OI, whereas on the other most investigators assert that certain fractures, particularly metaphyseal chip fractures and "bucket-handle" fractures, are typical and virtually diagnostic of abuse [296,297,299]. It seems likely that fractures of these types are seen far more commonly following abuse but may not be absent from children with OI. In some situations, biochemical studies have been helpful in trying to determine whether a child has OI [300]. However, because cells from only about 90% of individuals with a clinical diagnosis of nonlethal forms of OI have abnormalities in the amount or structure of type I collagen synthesized, such studies may not offer definitive proof of the presence or absence of OI. Perhaps, as studies evolve to the evaluation of gene structure in addition to protein abnormalities, more certainty will accrue. In the interim, it appears that if questions arise concerning the etiology of fractures, the infant or child should be evaluated by geneticists for the possibility of OI or other disorders that can simulate abuse (such as bleeding diatheses and some other forms of connective tissue disorder, e.g., Ehlers-Danlos syndrome) [66] (see also Chapter 9, this volume). If there is any question about the diagnosis of OI, then biochemical or molecular genetic studies should be undertaken with the full realization that not all affected individuals will be detected. Ultimately, the differentiation of abuse from OI and other disorders will rest on clinical grounds, with the results of a variety of laboratory studies playing an adjunct role. It is also conceivable that children with OI can be abused.

ANIMAL MODELS OF OSTEOGENESIS IMPERFECTA

Animal models of human genetic disorders can be valuable tools in the identification of effective therapies. An ideal model of OI would have the same type of mechanics for walking and the same types of weight distribution as in humans, but no such animals are available. The only currently available models are in cattle and mice, the latter comprising both naturally occurring recessive models and created dominant models. It is only with models that mimic human defects that therapies can be evaluated prior to their institution in people. Unfortunately, such models have been difficult to create and of little appeal to most investigators. The need for stable models with reproducible phenotypes as a consequence of engineered mutations cannot be emphasized too strongly.

In isolated herds of cattle, one in Denmark [301] and one in Australia [302], calves with a severe form of OI (similar to OI type III in humans) have appeared. In the Australian herd, almost half the calves born as a result of insemination of cows with sperm from a single bull had OI, although the bull was phenotypically normal. Outbreeding suggested that the most likely explanation for the high rate of affected calves was that each bull was mosaic in the germ line (at least) for the mutation. In one of the calves from the Australian herd, there was heterogeneity of mobility of the type I collagen molecules isolated from bone [303]. This finding is most compatible with heterozygosity for a mutation in a collagen gene. No molecular genetic studies have been published.

A mouse with a recessively inherited phenotype of fragile bones (the fragilitis ossium mouse [*fro/fro*]) has been described [304]. The phenotype is similar to the OI type III picture, but the molecular basis of the disorder is unknown. Another mouse strain with bone fragility (*oim/oim*), demonstrating recessive inheritance, is homozygous for a single base-pair deletion near the 3′ end of the *Col1a2* gene that encodes the mouse proα2(I) chain [305]. The mutation changes the sequence of the final 48 amino acids of the chain such that the domains of the carboxyl-terminal propeptide involved in chain folding are defective. Although the chains are synthesized, they cannot be incorporated into heterotrimers and appear to be very unstable. The phenotype is similar to the recessively inherited form of OI in humans characterized by defective proα2(I) chain association (see above). Although these mice provide a model of a rare form of human OI, they are being used in studies of bone marrow transplantation [205] and as a model with which to test potentially therapeutic drugs [306,307].

A strain of mice in which a retrovirus inserted into the first intron of one *Col1a1* allele created a model of OI type I [308]. Mice heterozygous for the insertion event, known as the Mov13 mutation, have early-onset hearing loss, bones that are more fragile than those of controls [23], and skin that contains about half the normal amount of type I collagen. Embryos homozygous for the insertion die at about 12 days gestation from rupture of the heart and arterial vessels [309]. Tissues in these embryos contain no

type I collagen, and death appears to result from mechanical failure of the organs. Teeth, in contrast, synthesize type I procollagen in a normal fashion, indicating that the promoter used in dentin differs from that in bone and other tissues [310,311]. Transfection of the normal *Col1a1* gene into cells grown from embryos homozygous for the Mov13 mutation rescues proα2(I) chains that are otherwise rapidly degraded [312]. Transfection into Mov13 cells of a human *COL1A1* cDNA, which contained a point mutation that resulted in substitution of a single glycine, resulted in the rescue of proα2(I) chains, but all the type I procollagen molecules synthesized were overmodified [312]. Introduction of the same mutant collagen gene into normal fertilized mouse eggs resulted in a lethal phenotype characterized by bone deformity similar to that seen in the OI type II phenotype [313]. This experiment is consistent with the findings in human infants with OI type II that a point mutation in one type I collagen allele is sufficient to produce the lethal phenotype.

Several transgenic mouse strains have been developed from founders in which a human *COL1A1* "minigene," lacking the coding sequences of 41 central exons, was inserted [314]. Multiple chimeric founders had no bone abnormalities but gave rise to offspring with different phenotypic effects, ranging from neonatal lethal to mild-moderate involvement, that may have reflected the load of the transgene [315]. In additional experiments, levels of the transgene mRNA did not appear to reflect the phenotypic severity in inbred lines derived from the same founder [315]. Bone fragility in these animals seemed increased early in life, appeared to normalize in adult life, and then to increase again as the animals aged [316]. Mice from these strains have been used as test animals to determine whether whole marrow transplantation, or the use of marrow stromal cells, could ameliorate the phenotype, even though the variability among animals in the same strain [207] could complicate interpretation of the results. Such studies serve to underscore the need for an animal model with a single genetic alteration that reflects the human mutations.

In an attempt to create such a model, Forlino et al. [317] used a *Cre/lox* strategy to incorporate a specific mutation (Gly349Cys, known to produce an OI type III/IV phenotype in man [318]) into one mouse *Col1a1* allele. The specific mutation was created in a cassette that also contained a *Neo* gene in the opposite orientation flanked by LoxP sites in an adjacent intron. This strategy was used to try to create two types of mutation—a "null" in which the *Neo* cassette was retained to interfere with expression of the allele, and an allele in which the cassette had been removed after animals carrying the recombinant allele had been mated with others that expressed the *Cre* recombinase. Although cassette removal did not work quite as planned, a strain of mouse developed in which bony abnormalities similar to those seen in people with OI type III/IV were seen. Additional study will determine the extent to which these animals can be used to test a variety of intervention strategies that could be useful in people with OI. Perhaps a more standard approach to the creation of animals with directed mutations created by homologous recombination could give a variety of phenotypes without the intervening step.

CONCLUDING REMARKS

The clinical heterogeneity in OI is striking among individuals from separate families and within some families. The variation between individuals from different families is explained, in large part, by the diversity of mutations in the two genes that encode the chains of type I procollagen. The variation within families remains to be explained. The phenotypic effects of mutations reflect the genes in which the mutations occur, the nature of the mutations, their locations within the genes, and, for point mutations, the location of the substitution and the nature of the substituting residue. Mutations that affect the amounts of the mRNAs of the type I collagen genes are milder in their phenotypic effects than those that affect the structure of the protein. Rearrangements (multiexon insertions and deletions), exon deletions, smaller deletions, and point mutations all have a similar effect on the assembly of type I procollagen molecules and thus may have similar phenotypic effects. Both the genetic background on which a mutation occurs and the extent of mosaicism (in mosaic individuals) are important in determining the phenotypic outcome. Because of the large number of potential mutation sites, it is not surprising that there is a very wide, almost continuous, phenotypic spectrum. Indeed, it is somewhat surprising, given the nature of the mutations, that there are discrete phenotypes that are almost instantly recognizable. Although a great deal is known about the mutations, the manner in which they are translated into phenotype remains to be fully appreciated. As more mutations are characterized, the nature of the relationship to phenotype and the role of other genes will become clearer and other elements that modulate phenotype can be explored. Effective medical treatments may be emerging that will alter the course of OI in both severely and mildly affected individuals. These therapies have the potential to change the character of bone, alter surgical management, and, potentially, to minimize some of the most severe complications. With the creation of new animal models, the chance to test a variety of therapies will emerge and remove some of the uncertainties prior to testing in humans.

RECENT DEVELOPMENTS

Expansion of the OI Phenotype and Nosology

OI Type V

Very soon after this chapter was completed, a fuller clinical, radiological and histological description of a subgroup of individuals with a clinical picture like that of OI type IV, but subject to hypertrophic callus formation after fractures, was published, which the authors proposed be known as OI type V [327] (see Table 1). They identified seven patients of their own and recognized additional individuals described in previous reports [328–330]. One of the major clinical features that distinguished this group from those with OI type IV was limitation of pronation and supination of one or both forearms as a consequence of calcification of the interosseous membrane. Neither blue sclerae nor dentinogenesis imperfecta were part of the phenotype. On average, this group was shorter than the mean for unaffected individuals, although five of the seven were within the normal range. Four of the seven had developed hyperplastic callus in one or more sites by the age of two, and all had radiographically abnormal vertebral bodies. In three of the families there were other affected members, consistent with autosomal dominant inheritance. The natural history of this entity, however, is not yet well studied, as most of the affected individuals identified have been children. At least one adult used a wheelchair for mobility but the reason was not clear.

Biochemical analysis of collagens synthesized by cultured fibroblasts from affected individuals displayed no alterations

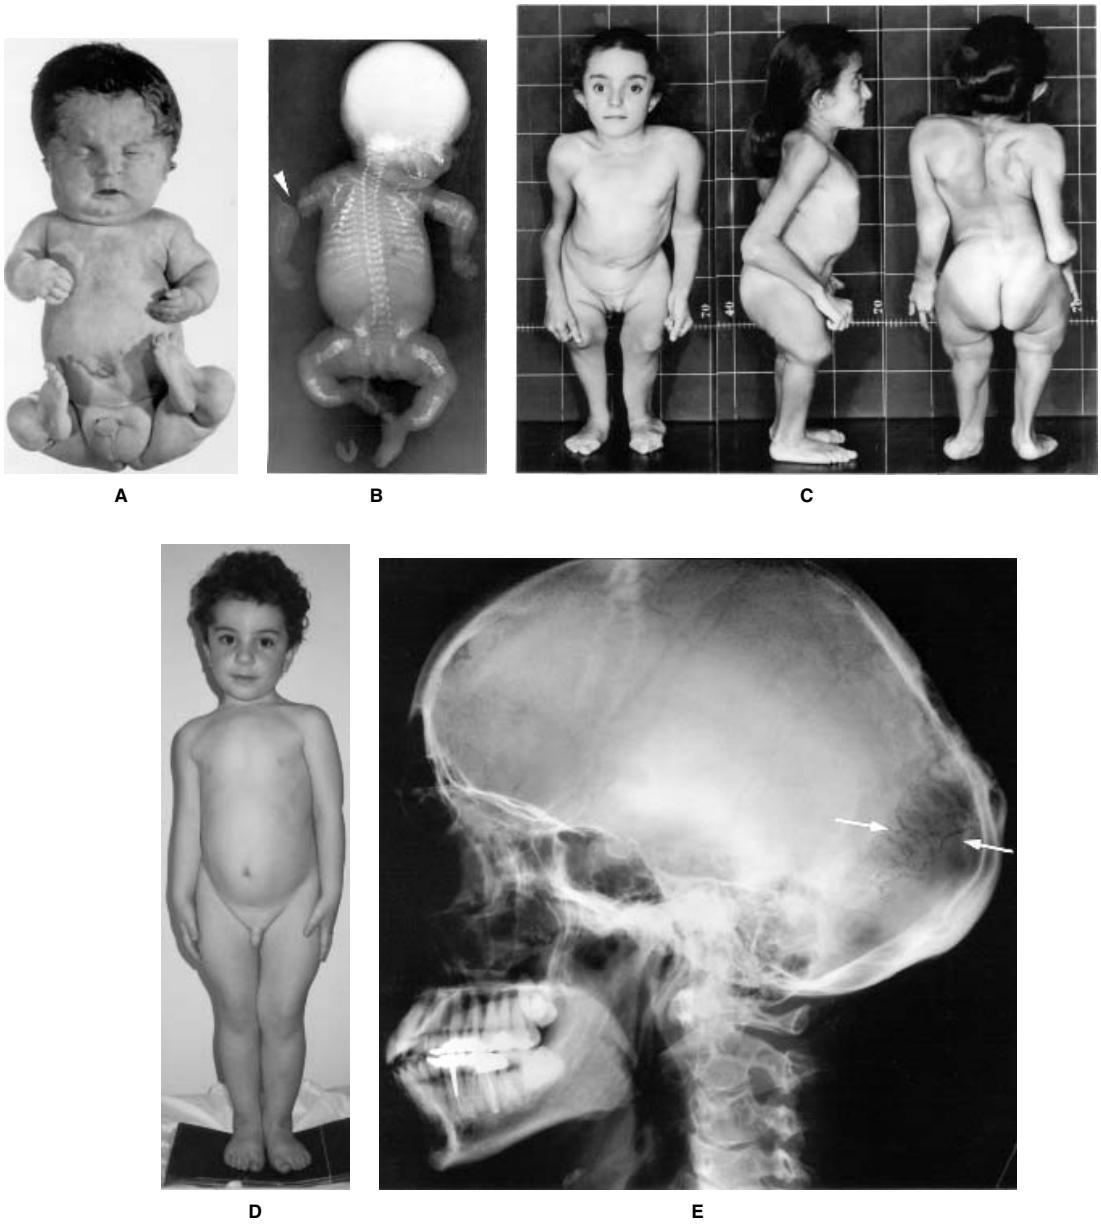

Figure 18. Clinical, radiological, and social aspects of osteogenesis imperfecta. **A**. Neonate (F.B., d.o.b. 20 Apr 1985) with OI type II, born at term with short stature (~36 cm), short and bowed extremities, a low birth weight (2070 g), a large (32 cm) and soft head resembling a balloon filled with water, and inguinal herniae; he died after 5 hours from respiratory failure. His condition was due to a 9 base pair deletion in *COL1A1* [136]. **B**. Radiological findings in a boy (A.K., d.o.b. 5 Jun 1979) with OI type II delivered by Cesarean section in the 32nd week of gestation because of premature rupture of the membranes and breech presentation. Note the right arm, which was torn off during this procedure (arrow), severe osteoporosis, deficient calcification of the skull, and innumerable fractures of the shortened and broad long bones and ribs. His condition was due to a point mutation in *COL1A1* resulting in a Gly988Cys substitution in one of the α1(I) chains [119,120]. **C**. A 14-year-old girl (D.L., d.o.b. 14 Jul 1959) (OI type III) with severe deformities and a height of only 87 cm and weight of 15.5 kg, not yet wheelchair-bound. **D**. A 4.5-year-old boy (OI type IV) with moderate short stature, varus deformity of the femora, and dentinogenesis imperfecta (''bad teeth''), so far without fractures. **E**. Lateral radiograph of the skull of a 48-year-old man (F.L., d.o.b. 10 Jan 1950) (OI type I) shows an ''overhanging occiput,'' Wormian bones along the lambda sutures (zone between arrows) (as in his affected monozygotic twin brother and his child), and basilar impression. **F**. Joint laxity in a 40-year-old woman with OI type IV. **G**. Dentinogenesis imperfecta in a 22-year-old woman (R.B., d.o.b. 17 Feb 1959) with OI type IV. Note the blue-grayish discoloration of all permanent teeth, as also seen in her affected sister; her father became edentulous at around 40 years of age. **H**. Dentinogenesis imperfecta in a 7-year-old boy (T.H., d.o.b. 5 Aug 1981) with OI type III to IV. Note the translucent, opalescent primary teeth and the white, normal-looking permanent teeth, which, radiologically and histologically, were not normal, as was also the case in his affected sister (A.H., d.o.b. 5 Aug 1979) [285,326]. The condition was due to a heterozygous point mutation in *COL1A2* resulting in a Gly688Ser substitution [230]. **I**. Stapes removed from a patient with OI (right) and a control (left). Note the broken plate of the stapes and its thin crura, which explains the conductive hearing impairment. **J**. Carole Piguet (d.o.b. 11 Mar 1962), with severe OI type III, is a well-known Swiss movie star and as helpless physically as the two physicians are professionally.

Figure 18. (*Continued*)

in either the amount or structure of the type I procollagen molecules produced. Screening of the *COL1A1* and *COL1A2* genes by CSGE identified no sequence abnormalities compatible with an OI phenotype [327], suggesting that the causative mutations were in other genes. However, no causative gene has yet been identified.

Natural History

Hearing loss is common in OI, but there has been some controversy about the age of onset of significant impairment and the ages at which affected individuals should be assessed. In a recent study of 45 children among 201 individuals in

Finland with OI, hearing loss was found to be rare [331]. The significant hearing loss noted in two children was thought to be the result of factors other than OI. Nonetheless, because intact hearing is vital for adequate school performance, formal assessments should be made prior to school and at any time school performance drops.

Treatment

The search for effective treatment of OI, with the aim of decreasing the likelihood of fractures, enhancing growth, and diminishing associated pain and diminished mobility, continues. The major threads of investigation include the use of bisphosphonates at ever younger ages, the assessment of bone marrow transplantation as a source of osteoblastic stem cells, and the use of intramedullary rods to increase bone strength and resistance to fracture and deformity.

Bone Marrow Transplantation

The clinical responses to bone marrow transplantation in children with severe osteogenesis imperfecta have recently been reassessed [332]. Five children have now received marrow transplants from related donors, of whom the follow-up study includes data on three. One was not in the original group, while two from the original group were removed from the study because osteoblast engraftment could not be demonstrated. All the children had clinical features of OI type III. The three children with low levels of donor osteoblast engraftment had a median 7.5 cm increase in body length six months after transplantation, compared with 1.25 cm for age-matched control patients. However, because crown-heel measurements were used for length, any change in limb deformity could have contributed to apparent growth. The children also gained 21–65 g total bone mineral content by three months after transplantation. With extended follow-up, the patients' growth rates either slowed or reached a plateau, although the bone mineral content continued to rise. Further studies are needed to determine the role of allogeneic bone marrow transplantation in severe forms of osteogenesis imperfecta, and to understand if a very small population of cells can contribute to the claimed growth.

Bisphosphonate Treatment

Although the results of a controlled study of bisphosphonate infusion with contemporary controls have not yet been reported, a second observational study in very small children has been published [333]. These children ranged from just over 2 months to about 20 months of age at the time of study and were followed for a year. A historical control group with a similar clinical range was also assessed. In both the treated group and the controls, height appeared to increase to an equal extent. Absolute vertebral area increased in the treated group, but diminished in the untreated group. At the same time, the Z score values for bone mineral density followed the same pattern. Fracture frequency was more variable in the treated group, but it is not clear if the criteria for fracture determination were the same in both groups. Overall, these data begin to add evidence that bisphosphonates may have benefits for some children with OI. Good comparative studies and the assessment of long term effects are still necessary to understand if these protocols will ultimately benefit some, or all, individuals with OI.

Collagen Mutations and Molecular Assembly

Almost 40 additional collagen mutations have been described in the last few months. Mutations that result in the substitution of glycine residues in the triple helical domain of the proα1(I) chain include Gly127Ser (OI type IV), Gly133Arg (OI type IV), Gly229Ser (OI type III), Gly526Ser (OI type III), Gly688Cys (OI type III) [334] and Gly238Cys (OI type IV). In the proα2(I) chain [335], newly identified mutations include Gly127Val (OI type IV), Gly184Asp (OI type IV), Gly196Ala (OI type IV), Gly208Arg (OI type IV), Gly247Pro (OI type III), Gly274Ser (OI type IV), Gly301Cys (OI type IV), Gly436Glu (OI type III), Gly442Glu (OI type IV), Gly481Arg (OI type IV), Gly511Ser (OI type IV), Gly538Arg (OI type IV), Gly574Asp (OI type III), and Gly586Arg (mild OI). Among these, the substitution of glycine by proline requires a two-nucleotide change (GG → CC), a rare mutational event. These mutations begin to provide a more highly saturated mutation map that will, ultimately, provide the basis for better modeling of the relationship between mutation and phenotype. That map, as can be seen from Figure 1, is still incomplete. Insertions and deletions of single amino acids and triplets of amino acids, or their multiples, appear to be somewhat more common than previously recognized, as a dozen such variants are included among the newly described mutations [334,336].

Mutations in the carboxyl-terminal domains of the type I procollagen chains have recently been described in a human family [337] and in a dog with osteogenesis imperfecta [338]. In the human family, a mild form of osteogenesis imperfecta was associated with a Cys1299Trp mutation that disrupted one of the intra-chain disulfide bonds in the carboxyl-terminal propeptide of the proα1(I) chain. The mutation allowed the slow assembly and secretion of overmodified, but stable, type I procollagen trimers. In the dog, a moderately severe form of osteogenesis imperfecta was associated with the formation of a premature termination codon that truncated the carboxyl-terminal propeptide of the proα2(I) chain. The excess proα1(I) chains appeared to form proα1(I) homotrimers. Few mutations in the carboxyl-terminal propeptide of the proα2(I) chain have been identified in humans.

N.B. With the permission of the authors, the editors have added as Fig. 18, a number of photographs that they felt might be of some clinical interest.

Chapter 9

The Ehlers-Danlos Syndrome

Beat Steinmann, Peter M. Royce, and Andrea Superti-Furga

Division of Metabolism and Molecular Pediatrics, Department of Pediatrics, University of Zurich, Switzerland

SUMMARY

- **The Ehlers-Danlos syndrome (EDS) is a clinically and genetically heterogeneous group of connective tissue disorders affecting mainly skin, joints, and ligaments but in some cases also arteries, intestine, and the gravid uterus. Its hallmarks are hyperelasticity of the skin, hypermobility of the joints, and tissue fragility.**
- **The classical type of EDS (EDS I and II) is the most common form and is characterized by marked skin hyperextensibility and fragility and by joint hypermobility. The disorder is most often inherited as an autosomal dominant trait, but there is considerable locus heterogeneity.**
- **The hypermobile type of EDS (EDS III) is characterized by marked joint hypermobility, moderate skin involvement, and an absence of tissue fragility. It is inherited as an autosomal dominant trait; the underlying defect is unknown.**
- **The vascular type of EDS (EDS IV) is the most severe form of the disorder, with a markedly reduced life span due to spontaneous rupture of internal organs such as arteries and intestine. It is inherited as an autosomal dominant trait and caused by mutations in the *COL3A1* gene coding for collagen III. Unlike in the classical type, the skin is not hyperelastic but thin, translucent, and fragile, joint hypermobility is restricted to the minor joints, and affected subjects may have a characteristic facial appearance.**
- **The kyphoscoliotic type of EDS (EDS VI) is characterized, in addition to the features of the classical type, by severe muscular hypotonia after birth, progressive kyphoscoliosis, a Marfanoid habitus, osteopenia, and occasionally rupture of the eye globe and great arteries. It is inherited as an autosomal recessive trait and caused by deficiency of collagen lysyl hydroxylase activity (EDS VIA). A subgroup of patients with similar clinical features does seem to exist, however, in whom lysyl hydroxylase activity appears to be normal (EDS VIB).**
- **The arthrochalasic type of EDS (EDS VIIA and VIIB) is characterized by congenital bilateral hip dislocation, severe generalized joint hypermobility, moderate skin involvement, and osteopenia. It is inherited as an autosomal dominant trait and caused by mutations leading to the loss of the amino-terminal telopeptide of one or other of the two distinct α-chains of the heterotrimeric collagen I molecule.**
- **The dermatosparactic type of EDS (EDS VIIC) is characterized by redundant and fragile skin, prominent herniae, joint laxity, and dysmorphic features. It is inherited as an autosomal recessive trait and caused by a deficiency of procollagen I N-terminal proteinase.**
- **Other classified forms of the EDS, the existence of which as separate entities is questionable, include X-linked EDS (EDS V), the periodontotic type of EDS (EDS VIII), and fibronectin-deficient EDS (EDS X). Further types of EDS include the progeroid form, unspecified types, and chance associations as confounding factors.**
- **Animal models — naturally occurring, transgenic, and experimentally induced — are useful models for the elucidation of physiological and pathophysiological processes.**

INTRODUCTION

The Ehlers-Danlos syndrome (EDS) is a heterogeneous group of heritable disorders of connective tissue characterized by articular hypermobility, skin hyperextensibility, and tissue fragility affecting skin, ligaments, joints, blood vessels, and internal organs. Its clinical and historical aspects have been reviewed in the classical monographs of Beighton [1] and McKusick [2]. In the preface to his book, Beighton [1] writes as follows:

> "Until recent years, no fairground was complete without an 'Elastic Man'. Audiences would be amazed by his ability to stretch his skin for a prodigious distance, before allowing it to snap back into place. He often had hypermobile joints, and would happily place his left great toe in his right ear, or his feet in his trouser pockets.
>
> As medicine became increasingly scientific, the appellation 'Ehlers-Danlos syndrome' was used and he is now more likely to be encountered in a clinical meeting than in a circus side show."

Connective Tissue and Its Heritable Disorders, pages 431–523

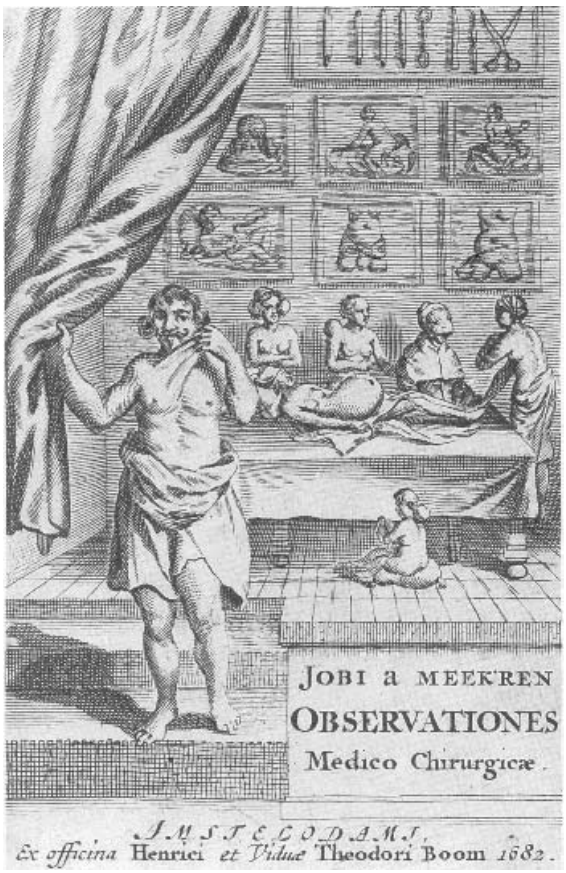

Figure 1. First description and picture of an individual with EDS published by Job Janszoon van Meek'ren. **Foreground**: Spaniard with hyperextensible skin. **Background**: On the table, a woman with a distended abdomen because of ascites and an ovarian tumor; she was the wife of Govert Flinck, a famous Dutch painter, and her case was also described in the same book [9]. Van Meek'ren was a notable surgeon of Amsterdam, who was a pupil of Tulp, the original of Rembrandt's ''Anatomist'' [12]. His observation made in 1657 was first reported posthumously in ''Belgian'' in 1668 [9] and translated into German in 1675 [10]. Below follows a translation from the German by Michael Roth and Ursula Zeller von Murg of Zürich. The original Belgian report was also translated into Latin in 1682 [11], and an English translation of this last is given in McKusick [2].

''Of a Soft-Skinned Spaniard''

''Out of pressing needs and unforgettable sufferings our ancestors raised us, as it were, from the cradle with the belief that there is no wilder, more merciless and cruel people to be found in the world than the Spanish. As the history books, especially the chroniclers of the Dutch wars and the American barbarities to excess prove.[1] In spite of this we must confess that we have not seen a softer or more lithe Spaniard than Gregorius Albes, begotten by Spanish parents and on a Canary Island born. However, in his skin alone was he such. We saw him together with the famous professors, Johann von Horne, Francisco Sylvio, Guil. Pisone, and Francisco von der Schaagen in the year 1657 in the large hospice. He was a young fellow, twenty-three years of age, healthy in body and build. In our presence he took with his left hand the skin from his right shoulder and pulled it to his mouth, like an archer pulls the string on a cross-bow. The skin, however, from the chin he pulled with both his hands into a point like a beard, to his breast, from whence he then pulled the self same skin over his head, covering his eyes in a manner such that we could no longer see them. Even more of a wonder was how his skin, when he let go of it, fell back immediately into its proper place in such a manner as if it had never been touched. In just such a way he pulled the skin from his right knee up and down about half an arm's length. And once he let go of it, a man could not notice that it had once been pulled up.

At the same time we were astonished to discover that the skin on his left shoulder and knee in no way let itself be pulled, as it was in these places so fixed and firm, it would have been impossible.

What however the causes of the soft parts as well as the firm parts were remains to us till this very hour unknown.''

Chapter 29 in ''Rare and Fantastical Observations of the Surgical and Healing Arts, as they were first made public five years ago, shortly after the passing away of the author, after much urging and desire to please the students of the Healing Arts; now for the advantage of High German speakers truly translated and printed. Throughout adorned with copper engravings and supplied with a complete register. Set and printed by Paul Fürstens, Art and Book dealer, Late Wittib and Successors, Nürnberg, An 1675'', pp 186–188. (Reproduced from [11] with permission of the British Library.)

Note that, most interestingly, there is no mention of joint involvement or scarring and that the left side is not involved.

[1] The author points out that Spaniards are the ''most cruel'' people in the world, a remark to be interpreted in the light of the fact that the Dutch had just undergone an 80-year war with Spain.

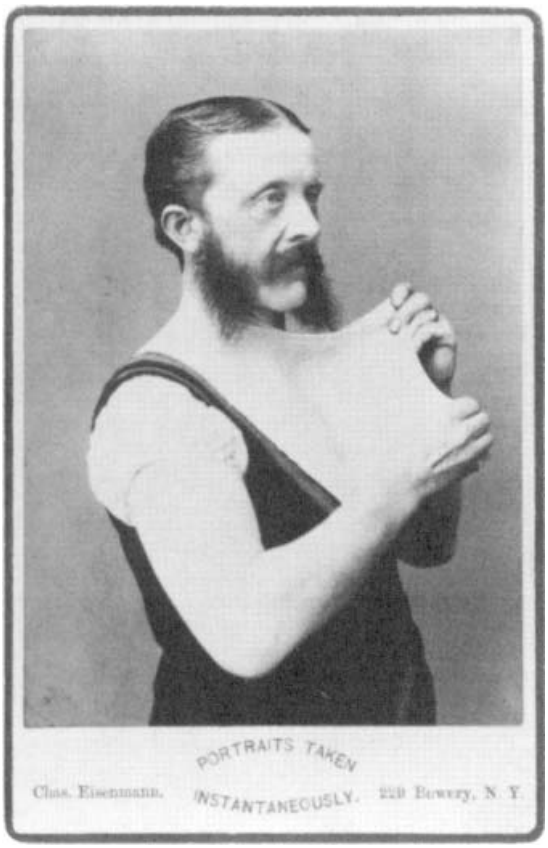

Figure 2. First known photographic documentation of a person with EDS. Felix Wehrle, the ''Elastic Skin Man,'' who, besides having the power to stretch his skin could readily bend his fingers backward and forward, was photographed by Charles Eisenmann[2] in about 1880 (Cabinet card photograph, private collection). The same person was photographed in 1888 in Budapest and his picture was published in 1896 [3]. Wehrle was apparently consigned to the ''museum circuit,'' where he did contortions along with skin stretching. His career seems to have been overshadowed by the more spectacular feats of James Morris, ''The India Rubber Man.'' An Eisenmann portrait in the files of the Museum of the City of New York shows that Morris was able to pull the skin of his throat up over his eyes, an achievement that won him long-standing contracts with various Barnum shows.

The changes in social structure and the advances in biomedical sciences have had as consequences that affected persons earlier enjoyed collectively as curiosities [3,4] are now regarded as individuals suffering from a disease and that the anecdotes and picturesque descriptions with their undoubtedly high didactic value (for examples, see [1]) have been replaced today by more scientific clinical, morphological, biochemical, and functional characterizations published in papers or monographs (for reviews, see [5–8]).

The first partial description of the syndrome was provided by Job Janszoon van Meek'ren (1611–1666), a surgeon from Amsterdam, who in 1657 described a 23-year-old Spaniard named Georg Albes in a report published posthumously in 1668 in ''Belgian'' [9], which was translated into German in 1675 [10] and Latin in 1682 [11], containing one and two etchings (Fig. 1), respectively. It is of note, however, that no mention was made of abnormal scarring or joint laxity and that the left side is not involved. Photography as a new method of clinical documentation started after 1850, and it was in about 1880 that the first known photograph of an individual with EDS was taken, the subject being a traveling showground performer (Fig. 2).

Merit for the classical description of the syndrome should be assigned to the Russian dermatologist A.N. Tschernogubow, who presented at the first meeting of the Moscow Dermatological and Venereological Society, November 13, 1891, a 17-year-old sporadic case with all the hallmarks of the syndrome [13] (translated by Denko [14]; abstracted by Lanz [15] and von Trautvetter [16][3]). He described the skin as pale, lusterless, velvety, thin, hyperextensible (''it is easily pulled away, far beyond normal limits, and rapidly like elastic it regains its normal position''), and friable, with scar formation in a ''strange fashion'' and with secondary wound dehiscence because all sutures cut through the skin; the joints had an extreme degree of mobility, and there was subluxation of a hip and an elbow; there were ''fleshy tumors'' mainly on protruding areas such as the elbows, and cysts on the buttocks and knees; upon palpating the skin, especially that of the extremities, there were round subcutaneous nodules, fine, small, quite hard, and painless, which on removal were found to be deposits of mineral salts; the patient was born feeble, had recurrent convulsions starting in infancy, began to walk only during his third year, and continued to fall frequently; he was rather intelligent, with a ''good head on his shoulders''; gentle natured, as a rule, with a ''good frame of mind and spirit.'' Tschernogubow then concluded that, in the future, ''there might be an opportunity to clarify the observed looseness of the connective tissue that impaired the generalized development of all connective tissue components... It is possible that the development of this looseness is due in part to a deficiency in the supporting structures with a resulting diminution in the ability of the skin to resist deformation.'' In the Russian literature, this condition is called today, quite appropriately indeed, ''Tschernogubow syndrome,'' but because the report was written in Russian, it was not known to most European and American dermatologists. Tschernogubow did not describe further patients (N.P. Bochkov, Moscow, personal communication, 1990).

In 1901, Edvard Ehlers (1868–1937) (Fig. 3), a dermatologist from Copenhagen, reported a patient with ''cutis laxa,'' a marked tendency to hemorrhages, and loose-jointedness [17]. Henri-Alexandre Danlos (1844–1912)

[2]Charles Eisenmann, ''the popular photographer'' as he called himself, was born in the then independent German State of Würtemberg in 1850 and moved to New York, where he opened his studio, in 1879. Eisenmann's interest in human grotesques was reflected in the world of second-string vaudevillians and first-rank freaks; he was the official photographer of the dime museum *demi-monde*. The term ''portraits taken instantaneously'' refers to the collodion process, which transformed the minutes of the daguerreotype exposure into approximately as many seconds and arose when early users of the wet plate system discovered that the process allowed them, for the first time, to record street scenes with arrested movement [4].

[3]Both abstracts are entitled ''cutis laxa'' instead of the original ''cutis laxae,'' and von Trautvetter [16] reported erroneously a 50-year-old woman who was, in fact, the healthy mother of the 17-year-old proband described by Tschernogubow, thereby giving the misleading impression to readers, including Beighton [1] and McKusick [2], that there were actually two different case reports.

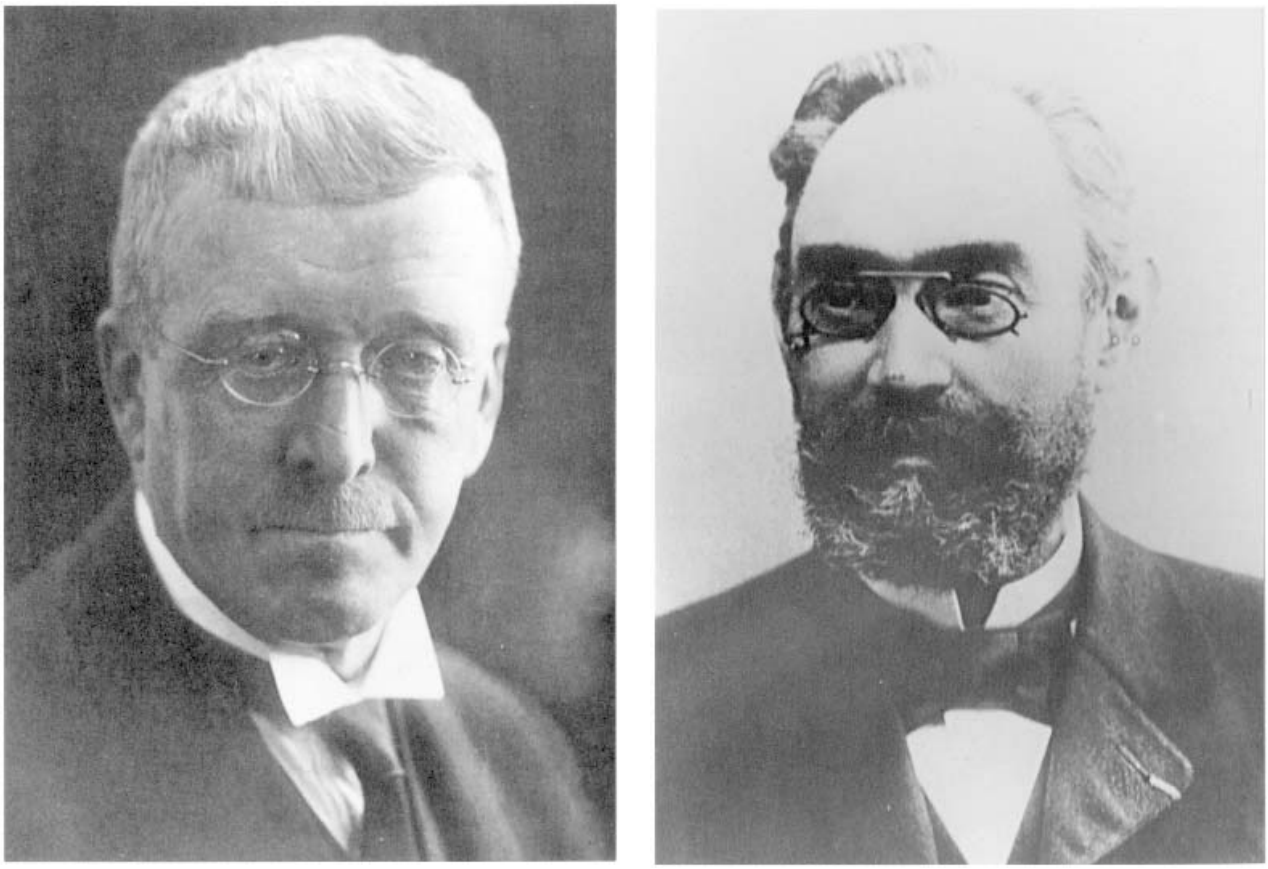

Figure 3. Portraits of Edvard Ehlers and Henri-Alexandre Danlos. Edvard Ehlers (1863–1937) (**left**) presented in 1899, at a meeting of the French Dermatological Society, a law student with lax skin, a tendency to hematoma of the skin, and generalized loose jointedness; he published this case in 1901 [17] but subsequently refrained from doing more work on the condition later bearing his name. Henri-Alexandre Danlos (1844–1912) (**right**) discussed in 1908, at a meeting of the French Dermatological Society, the nature of heaped-up lesions on the elbows and knees of a boy in whom a diagnosis of juvenile pseudodiabetic xanthoma had previously been made by his colleagues, Hallopeau and Macé de Lépinay. Danlos recognized that the skin of this patient was fragile and extensible, and he pointed out the similarity of these features to those of the patient presented by Danlos to the same society in 1899; he published the case the same year [18]. In 1900, Morris presented a similar case, a lad with "elastic" skin and numerous cutaneous nodules [19]. (Courtesy of Dr. Pierre Maroteaux, Paris.)

(Fig. 3), a dermatologist from Paris, described in 1908 another patient with hyperelastic, thin, and fragile skin and explained the molluscoid pseudotumors as chronic contusions of the vulnerable tissues [18]. The terminology became complex and, apart from general terms such as "dystrophia mesodermalis" and "fibrodysplasia elastica generalisata," many terms that were descriptive of various features of the syndrome were employed, such as "dermatorrhexis," "dermatolysis," "Gummihaut," "cutis pendula," "cutis hyperelastica," "chalasodermia," "human pretzel," and "India rubber man." Between 1932 and 1936, the condition received its eponymous title and (by this) achieved scientific respectability [20–23]. In 1936, Sack described a patient with excessive friability of the arteries and called the condition "status dysvascularis" [24]. Dominant inheritance was mentioned as early as 1888, and from then on occasionally [25–28]. In 1949, Johnson and Falls [29] demonstrated autosomal dominant inheritance on the basis of their study of an extensive kindred containing 32 affected persons over five generations. Six years later, Jansen [30] suggested that the defect affected the collagen "wickerwork," which he described as being excessively loose in this disorder.

In 1960, McKusick reported genetic heterogeneity of the EDS in the second edition of "Heritable Disorders of Connective Tissue" [2b]. In 1967, Barabas [31] delineated three clinical types, including the arterial-ecchymotic type, later also called the Sack-Barabas syndrome and now known as the vascular type of EDS, or EDS IV. One year later, Beighton [32] distinguished five clinical forms, and in 1972, McKusick listed seven types [2], including EDS VI, the ocular-scoliotic type, due to lysyl hydroxylase deficiency [33], EDS IV, the arterial-ecchymotic type, due to collagen III deficiency [34], and EDS VII, arthrochalasis multiplex congenita, which has turned out to be caused by a failure of removal of the amino-terminal globular propeptides of procollagen I [35,36,305].

The importance of identifying correctly the type of EDS with which a patient is affected cannot be stressed enough because the natural history and mode of inheritance differ among the types. Unfortunately, much of the older literature does not differentiate clearly between types, and the severe complications of EDS IV are often cited as characteristic of the syndrome as a whole, thereby creating unnecessary anxieties. In this chapter, we try to cover the EDS in a

comprehensive and authoritative way, to weigh the different aspects as objectively as possible, and to clarify earlier concepts and conclusions that today are no longer tenable. To give the reader an idea of how knowledge was gained, references are often cited in a historical sequence.

GENERAL ASPECTS OF THE EHLERS-DANLOS SYNDROME

Common Signs and Symptoms

The signs and symptoms listed in this section may be encountered in various of the different types of EDS, although to variable degrees, and are therefore described together (see Table 1).

Dermatological Features, Facies

The skin is of a white color and lusterless. It is thin, smooth, soft, and velvety, like "wet chamois leather," a "fine sponge," "the skin you love to touch," or "marshmallow," with a doughy feel. The thinness of the skin is best appreciated clinically on the dorsal aspect of the proximal phalange of the fourth finger. The face may be characteristic, with its pale, pastel-colored appearance resembling a portrait by Manet, with irregular scars over the forehead and chin, which are remnants from early childhood (Figs. 4b, 5b, 6a), epicanthic folds, or, later in life, telecanthus, secondary cutis laxa of the eyelid, a crooked nose with a soft cartilage, crowded teeth, and lopsided and floppy ears. In elderly patients, the forehead shows both horizontal and vertical creases (Fig. 6a), giving a peculiar reticular pattern.

Cutaneous hyperextensibility. This is a cardinal feature of EDS, except EDS IV. The skin, and also the mucosa, is hyperelastic[4]; that is, it extends easily and snaps back after release (unlike lax, redundant skin as in cutis laxa). It seems loosely attached to the subcutaneous tissues, and when traction is applied there is a sensation felt by the applier of the skin "coming away." This is particularly striking over areas such as the thenar, the upper part of the chest, and other parts of the body where the skin is usually tightly fixed (Figs. 2,4a, 25d). A "man who could hide behind his skin" is shown in Figure 1 ([11], from which the figure is reproduced).

Skin hyperelasticity should be tested at a neutral site, meaning one that is not subjected to mechanical forces or scarring, such as the volar surface of the forearm. Although in infants hyperelasticity of the skin is difficult to assess because of abundant subcutaneous fat, in the adult, with time, loose folds of skin may appear over the elbow joints like a dewlap (Fig. 4c); the palms may be peculiarly wrinkled (Fig. 25d), the skin of the hands resembles loose gloves, and the soles of the feet appear loose-fitting and resemble moccasins or oversized ankle socks (Figs. 5c–e). Cutaneous hyperextensibility varies with the site of the body, and simple clinical scores have been established to assess it [44,45]. Elderly individuals may also develop abnormally lax skin (acquired cutis laxa), such as of the eyelids (blepharodermatochalasis, see below). *In vivo* methods of measuring skin elasticity have been developed by Grahame and Holt [46], as discussed by Daly [47], and applied by Henry et al. [48]. In both normal individuals and affected persons, the module of elasticity increases with age, always being higher in females than in males, and clinical evidence of Langer's lines shows that skin is not mechanically isotropic [49]. Tensile testing shows this anisotropy to be related only to the magnitude of the initial large extension region and not to the low and final high stiffness [47].

Cutaneous fragility (dermatorrhexis). This is manifested by splitting of the dermis or mucosa following relatively minor trauma, which occurs mainly over pressure points (knees, elbows) and areas prone to trauma (shins, forehead, chin). The wounds often present a gaping, "fish-mouth" appearance with protruding subcutaneous fat lobules and usually bleed little because the edges retract due to the elasticity of the adjacent skin, thereby compressing the ends of the blood vessels. Stitches may hold poorly because the thread cuts through the skin, and dehiscence may occur; in addition, wound healing *per se* is delayed. Stretching of the scars after apparently successful primary wound healing is a characteristic of all EDS types; they become wide, thin, and shiny, with a "cigarette paper," papyraceous, or "burn scar"-like appearance (Figs. 4b, d; 5b, f; 25a, b, f). Due to repeated trauma, the scars often become darkly pigmented or violaceous and usually corrugated by fine wrinkles, and telangiectasia may form within their borders. Many lacerations occur during childhood when the child takes its first steps and then more frequently in boys than girls. Proneness to skin lacerations is later aggravated by the unstable joints and muscular hypotonia, which cause stumbling and falling. The tendency toward skin-splitting sometimes decreases as the patient grows older, but it is difficult to know whether this represents a change in the connective tissue itself or whether it is due to less frequent exposure to trauma when the patient reaches adult life. It has been shown that patients with the thinnest skin have the greatest tendency toward skin-splitting [50]. As a rule, the greater the degree of scarring, the more readily soft tissues inside the body will tear on operation.

Hematoma and bruising. Easy bruisability is common and is frequently the presenting complaint to the pediatrician. It is probably due to the friability of the perivascular connective tissue and the walls of the small blood vessels. Child abuse is often suspected (see legend to Fig. 7). Bleeding from the gums following brushing of the teeth and profuse bleeding after tooth extraction are frequent; gastrointestinal bleeding and hemoptysis, however, are rare (with the exception of EDS IV). The bleeding tendency may lead to an extensive search for a coagulopathy. The Rumpel-Leede test may be positive, indicating capillary fragility. Although a variety of plasma clotting factor or platelet abnormalities have been recognized as a result of a greater awareness of EDS, these are probably chance associations, and most patients will be normal in this regard (see EDS X).

Molluscoid pseudotumors and spheroids. The peculiar mechanical properties of the skin in EDS may lead to a

[4] "Elastic" is used synonymously with "stretchy" to indicate a rubberband-like property — that is, the ease with which a material is reversibly deformed — as opposed to the formal physical definition described by Hooke in 1670:

$$\Delta l = \frac{F \cdot l}{E \cdot q}; E = \frac{l \cdot F}{\Delta l \cdot q}$$

where Δ l is the change in length (l) of a material with cross section (q) when a certain force (F) is applied; E, the elastic modulus, is the constant, characteristic for the material. E is larger the less the material is deformed (e.g., steel) and is a measure of the resistance of a particular material against deforming forces. For a historical discussion about the difference between the terms "popular" and "physical" elasticity, see Cohn [43].

TABLE 1. The Ehlers-Danlos Syndrome

Nomenclature		Signs and Symptoms: Skin			Signs and Symptoms: Joint Laxity	Signs and Symptoms: Other Distinctive Features, Complications	Inheritance	Primary Defect	Relative Frequency	MIM No.
New*	Type	Hyperelastic	Fragile	Bruisable						
Classical type	I	+++	+++	++	+++	Vascular and intestinal complications occasionally	AD	Collagen V-defects, other defects	Common	130000
	II	++	++	+	++				Common	130010
	II/III					Normal wound healing	AR	Tenascin-X deficiency	Rare	
Hypermobile type	III	+	−	+	+++	Arthritis	AD	?	Common	130020
Vascular type	IV	−	++++	+++	+	Rupture of arteries, intestine, uterus; pneumothorax; acrogeria; periodontitis; thin skin with easily visible venous pattern; characteristic facial expression	AD	Abnormal and/or reduced type III collagen	Not so rare	130050 (225350) (225360)
Kyphoscoliotic type	VI A	+++	++	++	+++	Muscular hypotonia, kyphoscoliosis, osteoporosis, microcornea, ruptures of arteries and the eye globe	AR	Deficiency in lysyl hydroxylase (normal enzyme)	Rare	225400
	(VI B)									(229200)
Arthrochalasic type	VII A	++	+(+)	+	+++	Congenital hip luxations, osteoporosis, Wormian bones, fractures	AD	Missing N-telopeptide of α1(I) or α2(I) chains of collagen I	Rare	130060

MIM numbers [37] refer to the predominant form of each type for which the inheritance is given; MIM numbers in parentheses refer to less common variants, the existence or inheritance of which may be questionable. Inheritance: AD, autosomal dominant; AR, autosomal recessive; XL, X-linked.

*The new nomenclature is defined in [39]; see also Footnote 5, below.

**EDS IX, originally called X-linked cutis laxa, and EDS XI are included for historical completeness but, as mentioned in the text (see also [38,39]), have been reclassified as the occipital horn syndrome, a disorder of copper transport (see Chapter 14, this volume), and the familial joint hypermobility syndrome, a disorder of unknown cause, respectively. The existence of EDS V, VIII, and X as separate entities is questionable (see the text), as indicated by parentheses. For a description of EDS VIB, which clinically resembles EDS VIA but is characterized by normal lysyl hydroxylase activity, see the text.

Figure 4. Classical type of EDS (EDS I). A.V. (4 Jul 1933) and her son U.V. (29 Dec 1964) are two of four affected members of a three-generation Swiss pedigree who were nicknamed ''those with the worn-out skin.'' Ultrastructural analysis of the skin of U.V. and A.V. has been reported (patients 1 and 2 in Vogel et al. [40]). (**a**) Hyperextensible skin, moderate scar formation on the forehead, and discrete telecanthus in A.V. (43 years). (**b**) Extensive atrophic broad scars on the forehead and over the nose and cheekbones, which are remnants from early childhood (U.V., 12 years). (**c**) Hyperelasticity and loose folds of skin resembling a dewlap, and a soft, fleshy molluscoid pseudotumor over the elbow (A.V., 43 years). (**d**) Atrophic and hypertrophic hemosiderotic scars in the doughy-feeling skin over the knees and shins (A.V., 43 years).

As a schoolgirl, A.V. had recurrent posterior luxations of the left tibia, the last time being at the age of 16 years. Deliveries of her first two, unaffected children were 2 and 7 weeks before term, unexpectedly and rapidly on the couch at home. Her third child, U.V., and her fourth, unaffected child were born at term. She has had no striae gravidarum. At age 42 years, she had a hysterectomy because of prolapse of the uterus with urinary incontinence; postoperative wound healing was normal.

Follow-up at age 58 showed that this intelligent and witty person had had few further complications; she commented that even her ''loose mouth'' was firmer than her connective tissue.

Figure 5. Classical type of EDS (EDS I). B.S. (5 May 1955), at the time of the photographs a 21-year-old man, mentally retarded and institutionalized; nothing is known about his perinatal history; his father is also affected. A heterozygous mutation in *COL5A1* (IVS 28 + 1G > A) predicts a premature stop codon in the mRNA after the insertion of 178 bp of intronic sequence (see ''EDS43'' in [41]). (**a**) Marked pectus excavatum and moderate kyphoscoliosis. (**b**) Atrophic and hypertrophic scars on the forehead. (**c**) The skin over the hands is abnormally wrinkled and redundant, resembling a pair of oversized gloves. (**d**) Hyperlaxity of the small joints of the fingers. (**e**) Dynamic flat foot, hallux deformity, and formation of pseudotumors over pressure points. (**f**) Large, papyraceous, and hemosiderotic scars over both knees. (**g**) Electron microscopic pictures of the dermis of B.S., showing large composite fibrils with an irregular contour and an abnormally wide range of diameters of the round collagen fibrils in cross section (left), and a spiral-like appearance of the composite fibrils in longitudinal section (middle); for comparison, a site-matched skin from an age and sex-matched control is included (right). (Case 4 in Vogel et al. [40] copyright by U.S.-Canadian Academy of Pathology Inc., reprinted with permission; a–f reprinted with permission from Steinmann [42].)

Figure 6. Classical type of EDS (EDS II). (**a**) A three-generation family with EDS II. The grandmother is 55 years old, the father (E.C., born 29 Jan 1959) 32, the girl 9 (to the left), and the boy 6. Note the multiple scars on the forehead and the horizontal and vertical creases on the grandmother's. (**b**) Anteroposterior and lateral (**c**) radiographic views of the thorax of E.C. demonstrate an elevated diaphragm (relaxatio diaphragmae) on the left side. After a trivial accident with his motorcycle at age 35, E.C. complained of chest pain, and upon the radiological finding of an elevated diaphragm, rupture of the diaphragm with eventration of the stomach or paralysis of the phrenic nerve were considered. A diagnostic thoracotomy revealed relaxatio diaphragmae due to weak tendinous structures. One year later, he rapidly became anemic and had profuse melena due to a Dieulafoy ulcer, which necessitated ligation of the enlarged artery below the muscularis mucosae.

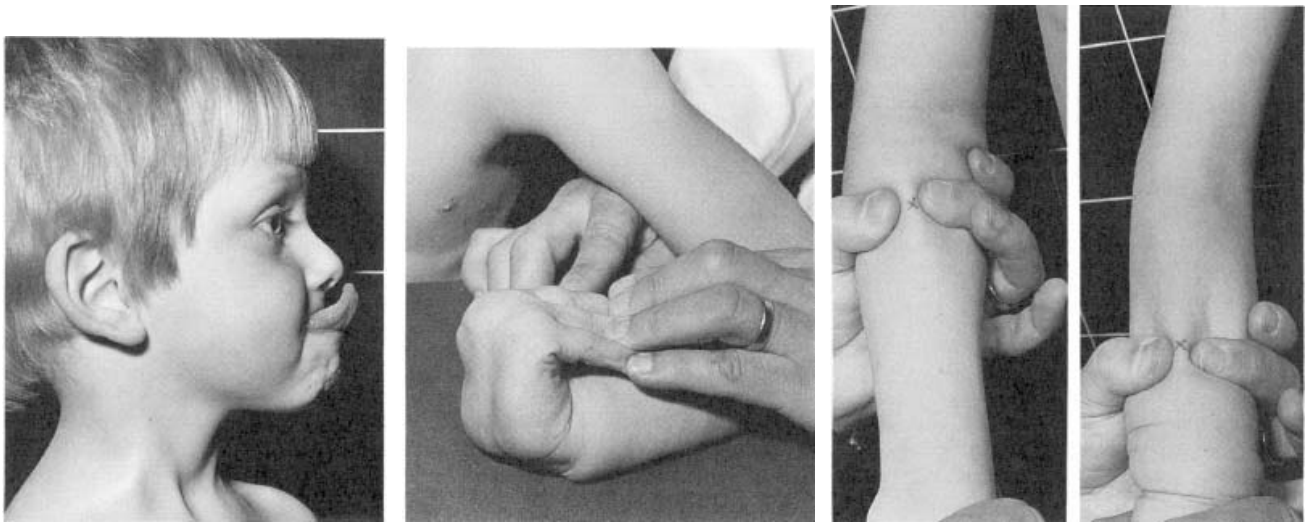

Figure 7. Classical type of EDS (EDS II). (**a**) Positive Gorlin sign (i.e., the ability of a patient to extend the tongue to the tip of the nose). (**b**) Hyperextensibility of the fingers and hands. (**c**) The skin can be displaced up (**left**) and down (**right**) over the subcutaneous fat of the forearm to a great degree. F.K. (20 Jan 1975) was hospitalized at age 2 years and 4 months because of suspected child abuse presenting with multiple hematoma and hemarthros. The diagnosis of EDS was only made at the age of 5 years (Figs. a–c). He is a sporadic case.

Because of recurrent luxations of the right shoulder while exercising, and especially during sleep, and the right patella, he was operated on successfully at the ages of 10 and 12 years, respectively. He luxated his left knee numerous times between the ages of 10 and 12 years but has not done so since. His skin feels doughy but is not excessively fragile.

Suspected child abuse, late diagnosis in a sporadic case, and the difficulty of classifying a patient into a defined group are characteristic of the situation with many individuals with EDS. ((**a**) reprinted with permission from Steinmann [41]).

variety of secondary lesions that develop with time in areas exposed to frequent microtrauma and pressure. Molluscoid pseudotumors are fleshy, heaped-up lesions associated with scars over pressure points such as the elbows (Figs. 4c, 25c) and knees, which usually appear after entering kindergarten (they were already described as features by Tschernogubow in 1891 [13] and Danlos in 1908 [18]). Redundant knuckle pads may develop over deformed and hyperflexed toes. These probably develop through frequent microtrauma, bleeding, and fibrotic scarring and may spontaneously rupture and discharge necrotic material. Spheroids (or spherulae) are small, cyst-like, hard shot-like nodules, freely movable in the subcutis over the bony prominences of the legs and arms. They occur in about one-third of patients [51], are numerous, and feel like hard grains of rice or small pieces of shot. On x-rays, they present an outer calcified layer with a translucent core. In contrast, phleboliths, although presenting a similar appearance, usually are not superficial and are rarely as numerous as spheroids, while calcified cisticerci taper in shape and are found in muscles rather than subcutaneous tissues [51,52]. The spheroids represent subcutaneous fat lobules that have lost their blood supply and then become fibrosed and calcified [53]. Alternatively, they may present as "subcutaneous mobile encapsulated lipoma" with or without tenderness [54].

Other dermatological features. These comprise hyperkeratosis follicularis; piezogenic papules, which are small, painful, reversible herniations of underlying adipose tissue lobules through the fascia into the dermis, such as on the medial and lateral aspects of the feet upon standing (Fig. 8) [55]; elastosis perforans serpiginosa (Miescher elastoma, [56]; MIM 130100) (see EDS IV), not to be confused with mycosis; acrocyanosis and chilblains; and a conspicuous lack of striae gravidarum, which are focal tears in the dermis perpendicular to the direction of stress without disruption of the overlying epidermis.

Figure 8. Classical type of EDS (EDS II). Piezogenic papules in a 20-year-old woman, M.M. (21 May 1973). These are small herniations of adipose tissue lobules through the fascia on the medial or lateral aspect of the foot upon standing, which may be painful and require support or special shoes.

Orthopedic Aspects

Significant orthopedic abnormalities are, in decreasing order of frequency: pes planus, joint dislocations, spinal deformity, joint effusions, thoracic cage deformity, osteoarthritis, talipes, and congenital hip dislocation [57].

Hyperextensibility or hyperlaxity of the joints. This is also frequently called "hypermobility" of the joints and is a result of laxity of the joint capsules, ligaments, tendons, and possibly muscular hypotonia. It may be a source of enjoyment to patients to show their double-jointedness, and in the past certain individuals amused people as contortionists in sideshows (for anecdotes, see [1,2]). On the other hand, it may cause the patient considerable discomfort in walking, writing, or performing other skilled functions. Questions such as "Are you double-jointed?" and "Can you do tricks with your fingers?" may elicit a remarkable display of maneuvers from a patient with EDS, such as finger contortions, placing the ankles behind the neck, or placing the head between the knees while bending backward. As a rule, joint laxity is generalized, affecting both large and small joints (with the exception of EDS IV), and is usually noted when the child starts to walk. It also depends on age, sex, and race, and on the dominant side of the body, especially with regard to the hands, and increases during pregnancy and decreases with the passage of time [58]. Several grading systems for the objective semiquantification of joint hypermobility using a simple score have been proposed [39,58–60], among which the "Beighton score" [58] has become the most widely accepted screen for detecting generalized hypermobility and correlates well with more quantitative, instrument-dependent methods (Fig. 9).

Ligamentous laxity may be observed by pulling on the distal phalanx of a finger, which results in a considerable lengthening of the finger ("telescoping"), with radiological widening of the joint spaces [61]. Dynamic swan neck deformity is occasionally observed.

Dislocations. Occasional or habitual dislocation of the shoulder, patella, digits and thumbs, hip, radii, and clavicles is common [62], and its frequency is proportional to the degree of joint laxity, although in some persons a surprising range of joint movement can occur without any problem. Dislocations are usually resolved spontaneously and are easily reduced by the patient. Dislocation of the shoulder may follow a simple everyday movement, such as putting on a coat or raising an arm during a school class. Dislocation of the interphalangeal joints of the thumb leads to difficulty in using a pinch grip (Fig. 20).

Joint effusions. These are common and may be persistent or recurrent. They are associated with activity, affect mainly joints of weight-bearing parts (in decreasing order: knees,

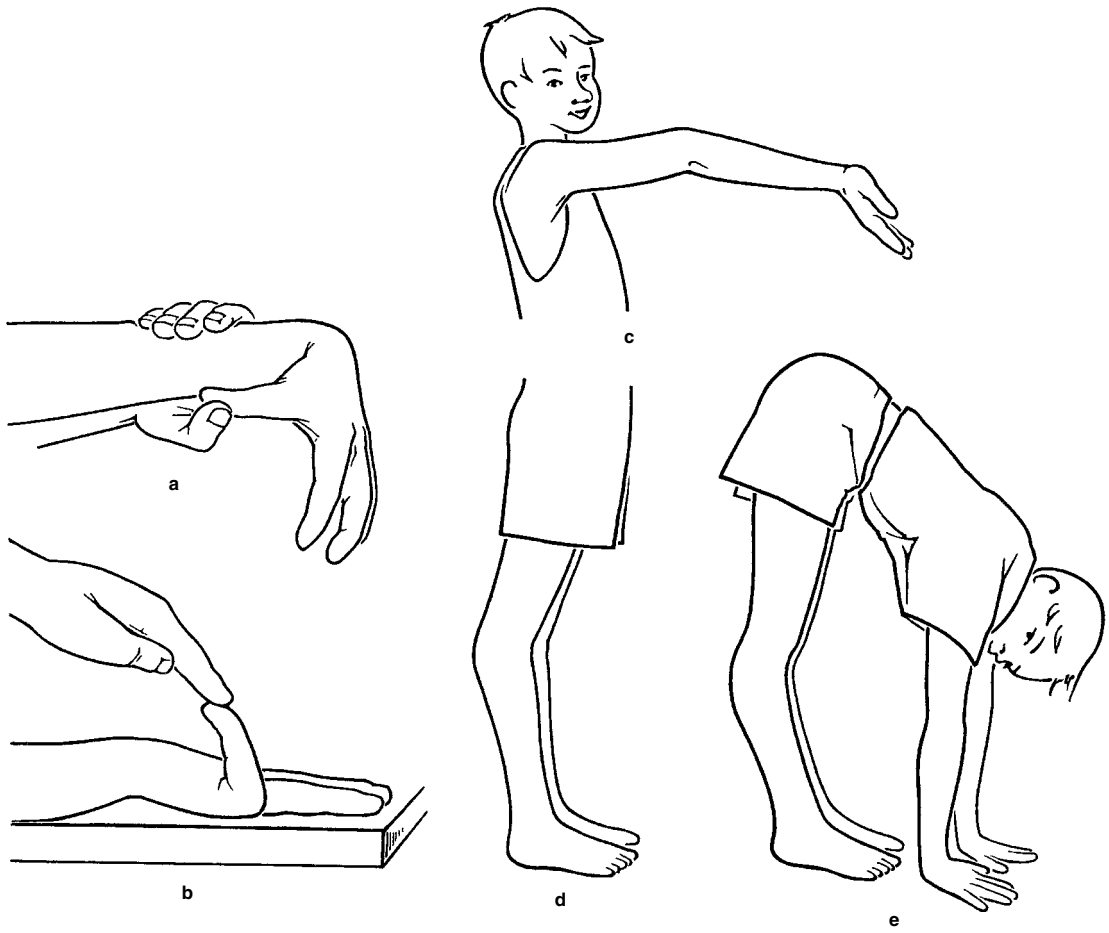

Figure 9. The "Beighton-score" to assess joint hypermobility. (**a**) Passive apposition of the thumb to the flexor aspect of the forearm; one point for each hand. (**b**) Passive dorsiflexion of the little finger beyond 90°; one point for each hand. (**c**) Hyperextension of the elbow beyond 10°; one point for each elbow. (**d**) Hyperextension of the knees beyond 10°; one point for each knee. (**e**) Forward flexion of the trunk with the knees fully extended so that the palms of the hand rest flat on the floor; one point.

A score of 5/9 or greater defines joint hypermobility [58]. (Figure drawn by Susanne Staubli, University Children's Hospital, Zürich.)

ankles, elbows, and also digits), and commonly appear at the end of the day. The tendency for joint effusions to develop is again proportional to the degree of joint laxity. Hemarthrosis may occur, mainly in EDS IV.

Joint instability. Joint instability results from lax ligaments and poor muscle tone. Children tend to walk late and fall easily because of the difficulty in controlling their unstable limbs. Unstable ankles and knees frequently need supportive bandages. The gait is typical: the feet are placed firmly and flatly on the ground, and the hips are hyperextended during weight-bearing to counteract the genu recurvatum. Running or wearing high heels may be impossible. The handshake may be characteristic and sometimes allows a diagnosis at the first encounter; the musculoskeletal structure of the hands seems to collapse on pressure, and the hand feels "like a bag of little bones." Trapeziometacarpal abnormalities lead to instability of thumbs and fingers and hence difficulty in picking up large or heavy objects with one hand or unscrewing bottle tops [63]. One of our patients never wanted to wash dishes for friends because she often crashed the plates — a not unprecedented excuse also for normal individuals — and, like this, other aspects of clumsiness in EDS may be explained, at least in part, by disturbed proprioception. Spinal deformity is usually due to strains and confined to thoracolumbar kyphoscoliosis, which progresses with age (Fig. 29e). Chest deformity such as pectus excavatum or carinatum does occur (Fig. 5a). Spondylolisthesis is not uncommon (see legend to Fig. 11). Foot deformities are the most prevalent signs: congenital clubfoot due to intrauterine malposition, progressive static and dynamic pes planus, talipes equinovarus, and hallux valgus (Figs. 5e, 23d, 25 g, 29c, 30d).

Osteoarthritis. Osteoarthritis as a consequence of joint instability is a major problem. In one study, 20 out of 100 patients were affected, or as many as 16 out of 22 patients over 40 years of age [57], the main complaints being the knees, hands, ankles, general joints, and shoulder. Here we might cite Beighton's patient, who said "When I was a baby they called me a floppy infant, and now the doctors tell me that I am a loose woman" [62], and might add that she may soon be a stiff elderly lady due to osteoarthritis.

Bursae. Over the olecranon and prepatellar region, enlarged bursae are often encountered, and these have to be distinguished from hematoma or molluscoid pseudotumors, which occur at the same sites. The excision of these bursae usually yields reasonably satisfactory results [1].

Bones. Bone involvement was not considered a feature of EDS until it was recognized that osteopenia is a constant feature of EDS VI, VIIA, VIIB, and VIIC, and a propensity to fractures has been reported in the latter group (see in EDS VII). In a case-control design study of 23 EDS individuals (10 with classical EDS and 13 with EDS III), Dolan et al. [64] showed that EDS subjects have a previously unrecognized tendency to fracture characterized by a low bone mass and abnormal bone structure, and concluded that this finding is likely to be multifactorial, with an inherited structural element accentuated by reduced mobility and exercise, and the possibility of a proprioceptive defect of the hypermobile joints. Carbone et al. [65] come to the conclusion that their 23 cases with EDS III had a significantly decreased bone mineral density at the femoral neck compared with controls but that this difference disappeared after adjustment for body height, weight, and physical activity levels.

Chronic joint and limb pain. This is a common complaint, but skeletal radiographs are normal. Frequently, it is difficult to establish the precise anatomical localization of the pain [39]. Osteoarthritis is more pronounced and pain is worse in the nondominant hand. Pain is worse during pregnancy because there is normally an increase in joint mobility in this state. Pain, swelling, dislocation of joints, a history of surgery of the joints, and impaired ambulation seem to be more frequent and more pronounced in patients with EDS III than in those with EDS I, II, or IV (see below, the hypermobile type of EDS [66]).

Dural ectasia. Enlargement of the spinal canal, with or without clinical complaints such as weakness in the lower extremities and abnormal gait, has occasionally been reported [67,68]. Dural ectasia and spinal canal widening seem to be more prevalent and pronounced in Marfan syndrome than in EDS, and their extents were found in two small series of ill-defined patients to be independent of age, sex, or symptoms, such as low back pain or sciatica [69]. Dural ectasia seems to be a major diagnostic criterion in Marfan syndrome [70].

Pregnancy, Obstetric, and Gynecological Features

The pregnancy of a woman with EDS bears risks for the newborn as well as the woman. During pregnancy, joint laxity may increase, but women enjoy the absence of striae gravidarum. Varicose veins in the legs and varicosity of the vulva may become prominent. Cervical insufficiency may lead to miscarriage or premature birth. Gross abdominal hernia and spinal deformity with backache may develop.

Fetal complications include prenatal rupture of the membranes (if the fetus is affected) and prematurity. Out of 18 children with nonspecified EDS, 14 were premature, and 13 of these had premature rupture of the membranes; in contrast, normal siblings were never premature, demonstrating that the fetal membranes are affected to the same extent as the fetus [71]. Breech presentation is more frequent if the baby is affected, and therefore hypotonic, and may lead to dislocation of the hips or to arms with injury of the plexus brachialis (Erb palsy).

Delivery may be unusually smooth or even precipitous (see legend to Fig. 4); however, severe pre- or post-partum hemorrhage may occur through perineal tears, the extension of episiotomic incisions, tearing by forceps, or prolapse of the uterus and bladder, all of which occur mainly in EDS I and IV. Rupture of the uterus and large arteries is a typical complication of EDS IV. The pubic symphysis may distract and cause pain for several months. Dehiscence of sutured incisions of skin, mucosa, or the uterine wall is frequent in EDS.

Dyspareunia and sexual dysfunction are occasional complaints in the classical and other types of EDS [72,73] and result from tissue fragility leading to small tears and recurrent infection in the vaginal mucosa and the skin of the external genitalia. Coital vulval laceration has been described occasionally, is possibly underreported for various reasons, and may be erroneously considered to be due to rape [74].

Gastrointestinal Complications

Gastrointestinal manifestations in the EDS can be subdivided into those that are a consequence of tissue extensibility and those that result from tissue fragility (see EDS IV). They include gastric, duodenal, and colonic diverticula, visceroptosis, gastric atony, megaesophagus, and megacolon. Constipation is a common complaint and probably results from flaccidity of the large bowel. Gastroesophageal reflux and irritable bowel syndrome are common complications of classical and hypermobile

EDS [75]. Inguinal and umbilical herniae are frequent and may recur after surgical correction. Femoral, incisional, hiatal, and diaphragmatic herniae, relaxation of the diaphragm (Fig. 6b), and even its eventration have been reported. Gastric, duodenal, jejunal, and colonic diverticula may lead to bleeding or perforation [76–78]. Recurrent rectal prolapse usually resolves before the age of 4–5 years ([79]; own observations).

Neuromuscular and Psychological Features

Primary muscular hypotonia in the newborn, and especially the premature, is frequent and may be so severe, especially in EDS VI, that affected infants cannot be breast-fed and need teats with especially large holes. Neuromuscular disease is often suspected, especially when clubfoot or hip dislocation coexist. A complete neuromuscular workup is usually performed in such "floppy infants," with unrevealing results. Hypotonia is also considered responsible for the increased frequency of breech presentation, which, together with the laxity of ligaments and joints, favors Erb palsy and congenital hip dislocation. In children, joint hypermobility and hypotonia may cause delayed motor development, problems with ambulation (delayed walking, frequent stumbling), and mild motor disturbance ("clumsiness"). Consequently, hypotonia may be maintained through the poor development of muscles resulting from an avoidance of exercise and activity because of the laxity and instability of the joints.

Fatigue is a frequent complaint. Muscle cramp in the calves, especially at night, is common in children but gradually disappears. Histology reveals that the connective tissue in the muscles is very sparse, so that the muscle bundles are hardly held together [1]; it may be speculated that the muscle fibers might lose their parallel orientation when they contract, thus decreasing mechanical efficiency. That dysfunction of the Golgi corpuscles embedded in the loose tendons may play a role in determining hypotonia is another possibility. Impaired proprioception has been documented in the hypermobility syndrome (MIM 147900), but its underlying mechanism remains open [80].

Genuine intelligence is normal; however, prematurity predisposes to birth trauma and complications, such as intracranial hemorrhage, respiratory distress syndrome, or sepsis, which may lead to epilepsy, as observed also in the patient described by Tschernogubow in 1891 [13]; epilepsy, however, has occasionally been reported in EDS [81]. The social consequences of disfiguring scarring, particularly of the face, and musculo-skeletal deformity may lead to personality problems and psychosocial distress, which is also common in chronic illnesses in general [73]. As a rule, there are many more affected women than men in EDS support groups (as is the case for other support groups as well). This may reflect a difference between the sexes in coping with the handicap rather than any true difference in clinical severity; however, this fact is important for the critical evaluation of studies based on circular letters, which may be skewed by selection bias [66,82]. Living with fear, living with pain, feeling stigmatized, and experiences of nonaffirmation in health care are identified as conditions leading to limited self-actualization in all areas of daily life [83].

Nerve compression and traction of the brachial and lumbar plexuses through hematoma and luxations at birth or later have occasionally been reported ([1,84–87]; H.A. with EDS VI, case 19 in legend to Figs. 22 and 23c). Occasionally, patients complain of cutaneous hyperesthesia/hyperalgesia when friction is applied to the skin, such as while drying with a towel or during the measurement of blood pressure [88]. Some patients report insufficient analgesia during minor surgery (e.g., dental and oral surgery) and may be characterized as hysterics [89,90]; it has been shown that the lack of effectiveness of local anaesthetic solutions is not due to their rapid dispersal through the loose connective tissues and therefore is unlikely to be compensated for by simply increasing the amount used [91]. An ill-defined polyneuropathy in two siblings of consanguineous parents together with typical signs of EDS VI has been described [92].

By far the most severe neurological complications are those due to intracerebral hemorrhages, such as transient aphasia or amaurosis, and hemiplegia or fatal stroke-like events caused by multiple arterial aneurysms or arteriovenous fistulae [93,94], which are typical findings of EDS IV.

Cardiovascular Features

Structural cardiac malformations are rare and are probably rather chance associations (for a review, see [95]). Mitral valve prolapse and, less frequently, tricuspid valve prolapse are due to redundant chordae tendineae and valve cusps [96]. However, stringent criteria should be used for the diagnosis of mitral valve prolapse [97]. Mitral valve prolapse and proximal aortic dilatation should be diagnosed by echocardiography, computed tomography, or magnetic resonance imaging. Mitral valve prolapse is a common manifestation, and aortic root dilatation may not be as uncommon as previously thought [98], although Dolan et al. [99] reported that none of their 12 patients with EDS I and II or 18 patients with EDS III had mean aortic diameters outside the normal range. In a small proportion of patients with EDS, aortic dilatation may be progressive [96]. Dilatation of the aortic root should be diagnosed when the maximum diameter at the sinus of Valsalva exceeds the upper normal limits for age and body size [100,101]; in such a case, annuloaortic ectasia needs to be considered in the differential diagnosis. Tortuosity of the aorta and its major thoracic divisions, including the coronary arteries, and peripheral pulmonary stenoses [102], aneurysm of the sinus Valsalvae [103,104], aortic root dilatation, and dissection of the aorta, sometimes familial, have been observed ([2c,105,106], own observation). Spontaneous rupture of large arteries [31,107,108] and intracranial aneurysms and arteriovenous fistulae [93,94] are all typical of EDS IV, and to a lesser degree of EDS VI, but may also occur in EDS I, sometimes even in persons with minimal external findings [109].

Acrocyanosis is a common complaint. The association of EDS II and III with orthostatic intolerance and chronic fatigue syndrome has been reported and tentatively explained by the connective tissue abnormality leading to excessive venous pooling and an exaggerated hemodynamic response [110].

Ophthalmological Aspects

It is not surprising that such a complex and delicate organ as the eye should be affected in many different ways, as tabulated by Pemberton et al. [111]. Extraocular signs are not uncommon. In a series of 100 affected patients, 27 had epicanthic folds (which lessen or disappear with age, or change to telecanthus, giving the impression of widely spaced eyes), seven had blueness of the sclerae, seven had strabismus (probably due to laxity of the tendons of the extrinsic muscles of the eyes), and eight had myopia, while redundant skin on the upper eyelids (blepharodermatochalasis, not to be confused with acquired or inherited blepharochalasis, in

which the whole eyelid is lax [112]; MIM 109900, MIM 110000), which makes putting on mascara difficult, and ease of eversion of the upper lid (Méténier's sign) were frequently encountered; none of the patients in this series, however, had any serious ophthalmological lesion [113]. Ocular signs are not frequent and include keratoconus (forward bulging and thinning of the central part of the cornea, which is a rare finding [114]; however, see also [115]); megalocornea; microcornea, which occurs mainly in EDS VI but occasionally also in EDS I (see [116]); myopia, due to distortion of the eye-globe or, very rarely, to subluxation of the lens; brittleness of the sclera and cornea; angioid streaks; retinal detachment; and retinitis proliferans due to hemorrhage. Eye fatigue may be a result of inappropriate eye movements because of increased concentration, tension, general fatigue, immobilization, or pain, such as a stiff neck. It is of interest that in the majority of individuals with sight-threatening lesions, autosomal recessive inheritance is likely (see EDS VI). Pulsating exophthalmos in EDS IV is due to retrobulbar arteriovenous fistula. It is of note that vision is not impaired by any corneal deficiency in patients with the classical type of EDS resulting from mutations in the collagen V genes. Since abnormal cauliflower-like collagen fibrils are observed in dermis from these patients (see classical type of EDS below) and in dermis and cornea of pN-knockout mice (see "Animal Models and Lathyrism" below), it is remarkable that the cornea, an organ rich in collagen V, seems to be normally translucent in these patients (see also Chapter 1, Part V, this volume).

Additional Features

Hemoptysis, hematothorax, and spontaneous and recurrent (hemato-)pneumothoraces, with or without mediastinal and subcutaneous emphysema, are typical of EDS IV [117]. Tracheobronchiomegaly (MIM 275300) has been reported [118,119].

Anatomical abnormalities of the urinary tract, such as urinary bladder diverticula, are common and usually asymptomatic. Cuckow et al. [120] reviewed 24 cases of bladder diverticula, all observed in males aged between $1\frac{1}{2}$ and 49 years, with 80% presenting before 16 years (for a further review, see [121]). Vesico-ureteral reflux may lead to recurrent urinary tract infection and renal insufficiency [116]. Multiple and large bladder diverticula are especially typical of the cutis laxa syndromes and the Menkes/occipital horn syndrome (EDS IX) (Chapters 10 and 14, respectively, this volume).

Oral aspects of the EDS have been described by Barabas and Barabas [122] (see also "Recent Developments"). The oral mucosa is fragile, easily bruisable, and often presents hemorrhagic blisters; bleeding from the gums is a common complaint. The gingival tissues are more liable to injury, leading to periodontal disease with early loss of teeth. The teeth are often crowded but are otherwise normal [1]; hypoplastic areas of enamel, the formation of pathologic dentin, and teeth with high cusps and deep occlusal fissures, stunted and deformed roots, and large pulp stones have been reported [8,123]. These manifestations, however, are not clearly associated with a particular type of EDS. Histological abnormalities include changes in the amelo-dentinal and cemento-dentinal junctional areas, irregular and ill-formed secondary dentinal tubules, vascular dentinal inclusions, and fibrinoid gingival deposits. Chronic habitual luxation and arthrosis of the temporo-mandibular joint may occur but rarely needs condylectomy [124]. The Gorlin sign (i.e., the ability of the patient to extend the tongue to the tip of the nose; Fig. 7a) is rather more astonishing or amusing than specific, 50% of EDS patients having this ability compared with 10% of controls [8]. A high prevalence of speech and swallowing difficulties has been reported [125]. In some individuals, inappropriate use of the voice, such as by shouting, may cause recurrent aphonia for which systematic voice training may be needed.

Radiological aspects of EDS have been reviewed (see above and [51,61,126,127]) and include telescoping fingers, calcified spheroids, and spondylolisthesis. Osteoporosis is a prominent feature of EDS VI and to a lesser degree also of EDS VII; exostoses may be observed in occipital horn syndrome (EDS IX) and EDS VII, acroosteolysis in EDS IV, and Wormian bones in EDS VII (see "EDS VII").

The fragility of the skin and most organs (except the skeletal system) may come as a bad surprise for the unaware surgeon at operation and may be remarked upon by the pathologist during subsequent autopsy. The friability of organs has frequently been described as being like "wet blotting paper" and making surgical incisions as "like cutting with a knife through butter" or through "cold porridge."

Diagnostic Approach to the Patient

As with most other genetic disorders, the first step in making the diagnosis of EDS is clinical awareness. The possibility of EDS will be brought to mind by complaints and physical findings such as hyperextensible joints, hyperelastic skin, and abnormal wound healing, or by personal history such as easy bruisability, habitual luxations, joint effusions, and recurrent herniae. The next step then consists of looking for elements that can reinforce the diagnostic suspicion, positive family history, and a more detailed personal history with regard to possible connective tissue disease such as prematurity, breech presentation, hypotonia, and delayed motor development. The importance of comprehensive anamnestic and clinical assessment of individuals cannot be overemphasized.

If the suspicion of a connective tissue disorder can be substantiated, an attempt should be made to understand whether it is a "genuine" connective tissue disorder such as the EDS or whether it is part of a "broader" genetic disorder or syndrome. Although exceptions exist, the presence of significant mental retardation and/or overt dysmorphic features argues against EDS. If clinical and anamnestic evidence points to an isolated connective tissue disorder such as EDS, consultation of textbooks, experts, and synoptic tables (see Table 1) may help in establishing which EDS type is more probable. This is crucial for further diagnostic investigations, such as skin ultrastructure and/or fibroblast culture and/or urinary cross-link products.

The clinical assessment of individuals with hyperextensible and thin skin and/or with lax joints needs some clinical experience, not so much in the case of patients with marked findings but rather in those with moderate findings; clinical experience is required especially in the latter group because the findings are graded according to age, anatomical location, sex, and race, as they are in normal individuals. Skin hyperelasticity [44,45] and thickness, and joint hyperextensibility [59,60,62], can be assessed semiquantitatively with scoring systems or with physical devices (see also Fig. 9). Unless diagnostic findings such as congenital bilateral hip dislocation and generalized joint laxity are present (EDS VII), the diagnosis of EDS is difficult in neonates and infants because the adipose tissue is normally abundant in healthy subjects and masks

hyperelasticity of the skin, because muscular hypotonia is frequent and unspecific, and because bruising and splitting of the skin do not occur until the child begins to walk and fall. In the adult individual, the diagnosis of EDS is usually made easily and can sometimes be made instantly — the characteristic handshake upon the first encounter in the office or at a cocktail party may be diagnostic; the velvety touch of the dorsal skin on a darkened dance floor may immediately enlighten the clinical geneticist.

Since all the signs are graded and age-, sex-, and race-related, semiquantitative assessments of the extensibility of the skin [44,45] and joints [59,60,62] must be compared by the same observer with the appropriate controls, and because these parameters also vary with anatomical location, identical sites should be chosen for better comparison, such as the skin over the fourth metacarpal, the thenar, the dorsum of the wrist, the neck, and so forth.

The diagnosis of EDS is difficult in newborns or infants because the laxity of the joints may be indistinguishable from that of infants with unrelated muscular hypotonia, hyperelasticity of the skin may be masked by the abundant subcutaneous tissue, and other skin changes are not easily assessed because the bruising and skin-splitting tendency do not usually become apparent until the child begins to walk and fall. In older persons, the skin is more redundant and somewhat lax, but atrophic, hemosiderotic scars easily distinguish the condition from cutis laxa.

Classification, Nomenclature, and Relative Frequency

The classification of EDS is first made on clinical grounds and substantiated by consideration of the most likely inheritance pattern and by biochemical and molecular analysis when possible. This is reflected in the historical development of EDS classification, which comprised three types in 1967 [31], five types in 1968 [32], and seven types in 1972 [2]. The formerly most generally used classification, which comprises ten or more types, is based on a combination of clinical, genetic, and biochemical criteria (Table 1) [37,38].

Over time, it became apparent that the diagnostic criteria established and published in 1988 [38] do not adequately discriminate between the different types of EDS or between EDS and other phenotypically related conditions. In addition, elucidation of the molecular basis of several types of EDS has added a new dimension to the characterization of this group of disorders. A revision of the classification of EDS, the "Villefranche Nosology, 1997," has thus been proposed, based primarily on the cause of each type [39][5]. Major and minor diagnostic criteria are defined for each type and complemented wherever possible with laboratory findings. This simplified classification will aid in accurate diagnosis of the types of EDS, thereby facilitating development and improvement in the following aspects: (1) diagnostic uniformity for clinical and research purposes, (2) natural history, (3) management, (4) genetic counseling, and (5) identification of potential areas of research [39].

In this revised Villefranche nosology [39], a simplified classification of EDS into six major types is proposed (Table 1). The guiding principle in formulating the classification was its usefulness to the "generalist." For each type, major and minor diagnostic criteria are defined. A major criterion has high diagnostic specificity because it is infrequent in other conditions and in the general population. The presence of one or more major criteria is either necessary for clinical diagnosis or highly indicative, warranting laboratory confirmation whenever possible. A minor criterion is a sign of lesser diagnostic specificity; the presence of one or more minor criteria contributes to the diagnosis of a specific type of EDS. However, in the absence of major criteria, minor criteria are not sufficient in themselves to establish the diagnosis. Their presence alone might be more suggestive of other EDS-like conditions, the nature of which will be elucidated when their molecular basis becomes known [39].

In this chapter, both nosologies are used interchangeably — the traditional one, using Roman numerals I to X, as well as the newly designated types — for reasons of convenience and completeness.

In many cases (20–40% as estimated by Hollister [128]), however, an unambiguous classification is not possible because there is a phenotypic continuum and, especially in children, the appearance of recognizable symptoms is age-dependent.

The relative frequencies of the different EDS types are not known precisely. In 1966, during a survey in southern England, Beighton examined a unique series of 100 patients with EDS. Seventy-one of them were members of 50 separate families, while 29 (17 males and 12 females) were sporadic cases [1]. A follow-up of eight of the 17 sporadic males revealed that three had produced children with EDS I, two had normal offspring, and three had no children [129]. Among the 50 families, EDS I had occurred in 22, EDS II in 17, EDS III in six, EDS IV in three, and EDS V in two. Although these figures are quite realistic in genetic terms, they are prone to inherent ascertainment bias, the more severely affected patients being most likely to have been diagnosed and hence reported in the literature, whereas patients with milder symptoms (EDS II) are more likely to have been able to escape medical attention and malpractice; on the other hand, severe cases leading to early death (EDS IV) are frequently missed, especially when sporadic. Individuals at both ends of the spectrum of severity may therefore be underrepresented.

Differences between individuals with the same type of EDS may reflect inter- or intra-familial variability or genetic heterogeneity (see EDS I, II, IV, VI, VII, IX). The definition of a genotype may then help to describe better the phenotypic spectrum. The Villefranche nosology will doubtless have to be revised and extended in the future as distinct, specific clinical signs and molecular defects are recognized and as genotype-phenotype correlations become clearer.

Prevalence and Epidemiology

There are no well-founded figures for the prevalence of EDS. While Beighton [1] gives a figure of 1:156,000 for southern England, McKusick states that EDS is one of the more frequent heritable disorders of connective tissue [2]. It seems likely that only a fraction of patients are ever diagnosed, owing to the lack of symptoms alarming to both patient and doctor and to the fact that single symptoms, such as habitual luxation of the patella, easy bruisability, or recurrent inguinal hernia, may not be considered as part of one generalized disorder. With increased medical awareness, however, the presumed rarity seems likely to disappear. At the other end of the spectrum, Holzberg et al. [45] claim a frequency of 9% in a predominantly black population. The aggregate frequency of EDS may be about 1:5,000 births,

[5]In this chapter, we designate the different types of EDS with adjectives throughout rather than a mixture of nouns and adjectives as given in [39].

with no racial or ethnic predisposition. The syndrome has been observed all over the world [1,2].

THE CLASSICAL TYPE OF EDS — EDS TYPE I (MIM 130000) AND EDS TYPE II (MIM 130010)

Diagnostic Criteria

These two types of EDS are described together because they differ only in their degree of involvement and occasionally are allelic. They comprise about 90% of all cases of EDS and correspond to the first historical descriptions, hence the term "classical." Locus heterogeneity has been demonstrated. The classical type of EDS is inherited as an autosomal dominant trait and characterized as follows [39]:

- Major diagnostic criteria
  - Skin hyperextensibility
  - Widened atrophic scarring (manifestation of tissue fragility)
  - Joint hypermobility
- Minor diagnostic criteria
  - Smooth, velvety skin
  - Molluscoid pseudotumors
  - Subcutaneous spheroids
  - Complications of joint hypermobility (e.g., sprains, dislocations, subluxations, pes planus)
  - Muscular hypotonia, delayed gross motor development
  - Easy bruisability
  - Manifestations of tissue extensibility and fragility (e.g., hiatal hernia, anal prolapse in childhood, cervical insufficiency)
  - Surgical complications (postoperative herniae)
  - Positive family history

Severity, Special Signs, Features, and Complications

EDS I (MIM 130000). In EDS I, skin involvement is marked and joint laxity is generalized and gross, with musculoskeletal deformity and diverse orthopedic complications. This form is also called the "*gravis type*" (severe type) according to an earlier nomenclature. Its frequency has been estimated to be 1:20,000 [5]. Prematurity occurs in ~50% of cases. It is in this severe (gravis) group, in addition to EDS IV, that internal complications such as aortic and bowel rupture may occasionally occur.

EDS II (MIM 130010). EDS II is probably the most prevalent type of EDS. It has all the stigmata of EDS I to a minor degree, and some patients may easily remain undiagnosed. This form is also called the "*mitis type*" (mild type) according to an earlier nomenclature. Joint laxity is limited and may be confined to the hands and feet. Skin involvement is less evident. Prematurity does not occur more frequently than normal. Mitral valve prolapse is rare.

The "late onset of EDS" [130,131] may represent mild conditions that become manifest only in adulthood; other cases may be acquired, especially when the symptoms appear late in life and are restricted to skin in a particular area [132].

Genetics

The first pedigrees compatible with autosomal dominant inheritance were published as early as 1888 [25–28,133]. In 1949, Johnson and Falls [29] demonstrated autosomal dominant inheritance on the basis of an extensive kindred containing 32 affected persons (21 males and 11 females) over five generations. Among them, a consanguineous couple of affected cousins had eight children, three of whom were unaffected, three of whom had the same stigmata as their parents, and two of whom had the condition to a very severe degree. The authors concluded that the latter two may have been homozygous in which case all of their children should have been affected; unfortunately, no follow-up is available. The heterozygous mother also had four miscarriages, which, according to the authors, might also have represented homozygous, severely affected fetuses or might have been due to cervical insufficiency, which, as we now know, is quite typical of EDS. A severe, presumably homozygous form of EDS has also been observed in a highly inbred kindred with EDS type I [134]. Jansen [135] reviewed the literature and came to the same conclusion of autosomal dominant inheritance. Parental gonadal mosaicism may explain why neither parent of the two affected sisters, cases 6 and 7 in [40], has the syndrome.

In Beighton's series of 100 patients with EDS, 63 were from 20 families and inherited the condition as an autosomal dominant trait [1,136]. The 29 sporadic cases were clinically indistinguishable from the familial cases, and no parental age effect was evident, paternal age being 30.7 versus 29.3 years and maternal age 29.3 versus 28.4 years; birth rank did not deviate from normal.

Segmental cases, confined to one or more body segments, were already described by van Meek'ren [9] (Fig. 1) and Du Bois [137] and have subsequently been reported by Beighton [1] and Cullen [132]. These may represent somatic mutations similar to the reported case of asymmetric Marfan syndrome [138]. However, no mention is made of articular involvement in these cases.

Interfamilial variability may be due to genetic or locus heterogeneity, and intrafamilial variability may be due to differences in genetic background (i.e., differences in the composition of other connective tissue components inherited in a multifactorial way), age dependence, and, apparently, differences in the assessment of clinical severity. Allelism in EDS I and II has been demonstrated [139,140].

Basic Defect(s) in EDS I/II

In EDS types I and II, the basic defects were unknown until recently and are heterogeneous. In 1955, Jansen [30] described a loose, disorderly arrangement of apparently normal collagen fibers and postulated that the collagen fibrils might be abnormally cross-linked in such a way that the interlacing network of connective tissue was deficient. This theory would account for the changes in the physical properties of the skin in the classical form of EDS and for the lack of specific histological abnormalities. In the past, urinary excretion of hydroxyproline, uronic acid, mucopolysaccharides (glycosaminoglycans), and amino acids, serum levels of elastase inhibitor, and amino acid profiles of skin and elastin in skin were measured (for references, see Beighton [1]), but no consistent abnormality has been described. An abnormal cross-link profile was observed in the dermis of one patient, but no clinical data were given [141].

Occasionally, chromosomal anomalies have been found in EDS, most of which have been considered insignificant [142,143]. Scarbrough et al. [144] speculated that genes located in the area of breakpoint 6q27 or 13q11 may be responsible for EDS II. Linkage analysis has excluded changes in the genes for collagens I, II, and III as being responsible for the classical type of EDS [145–147].

Mutations in the Collagen V Genes

Evidence for *COL5A1* on chromosome 9q34 and *COL5A2* on chromosome 2q24.3-q31 as candidate genes for EDS I and II came from the following studies, which indicated the role of collagen V in regulating the formation of heterotypic fibrils in the extracellular matrix. First, the high concentration of collagen V in the chick corneal stroma is one important factor responsible for the small, uniform collagen fibrillar diameter observed in this tissue in contrast to other collagen I-containing tissues with larger diameter fibrils, as shown by *in vitro* collagen fibrillogenesis [148]. $[\alpha1(V)]_2\alpha2(V)$ heterotrimers are localized within the mature heterotypic fibrils, with their N-telopeptides exposed at the fibril surface, and modulate fibril diameter by a steric or electrostatic mechanism [149]. Second, genetically altered homozygous mice lacking the exon 6-encoded N-terminal telopeptide of the α2(V) chain demonstrated collagen fibrils displaying abnormal diameter, contour, and packing in skin and, especially, cornea, and presented with EDS-like features (see "Animal Models and Lathyrism" below; [150]).

Linkage studies in man strengthened this concept [139,140,151], which has now been proven by the direct demonstration of structural mutations in *COL5A1* [116,152–155] and *COL5A2* [156,157], which exert a dominant negative effect. In one patient, however, EDS I was found due to haploinsufficiency of collagen V caused by a translocation that disrupted one *COL5A1* allele [158]. It must be stressed, however, that mutations in *COL5A1* and *COL5A2* account for only a minor fraction of EDS-causing mutations because evidence for a collagen V defect was found in only six patients in a series of 35 patients/families [159].

Protein chemical demonstration of abnormal α1(V) or α2(V) chains produced in fibroblast cultures is, unfortunately, rather ineffective. For documented mutations in *COL5A1* and *COL5A2*, gel electrophoretic changes have been reported only rarely [116,152,154,157,159a]; these include faint doublets, reduced mobility of the chains, or decreased amounts of collagen V. This last is not unexpected, in any case, given the low amount of collagen V deposited in the cell layer and the variability in the relative amounts of collagens I, III, and V deposited from experiment to experiment. In the previously mentioned series of 35 patients/families, only two showed abnormal collagen V profiles, fewer than the six detected as having *COL5A1* and *COL5A2* mutations by molecular means [159]. Despite linkage, cDNA abnormalities of *COL5A2* and *COL5A1* were found in only four and eight, respectively, among 28 families, and the different authors concluded that the classical type of EDS is mainly due to haploinsufficiency caused by nonsense mutations [41,157,159a,160] in one-third of the cases of *COL5A1* [41,160].

Intrafamilial clinical variability in a three-generation family with the classical type of EDS has been explained by the finding that the more severely affected propositus was a compound heterozygote carrying the disease-causing mutation Gly1489Glu and an additional, putative disease-modifying substitution Gly530Ser in *COL5A1* (Fig. 10; [116]). The hypothesis that the heterozygous Gly530Ser substitution is indeed disease-modifying seems to be strengthened by the observation that the same substitution in the homozygous state appears to be disease-causing. Giunta et al. found that a Turkish boy with classical EDS born to consanguineous parents was homozygous for the Gly530Ser substitution and had no further mutations in the *COL5A1* and *COL5A2* genes, and linkage to the genes coding for

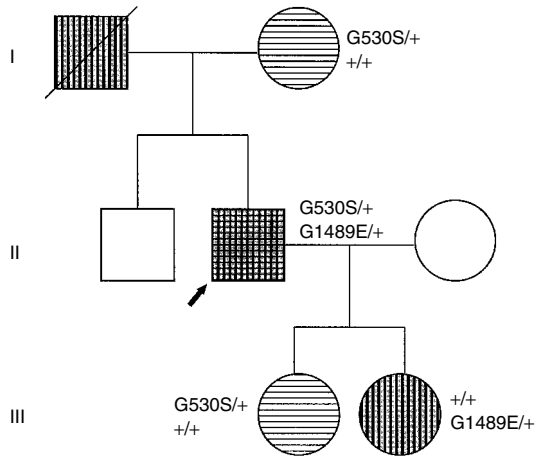

Figure 10. Intrafamilial variability in the classical type of EDS (EDS I) due to compound heterozygosity for the *COL5A1* genes. In each affected individual in family K, the genotype for the disease-causing mutation in exon 58 of *COL5A1* (Gly1489Glu) is represented by bold vertical lines and the disease-modifying substitution in exon 13 (Gly530Ser) by horizontal lines. The compound heterozygous propositus G.K., indicated by the arrow, is the most severely affected individual among the three with classical EDS. (Taken and corrected from Giunta and Steinmann [116] with permission.)

the α3(V) chain, decorin, thrombospondin 2, and tenascin-X was excluded by homozygosity mapping [161].

Because the α3(V) chain is primarily expressed in the epimysial sheaths of developing muscles, in nascent ligaments to forming bones, and in joints [162], *COL5A3* is a candidate locus for at least some cases of classical EDS in which *COL5A1* and *COL5A2* have been excluded and for at least some cases of the hypermobile type of EDS (see below).

Tenascin-X Deficiency

The tenascins (see Chapter 5, this volume) constitute a family of large extracellular matrix proteins. Although they have been implicated in several cellular processes, such as cell adhesion to collagen, no function has been clearly established for any of them. Tenascin-X (TN-X; MIM 600261) is a collagen fibril-associated protein that is highly expressed in dermis, tendon, and ligaments and in the connective tissue of striated muscle. The human *TNXA* gene is on chromosome 6p21.3 at the MHC class III locus, and its 3′ end overlaps the steroid 21-hydroxylase gene on the opposite strand of DNA. In 1997, Burch et al. [163] described a new contiguous gene syndrome, involving the *CYP21B* and *TNXA* genes, that resulted in 21-hydroxylase deficiency combined with a connective tissue disorder resembling EDS II, which is inherited in a presumed recessive fashion.

The proband was a 26-year-old man in whom a diagnosis of severe salt-wasting congenital adrenal hypoplasia due to 21-hydroxylase deficiency had been made at $1\frac{1}{2}$ weeks of age. He complained of a 2–3 year history of worsening joint pain and easy bruisability of many years duration. His history was significant for the release of a trigger finger at age 10, the repair of testicular torsion at age 15, and bronchiectasis confirmed radiographically at age 23. He had always had slow healing of wounds. Physical findings included micrognathia; a high, narrow palate; patellar chondromalacia; talipes planus; hypermobile joints of the fingers, wrists, and knees; a soft, doughy, hyperextensible

skin; and vascular fragility as evidenced by multiple small bruises and ecchymoses. The only family history of connective tissue disease was in his father, who also had hyperextensible finger joints but was otherwise normal [163].

Unusual for EDS II were the ultrastructural findings in his skin [163] but not in skin of further TN-X-deficient patients (see below). The collagen fibrils were not irregular in contour, had a diameter somewhat smaller than normal, and were reduced in number in the reticular dermis, where tenascin-X is mainly expressed. Also, there were abnormal elastin bodies beneath the dermo-epidermal junction. Capillaries in the papillary dermis were prominent and demonstrated increased perivascular matrix, and cutaneous nerves showed abnormal packing of the lamellae of myelin sheaths.

Biochemical and molecular studies of the patient [163] showed that he had a *TNXA*-null phenotype: no mRNA for tenascin-X was detectable, and tenascin-X was absent from skin and fibroblasts. He, as well as his father and one of his two sisters, carried a novel 30 kb deletion arising from the recombination of *TNXA* and its partial duplicate gene, *XA*, precluding TN-X transcription. The nature of his second maternal *TNXA*-null allele remains unresolved.

The patient's distinct histopathologic status suggests a novel mechanism of disease. Hence, TN-X may regulate the macromolecular organization and distribution of matrix elements such as fibronectin, collagen, and elastin; it could interact with cell receptors, modulating the cellular deposition of matrix; it may cross-link matrix fibers or proteoglycans, thereby strengthening the matrix; or, alternatively, it may play a primary structural role in skin, joints, and vascular connective tissues [164]. Definition of the precise role of TN-X in the EDS phenotype will require the identification of other TN-X-deficient patients and *Tnx* knockout mice, as well as the further study of this complex protein.

A quite similar but unrelated patient has been identified [165], who, however, does not present the same morphological findings (L. Smith, personal communication, 1999). A further patient, heterozygous for the *CYP21/TNXA* deletion with an unidentified inactivating mutation on the second *TNXA* allele, and three patients with isolated such mutations have been reported [166], but it remains unclear whether EDS resulted from TN-X deficiency alone and what proportion of patients with EDS might be accounted for by *TNXA* mutations [167].

The same group identified a 140 kDa carboxyl-terminal fragment of TN-X in serum of normals by western blotting, which facilitated the large-scale screening of 151 patients with EDS (35 classical, 87 hypermobile, 1 vascular, and 28 unclassified types of EDS). Among these, TN-X was absent in five individuals with unclassified EDS in each of whom the mutation was identified [167,168]; examination of TN-X-deficient fibroblasts confirmed the failure of TN-X synthesis and showed abnormal deposition of collagen I into matrix *in vitro*. The phenotype of the five patients is characterized by joint laxity, hyperelasticity of the skin, easy bruising, and absence of atrophic scarring. Ultrastructural examinations of the dermis did not show the typical cauliflower collagen fibrils observed in dermis of individuals with EDS caused by mutations of the genes coding for collagen V, nor was the density of the collagen fibrils reduced as observed in the tenascin-X knockout mouse (see "Animal Models and Lathyrism" below). Obligate heterozygotes had approximately 50% of normal TN-X levels in serum and conditioned culture medium.

Mutations in Collagen I

α2(I)-deficient collagen I. Patients with a total α2(I) deficiency are extremely rare — only four have been described so far — and they show markedly different clinical phenotypes. Sasaki et al. [169] described a 30-year-old man, born to parents who were second cousins, with hypermobility of the joints and hyperextensibility of the skin, who was operated on because of severe aortic regurgitation. Hata et al. [170] reported a 35-year-old woman with EDS II (hypermobility of the joints, hyperextensibility of the skin, with easy bruising and a tendency toward scar formation) with slightly blue sclerae and mitral valve regurgitation. Her unrelated parents and her son are healthy. At age 42, she was operated on for mitral valve replacement; by electron microscopy, dermal collagen fibrils were more variable than normal in diameter and contour [171]. Nicholls et al. [172] described a 9-year-old girl with normal height, generalized joint laxity, pes planus, and valgus heels leading to a secondary shortening of the Achilles tendon. Her skin was normal, her sclerae were pale blue, and her teeth were without signs of dentinogenesis imperfecta. She was born prematurely. There was a history of recurrent patellar dislocations and fractures of the skull, clavicle, fingers, and a toe. Her parents were consanguineous. Skin fibroblasts from the three patients synthesized no proα2(I) chains, produced only half the normal amount of collagen, and degraded newly formed collagen intracellularly to a greater extent than normal. In the first and third cases, α1(I) chains were reported to be overmodified (i.e., to show excessive post-translational modification of lysyl and hydroxylysyl residues), apparently as a result of slowed helix formation of the α1(I) homotrimer [169]. In the first two cases, mRNA for the proα2(I) chain was present at less than 10% of the normal amount [170,173] and was interpreted as being unstable because the rate of transcription was normal [173]. Neither stimulation of transcription of the *COL1A2* gene nor increase in the level of mRNA was observed after activation by ascorbic acid 2-phosphate, in contrast to the situation with *COL1A1* in the patient and both genes in controls. From Southern blot analyses, it was further concluded that the patient was homozygous for a functionally defective *COL1A2* gene [174]. The third case had a homozygous substitution in IVS46+2T>C of *COL1A2*, which leads to the use of a cryptic donor splice site 17 bp upstream of the normal splice site; as a result of this, the last 17 bp of exon 46 are deleted and the resultant frame shift introduces a new termination codon just three codons further downstream.

The three patients have normal bones, in striking contrast to the patient with severe osteogenesis imperfecta type III in whom a homozygous 4 bp deletion in the C-propeptide of the proα2(I) chain prevents these chains from assembling and being incorporated into normal heterotrimers [175]. Although studies on collagen extracted from skin and bone have not been performed in either of the patients, the discrepancy may well be explained by tissue-specific differences in expression of the proα2(I) chain. (Similar tissue-specific differences in collagen gene expression have been documented in fibroblasts, odontoblasts, and osteoblasts derived from the Mov-13 mouse [176,177]). Given the relatively benign EDS phenotype without bone involvement on the one hand [169] and the severe OI phenotype on the other [175], we speculated that the EDS patient may have lacked a putative tissue-specific transcription factor in skin, ligaments, and aorta, transmitted as an autosomal

recessive trait, but that a different transcription factor was present in bone and thus allowed the production of normal heterotrimeric collagen I and the formation of normal bones. However, polyethyleneglycol-induced hybridization of the EDS and the OI fibroblasts failed to result in complementation of the α2(I)-deficient cell strains in heterokaryons (C. Giunta and B. Steinmann, unpublished experiments).

Mutations in the *COL1A1* and *COL1A2* genes. Different mutations in three unrelated families led to skipping of exon 9 in *COL1A2* (A. Nichols, personal communication, 1999), and in two sporadic cases substitution of the conserved arginine in exon 14 led to an Arg134Cys substitution in the α1(I) chain, which also resulted in the classical type of EDS [178].

Other Candidate Genes

Decorin and lumican, as well as thrombospondin-2, play an important role in collagen fibrillogenesis. Targeted disruption of the decorin gene led to viable homozygous mice whose skin was fragile, with a markedly reduced tensile strength. Ultrastructural analysis revealed abnormal collagen morphology in skin and tendon, with coarser and irregular fibril outlines [179]. Mice homozygous for null mutations in lumican [180] and thrombospondin-2 [181] displayed skin laxity and fragility similar to that in EDS (see "Animal Models and Lathyrism" below). Thus, decorin, lumican, and thrombospondin-2 are candidate genes for human EDS.

Physical and Morphologic Properties of Connective Tissue and Pathogenesis of the Disorder

Skin elasticity. In normal individuals, elasticity has been assessed using a "pinchmeter" by determining the ease with which a fold of skin from the dorsum of the wrist could be raised by a spring-loaded caliper, or by a suction cup with increasing negative pressure, and recording the resulting distortion [46]. Using the latter method, it was determined that the modulus of elasticity is significantly higher in female than in male control individuals [50] and that it rises progressively with age in both sexes [46]. Mechanical properties of skin have also been evaluated in 17 children aged 3–10 years with EDS I, II, or III and compared with normal values from 63 healthy age-matched children; prominent increases in skin extensibility and elasticity were the most distinctive and diagnostic features, being the greatest in EDS I and the least in EDS III [48].

Stress-strain analysis carried out on skin from EDS patients has shown that the initial lag phase is prolonged and followed by a phase in which the stress-strain relationship is linear and parallel to that of the control tissue [50,182]; that is, the fibrils must be cross-linked and virtually inextensible at this stage. The long lag phase is therefore not due to an absence of cross-links within the fibrils but to an abnormal packing of these fibrils into tight bundles. This interpretation is supported by observations made by scanning electron microscopy that the fiber bundles are less tightly packed than normal [183]. Under tension, considerable extension will be required before the majority of the bundles are aligned in the direction of the tension, at which point they will be tightly packed and resist further extension. If a defect in cross-linking had been present, such as that which occurs in lathyrism or in dermatosparaxis in cattle, continuous extension of the fiber would have occurred as the fibrils slipped past one another, up to the point of rupture. In such conditions, no restoring force would be present, and the effect would not be reversible, whereas in EDS subjects the skin returns to its normal position after hyperextension [183]. These studies have provided support for the previously unsubstantiated proposal by Jansen [30] that skin hyperextensibility in EDS is due to a defective "wickerwork" of apparently structurally normal collagen fiber bundles.

In vitro studies of skin have shown that its tensile strength depends on its water content, the texture of the dermis, and the strength of each single collagenous fiber, and that it increases with age. In a 35-year-old patient with EDS, the tensile strength of the skin was 0.34 kg/mm^2 versus 1.61 ± 0.08 in controls [184], whereas the difference in tensile strengths of the tendons was less marked, namely 4.3 kg/mm^2 versus 9.0 in controls [185].

Skin thickness. Skin thickness can be assessed *in vivo* by the Harpenden caliper [50,186–188], radiographically [189], or by ultrasound [188]; all three methods give quite similar results. There is a direct relationship between dermal thickness measured *in vivo* or histologically and the content of collagen; skin collagen in normal individuals decreases linearly with age by about 1% per year throughout adult life and is less in females at all ages [190]. The skin of 14 patients with EDS studied was thinner than that of controls (0.8 mm versus 1.15 mm), and there was a significant inverse relationship between thickness and the tendency toward skin-splitting as evidenced by the degree of scarring [50].

Morphology of skin. For a historical review of the morphology of the skin, molluscoid pseudotumors, spheroids, and tendons, and of the cardiovascular, gastrointestinal, and pulmonary systems in EDS, see references in Beighton [1] and Wechsler and Fisher [191].

Light and electron microscopic studies of skin from patients with inherited connective tissue disorders are excellently reviewed by Holbrook and Byers [192]. Their generalizations indicate that mutations rarely affect only a single aspect of macromolecular function and that, because of the interactions of matrix components in this complex organ, they often disturb the organization of the entire dermis. Because similar structural abnormalities may result from different molecular defects, most morphological findings are not specific and are often subtle due to a limited repertoire of the dermis for changes. Structural alterations of matrix components include collagen fibrils that are excessively large and irregular in cross-sectional appearance, which have been called composite fibrils or flower or cauliflower figures, and mixed populations of large- and small-diameter fibrils; these changes were first recognized in individuals with EDS I by Vogel et al. [40] (Fig. 5g). Although structural alterations in connective tissue fibers are rarely specific for a given disease, there are characteristic patterns of structural changes in the matrix that may be used to confirm a diagnosis. Hausser and Anton-Lamprecht [193] found a certain correlation between the ultrastructural changes and the severity of the phenotype. In EDS I, ultrastructurally abnormal fibrils were present immediately below the dermo-epidermal junction and, in contrast to EDS II and III, there were almost no normal fibrils. In EDS II, the upper dermis contained only a few abnormal fibrils, in contrast to the middle and deep dermis, which had many abnormal fibrils. In EDS III, on the other hand, isolated smaller collagen "flowers" were only present in the reticular dermis. Such a morphologic gradient, however, needs to be confirmed by genetic analysis.

What is intriguing to us is the fact that the morphology of the collagen fibrils is so patchy and heterogeneous. Why are the cauliflower fibrils sparse and scattered widely apart, and why are there normal-appearing fibrils at all instead of a homogeneous distribution of abnormality? Is haploinsufficiency for collagen V not operative in all sites due to local differences? In this context, it is of note that vision seems not to be impaired by any alteration in translucency of the cornea, an organ rich in collagen V, because abnormal cauliflower-like collagen fibrils are observed in dermis and cornea of pN-knockout mice (see "Animal Models and Lathyrism" below and Chapter 1, Part V, this volume); ultrastructural studies on the cornea of patients with the classical type of EDS have not been reported.

Elastic arteries. The mechanical properties of elastic arteries have been measured by noninvasive monitoring of the pulsatile changes in diameter of the distal abdominal aorta and the common carotid artery by the use of an electronic echo-tracking instrument; however, the diameter and stiffness in several EDS I and II patients were not different from those in the reference population, and the study was unable to demonstrate any alteration in wall mechanics as a sign of disturbed vessel wall integrity [194].

In conclusion, the whole spectrum of tactile, mechanical (log phase), histological and ultrastructural (cauliflower collagen fibrils), and biochemical changes (decreased collagen and increased elastin content) are not yet well-understood.

Diagnosis and Differential Diagnosis

For most practical purposes, diagnosis remains syndromic thus far (see Table I). For specific practical or research purposes, laboratory investigations include a skin biopsy for the following analyses: (1) Ultrastructure quite often may suggest disturbed collagen fibrillogenesis [40,192,193], as in most cases with mutations in the collagen V genes, or other causes such as decorin deficiency, which has not yet been observed in man (see "Animal Models and Lathyrism" below). (2) Analysis of collagens produced by cultured fibroblasts may indicate abnormal collagen V, although this is not a sensitive assay, or, exceptionally, may reveal α2(I)-deficient collagen. Frozen cells may be useful for later studies. (3) A piece of skin should be stored frozen for immediate or later studies. (4) In large pedigrees, linkage analyses should be done to include or exclude known genes responsible for EDS or to map candidate genes.

Joint laxity may be found in the Marfan syndrome (MIM 154700), the Marfanoid hypermobility syndrome (MIM 154750), the familial articular hypermobility syndrome(s) (MIM 147900; the distinction between this syndrome and EDS III may be artificial), the Larsen syndrome (MIM 150250, MIM 245600), certain forms of osteogenesis imperfecta, and muscular hypotonia of various causes. Contortionists may achieve extraordinary hypermobility of the large joints by training. Stickler's hereditary arthroophthalmopathy (MIM 108300), the osteoporosis-pseudoglioma syndrome (MIM 259770), pseudoachondroplasia (MIM 177150, MIM 264150), Morquio syndrome (MIM 253000, MIM 253010), spondyloepimetaphyseal dysplasia with joint laxity (MIM 271640), Desbuquois syndrome (MIM 221880), and hyperlysinuria (MIM 238700) share with EDS hyperextensibility of the joints but are readily differentiated by other distinct features. Ligamentous laxity is also a feature of many other genetic disorders, such as the fragile X-syndrome (MIM 309550), trisomy 8-mosaic syndrome, and multiple endocrine neoplasia type 2b (MIM 162300). Joint laxity and soft skin are frequent in the renal-coloboma syndrome (MIM 120330) and the Langer-Giedion syndrome (MIM 150230). Hyperelasticity of the skin and joint laxity together with mental retardation and cataracts have been described in siblings with an autosomal recessive disorder due to impaired proline synthesis (MIM 138250) [195,196]. Skin and joint laxity has been reported together with lengthening and tortuosity of systemic, pulmonary, and coronary vessels and an elongated facies [197]. In the fetal anticonvulsant syndrome, joint laxity is a frequent finding, involves all sizes of joints, and is part of a generalized connective tissue disorder [198].

Hyperelastic skin can be found in the Noonan syndrome (MIM 163950) and should be distinguished from that observed in cutis laxa syndromes (MIM 123700, MIM 219100, MIM 219150), the De Barsy syndrome (MIM 219200, MIM 304150), gerodermia osteodysplastica hereditaria (MIM 231070), and Menkes disease (MIM 309400), in all of which the lax redundant skin, which is not fragile, hangs in loose folds and, although it may be stretched, will return only very slowly to its former position. Such patients have a "bloodhound facies" and look considerably older than they are. In the autosomal recessively inherited wrinkly skin syndrome (MIM 278250), the skin is wrinkled over the dorsum of the hands and feet, and the palms and soles, and the abdomen [199] (see also Chapter 10, this volume).

Increased skin fragility is found in osteogenesis imperfecta and in senile people, and may be mimicked by self-affliction by retarded or hysterical persons (Münchhausen syndrome). Excessive bruising is found in thrombo- and coagulopathies (see EDS IV) and in nonaccidental injury ("battered child") (see legend to Fig. 7).

Cardiovascular anomalies similar to those in EDS I may be found in familial mitral valve prolapse (MIM 157700) and annuloaortic ectasia Erdheim (MIM 132900), and are frequently associated with adult polycystic kidney disease (MIM 173900) [200], sometimes together with a Marfanoid habitus [201]. Dilatation of the aorta is typical of the Marfan syndrome (MIM 154700), aortic arch arteritis Takayasu, and other forms of arteritis and aortic malformations. For multiple arterial aneurysms, see EDS IV.

Musculoskeletal deformities, especially in EDS VI (Figs. 24,25), may resemble those in the Marfan syndrome.

Keratoconus was found in 22 of 44 patients with hypermobility, mainly of the fingers and thumbs, but without hyperelasticity or fragility of the skin; this condition is compatible with autosomal dominant inheritance and, according to the author in question, with EDS II [115].

Management and Genetic Counseling of EDS I and II

Because causal therapies are not available, medical intervention is limited to symptomatic therapy, prophylactic measures, and counseling.

Medical Therapy

Ascorbic acid, a cofactor of prolyl and lysyl hydroxylases, has been given to some patients with EDS but in spite of anecdotal reports of a beneficial effect does not change the basic clinical picture. The same holds true for zinc therapy [202,203]. Mild antirheumatic drugs may be indicated in patients with articular pain. Patients with mitral valve regurgitation require antibiotic prophylaxis for bacterial endocarditis and should carry a medical identification card with the appropriate instructions. The bleeding tendency is thought to be caused primarily by tissue

and capillary fragility rather than an intrinsic platelet or plasma defect. DDAVP (vasopressin) has been successfully used to reduce blood loss in patients without connective tissue disorders undergoing heart surgery and may be useful in EDS patients with chronic bruising and epistaxis, or perioperatively (e.g., for tooth extraction), in whom bleeding time is normalized by DDAVP (P. Tuchschmid and B. Steinmann, unpublished, 1996; [204]).

Physical Therapy, Orthopedics, and Prevention

A physiotherapeutic program is important in children with hypotonia and delayed motor development. In milder cases, light, non-weight-bearing muscular exercise (e.g., swimming) is useful to correct hypotonia and promote development of the musculature and muscular coordination, thus stabilizing the loose joints; gymnastics and sports with heavy joint strain are to be discouraged. Sports instructors should be informed about those with EDS. High-impact activities and hyperextension of all joints are to be avoided. If there is significant joint laxity and hyperextension at the interphalangeal joints, the occupational therapist should evaluate patients for ring splints. Bracing of the lower limb is indicated when joint instability and hypotonia prevent walking and physiotherapy has not been effective; ultimately, surgery is indicated when other means have failed. Special shoes may be required by patients with flat feet, other foot deformities, or painful piezogenic papules. Osteopathy and relaxation for pain control and management may be helpful.

Surgery

Because of tissue fragility, any type of surgery may be more difficult in patients with EDS, and it is not unusual for the original problem (e.g., herniae) to recur after intervention. Surgery may be indicated for fixation of a particularly unstable or habitually luxated joint, for the correction of dislocated hips (see EDS VII), for the repair of herniae or diverticula, and for scoliosis or cardiovascular problems [205]. Wounds should be closed without tension, preferably in two layers. Deep stitches should be applied generously and cutaneous sutures left in place for twice as long as usual. Long-lasting cutaneous analgesia may be difficult to obtain [89]. Tooth extraction may be difficult because of dilated irregular and poorly formed terminal roots, and prolonged post-extraction hemorrhage should be anticipated because of the poor vascular retraction. From a retrospective study, based on the patients' reports of their own experiences after surgical procedures to the shoulder, the elbow, the knee, or the ankle for pain, instability, poor range of motion, or a combination thereof, Weinberg et al. [206] conclude that surgical complications are common in EDS.

Prophylaxis of Skin Changes

Young children with pronounced skin fragility should wear protection in the form of athletes' pads or bandages over the forehead, knees, and shins in order to avoid skin tears. Later, the child may learn to avoid violent sports. When skin tears do occur, irregularly frayed wound margins should be excised and precisely adapted to allow (rapid) healing without dystrophic scarring, which is especially important in the case of facial wounds. Numerous fine, atraumatic stitches should be used and left in place for twice as long as usual. Additional fixation of the adjacent skin with adhesive tape is very helpful in preventing stretching of the scar; however, removal of adhesive material has to be done carefully to avoid secondary dehiscence. Hyperpigmentation and premature aging of both the scars and normal skin are of concern to many patients.

Other

The majority of patients with EDS learn to cope with their disease and eventually adapt well to daily life. However, some patients are troubled by hypotonia and joint instability, and many by chronic joint pain. These handicaps should be recognized and discussed, and lifestyle and professional choices should be adapted accordingly; strenuous physical activity should be avoided. Behavioral and psychological therapy may be indicated. Patients may gain valuable up-to-date information, confidence, emotional support to accept and cope with their handicap, and much practical advice from meeting other patients who are members of self-help organizations (see "Patient Support Groups" below).

Genetic Counseling

EDS types I and II are inherited as autosomal dominant traits. Affected persons have a 50% risk of transmitting the disorder. Affected first-degree family members should be examined to obtain an estimate of intrafamilial variability and thus the phenotypic range to be expected should the child be affected. Prenatal diagnosis has not been attempted.

THE HYPERMOBILE TYPE OF EDS — EDS TYPE III (MIM 130020)

Diagnostic Criteria

The hypermobile type of EDS is inherited as an autosomal dominant trait and characterized as follows [39]:

- Major diagnostic criteria
  - Skin involvement (hyperextensibility and/or smooth, velvety skin, absence of tissue fragility)
  - Generalized joint hypermobility
- Minor diagnostic criteria
  - Recurring joint dislocations
  - Chronic joint/limb pain
  - Positive family history

EDS III (hypermobile type) (MIM 130020) is characterized by quite severe, generalized joint laxity (Fig. 11) and the sequelae thereof, such as dislocations, effusions, and precocious arthritis. Certain joints, such as the shoulder, patella, and temporo-mandibular joints, dislocate frequently. Pain, swelling, dislocation of joints, a history of surgery of the joints, and impaired ambulation were reported by questionnaire during a National Ehlers-Danlos Syndrome Foundation Conference to be more frequent and pronounced by patients with EDS III than by patients with EDS I, II, or IV; the authors came to the conclusion that EDS III is the most debilitating form with respect to musculoskeletal function, although the data reflected an inherent bias because the patients were voluntary attendees at the educational symposium [66]. Skin hyperextensibility is variable; because tissue fragility is absent, the presence of atrophic scars, spheroids, or molluscoid pseudotumors with joint hypermobility suggests diagnosis of the classical type. The frequency of prematurity is not increased. Mitral valve prolapse is more prevalent than normal.

Musculoskeletal pain in EDS III is early in onset, chronic, and sometimes debilitating [207]. Its anatomical distribution is wide, and tender points can sometimes be elicited (a tender point is defined as an area that, when palpated with the thumb or two or three fingers, will be painful at a pressure of 4 kg or less [208]). In rheumatology practice, large numbers of patients present with generalized joint hypermobility.

Figure 11. Hypermobile type of EDS (EDS III). General joint hypermobility in a 10-year-old boy (A.T., 18 Apr 1981) with hyperelastic, smooth, velvety skin, which is not fragile and has no abnormal scars, and hyperelastic, floppy ears.

He is a sporadic case and had several episodes of rectal prolapse starting at age 2.5 years, which was operated on; rectal prolapse has not recurred but it remains open if this is due to the operative fixation or simply represents the natural history. Because of chronic back pain, spondylolisthesis L5/S1 was operated on by dorsal spondylodesis, and an indwelling urinary catheter was inserted, which led to urethral strictures needing several bougienages. He suffered from several hemorrhages into the knee joints and complained of chronic fatigue.

For clinical research purposes, it is important to distinguish these individuals from those affected with the hypermobile type of EDS. There is considerable debate as to the causal interrelationship, if any, between the two phenotypes.

EDS III is similar to, although by no means as severe as, EDS VIIA and VIIB, but congenital hip dislocation does not usually occur. Furthermore, a separate autosomal dominant condition, familial articular hypermobility syndrome, the former EDS XI (MIM 147900; Table 1), which is characterized by severe joint laxity, occasional congenital hip dislocation, but no skin changes, has to be distinguished. Whether the familial articular hypermobility syndrome represents the upper end of the normal spectrum of variation of joint mobility or reflects a mild connective tissue disorder remains open, and in the absence of biochemical and genetic markers, the nosologic relationship between it and EDS III remains unclear.

Surprisingly, Narcisi et al. [209] described a family in which a point mutation in the *COL3A1* gene (Gly637Ser) was associated with a phenotype they described as EDS type III, a condition that is unlikely to be confused with EDS IV; it may well be that individuals of this family will have a later onset of significant symptoms of EDS IV because at description most were well below the age at which major complications would have been expected. Only the first affected individual was over 60 years of age, and mosaicism for the mutation was not excluded.

COL5A3 is a candidate gene for at least some cases of the hypermobile type of EDS (and some cases of classical EDS in which *COL5A1* and *COL5A2* have been excluded, see above) because the α3(V) chain is primarily expressed in the epimysial sheaths of developing muscles, in nascent ligaments to forming bones, and in joints [162].

To control the pain, which is sometimes considerable in this type of EDS, and the consequent impairment of well-being, behavioral, physical, medical, and psychological therapy may be indicated (see classical type of EDS above).

VASCULAR TYPE OF EDS — EDS TYPE IV (ARTERIAL-ECCHYMOTIC TYPE OF SACK-BARABAS) (MIM 130050)

Diagnostic Criteria

The vascular type of EDS is inherited as an autosomal dominant trait and is caused by structural defects in the proα1(III) chain of collagen III encoded by *COL3A1*. It has the worst prognosis and is characterized as follows [39]:

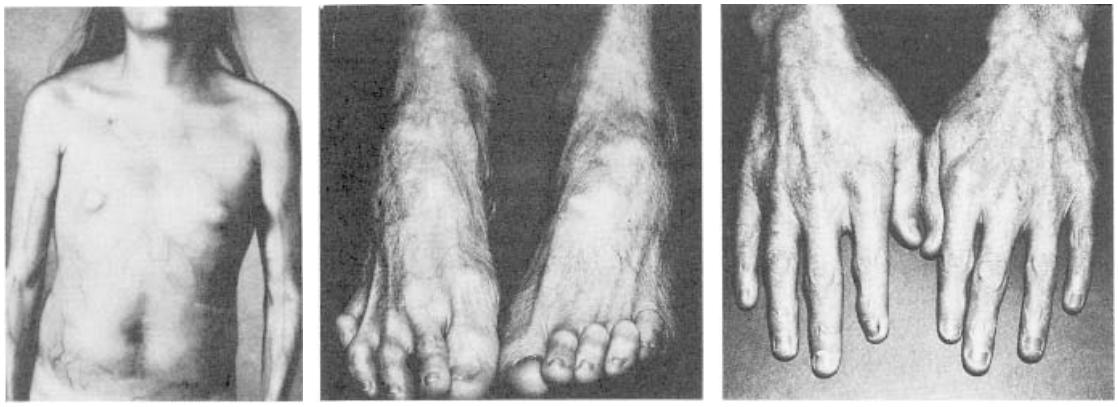
- Major diagnostic criteria
  - Thin, translucent skin
  - Arterial/intestinal/uterine fragility or rupture
  - Extensive bruising
  - Characteristic facial appearance (Fig. 13)
- Minor diagnostic criteria
  - Acrogeria
  - Hypermobility of small joints
  - Tendon and muscle rupture
  - Talipes equinovarus (clubfoot)
  - Early-onset varicose veins
  - Arteriovenous, carotid-cavernous sinus fistula
  - Pneumothorax/pneumohematothorax
  - Gingival recession
  - Positive family history, sudden death in (a) close relative(s)

Note: The presence of any two or more of the major criteria is highly indicative of the diagnosis, and laboratory testing is strongly recommended.

Historical Introduction

EDS IV is a life-threatening and disabling disease, "dramatic, deceptive and deadly" [210]. In 1967, Barabas [31] pointed out that the extensive tendency toward bruising and bleeding and the extreme arterial fragility distinguished this variant from other forms of EDS. Sack [24], and probably others, had described the same entity many years before. Affected individuals have only slight joint hypermobility, usually limited to the digits, and skin hyperextensibility is minimal or absent [142], hence the designation ecchymotic or arterial type (or Sack's type) [1,2,211], now the vascular type of EDS [39]. It is unfortunate that the complications typical of EDS IV are sometimes cited in texts as characteristic of other types of EDS, thus creating unnecessary anxieties.

EDS IV was the second of the disorders of collagen to gain a biochemical identity. It was recognized that "patients with Ehlers-Danlos syndrome type IV lack type III collagen" [34], a description still confusing to clinicians less familiar with the terminology. The possibility that the manifestations of EDS IV could be caused by an absence of collagen III was first raised by Pope et al. [34]. They found that in the aorta and skin of their patient P.P. (Figs. 12b and 13a; also Fig. 6–10 in [2]), the total amount of collagen was markedly decreased and neither collagen III nor its CNBr-derived peptides were detectable. Fibroblasts grown from this and four additional patients did not secrete medium proteins that eluted on DEAE-cellulose column chromatography in the region expected for procollagen III. Furthermore, cells in culture from two of the five patients failed to stain by immunofluorescence with antibodies specific for procollagen III [212]. These authors concluded, wrongly as it happens (see below), that the defect was absent synthesis of procollagen III rather than a post-translational abnormality of procollagen secretion. Because clonal cells from dermatosparactic animals produce both collagens I and III [231], and because normal fibroblasts react with antibodies to both procollagens I and III, it was considered unlikely that there was a deficiency of a specific cell type synthesizing procollagen III [212]. Studying another patient by more sensitive methods, Byers et al. [232] found that the amount of procollagen III in fibroblast culture medium was indeed reduced to 10–15% of that in controls but that it was retained within the cells both *in vitro* and *in vivo* [233]. The finding that the stored collagen III was of higher molecular weight than expected suggested to them that the procollagen might have extensive post-translational modifications, possibly secondary to some structural alteration of the proα1(III) chains. They further proposed that the relatively low amount (10%) of normal collagen III secreted would be approximately that predicted if only one allele at a single locus were normal: because procollagen is a homopolymer containing three identical chains, only one-eighth of the assembled molecules would be normal if the molecules were assembled randomly from a pool containing equal numbers of normal and mutant chains. The seven-eighths of abnormal collagen III molecules might then be retained and/or degraded intracellularly. Finally, it could be predicted that such an abnormality would be inherited as an autosomal dominant trait [232]. Their concept of heterozygous mutations leading to structural defects of collagen α-chains and instability and/or nonsecretion and degradation of the abnormal



a b

Figure 12. Vascular type of EDS (EDS IV). (**a**) Thin, translucent skin with an easily visible venous pattern in E.A., born 1949 (Johns Hopkins Hospital #1287186), at 12 years of age. She also had acrogeria and acrocyanosis with atrophy of the fingertips and toe tips.

She was the second child born to healthy parents at term; her four brothers were unaffected. Labor was induced because of ruptured membranes before the onset of uterine contractions. Birth weight was low (1.8 kg), in contrast to that of her brothers, which ranged from 3.2 to 3.6 kg. She had pyloric stenosis operated on at 7 weeks, easy bruisability and skin fragility from infancy, splenic rupture at age 12 years, intramural hematoma of the colon at 17 years, and bleeding into the peritoneal cavity at 19 years. At age 25 years, she had recurrence of colonic hematoma, which required surgical intervention. She had extensive postoperative bleeding into the rectus muscle sheet and the abdominal cavity, was reoperated on twice, and died in shock ([2], and follow-up by B. Steinmann, 1978). (**b**) Acrogeria in P.P. (born 11 Nov 1957, died 17 Nov 1973) at age 14 years; see also Fig. 13a. (For references, figures, and cell strains see [34,212–220]; Fig. 6-10 in [2]; CRL 1145, and CRL 1243).[6] ((**a**) is (Fig. 6-21 in McKusick [2], reprinted with permission.)

procollagens — a process that later became known by the somewhat misleading term "protein suicide" coined and propagated by Prockop [234] — proved not only to be correct but crucial also for the understanding of mutations of procollagens I, II, IV, V, VI, VII, IX, X, XI, XVII and XVIII, leading to osteogenesis imperfecta and various other connective tissue disorders described in this volume.

Clinical Findings, Natural History, and Prevalence

Unlike in other types of EDS, affected individuals have nonhyperelastic, thin, translucent skin, through which the venous pattern over the chest, abdomen, and extremities is readily visible (Fig. 12a). Bruising is marked and wound healing delayed. Joint hypermobility is minimal and limited to the small joints of the hands and feet, although shoulder dislocation may occur. The skin covering the hands and feet may be extremely thin, finely wrinkled, and look "older" (so-called acrogeria — see Fig. 12b; some individuals with acrogeria in the older literature [235–239] probably had EDS IV). In contrast, tightness of the skin over the face may result in a "younger" appearance, not unlike after a face-lifting procedure (Fig. 13). The nose is thin, delicate, and pinched, the lips are thin, the cheeks are hollow, and the eyes appear prominent and staring because of a paucity of adipose tissue; the pinnae of the ears are firm and tight and frequently without a free ear lobule (Fig. 13h); there is a tendency to alopecia. The facies is therefore often quite characteristic (Fig. 13a–g) [220–222].

Congenital club foot and inguinal hernia are common, as are keratoconus [240], periodontal disease, and venous varicosity and thrombophlebitis. Elastosis perforans serpiginosa ([241–243]; MIM 130100) is not uncommon in EDS IV and presents as a circular rash with raised rough edges and a clear center, sited over the neck and flexures. This is the result of fragmented elastic fibers that are extruded through the epidermis.

Keloid formation (Fig. 14a) [246], Raynaud phenomenon, acroosteolysis [222,247,248], and skull defects [249] have been reported. Adult patients have been subdivided into ecchymotic and acrogeric varieties [250]. This distinction is more confusing than helpful because all patients with EDS IV tend to have ecchymoses, whereas only a proportion will show the additional feature of overt acrogeric changes of hands and feet. In children, even if at risk, it is often difficult to make the diagnosis on clinical grounds alone unless bruising is severe or the venous pattern particularly noticeable [222]. Although mitral valve prolapse was observed in most affected individuals from a large pedigree with EDS IV [251], it does not appear to be a consistent finding.

The hallmarks of EDS IV are the severe, life-threatening internal complications, that usually occur after puberty and include spontaneous rupture of the arteries, the colon, and the gravid uterus, and (hemato-)pneumothorax [252]. There does not appear to be any familial predisposition for a certain type of complication because different catastrophic events can occur in different individuals within one large family (Fig. 18) or sequentially in one person [210,253].

Arterial complications have been collated in a large collective review of literature published over 20 years, from 1975 to 1995, in which only patients for whom biochemical confirmation was available are included; not considered were intracranial vascular complications [254]. The 45 vascular

[6]Cell strains detailing the cells studied in the original papers are given in the 1st edition of this volume; these cells, designated CRL, are commercially available from: American Type Culture Collection, 12301 Parklawn Drive, Rockville, MD 20852.

[7]The known tendency toward keloid formation in patients with EDS IV is somewhat at odds with the observation that keloid tissue in other subjects contains 32% collagen III relative to collagen I, as compared with 21% collagen III present in dermis of normal skin [245].

Figure 13. Facial appearance in the vascular type of EDS (EDS IV). The facies in EDS IV patients is often quite typical (**a**, **b**, **f**), with a thin, delicate, and pinched nose; thin lips; tight skin; hollow cheeks and prominent and staring eyes because of a paucity of adipose tissue; and tight, firm, lobeless ears. In some patients (**e**), however, the facial characteristics are less apparent. For further illustrations, see [220]. (**a**) P.P. at age 14 years (see also Fig. 12b). His molecular defect is a Gly1021Arg substitution in the α1(III) chain [220]. (**b**) and (**c**). The defects are a Gly1021Glu substitution and skipping of exon 43, respectively [120]. (**d**) M.D. (2 Jan 1933) at age 55 years. Her molecular defect is a Gly910Val substitution (for further references, see [223–225]). (**e**) D.S. (born 27 May 1964, died 27 Sep 1990) with a multiexon deletion [226,227] at age 22 years (for further references, see [213,219,228,229]). (**f**) Baby, childhood, and adult facies of a woman with EDS IV who died at age 33 years from a rupture of the splenic artery. The authors claim that ''the diagnosis is unmistakable in all three pictures''; although we do agree that the adult face is typical, the two younger facies would be quite inconspicuous to a pediatrician. This demonstrates that in children it is often difficult to suspect the diagnosis on clinical grounds unless bruising is severe and/or the venous pattern particularly noticeable, or unless there is a positive family history. Her molecular defect is a Gly1003Asp substitution [220]. (**g**) R.I. (11 Feb 1976) at age 18 years. He was born to healthy unrelated young parents after premature rupture of the membranes three weeks before term. At three months, bilateral inguinal herniae were operated on and his skin was noted to be unusually fragile with an easily visible venous pattern. Subcutaneous fat was sparse and, according to his mother, he never ''looked like a baby.'' At 5 months, hydrocephalus due to chronic subdural hematoma was diagnosed, and it was drained at 9 months. Easy bruising was a continuous complaint. At age 17 years, after an excess of alcohol, vomiting provoked pneumothorax with subcutaneous emphysema and rupture of the lower esophagus (Boerhaave syndrome) with consequent mediastinitis and chronic pericarditis responsible for heart failure. Dilatation of the esophageal stricture — before the diagnosis was appreciated — led to pneumomediastinum and massive symptomatic pneumoperitoneum that required needle aspiration. Over a year later, he had recurrent left inguinal hernia repaired, an operation that was complicated by severe intraoperative hemorrhage from extremely dilated, tortuous, and fragile veins at the level of an almost nonexistent fascia transversalis. He developed pterygium-like contractures of the knees, which made ambulation difficult. His molecular defect was a single nucleotide exchange (IVS42+5G>A), which led to an insertion of ten amino acids. At age 23 years, he died the victim of a tragic car accident [230]. (**h**) Ear of L.R. at age 62 years, which is poorly modeled, lobeless, and has a very tight feel. Her molecular defect is a G to A transition at nucleotide 730, which leads to a Gly43Asp substitution [230] (see also legend to Fig. 20). ((**a**) reprinted from Pope et al. [221] with permission; (**b**) and (**c**) reprinted from Pope et al. [222] with permission; (**d**) and (**e**) reprinted from Steinmann [42] with permission; (**f**) reprinted from Pope et al. [221] with permission.)

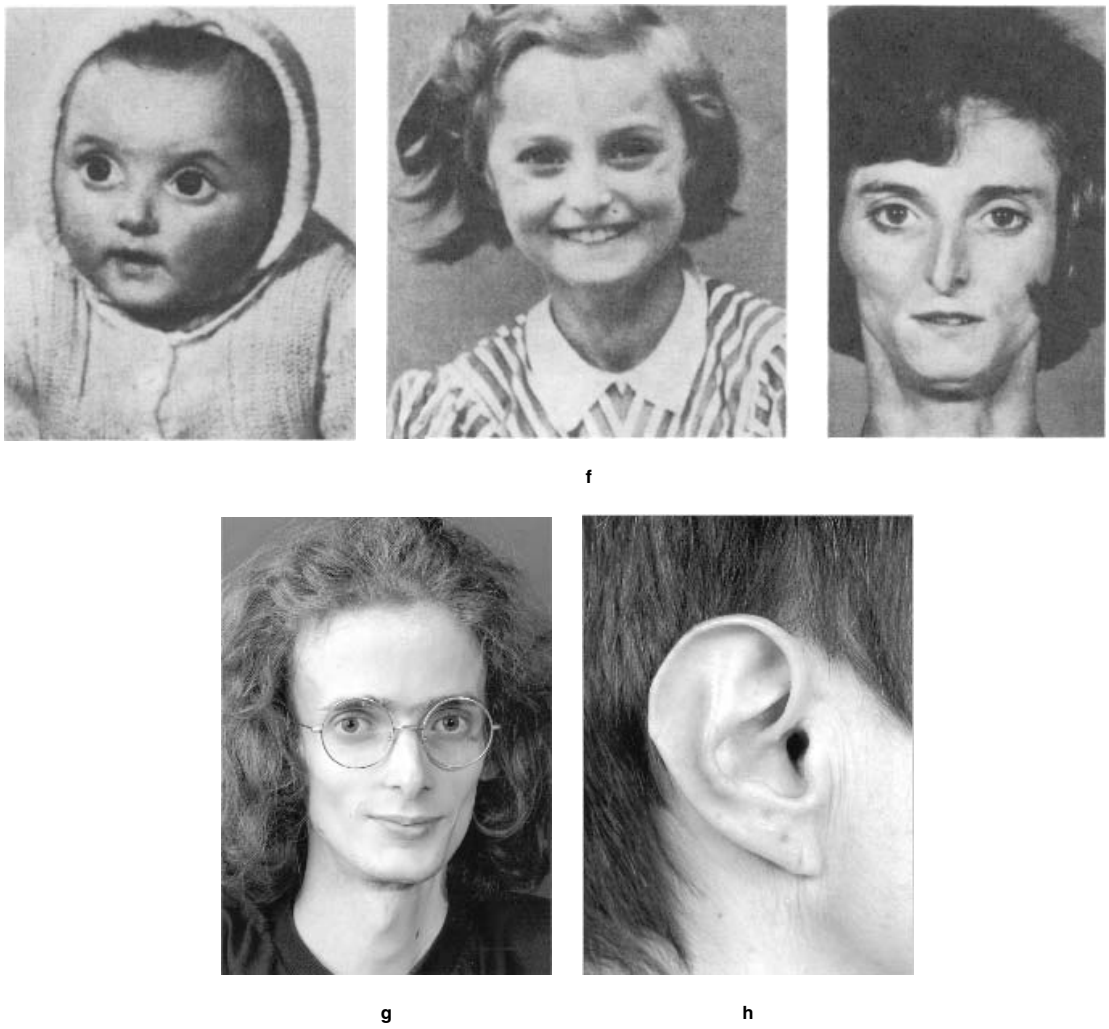


Figure 13. (*Continued*)

complications reported comprise 22 spontaneous hemorrhages, 17 aneurysms, five arterial dissections, and one arteriovenous fistula. The patients, 20 males and 20 females, had a mean age of 27.2 ± 10.9 years (range 11–63 years).

Bleeding seems to be more frequent in young males [255,256] and in patients during the postoperative period, and may occur at virtually every possible site and lead to symptoms such as sudden death, cerebral stroke, hemoptysis, hematemesis [244,253,257], renal colic and hematuria (see legend to Fig. 20) [219], acute abdomen, respiratory distress, retroperitoneal bleeding, and muscle swelling and shock. The most common locations of arterial bleeding are in the abdominal cavity and involve the small arteries rather than the aorta itself (Fig.15). In some individuals, there is evidence of aneurysmal dilatation and dissection or of arterio-venous fistulae, whereas in others, slit-like defects detectable at autopsy may occur in arteries that appear normal by angiography. In a review of the literature, Bergqvist found 112 cases in which vascular complications had been reported, and aortic dissection had occurred in 12 of these [261]. Acute myocardial infarction is a rare complication, reported in only eight cases, and is due to coronary dissection or rupture (see [262]).

Tortuosity of arteries has also been documented. Arterial rupture accounts for most deaths in EDS IV because it is frequent, the hemorrhage is rapid, and repair, even when timely, is difficult due to the marked friability of the tissues [255]. Carotid-cavernous sinus fistula formation and resultant exophthalmos has been described in several individuals [72,93,94,263–267]. Of 212 patients with carotid-cavernous fistulae treated by Halbach et al. [268], four had both EDS IV and spontaneous onset of their fistulae. Out of 202 individuals from 121 families with EDS IV proven by biochemical or molecular studies, 19 had cerebrovascular complications at a mean age of 28.3 years (range 17–48), of whom four died [269].

EDS IV has been proposed as a model of more common forms of aortic and intracranial aneurysms which often cluster in families, but, to date, most studies have excluded the *COL3A1* gene as the locus for such mutations in the absence of some findings of EDS IV [270–272]. However, there is evidence that a small number of cases of familial aortic aneurysm may be caused by collagen III deficiency [273–276] in the absence of significant skin changes. However, it must be noted that familial aortic dissection has been reported in EDS I as well [2]. The first

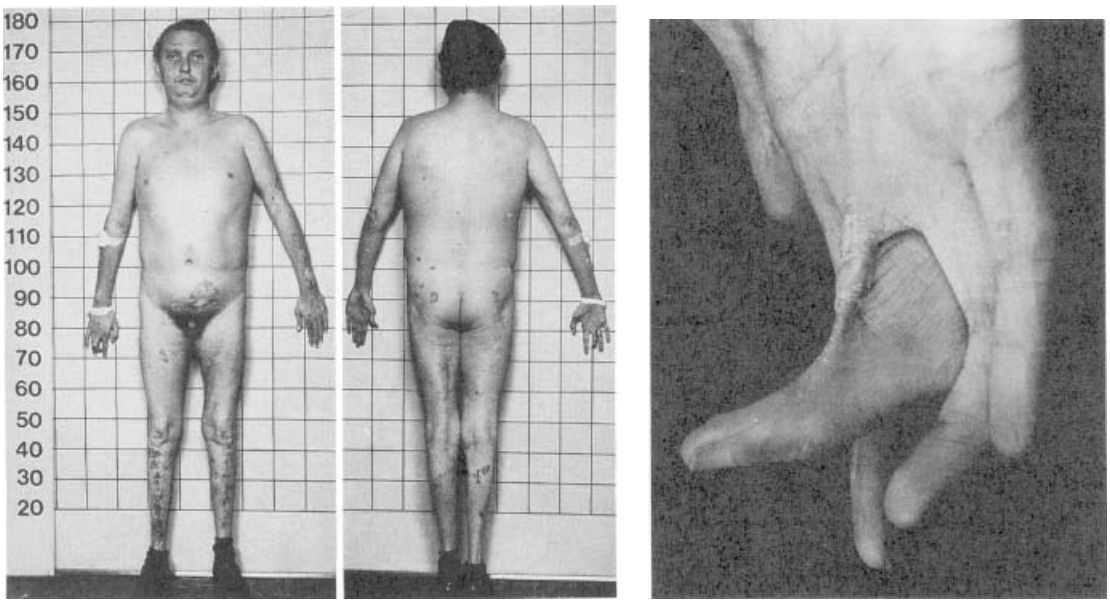

Figure 14. Vascular type of EDS (EDS IV). C.E. (3 Jul 1946, died ~35 years), at age 27 years showed atrophic scars on the shins, keloid formation[7] on the abdomen over the symphysis, numerous scars on the forehead and over the chin (**a**), and pterygium-like cutaneous flexion contractures of the thumb and the third finger of the right hand (**b**). For further references, see [34,212–214,216–219,244] and CRL 1299 and CRL 1409[6]. His molecular defect was a single nucleotide substitution (IVS25+5G>T) leading to skipping of exon 26 [227]. Sporadic case, bilateral clubfoot at birth; easy bruising since boyhood, several episodes of hemorrhage. (Reprinted from Steinmann [42] with permission.)

demonstration of microangiopathy in EDS IV is presented in Figure 16.

Rupture of the colon, usually in the sigmoid region, is the most common of the bowel problems and occurs at sites where the bowel surface appears normal. Constipation seems to play an important role in the pathogenesis of colonic perforation [279]. In a literature review spanning 20 years (see above), 41 colonic perforations among 44 gastrointestinal complications were cited: 33 of the sigmoid, four of the descending, two of the ascending, and one of the transverse colon, and one of the rectum. The mean age of patients with gastrointestinal complications was 31.5 ± 16.9 years (range 7–66 years), and the sample included 17 males and 13 females [254]. The small intestine rarely ruptures (for exceptions, see [279,280]), but intramural hemorrhage may lead to recurrent abdominal pain. Spontaneous esophageal rupture after vomiting — Boerhaave syndrome — has been observed only exceptionally [230,281,282].

Complications in late pregnancy, or during or after delivery, are not so rare and include vascular, intestinal, or uterine rupture (Fig. 17), vaginal lacerations, prolapse of uterus and bladder, and premature delivery because of cervical insufficiency or fragility of membranes [1,241,283–288]. In the largest survey of "classical" EDS IV individuals, pregnancy-related complications led to death in 9–15% of women who became pregnant [256].

Pulmonary complications may arise either from a primary defect in the lung parenchyma or from primary intrathoracic vascular rupture. Lung disease has been reviewed by Dowton et al. [289], who concluded that no death has been recorded as solely due to pulmonary manifestations of EDS IV.

Liver rupture is rare. A report describes the spontaneous rupture of a transplanted donor liver, which was most probably derived from an unrecognized individual with EDS IV [290]. After completing the caval and portal anastomoses, the liver was revascularized; within seconds, the donor liver developed multiple large subcapsular hematoma that spontaneously ruptured with extrusion of liver parenchyma. Despite efforts to obtain hemostasis, the liver continued to fragment, requiring hepatectomy (later retransplantation with another liver was successful). The donor was a 38-year-old woman with brain death secondary to subarachnoid hemorrhage. During collection of several internal organs, the right renal hilum was torn during removal of the kidney, and it was noticed that the heart valves were fragile and had to be discarded. Little was known about her personal and familial history except that her cousin had died from rupture of a visceral aneurysm. Attempts to culture fibroblasts failed, but electron micrographs showed that collagen fibrils from small hepatic arteries were smaller than normal in diameter and irregularly packed [290].

Descriptions of tissues as "fragile like wet blotting paper" are not uncommon in surgical and autopsy reports [2,291]. In the father of the propositus D.S. (Figs. 13e and 16), open chest cardiac massage resulted in avulsion of the heart from the superior vena cava and death [226]. For a similar case, see Krog et al. [292]. In two patients with shoulder dislocation, closed reduction and surgery resulted in the rupture of the brachial plexus (see also legend to Fig. 15) and rupture of both brachial plexus and brachial artery, respectively [85]. The degree of tissue friability differs among individuals and even in the same individual with aging [210]. An unusual combination of multiple aneurysms, a hepatic artery to portal vein fistula, and diverticula of the biliary passages, the sigmoid colon, and bladder has been reported in a patient possibly affected by EDS IV [293].

Natural history. In the largest survey [256] available of patients with "classical" EDS IV (comprising 220 index

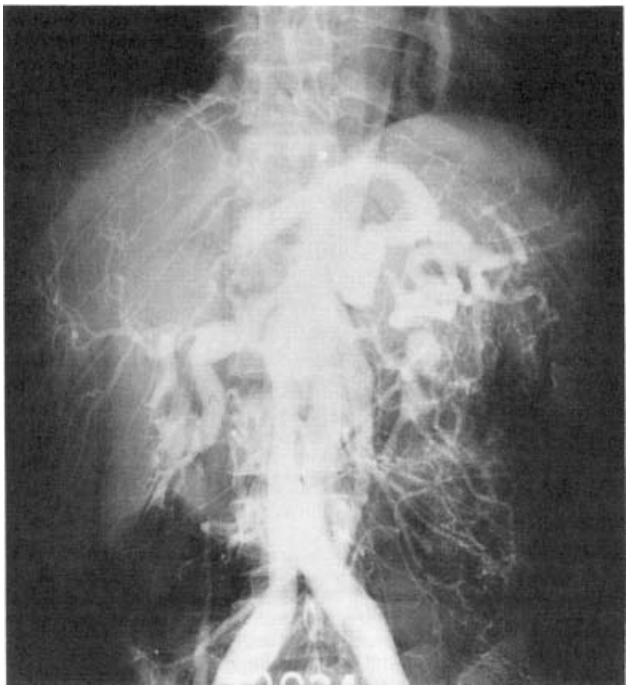

Figure 15. Diffuse dilatations of abdominal arteries and dissecting aortic aneurysms in vascular type of EDS (EDS IV). Y.P. (2 Dec 1941), mother of F.P. (see below), spent a normal childhood and adolescence and practiced many sports, including judo and horseback riding. Two deliveries at ages 24 and 29 years were uneventful. She always had skin of ''bad quality,'' a tendency to keloids and scar dehiscence; alopecia started at age 30 years. She had bilateral club feet, as has her daughter, needed early dental prostheses, and had hyperextensible elbow, knee, and foot joints (requiring arthrodesis), and recurrent luxations of both shoulders. Surgery on the left shoulder resulted in rupture of the brachial plexus at age 37 years.

At age $37\frac{1}{2}$ years, because of suspected inguinal adenopathy and deep venous thrombosis on the left side, she was given antibiotics, anticoagulants (Marcumar®), and anti-inflammatories (Tanderil®). Shortly thereafter, she was in deep shock, with bilateral hematothorax and bleeding in the abdominal cavity, the retroperitoneum, and the subpericardial and hepatic subcapsular spaces. After resuscitation, angiography was done (the diagnosis was still unknown at that time) disclosing diffuse dilatations of abdominal arteries and dissecting aortic aneurysms.

At age 42, she had a spontaneous rupture of the right posterior tibial artery, which was diagnosed by arteriography of the right femoral artery performed in a peripheral hospital. Because of the fragility of the artery, a repair with sutures was impossible and a simple ligation was performed; nevertheless, the leg remained viable [258]. She also had vertigo due to a vertebro-basilar syndrome; radiographically, both vertebral arteries were markedly calcified. Four years later, she suddenly experienced a heavy pain in the right groin and died in shock two hours later. Autopsy was not performed (own observation).

Her daughter, F.P. (21 Aug 1965), was shown to have a Gly595Cys substitution, which resulted in the formation of unusual trimers that contained, in addition to the normal disulfide bonds at the C-terminus, two proα1(III) chains which were disulfide bonded in the middle of the chains and, probably for ill-understood conformational reasons, migrated faster than the regular normal homotrimers [259]. By direct collagen analysis of chorionic villus biopsies, two prenatal diagnoses predicted normal fetuses, and she delivered vaginally and without further complications two babies who were confirmed to be normal [260].

Comments: (1) The first hemorrhagic event in Y.P. occurred shortly after beginning therapy with anticoagulants, nonsteroidal anti-inflammatory drugs, and penicillin. These drugs are likely to have promoted the hemorrhage and are contraindicated in EDS IV. (2) Although the second arteriography was uneventful, the lethal hemorrhagic event 4 years later could have been promoted by this intervention. (3) The general risk of arteriography was recognized in the university hospital but was not conveyed to the peripheral hospital; therefore, this type of information should be marked on a medical identification paper. (4) The risk of injuring the plexus brachialis while operating on the shoulder should also be noted.

patients with biochemically confirmed disease and 199 of their affected relatives), complications were rare in childhood; 25% of the index patients had a first complication by the age of 20 years, and more than 80% had had at least one complication by the age of 40 years. The calculated median survival was 48 years (range 6–73) and did not differ between men and women. The most frequent complications were, in decreasing order, arterial rupture (79%), organ rupture (uterus, heart, liver, spleen) (10%), and gastrointestinal rupture (8%). Bowel rupture was often amenable to surgical treatment and thus rarely fatal, while arterial or organ rupture was associated with higher mortality with or without surgical intervention. The different types of complications were not associated with specific mutations in *COL3A1* (Figs. 18 and 19).The relative frequencies of arterial and gastrointestinal complications were similar for the first and second complications; thus, the nature of the first complication does not predetermine the nature of the following complications. We have documented the condition in a woman, L.R., with a Gly43Asp substitution (Figs. 13 h and 20) [230], who reached the age of at least 62 years in spite of numerous complications, whereas another report describes sudden infant death [296]. Gilchrist et al. [297] described a large kindred with a low risk of pregnancy complications and

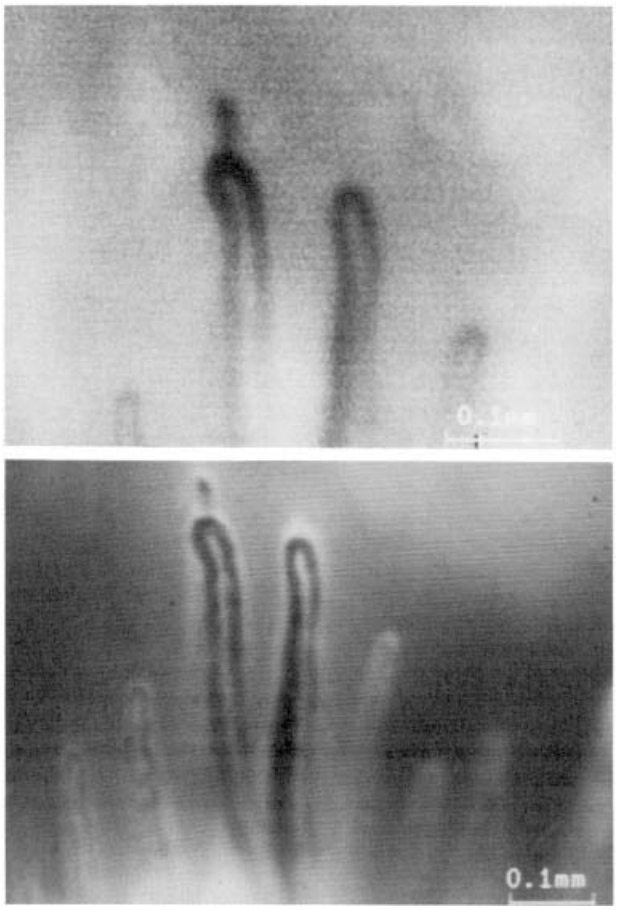

Figure 16. Microangiopathy in vascular type of EDS (EDS IV). In patient D.S. (see also Fig. 13e), intravital fluorescence microscopy of the nailfold was carried out with a fluorescence videomicroscopy system [277]. Before the application of dye, the morphology was examined under incident white light (**top**). Transcapillary diffusion was studied after i.v. bolus injection of sodium fluorescein (**bottom**), and the diameter of the capillaries of the arteriolar and venular limbs was measured after i.v. injection of indocyanin green (Cardiogreen®).

The microangiopathy consisted of multiple microaneurysms located at the apices of the capillary loops, which had a smaller neck and a larger head (indocyanin green); enlargement of the apical, arteriolar, and venular limbs of several loops; presence of microbleedings; and increased transcapillary diffusion of sodium fluorescein. Similar results were obtained in F.P. (legend to Fig. 15) [278].

The demonstration of microangiopathy in EDS IV indicates that the disease is not restricted to large vessels and thus points to a role of collagen III in the function of the capillary vessels.

unexpected longevity in some affected relatives; no deaths and few significant complications occurred among the eight affected women over a total of 30 full-term deliveries. For a family with a *COL3A1* mutation and apparent EDS III [209], see above.

The prevalence of EDS IV is not so low and is currently estimated to be 1:50,000. This estimate suggests that the frequency of mutations in the *COL3A1* gene is about the same as that of mutations in the collagen I genes that result in osteogenesis imperfecta, that the pleiotropic effects of the mutations obscure the diagnosis, and that, most unfortunately, knowledge about the disorder is still not widespread.

Defect and Pathogenesis

EDS IV is due to mutations in the *COL3A1* gene, located at 2q31-q32, which contains 51 exons distributed over 44 kb. The gene encodes a protein of 1,467 amino acids, of which 1,029 are located within the central triple-helical domain. The triple-helical domain is encoded by portions of 44 exons, of which 42 are cassettes that begin with a glycine codon and end with a Y-position codon, so that deletion of a single exon would result in an in-frame but shortened protein. The majority of published mutations in *COL3A1* result in substitutions of single glycine residues within the triple-helical domain, approximately one-third result in exon skipping, and a small number are larger genomic deletions [220,256,298] (for a list of over 200 mutations and numerous polymorphisms in *COL3A1*, see the Web site http://www.le.ac.uk/genetics/collagen/col3a1.html — see "Appendix", below).

Because procollagen III is a homotrimer, the synthesis of an equal number of normal and mutant α1(III) chains results in 7/8 of the collagen III molecules produced being abnormal and containing one, two, or three mutant chains. The abnormal collagen III leads to a quantitative deficiency of collagen III and sometimes, more deleteriously, to disturbed fibril formation by the remaining normal collagen III molecules. Therefore, tissues normally rich in collagen III, such as skin, blood vessels, and internal organs, are affected, in contrast to bone and cartilage, for example, which lack collagen III. In all cases studied at the molecular level, and in many less well-characterized patients, structural defects in collagen III lead to impaired secretion, intracellular storage and degradation, or lower stability of the secreted molecules, or both.

Different types of mutation most certainly have different consequences.

(**1**) In the case of glycine substitutions, triple-helix formation of molecules containing one, two, or three mutant α1(III) chains seems to be delayed for sterical reasons, as shown directly for abnormal collagen I in fibroblasts from patients with osteogenesis imperfecta [299] and suspected for collagen III in cells from EDS IV patients [300]. As a result, abnormal collagen III is overmodified and secreted only slowly or not at all and is degraded intracellularly to a significant extent [301,302].

(**2**) In the case of mutations leading to exon skipping, the abnormal molecules contain one, two, or three shortened chains, there is efficient secretion only of normal homotrimers and abnormal, shortened homotrimers, which are deposited efficiently into the extracellular matrix. Among individuals with exon skipping due to a single base substitution, Schwarze et al. [303] identified only two among 28 in whom the splice-acceptor site was affected, Pope et al. [220] two among five, and Giunta and Steinmann [230] one among four. The underrepresentation of splice-acceptor site mutations suggests to the current authors that the usual consequence of such mutations is the use of an alternative acceptor site that creates a null allele with a premature termination codon and thus leads to a 50% reduction in normal collagen III and a phenotype that may escape medical attention (see "Recent Developments").

(**3**) Splicing efficiency has been shown to be temperature-dependent in one patient, C.E., in whom a G to T transversion at position +5 of intron 25 resulted in skipping

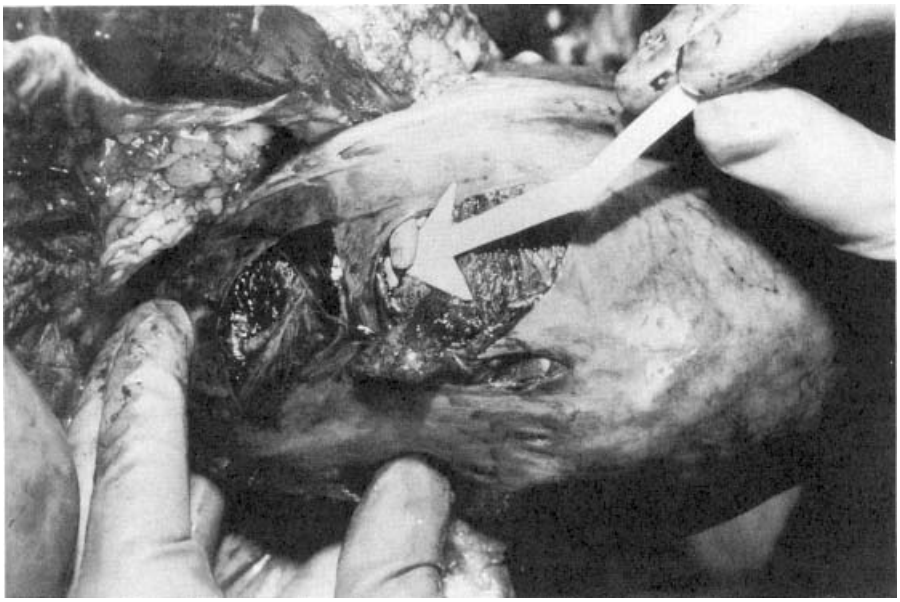

Figure 17. Rupture of the gravid uterus in vascular type of EDS (EDS IV). N.K., with a negative family history of EDS IV, had suffered spontaneous rupture of her sigmoid colon after an 8 week gestation at age 31 years; a therapeutic abortion was performed at the time of operation. Two years later, she was readmitted at 28 weeks gestation in premature labor and died shortly thereafter. At necropsy, the tissues were unusually easy to dissect. The thoracic aorta was torn transversally above and below a large dissection. The uterus had a complete, irregular 4 cm tear of the myometrium. The arrow points to fetal fingers stretching out of the torn uterus. It is of note that death may also occur several days or weeks postpartum [230]. (Reprinted from Rudd et al. [283] with permission.)

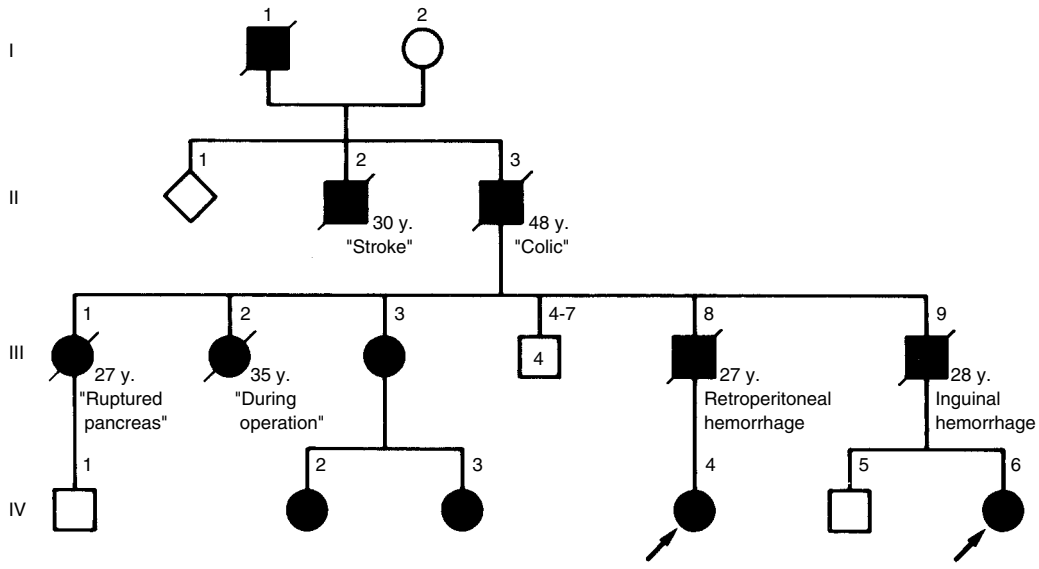

Figure 18. Pedigree of a family with vascular type of EDS (EDS IV). The index cases (**arrows**) came to medical attention in childhood because of easy bruising; the clinical diagnosis of EDS IV had earlier been made in subject III-9, who presented with recurrent bacterial meningitis due to bony defects in the skull [249]. The pedigree illustrates the manifold causes of death in EDS IV at various ages. It is also noteworthy that III-1 and III-3 brought pregnancies to term without major complications. The unaffected wife of individual II-3 could readily tell who among her nine offspring had the disease.

The molecular defect in this family consists of a Gly1003Asp substitution, which leads to a markedly reduced secretion of collagen III with intracellular retention and overmodification [259]; serum collagen III aminopropeptide is low in the two index patients [228]; for morphological studies, see [294,295].

This family originates from a small village in southern Italy where it was known as ''the family with the thin skin.'' The social implications of the disease are illustrated by this nickname and by the fact that the father of two young women tried (in vain) to dissuade them from marrying two brothers from the family (III-8 and III-9) because it was known that ''something was wrong'' with this family.

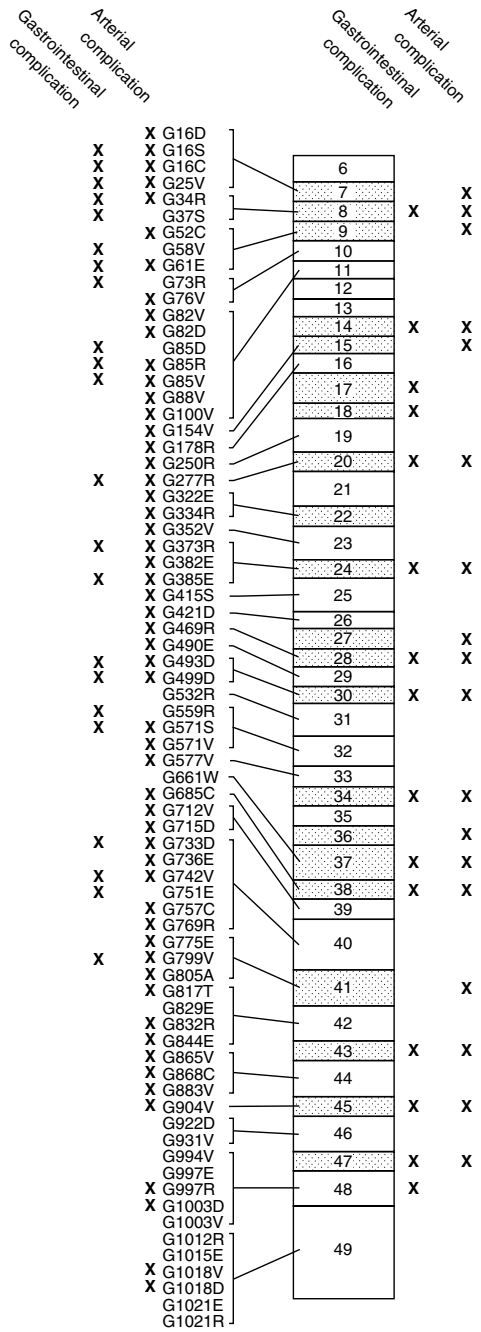

Figure 19. Lack of relationship between the nature and location of mutations in *COL3A1* and the types of complications in the vascular type of EDS (EDS IV). Causative mutations in the *COL3A1* gene were identified in 135 index patients, among whom there were 73 different mutations in 85 index patients that resulted in the substitution of some other amino acid for glycine (G) within the triple helix. Mutations in 41 patients led to skipping of a single exon (indicated by the stippling). The remaining mutations were more complex. The presence of an X at the site of a mutation indicates that one or more patients with that mutation had a complication of the indicated type. The amino acids are numbered from the first glycine of the major triple helix, which is residue 168 of the preproα1(III) chain. A denotes alanine; C, cysteine; D, aspartic acid; E, glutamic acid; R, arginine; S, serine; V, valine; W, tryptophan; and T, threonine. (Reprinted from [256] with permission.)

Figure 20. Vascular type of EDS (EDS IV). The x-ray of the left hand of L.R. (8 Jul 1928), at age 62 years, shows a chronically dislocated carpo-metacarpal joint of the thumb, marked arthritic degeneration of all joints, and a lack of adipose tissue.

Since the age of 50 years, recurrent luxations of the first metacarpal joint and arthritis of the trapezio-metacarpal joints had precluded a pinch grip, the picking up of large or heavy objects, and unscrewing bottle tops.

The patient was a sporadic case, born at term with a birth weight of 1.8 kg. Since early childhood she had suffered from easy bruisability, skin fragility, and mild joint laxity. She had had strabismus, hemopneumothorax, and hip dislocation after a car accident at age 29 years, the uneventful delivery of a healthy girl, an episode of ''nephrolithiasis'' due to a dissecting renal artery at age 45 years, several stroke-like episodes, and diverticulosis of the large intestine. Now she presented with a younger-looking face, often being asked if she had had a face-lift, with tight and lobeless ears (Fig. 13h); her skin was thin, and she had acrogeric hands and feet and suffered from the Raynaud phenomenon (for references and cell strains, see [213,214,217–219,228,230] and CRL 1384 and CRL 1397)[6]. Her condition was due to a Gly43Asp substitution [230].

of exon 25, which was almost corrected when his cells were incubated at a lower temperature [244]. The fact that his cells produced more collagen III at a temperature lower than 37°C is therefore due to a combination of reduced thermal stress on helix formation (see below), and hence rescue of mutant collagen [213], and a decrease in exon skipping [244]. An inverse temperature-splicing relationship has also been reported in a further patient [304]. (Another case of temperature-dependent splicing has been described in a patient with EDS VIIB [36,305].)

(4) Larger in-frame deletions may also lead to the secretion of two main populations of collagen III molecules, normal-sized and shortened ones. Patient B.H. had a 9.0 kb deletion spanning from intron 33 to exon 48 of *COL3A1*, and half of her α1(III) chains lacked the sequence corresponding to residues 586–999 [219,306,307]. Procollagen III molecules composed of either three normal length or three shortened chains were thermally stable and efficiently secreted, whereas those containing one or two shortened chains were unstable and completely excluded from secretion. Failure to secrete unstable molecules, and a possibly residual functional role of the stable "minicollagen III," which lacks the collagenase cleavage site, may explain the milder phenotype of this patient [306,307] compared with another EDS IV patient, D.S., who bore a similarly sized deletion toward the amino-terminal end of the α1(III) chain [226,227]. However, this concept of a possible role of the shortened homotrimeric collagen III *in vivo* may be challenged by the report of a 14-year-old sporadic patient [308] whose mutant collagen III lacked exon 41 and hence also the collagenase cleavage site; his mutant homotrimeric collagen III was efficiently secreted, not cleaved by collagenase, and had normal thermal stability. In the small skin biopsy specimen available, there was only 11% of the normal amount of collagen III; however, there was no evidence that the mutant homotrimers, which would be resistant to mammalian collagenase digestion, had accumulated in the dermis [308]. In another cell strain showing skipping of exon 17, Chiodo et al. [309] showed that the mutant shortened homotrimers were secreted normally and had a normal thermal stability but were not incorporated into the extracellular matrix of an *in vitro* model of dermis.

The stability of the triple helix of procollagen III in EDS IV is reduced as judged by its lower melting temperature when probed with proteinases. Approximately one-eighth of procollagen III molecules, composed of normal α1(III) chains, are secreted normally, which indicates that there is no defect in any putative secretory mechanism for procollagen III. Incubation of cultured fibroblasts at 30 °C decreases the thermal stress on helix formation and can increase the secretion of molecules that contain the abnormal chain for some, but not all, mutations [213]. The possibility that the presence of acrogeria correlates with the secretion of a thermally unstable collagen III, the extremities having a lower temperature than the core of the body, is intriguing but is at variance with findings in fibroblasts from the "acrogeric" patient, P.P. (Figs. 12b and 13a), from which no secretion of such unstable procollagen III could be demonstrated. One mutant cell strain did secrete abnormal collagen III almost as efficiently as normal [214]; however, it was extremely sensitive to proteases due to its Gly790Ser substitution (for further references concerning this case, see [228,310,311]).

Morphologic and Functional Aspects

Morphologic aspects. There have been only a few autopsies in which EDS IV-specific changes have been studied. Collagen III deficiency is most evident in the connective tissue scaffold of the blood vessel walls, dermis, intestine, lungs, and liver, and even in intervertebral disc tissue, where normally only little collagen III is present. The total amount of collagen extractable from lung and liver expressed per gram dry weight is similar in patients and controls, whereas the fraction of collagen III in pepsin-solubilized material is lowered to 3–4% of total collagen as compared with ~20% in control tissues [252,312,313]; in uterine leiomyoma tissue from an EDS IV patient, collagen III as determined by CNBr digestion was ~25% of that of controls [314]. Immunofluorescent staining of retained procollagen III with anti-procollagen III antibodies has been demonstrable in most fibroblasts [232,315], except in a few earlier reports [212,316]. In one case, C.E., the failure to stain [212] is clearly at variance with the biochemical evidence of retention of procollagen III by his fibroblasts [213].

Although collagen III constitutes only 10–22% of the total collagen in normal skin [317,318], at all levels of the dermis [319], its reduction in patients with EDS IV has a dramatic effect on both the thickness and architecture of their skin. In some patients, the skin measures only a quarter of the normal thickness and the reticular dermis is nearly identical in architecture to normal papillary dermis [233]. Collagen fiber bundles are small, and fibril diameters are either uniformly small or show marked variation. Elastic fibers are relatively abundant because of the decreased amount of collagen in the dermis. Because in the skin of normal fetuses below 20 weeks of gestation collagen III is the major collagenous protein present [317], it seems likely that it is important for the formation of a normal scaffold that can be elaborated upon by the subsequent synthetic activity of dermal fibroblasts and that its deficiency leads to the abnormal tissue structure observed in affected individuals. This notion is supported by the finding that all collagen fibrils in skin contain both collagens I and III, so-called heterotypic collagen fibrils [320]. The solubility of collagen in the lungs is markedly increased, which might also reflect an altered fibrillar organization resulting from a decreased content of collagen III [252].

Laurent and Agache [321] performed an early ultrastructural study demonstrating an engorged rough endoplasmic reticulum in fibroblasts from the dermis of an affected individual and suggested defective secretion of an unknown substance. This observation was crucial for the concept of Byers et al. [232,233,246] of impaired secretion of structurally abnormal procollagen III. Since then, dilatation of the endoplasmic reticulum in fibroblastic cells from skin [226,233,294,295,322] as well as in the lung [252] has been demonstrated in numerous other reports. Smith et al. [323] studied skin from 22 individuals with EDS IV in whom the *COL3A1* mutation had been identified. Dermal thickness ranged from 0.66 to 1.54 mm in affected skin compared to a mean of 1.25 ± 0.25 mm in 14 controls, elastic fibers were proportionally increased in relation to collagen fibers, and the collagen fibers themselves were finer and more loosely organized, as observed by scanning electron microscopy. The study suggested that different mutations in the *COL3A1* gene may have different effects on such parameters as secretion, fibrillogenesis, and skin architecture, depending on the nature and location of the sequence changes they induce. Substitutions for glycine and exon-skipping mutations at the C-terminal end of the triple helix led to very marked intracellular accumulation of mutant collagen III in the rough endoplasmic reticulum and to a considerably smaller than normal collagen fibril diameter (65–80 nm versus 92 ± 7.5, range 95–110 nm, respectively), as had been observed previously [193]. In contrast, mutations near the N-terminal end were associated with a more variable fibril diameter (85–120 nm), and there was less evidence of intracellular retention of abnormal collagen III [323]. The cross-sectional shape of fibrils often deviated from the regular rounded profiles of controls, but the changes were relatively subtle and different from the composite fibrils found in EDS I and

II [40,192,193]. In postcapillary venules in EDS IV skin, there was increased perivascular matrix and pericytes had dilated rough endoplasmic reticulum [323]. Why smooth muscle and endothelial cells, which also normally synthesize collagen III, do not have a similarly altered rough endoplasmic reticulum in the same patients is not clear [233,323]. Several features of EDS IV, namely the characteristic facial appearance, the frequently observed low birth weight [221], and clubfoot, are suggestive of a primary, morphogenetic defect. If one considers the preponderance of collagen III in the embryo, it is surprising that even more severe defects are not observed.

Because arterial ruptures are the most severe complications in EDS IV, arterial morphology is of interest. Arterial vessels may have a small bore and a thin wall, and their total collagen content is markedly reduced [34,324,325]. The adventitia is thin, and in the media collagen fibrils are diminished in number, while elastic fibrils are irregular, fragmented, and accumulated. The elastin appears accordion-pleated with a high waviness index, this being the ratio of the length of elastin in the internal elastic lamina to its circumference [326]. The average collagen fibril cross-sectional area was decreased in the media of all arteries and in the adventitia and intima of some arteries, whereas it was increased throughout the vena cava [325]. Immunofluorescence studies on tissues from patients whose fibroblasts secreted only 10% of the normal amount of collagen III did not reveal an abnormal distribution of collagen III, nor was the intensity of staining indicative of the amount of material deposited in the tissues of L.R. and C.E. [327] (K. von der Mark and B. Steinmann, unpublished observations, 1985). There have been only a few studies of the architecture of the gastrointestinal tract or of most other organs. Collins et al. [328] reported that even in areas away from rupture sites, the bowel wall was thin because of diminished submucosa and muscularis propria; similarly, the walls of the blood vessels in bowel submucosa and elsewhere in the abdomen varied in thickness and contained quite striking frayed and fragmented elastic tissue fibers.

Functional aspects. Only a few studies have been devoted to functional aspects of tissues from EDS IV patients. Nemetschek et al. [329] have shown by electron microscopy that the elastic lamellae of the media of an affected aorta seem to be rather isolated from the surrounding collagen fibrils, in contrast to control specimens, in which they are in close contact with the collagen fibrils. Because stress-strain curves show an increased stiffness of the affected arterial wall, the authors speculated that collagen III is involved in the optimal integration or anchoring of elastin in the arterial wall. In contrast, Østergaard and Oxlund [330] found an increase in the extensibility of the middle cerebral artery of patients not specifically classified as having EDS IV but dying from the rupture of intracranial saccular aneurysms at stress values between 100 and 200 mm Hg, but no such extensibility was found in brachial arteries of the same patients despite a deficiency of collagen III. Holzschuh et al. [331] determined by Doppler sonography the pulsatility index (i.e., the difference in flow velocity between systole and diastole compared with an overall mean flow velocity throughout the cardiac cycle) in the cerebral arteries of a 34-year-old woman and showed that it was lower than that in controls; they concluded that the elasticity was increased, which may favor the formation of aneurysms.

Abnormal myoelectric activity was measured *in vitro* in sigmoid and descending colon from an affected individual with colonic perforation, which suggested to the investigators concerned a possible link between abnormal myogenic activity and colonic perforation [332].

Genotype-Phenotype Correlation

At present, there is no clear correlation between the nature and location of mutations within the *COL3A1* gene and the clinical features of EDS IV. The most likely explanation of failure to find such a correlation is that the criteria for inclusion in studies require that most of the clinical findings be met. Thus, the range of phenotypic variation is likely to be small and may be limited to minor features such as acrogeria.

The phenotype to be expected for *COL3A1* null alleles is uncertain. In a small number of families, the synthesis of procollagen III is reduced, perhaps to only about half the normal level, and there is no evidence of intracellular storage. Such a biochemical phenotype would be expected to result in a milder clinical phenotype than classical EDS IV [333]. If these preliminary studies are confirmed, this type of defect would establish a distinct subclass analogous to mild osteogenesis imperfecta (OI type I, see Chapter 8, this volume). The negative results of two large studies of individuals with abdominal aortic aneurysms [271] and cerebral aneurysms [272] make it unlikely that *COL3A1* null alleles are frequent causes of these conditions. Also, heterozygous mice with a *COL3A1* null allele generated by targeted gene inactivation appear phenotypically normal [334] (see "Animal Models and Lathyrism" and below). Given that null alleles of the *COL1A1* gene result in the mildest form of osteogenesis imperfecta [335], type I, milder or late-onset visceral involvement may yet be a candidate phenotype for the *COL3A1* null allele phenotype. It will be interesting to see whether the so far underrepresented mutations that affect the splice-acceptor site, supposedly leading to null alleles [220,230,303], will be detected (see above); such an approach will have to be made by direct molecular genetic means because the ability to discern heterozygous null cells by protein assay is limited (see "Diagnosis"). A putative "mild" *COL3A1* mutation (Gly637Ser) has been associated with an EDS type III-like phenotype without arterial disease in a single family, but the phenotypic characterization of this family was incomplete [209] (see "Recent Developments").

Genetics

EDS IV is a dominantly inherited disorder, with a significant proportion (~50%) of cases representing new mutations [215]. As a rule, each patient or family has its own specific mutation. No paternal age effect has been demonstrated. Early linkage analysis studies showed cosegregation of the phenotype with *COL3A1* alleles [336,337].

Parental mosaicism has been documented in several instances. A clinically healthy father with an affected daughter was shown to be mosaic for a 2 kb deletion in *COL3A1*, which was present in only 10% of his leukocytes but 40% of his fibroblasts [280]. This difference in proportions of normal and mutant alleles between white cells and skin fibroblasts could have resulted from a difference in the allocation of cells early in embryogenesis or, alternatively, may reflect sampling from a clonally derived region in skin enriched for cells containing the mutant allele. If progenitor cells that contained the mutant allele were not selected against, and if they divided at the same rate as normal cells, then the proportion of cells with mutant alleles in blood indicates that the mutation occurred prior to lineage determination. Further cases of mosaicism

have also been documented [310,338,339] or have to be presumed or postulated because of the oligosymptomatic founder [209,230].

Autosomal recessive inheritance has never been demonstrated. On the basis of a study of two cases in which the putatively heterozygous parents were found to have apparently decreased levels of collagen III in skin compared with controls, and whose fibroblasts in culture seemed to secrete lower than normal quantities of procollagen III, it was suggested that the mode of inheritance of EDS IV was autosomal recessive [216]. This proposal is, however, invalid because it relied on the use of DEAE-cellulose column chromatography, which is markedly insensitive as a quantitative technique because of incomplete recoveries. More recent reinvestigation by SDS-polyacrylamide gel electrophoresis has disclosed that the cells of the first case, P.P., secrete approximately 10–15% of the normal amount of procollagen III and that small amounts of heavily overmodified procollagen III are retained within the cells. Normal amounts of mRNA with normal translation activity are detectable [217,226]. The demonstration of a heterozygous Gly1021Arg substitution in this case ends this debate definitively [220]. The second case, C.E., has since been defined as heterozygous for a point mutation leading to exon skipping [244]. The existence of a recessively inherited variant of EDS IV remains to be proven and, if such were confirmed, would appear to be unrelated to defects in collagen III [340].

The division originally proposed by Byers et al. [246] into subtypes A, B, C, and D is no longer meaningful because distinct biochemical and ultrastructural phenotypes can arise from different mutations at the *COL3A1* locus.

Diagnosis

This type of EDS has the worst prognosis, and biochemical confirmation should be sought, although analysis is labor-intensive and expensive. For this reason, careful examination of the patient is mandatory. The diagnosis is made by demonstration of structurally abnormal collagen III and/or direct mutation analysis (see "Recent Developments").

(1) Structurally abnormal collagen III produced by ascorbate-stimulated cultured skin fibroblasts or cells derived from noncutaneous tissues, such as artery, vein, or peritoneum [225], leads first to decreased overall production, defective secretion into the culture medium, and retention within the cells; second, to post-translational overmodification as judged by a slower electrophoretic mobility on SDS-polyacrylamide gels, especially of the portion retained within the cells; and, third, to lowered thermal stability and abnormal sensitivity toward proteases (Fig. 21). Procollagens or pepsin-treated collagens from culture medium and cell layers are best analyzed separately after radiolabeling the cells at 30 °C in addition to the normal temperature of 37 °C [213]. Culture conditions should also be standardized because cell density influences the ratio of collagen III to collagen I synthesized [218,342]. Because an apparent reduction of collagen III may occasionally be found in control fibroblasts, the demonstration of collagen III with abnormal stability or electrophoretic mobility is a better diagnostic criterion than quantitative measurements. Collagen III produced by fibroblasts from one large family with EDS IV was originally reported to be normal [336]; however, a more extensive analysis of the CNBr-derived peptides of collagen III revealed the abnormal migration of peptide α1(III)CB5 [343] due to a 27 bp deletion in exon 37 [344]. It should again be stressed that heterozygotes for a null allele would most probably be missed by this approach and that this may be one reason why such individuals have never been diagnosed; of course, an alternative explanation is that such individuals do not present an abnormal phenotype and thus escape medical attention (see "Recent Developments").

(2) Searching for a reduced amount of collagen in pepsin or cyanogen bromide extracts of skin is not recommended because of the excessive amounts of material required and the unreliability of results with regard to quantitative changes.

(3) Many cases of EDS IV can be detected by quantitative radioimmunoassay of the serum level of the procollagen III aminopropeptide (PIIINP), which is released during the conversion of procollagen to collagen. Indeed, the amount of procollagen III aminopropeptide is low in a major subset of patients with EDS IV whose fibroblasts secrete only little procollagen III [228]. However, this approach is experimental and not generally recommended because of biological variability, confounding concomitant conditions, and the analytical modification of the assay necessary for the detection of low serum procollagen III aminopropeptide levels [39,228]. Whether measurement of PIIINP in skin interstitial fluid (i.e., suction blister fluid), which is independent of its clearance by the liver, is superior remains to be proven [345]. Prolonged bleeding time has been used at the beginning of a study to ascertain family members [346], but this approach is to be discouraged because bleeding time is prolonged in most types of EDS and because it is an unreliable test.

(4) Direct molecular genetic analysis of the *COL3A1* gene will become faster and will provide a high analytical efficiency, especially when combined with the biochemical analyses obtained using cultured cells [230].

Differential Diagnosis

Excessive bruising is found in several coagulation disorders (hemophilias; von Willebrand disease [MIM 193400, MIM 277480]), platelet disorders (including leukemia), scurvy, and nonaccidental injury ("battered child") [347].

Poor wound healing is a feature of scurvy, dysfibrinogenemia (MIM 134820), and factor XIII deficiency (MIM 134570).

Ruptures of arteries occur in the Marfan syndrome (MIM 154700), arterial tortuosity (MIM 208050), isolated multiple cerebral aneurysms with or without polycystic kidney disease (MIM 173900) (for discussion, see Leblanc et al. [270]), arterial dissection with lentiginosis (MIM 600459), different forms of cerebral cavernous malformations (CCM1, CCM2, and CCM3; MIM 116860, MIM 603284, and MIM 603285, respectively), and hereditary cerebral hemorrhage with amyloidosis (MIM 105150) and have also been documented in mild osteogenesis imperfecta [348]. Spontaneous coronary artery dissection (MIM 122455), a rare event, occurs in relatively young persons, with a striking predilection for women. The association of lengthening and tortuosity of systemic, pulmonary, and coronary vessels together with skin and joint laxity and an elongated face seems to be an autosomal recessive disorder [197].

Recurrent pneumothoraces occur in the Marfan syndrome or as an isolated familial disorder (MIM 173600). Periodontal disease is also a major finding in the questionable entity EDS VIII [39]. Acrogeria of Gottron (MIM 201200) [349] and mandibuloacral dysplasia (MIM 248370) [350] are characterized by atrophic skin localized to hands and feet, but without translucent thin skin, mottled hyperpigmentation of

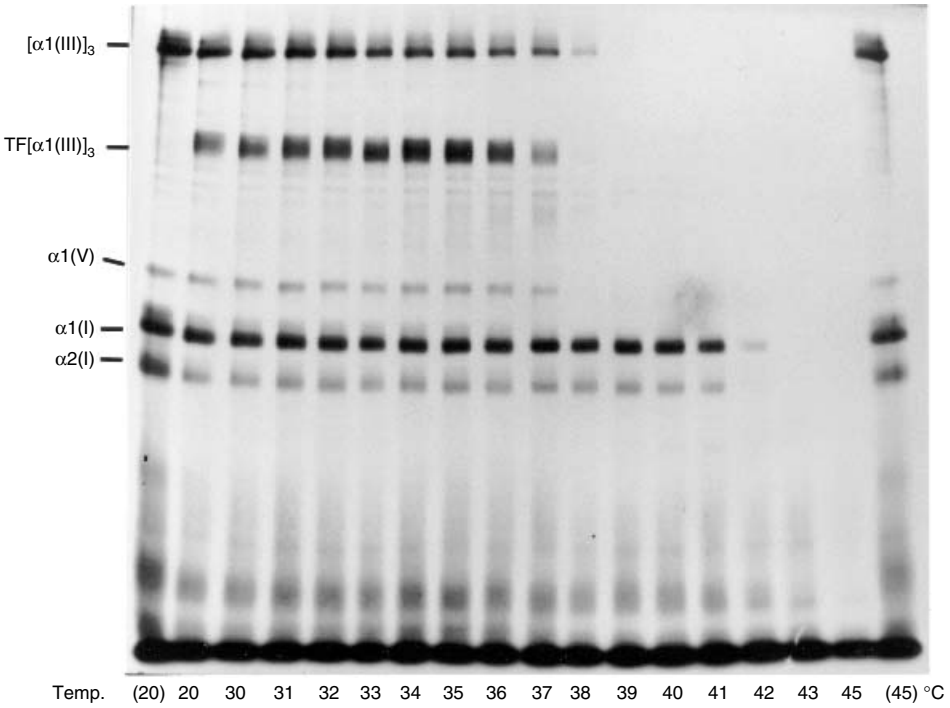

Figure 21. Abnormal thermal stability of collagen III in a patient with vascular type of EDS (EDS IV). Thermal stability of collagens produced at 37 °C in the cell layer of fibroblast cultures from Ch. W. Aliquots of pepsin-purified collagens were heated to the temperatures indicated, incubated with trypsin for 2 minutes, subjected to SDS-polyacrylamide gel electrophoresis, and visualized by fluorography (as a control, trypsin was omitted from the samples incubated at 20 °C and 45 °C, indicated by brackets). The results are summarized as follows.

First, the proportion of collagen III in relation to collagen I is increased, indicating cellular retention of abnormal collagen III molecules [341].

Second, the band representing collagen III is broadened as a result of overmodification caused by slower helix formation.

Third, incubation with the proteolytic enzyme produces a tryptic fragment (TF[α1(III)]$_3$) of abnormal molecules not seen in control preparations. This fragment loses helical conformation at approximately 37 °C. Moreover, [α1(III)]$_3$ trimers in this preparation are completely digested at 37–38 °C, whereas control [α1(III)]$_3$ trimers are resistant up to 39 °C (not shown).

Fourth, the thermal stability of collagen I (41.5 °C) and collagen V (37 °C) is identical to that in control preparations and serves as an internal control. (Reprinted from [259] with permission.)

the skin, thickened nails, micrognathia, and atrophic skin on the tip of the nose, there is no bruisability and no tendency to rupture of internal organs or vessels, and collagen III production is normal [351]. In the literature, the term acrogeria of Gottron has, unfortunately, often been used synonymously with EDS IV and *vice versa* [235,352,353]. Occasionally, patients with similar phenotypes, which may be dominantly or recessively (MIM 225350; MIM 225360) inherited, but with apparently normal collagen III metabolism, may be found ([215,340]; own observations).

Treatment and Management

Because causal therapies are not available, medical intervention is limited to symptomatic therapy, prophylactic measures, and counseling. Because of the danger of sudden arterial hemorrhage and bowel perforation, and the high risk associated with surgery, patients with EDS IV should carry a medical identification paper noting information about their diagnosis, possible complications, and blood group. General recommendations for anesthesia [265] and surgery [328] have been formulated; these include cross-matching of adequate amounts of blood, avoidance of intramuscular premedication, establishment of an adequate peripheral intravenous access and avoidance of arterial lines and central venous catheters if possible, control of hypertension, and gentle intubation maneuvers.

EDS IV represents a formidable challenge to the cardiovascular surgeon. The management of bleeding should be conservative as long as possible, especially when it is interstitial (muscular, retroperitoneal) [254,255,292]; bleeding in the abdominal cavity usually requires immediate transfusion and surgery. When operative therapy is required, minimal vessel dissection with balloon catheter or tourniquet occlusion should be performed, and vessel loops and vascular clamps, which frequently produce injuries that cannot be repaired, should be avoided. Standard anastomoses similarly often fail because of the poor tensile strength of the blood vessels. Primary arterial repair, if attempted, should be tensionless, using interrupted horizontal mattress sutures reinforced with pledgets. Vessel ligation with umbilical tapes, however, appears to be the safest operative therapy. Bypass grafting is then performed only if distal ischemia develops [254]. A review of the treatment of spontaneous carotid-cavernous fistula and outcome is given in [354].

Angiography should be avoided because of possible severe morbidity and frequent mortality [94,95,254,255,292] and replaced by ultrasonography [355] and/or subtraction angiography, although even this procedure is not free of risks [356].

The stripping of varicose veins may be difficult because they tear readily [312]. Surgical repair or embolization of carotid-cavernous fistula has been attempted with success in some patients [268,357].

Because of the high recurrence rate of distal colon perforation (15 cases out of 41 [254]), it is advisable to perform total colectomy and ileostomy when the first episode of perforation occurs [254,284].

Pregnancy in women with EDS IV should be closely monitored. Whether bed rest after 32 weeks of gestation and elective Cesarean section before incipient labor, to avoid the risks associated with vaginal delivery, should be recommended is still unclear [220,283,358]. It is worthy of note that sudden death may also occur several days postpartum. In the largest survey of "classical" EDS IV individuals, pregnancy-related complications led to death in 9–15% of women who became pregnant [256].

Because cerebrovascular complications occur in a minority of patients, screening for aneurysms is not warranted, and the risk of surgery would preclude intervention before the development of symptoms. Nevertheless, the occurrence of neurological symptoms, including headache, in individuals with EDS IV should alert the physician to exclude intracranial vascular pathology by noninvasive methods.

The management of hemopneumothoraces and thoracic cysts seems to be satisfactory using standard approaches [289].

Cough and constipation should be prevented by the timely use of antitussives and high-fiber diets and laxatives; enemas should not be given because colonic distention may result in perforation.

Many commonly used drugs interfere with platelet function, either alone (e.g., acetylsalicylic acid, nonsteroidal anti-inflammatory drugs) or in combination (penicillins and cephalosporins), and should be avoided or used with caution; paracetamol, pyrazolone derivatives, or synthetic opioids can be used instead. Anticoagulation therapy for venous thrombosis, or for the prevention of thrombosis during prolonged bed rest, should be avoided because it may lead to fatal bleeding (own observation; see legend to Fig. 15). In one patient, the administration of aspirin had to be discontinued because of a marked increase in spontaneous bruising [359].

Because atheromatous plaques, as observed in a patient described by Kontusaari et al. [275], may initiate arterial rupture, the prevention of atherosclerosis may be potentially beneficial.

Heavy physical exercise (isometric exercise, weightlifting), or procedures that lead to increased intrathoracic pressure such as blowing the alpenhorn or French horn [360], and contact sports are contraindicated. Psychological support may be important.

Genetic Counseling and Prenatal Diagnosis

In EDS IV, dominant inheritance should be assumed in sporadic cases also unless proven otherwise. When a low serum procollagen III aminopropeptide level or a defect in collagen III metabolism has been documented in the index case, this may be used for screening other family members [228], with the caveats outlined above. Linkage of EDS IV to *COL3A1*, direct demonstration of the gene defect, or protein studies on a chorionic villus biopsy are all methods of prenatal diagnosis. We have been able to rule out EDS IV in two pregnancies of one case (F.P.) by excluding the presence in a chorionic villus biopsy of a structurally abnormal collagen III previously observed in fibroblasts from the mother [260].

KYPHOSCOLIOTIC TYPE OF EDS — EDS TYPE VI (OCULAR-SCOLIOTIC TYPE) (MIM 225400)

Diagnostic Criteria

The kyphoscoliotic type of EDS is caused by a deficiency of lysyl hydroxylase 1 (PLOD1), a collagen-modifying enzyme, due to homozygosity or compound heterozygosity for a mutant *PLOD1* allele(s). It is characterized as follows [39]:

Major diagnostic criteria
- Severe muscular hypotonia at birth
- Generalized joint laxity
- Kyphoscoliosis at birth, which is progressive
- Scleral fragility and rupture of the ocular globe

Minor diagnostic criteria
- Tissue fragility, including atrophic scars
- Easy bruising
- Arterial rupture
- Marfanoid habitus
- Microcornea
- Radiologically considerable osteopenia
- Family history (i.e., affected sibs)

Note: The presence of three major criteria in an infant is suggestive of the diagnosis, and laboratory testing is warranted. In the majority of cases, the condition is caused by the enzyme deficiency and specified as EDS VIA, whereas a rarer, similar condition with normal lysyl hydroxylase activity is designated EDS VIB (see Table 1 and below), the biochemical/molecular basis of which is still unclear.

Historical Introduction

The existence of an autosomal recessively inherited, "ocular" form of EDS was suggested by Beighton in 1970 on the basis of case 3 in the legend to Fig. 22 (Fig. 6.16 in [2c]) because of the overall rarity of sight-threatening eye complications, which were, however, clustered in families with only sibs affected and/or with consanguineous parents [113]. Investigation of such a family led to the first definition of a chemical abnormality of collagen in man, a milestone achieved by Krane and his colleagues [33]. In 1970, they studied two sisters (cases 1 and 2 in the legend to Fig. 22) who, in addition to typical EDS, had marked muscular hypotonia, severe progressive kyphoscoliosis from birth, microcornea, and fragility of ocular tissues leading to rupture of the globe or retinal detachment. The mother ruptured her membranes while 3 months pregnant with the older child yet still managed to carry the pregnancy to term. The younger affected girl required enucleation following a relatively mild trauma to the eye. Biopsy specimens of skin from both children contained collagen that was normally soluble in nondenaturing solvents (such as dilute acid) but more soluble than normal in denaturing solvents (such as 4 M $CaCl_2$ or 9 M KSCN). In view of this, it was assumed that there was some defect in the intermolecular cross-linking of the dermal collagen. The most striking chemical abnormality, which came as a "surprise to the authors" (S. Krane, personal communication, 1991), was the decreased hydroxylysine content in skin (0.2 to 0.3 residues per 1,000 amino acid residues; 5–7% of normal). Because the hydroxylysine content of the skin of the clinically normal parents and older sister was normal, it was assumed that the disorder was inherited as an autosomal recessive trait

and was due to a reduced enzymatic hydroxylation of lysyl residues [33,362]. Indeed, when in a later study enzyme extract from the cells of case 3 was mixed with that from a control, the activities were essentially additive [374], an observation that favored the conclusion that a structural defect of the enzyme rather than a defect in the activation step or the presence of an inhibitor led to the deficient enzyme activity.

Because these patients had both features of the EDS and ocular abnormalities, but a distinct biochemical defect, it was suggested that they be classified as a new subtype, EDS VI, the ocular type [2], or the ocular-scoliotic type [37e], now the kyphoscoliotic type [39], of EDS because ocular signs, though dramatic, are less frequent features in larger series than was initially reported [39,363].

It remains to be explained how the chemical abnormality relates to the clinical manifestations because the presence of typical symptoms even in patients with an apparently normal or only somewhat decreased content of hydroxylysine in skin, and normal lysyl hydroxylase activity in fibroblasts ([88,92,409,410]; cases 4 and 5 in [383,411]), suggests a more complex relationship between the known molecular defects and clinical manifestations than has been thought up to now. As mentioned above, patients with a phenotype resembling that of the kyphoscoliotic type but with normal lysyl hydroxylase activity do exist, and these individuals are now classified as EDS VIB [37f].

Clinical Findings

The legend to Figure 22 lists the 57 reported and unreported patients with EDS VIA known to the authors, derived from 49 families, who have been described clinically and confirmed biochemically. Those newborns whose neonatal history is available were usually described as floppy, with a poor cry, difficulty in sucking, and delayed motor development (cases 1, 2, 5–8, 10, 12, 14–16, 18–20, 22–29, 51). Sometimes poor fetal movements were noted by the mothers. Because of the severe muscular hypotonia, many of the patients had undergone a neuromuscular workup. Leg cramps are a common complaint.

Kyphoscoliosis is often present at birth and is progressive and severe (cases 1–4, 7–14, 16, 18–20, 22–24, 33, 51) (Figs. 23a,b and 24). It is probably the result of muscular hypotonia together with ligamentous laxity because the vertebral bodies are structurally normal, and is often resistant to external bracing. Thoracic cage deformity and hypotonia

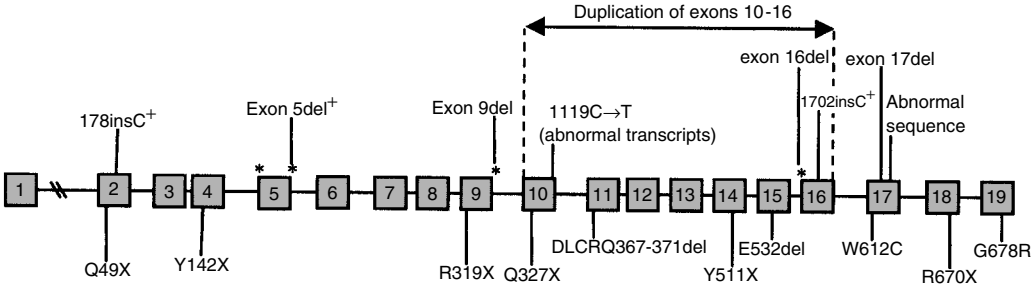

Figure 22. Structure of the *PLOD1* gene coding for lysyl hydroxylase 1 and mutations leading to the kyphoscoliotic type of EDS (EDS VI). The shaded boxes represent the 19 exons in the *PLOD1* gene joined by single lines indicating introns (not drawn to scale). The effects of point mutations and deletions on the amino acid sequence are shown below the line; above the line, the effects of other mutations are shown in the DNA: mutations that produce downstream preterm termination codons, PTCs, (+); splice-site mutations that result in exon skipping (*); as well as the common duplication of exons 10–16 (↔). (Adapted from [361] with permission.)

All biochemically proven patients known to the authors are listed below. The case numbers are followed by the mutation(s), sex, initials, and date of birth in parentheses, the ratio of urinary pyridinolines (LP/HP), and the references describing them, if the information is complete. Dup refers to the prevalent duplication of seven exons (exons 10–16) due to (a) homologous recombination event(s), Ter to a stop codon, PCT to preterm termination codon, and 0 to a functional null allele.

Cases 1 and 2, dup/dup, sisters (born 3 Dec 58 and 4 Jul 61) [33,362]; cases 7 and 8 in [363–373]; *cases 3 and 4*, dup/dup, sister and brother (J.L., 1924 and G.B., 1915), see Fig. 6-16 in [2], [37,111,113,373–378]; *case 5*, male [369,379,380]; *case 6*, male (J.D.H.), case 5 in [363,381,382]; *case 7*, del exon 16/del exon 17, male (9 Jan 76), case 1 in [383], [384–386]; *case 8*, male (18 years), case 2 in [383], [387–389]; *case 9*, male (33 years), case 3 in [383]; *case 10*, male (19 years), case 6 in [383]; *case 11*, del Glu532/Gly678Arg, male (A.T., 28 Jan 78), case 4 in [363], [390–393]; *case 12*, female (2 years) [392]; *case 13*, male (42 years), case 10 in [363], [426]; *cases 14–18*, cases 1,2, 3,6,9 in [363]; *cases 19 and 20*, Arg319Ter/Arg319Ter, sisters (H.A., 30 Jul 76 and N.A., 31 May 81), LP/HP 5.3 and 5.9 [394,395]; *case 21*, Tyr511Ter/del exon 5, male (SF 996, 3 Jul 89) [396,397]; *cases 22 and 23*, sisters (O.A., 29 Jun 84 and M.A., 16 Dec 94), LP/HP 6.3 and 5.9 [398]; *case 24*, dup/dup, male (A.R., 13 Mar 80), LP/HP 5.1 [373,399]; *case 25*, dup/dup, female (S.B., 12 Apr 77), LP/HP 5.3 [389,400,401]; *cases 26 and 27*, dup/?, brothers (A.B., 15 Sep 86 and H.B., 15 Oct 91), LH/HP 6.8 and 6.0 [373]; *cases 28 and 29*, dup/dup, brothers (T.D., 15 May 81 and A.D., 31 May 85), LP/HP 5.7 and 5.7 [373]; *case 30*, del exon 9/del exon 9, female (D.I., 18 Jan 90), LP/HP 4.3 [402]; *case 31*, dup/dup, male (A.R., 19 May 79) [401]; *case 32*, Trp612Cys/0, male (A.K., 14 Feb 80) [401]; *case 33*, male (T.O., 4 Oct 92), LP/HP 5.7 [own observation]; *case 34*, Tyr511Ter/Tyr511Ter, male (D.B. (1122), 34 years) [403]; *case 35*, D367LCRQdel/Gln49Ter, male (J.H., 3 Mar 84) [404]; *case 36*, D367LCRQdel/abnormal transcripts, female (C.C.) [404]; *case 37*, c.1702insC/c.1702insC, PTC in exon 16, female (K. (1072)) [405]; *case 38*, Tyr511Ter/Tyr511Ter, female (L.T., 17 May 70) [405]; *case 39*, Gln327Ter/Gln327Ter, female (A.C., 3 May 94) [405]; *case 40*, Tyr142Ter/del exon 14, female (A.F., 12 Aug 71) [405]; *case 41*, Arg670Ter/dup, male (M.C., 7 Feb 94) [405]; *case 42*, Tyr511Ter/Tyr511Ter?, male (J.H. (716)) [405]; *case 43*, IVS4-2A del/c.353insC, female (N.) [406]; *case 44*, Tyr511Ter/?, female [407]; *case 45*, female (D.A., 22 Apr 90), LP/HP 6.5 [own observation]; *case 46*, (A.A., 12 Mar 82), LP/HP 7.7 [own observation]; *case 47*, female (N.A-T., 31 Mar 95), LP/HP 6.9 [own observation]; *case 48*, female (Y.I., 10 Jun 93), LP/HP 7.8 [own observation]; *case 49*, male (J.S., 14 Jun 71), LP/HP 8.1 [own observation]; *Cases 50 and 51*, sisters (S.G., 14 Jun 70 and C.G., 23 May 65), LP/HP 4.6 and 7.8 [408]; *cases 52 and 53*, brother and sister (S.F., 12 Feb 80 and A.F., 28 Dec 81), LP/HP 3.9 and 4.1 [own observation]; *case 54*, female (F.Al-M., 9 Nov 00), LP/HP 8.1 [own observation]; *case 55*, female (K.K., 11 Oct 73), LP/HP 5.47 [own observation]; *case 56*, male (S.K., 20 Jul 93), LP/HP 3.5 [own observation]; *case 57*, male (D.D., 3 Oct 91), LP/HP 4.38 [own observation]; *case 58*, female (M.K., 9 Dec 95), LP/HP 3.4 [own observation].

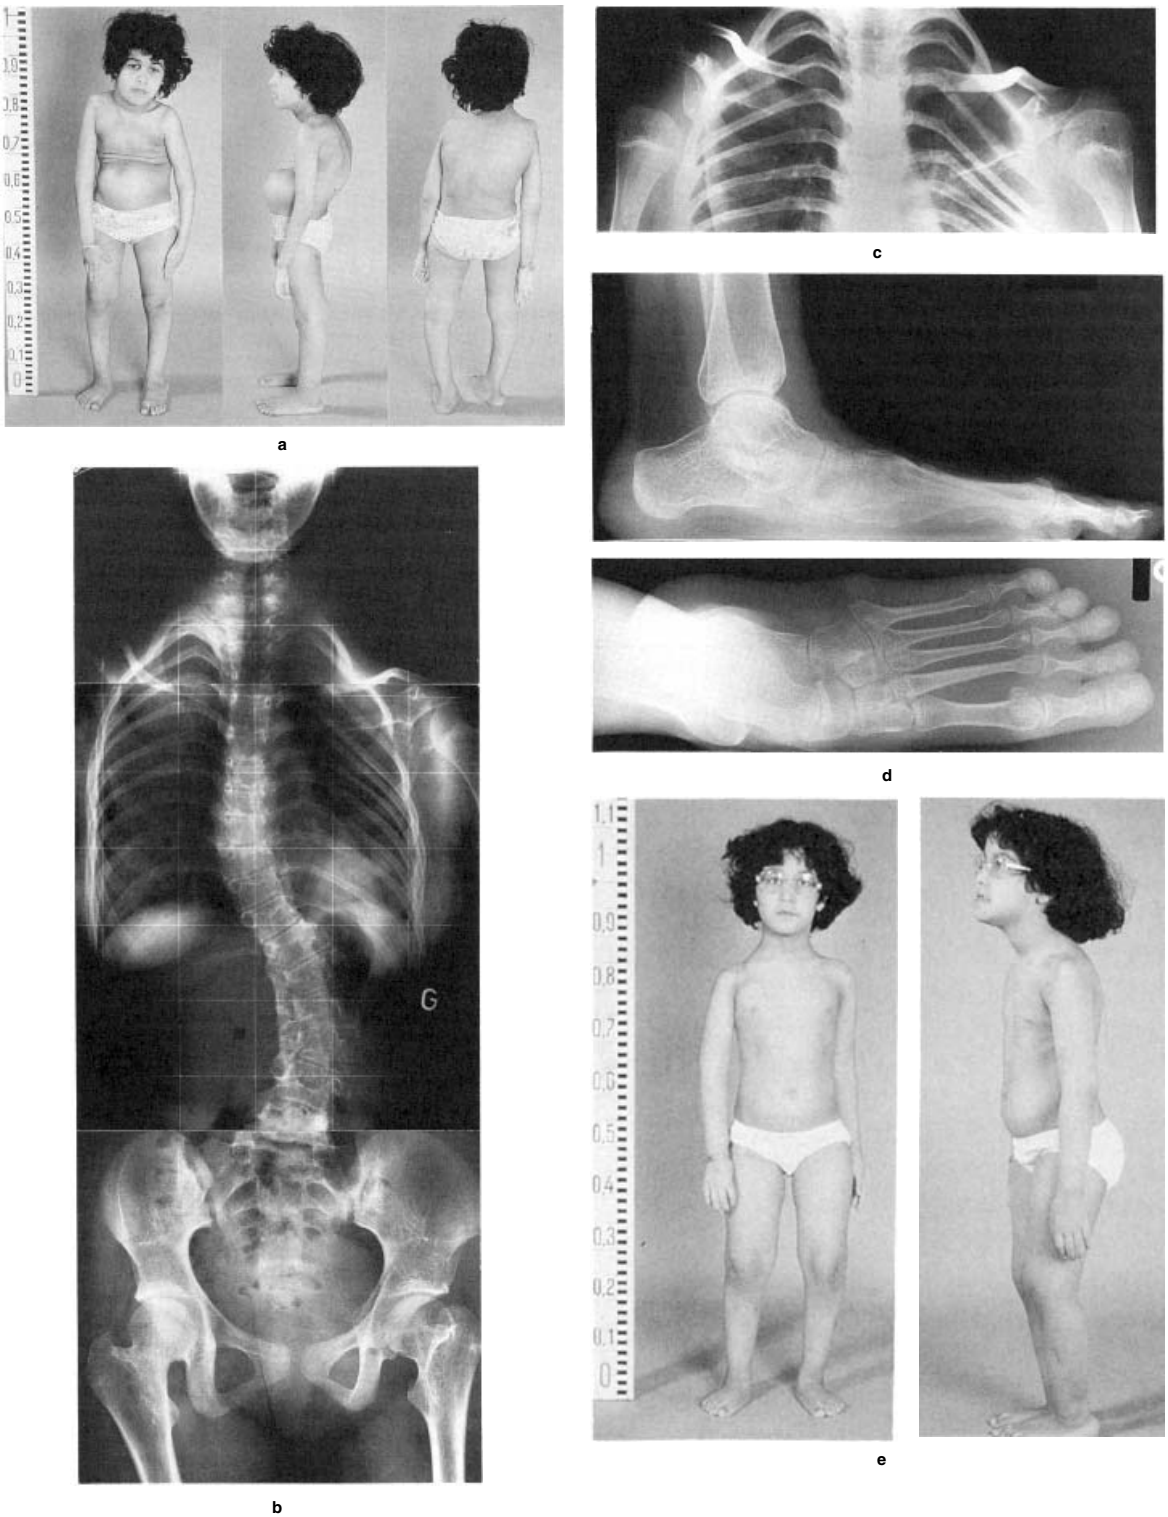

Figure 23. Kyphoscoliotic type of EDS (EDS VIA). H.A. (30 Jul 1976) and N.A. (31 May 1981) (cases 19 and 20 in the legend to Fig. 22) are the third and fifth children of healthy parents from Qatar who are first cousins. This family was the first in which the disorder was characterized at the molecular level [395]. (**a**) H.A. ($5\frac{1}{2}$ years old): severe kyphoscoliosis, dislocation of the right shoulder, flat feet in valgus position, microcornea. (**b**) X-rays of the spine 4 years after Harrington rodding and 3 years after removal of the rod because of its displacement due to premature loading (11 years). (**c**) X-ray of the shoulder showing dislocation of the right humerus (11 years). (**d**) X-ray of the foot showing marked osteoporosis and flat feet (11 years). Because of joint instability, arthrodesis of the lower ankle joint was required 2 years later. (**e**) N.A.: younger affected sibling who has a much milder phenotype, at age 5 years, shown for comparison, and thereby demonstrating marked intrafamilial variability. ((a), (e) reprinted from Steinmann [42] with permission.)

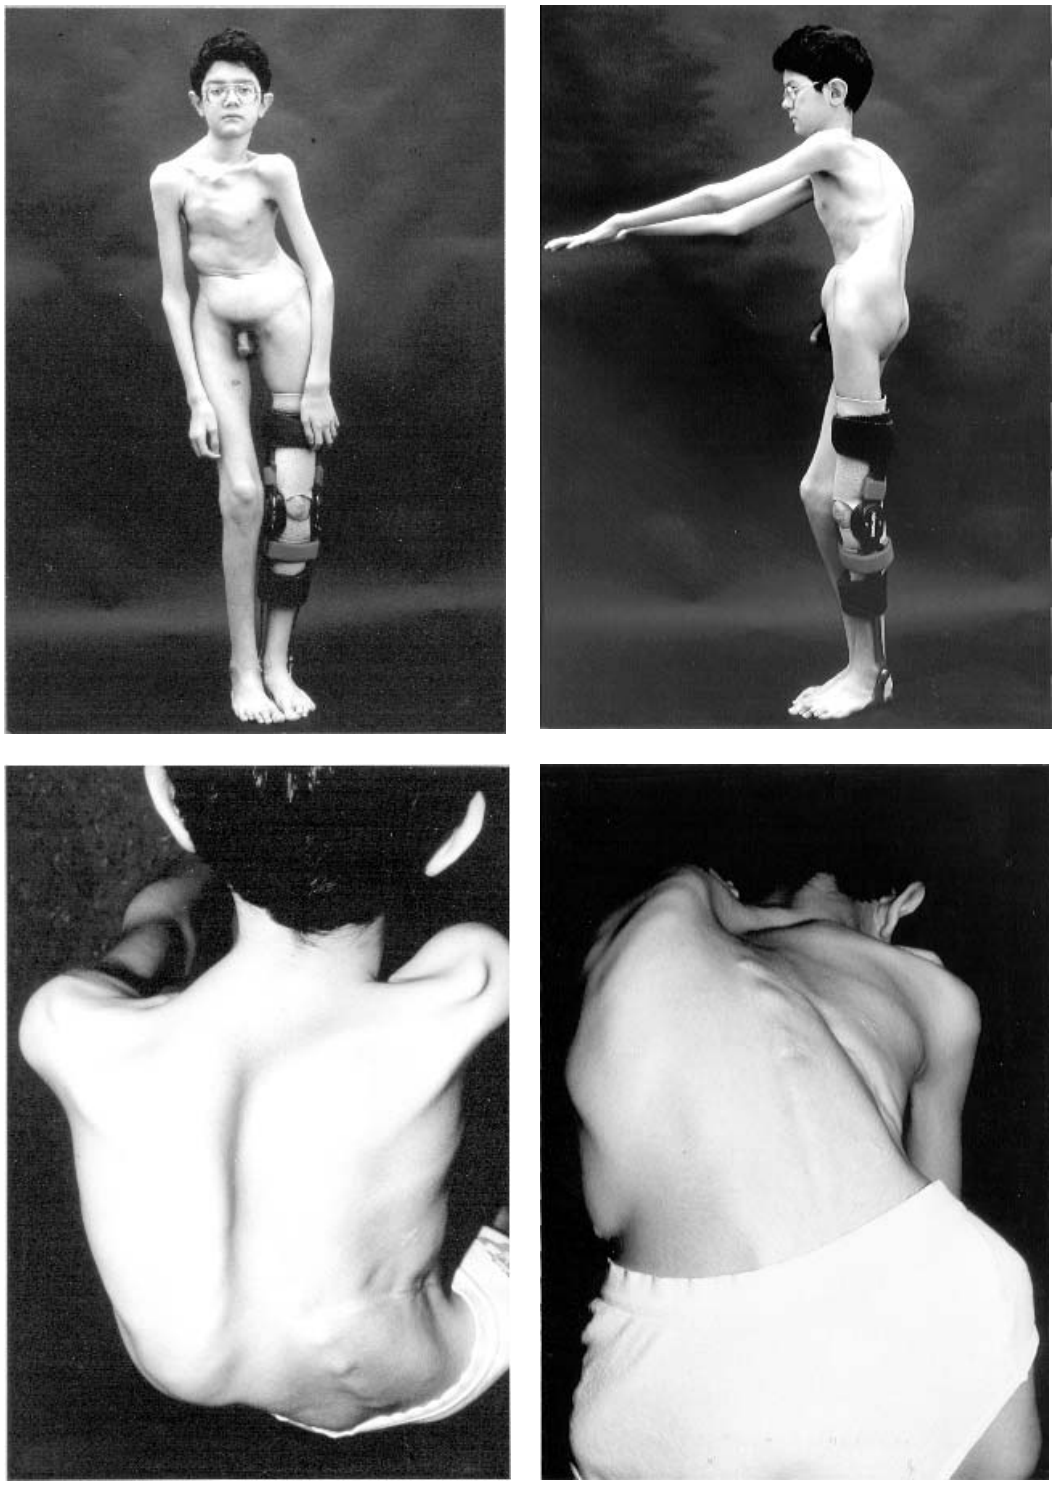

Figure 24. Kyphoscoliotic type of EDS (EDS VI). A.R., aged 13.3 years (case 24 in the legend to Fig. 22), with severe thoracic kyphoscoliosis and a Marfanoid habitus. He was only able to walk with the upper part of the body bent forward and preferred sitting in a wheelchair. He had microcorneae, brownish sclerae with decreased rigidity, and tortuous retinal arteries. Generalized joint hypermobility, habitual luxation of the shoulder, hypotrophic muscles, and marked skin hyperextensibility were present. There was mild aortic regurgitation, and lung function was severely restricted with a vital capacity of 30%. Only at age 13 years was EDS VI suspected and appropriate diagnostic procedures initiated.

He was born to consanguineous Iranian parents in the breech position. He was a weak baby and had difficulty in sucking. Treatment of the progressive kyphoscoliosis with a brace was not effective. Extensive and invasive neuromuscular workup remained noncontributory. During a ventral derotation spondylodesis from T11 to L5 at age 10.9 years, the inserted catheter led to an ectasia of an internal jugular vein, which was later resected. (Reprinted from Heim et al. [399] with permission.)

Figure 25. Kyphoscoliotic type of EDS (EDS VIB). A.S. (27 Apr 1956), 17 years old, the younger of two affected children born to healthy young parents from Pakistan who were first cousins. (**a**) Marfanoid habitus, moderate kyphoscoliosis and chest deformity, atrophic hemosiderotic scars, especially over the right shin, foot deformity, and mitral valve prolapse and regurgitation as judged by auscultation and echocardiography. His head circumference was normal (55 cm), and thus he differs from the cases with macrocephaly described by Cadle et al. [411] and Judisch et al. [409]. (**b**) Microcornea (9 mm in diameter), droopy eyelids, epicanthal folds, atrophic scars over the saddle of the nose, slightly lopsided and quite floppy ears. (**c**) Molluscoid pseudotumor over the elbow and spider-like fingers. (**d**) Hyperelasticity of the skin over the thenar and excessively wrinkled skin over the palm and fingers. (**e**) Hyperextensibility of the fingers. (**f**) Cigarette-paper-like scars over the knee. (**g**) Foot deformity and pseudotumor. Clinical follow-up: A.S. died at age 28 years of heart failure due to acute noncontrollable, bacterial endocarditis in his mother country (B. Steinmann, unpublished). (Reprinted from Steinmann et al. [88] with permission.)

lead to a decrease in pulmonary function and favor recurrent episodes of pneumonia, cardiac insufficiency, and early death (this occurred in case 4 at 54 years; in case 8 at 20 years; and in case 13 at 43 years). A Marfanoid habitus is quite common (Figs. 24, 25a). Osteoporosis seems to be a common finding but without any tendency toward fractures (Fig. 23d).

Ocular fragility leads to retinal detachment (case 3) and bleeding (case 3) and rupture of the globe, rather than of the cornea as in the brittle cornea syndrome, after minor trauma (cases 2–4, 9). Attempts to suture scleral tissue are often in vain (case 4). Microcornea is common (Fig. 25b) (cases 1–3, 6, 8, 10, 19, 20), the diameter in normal individuals being approximately 11.7 mm (range 11.0–12.5 mm) [412]; however, it also occurs in EDS I (as in the propositus and his affected daughter, Fig. 10). The sclerae are often bluish, in contrast to those in EDS I, II, and III, which are of normal hue.

Arterial rupture may be another prominent finding in EDS VI [363; personal observations]. Case 3 died at 51 years with symptoms typical of dissecting aneurysm of the

aorta; however, autopsy was not performed [37e]. Case 4 had a cerebrovascular accident in the distribution of the right middle cerebral artery at the age of 19 years [374]. Other impressive clinical descriptions of patients with classical features of EDS VI who were not studied biochemically have been reported in the older literature [2,119,413]. The natural history in relation to the vascular system is still not well-known. An ill-defined polyneuropathy in two siblings of consanguineous parents together with typical signs of EDS VI has been described [92].

To the authors' knowledge, affected females with proven EDS VI (see legend to Fig. 22) have not been reported to have given birth; in contrast, case 4 fathered four healthy children (see "Recent Developments").

Life span is markedly reduced because of arterial rupture and cardiopulmonary insufficiency due to severe kyphoscoliosis; there are, however, no precise data on mean age of survival (see above).

Obligate heterozygotes are clinically normal in our experience.

Macrocephaly has been reported in six patients with EDS VIB from three separate families and claimed to be a feature of a distinct syndrome [411] (R.G. Cadle, personal communication, 1990) (MIM 229200), but macrocephaly is clearly not present in other patients with EDS VIB (Fig. 25a) [88,440].

Interfamilial variability of EDS VI is quite considerable within EDS VIA, and even more so if EDS VIB, with its unknown genetic defect, is included. Intrafamilial variability as observed in the pairs of siblings (cases 1 and 2, 3 and 4, 19 and 20, 22 and 23, 26 and 27, 28 and 29, 50 and 51, 52 and 53; see legend to Fig. 22, Figs. 23a and 23e) further indicates that environmental factors and complications, such as neonatal brain hemorrhage in case 50 [408], and genetic factors other than mutations in the gene coding for lysyl hydroxylase are also important in determining clinical expression; the phenotype in case 51 is unusually mild [408].

Genetic Defect

The Gene, the Enzyme, and Physiology

Lysyl hydroxylase 1 (LH1) (EC 1.14.11.4; procollagen-lysine, 2-oxoglutarate 5-dioxygenase; PLOD1; MIM 153454) is a homodimer consisting of subunits with a molecular weight of about 85,000, each comprising 709 amino acid residues and a signal peptide of 18 amino acids. The C-terminal region is especially well-conserved, with a 139 amino acid region, residues 588–727, being 94% identical between the human and chick at the amino acid level, and with a 76 amino acid region coded for by exons 18 and 19, residues 639–715, being 99% identical [414,415]. By site-directed mutagenesis, it has been shown in expression systems that three residues, histidines 656 and 708 and aspartate 658, provide the three ligands required for the binding of Fe^{++} to a catalytic site, whereas the role of a third critical histidine (residue 706) remains to be established [416]. The enzyme appears to be a true resident of the endoplasmic reticulum despite the fact that it does not contain any known endoplasmic-reticulum–specific retention signals in its primary structure [417].

The ascorbate-dependent enzyme requires α-ketoglutarate, Fe^{2+}, and O_2 as cosubstrates and cofactors [418] and catalyzes the formation of hydroxylysine in collagen chains and other proteins with collagen-like amino acid sequences by the hydroxylation of lysyl residues in Gly–X–Lys sequences (for a review, see [419]). The hydroxylysyl residues formed have two important properties: first, their hydroxyl groups serve as sites of attachment for a monosaccharide or a disaccharide — galactose or glucosylgalactose, respectively — the function of which is unknown so far, although they may play a role in recognizing and activating collagen receptors in the cell membrane [420]; second, they are essential for the stability of the intermolecular collagen cross-links that provide tensile strength to most soft tissues and bone.

Cross-linking involving lysyl and hydroxylysyl residues occurs after the processing of procollagen and secretion of the molecules into the extracellular space. The first step in cross-linking is the oxidation of specific lysyl and hydroxylysyl residues in the telopeptide regions at both ends of the collagen molecule to form aldehydes [421]. This reaction is catalyzed by the extracellular copper-dependent enzyme lysyl oxidase (protein lysine 6-oxidase, EC 1.4.3.13, MIM 153455). When hydroxylysyl residues are present in the telopeptides, the hydroxylysine-derived aldehyde, hydroxyallysine, reacts with a specific peptidyl lysyl or hydroxylysyl residue in the triple-helical domain of a neighboring molecule in a fibril to form a bifunctional reducible intermediate that matures into a trifunctional nonreducible pyridinium cross-link through the addition of a third residue of hydroxylysine [421]. Two forms of pyridinium cross-link have been identified: hydroxylysyl pyridinoline (HP, or "pyridinoline"), formed from three hydroxylysyl residues, and lysyl pyridinoline (LP, or "deoxypyridinoline"), formed from one lysyl and two hydroxylysyl residues. These pyridinolines are especially abundant in bone, cartilage, and dentin [422]. Both compounds are biologically and chemically stable and are excreted in urine in free and peptide-bound forms as products of collagen degradation. Their urinary excretion correlates with bone turnover in acquired and inherited disorders affecting bone (see Appendix II, this volume), whereas a highly increased ratio of LP to HP is diagnostic for EDS VI (see below).

Lysyl hydroxylase 1 is coded for by the gene *PLOD1* (MIM 153454) on chromosome 1p36.2→p36.3 [415], which contains 19 exons and a 5′-flanking region with characteristics shared by housekeeping genes; the constitutive expression of the gene in different tissues suggests that lysyl hydroxylase has an essential function [423]. From sequencing the introns, where many mutations and rearrangements have been found to be concentrated, Heikkinen et al. [424] demonstrated extensive homology of intron 9 and intron 16 resulting from five and eight Alu sequences, respectively, contained therein (see Fig. 22).

The Mutations in the Gene Coding for Lysyl Hydroxylase

The mutations so far elucidated in lysyl hydroxylase in EDS VIA are indicated in Figure 22. Of special interest is the high frequency of the large duplication of nucleotides 1176 to 1955 corresponding to amino acids 326 to 585 in the normal sequence [415]. The seven-exon duplication in *PLOD1* is 8.9 kb in size, is caused by an Alu–Alu recombination in introns 9 and 16 of the gene, does not disturb the splicing of introns, and leads to a duplication of amino acids 326–585 [415,424]. This duplication was found in 19% of mutant alleles among 35 EDS VI families, but haplotype analysis showed variations in the sequence of the DNA region surrounding the duplication, thereby excluding a founder effect [373] and suggesting that it must be a frequent, independent event.

Pathogenesis

EDS VIA was shown by Krane et al. [33] to be due to a marked deficiency of lysyl hydroxylase. Residual activity in cultured skin fibroblasts ranges from 2% to 50% of normal using radiolabeled chicken protocollagen (unhydroxylated procollagen) as a natural substrate. These figures have to be treated with caution because the results may vary considerably from assay to assay, and even more so from laboratory to laboratory, making direct comparison difficult (e.g., in cases 1 and 2, residual activity was variously 14% and 10% [33] and 14.6% and 26.6% [363], respectively, in the same patients). Only a few studies of the kinetic and physicochemical properties of crude enzyme preparations from patients and controls have been performed. In one study using cultured fibroblasts from the two siblings above (cases 1 and 2), a mutant enzyme had optimal activity at 30 °C, rather than 34 °C, as for the wild-type enzyme, and did not form high-molecular-weight aggregates in low-ionic-strength buffers as did the normal enzyme. It also exhibited a higher apparent K_m for ascorbate (20 μM) than the wild-type enzyme (4 μM), and its activity was stimulated threefold or more by prior dialysis against buffer solutions containing 10 mM dithiothreitol, but no such effect was observed with the normal enzyme [364]. These differences in kinetic properties suggest that there is not simply a deficiency of enzyme protein in affected individuals but that an enzyme protein is present with abnormal properties. Miller et al. [382], in their study of cultured fibroblasts from case 6, found that the mutant enzyme had the same K_m for ascorbate (0.1 mM) as the wild type but that its apparent V_{max} was reduced to 25% of the control figure.

As a consequence of the lysyl hydroxylase deficiency, the hydroxylysine content of collagen is diminished, with a concomitant increase in lysine, although to variable degrees in different tissues. The amount of hydroxylysine is only 5% of normal in skin [362], 14–28% in fascia [362], 55% in tendon [387], 10–20% or 43–100% in bone, depending on the mode and site of sampling [363,365,387,425], and ~90% of normal in cartilage [362]. The level of hydroxylation in the C1q component of complement was initially reported as being 77% of normal by Pinnell [366], but a later study found it to be normal [384]; in both studies, the C1q was functionally normal. The analysis of different collagen types extracted from various tissues of case 8 and their respective chains gave similar results [387]. The extent of lysyl hydroxylation of collagen I extracted from skin was 0%, from bone 17%, tendon 36%, kidney 71%, and from lung 73% of normal. Collagen III extracted from skin and lung contained 0% and 50%, respectively, of the normal content of hydroxylysine, whereas collagens II, IV, and V from cartilage, kidney, and bone, respectively, were almost normally hydroxylated [387]. The authors of this latter study concluded that the varying degree of impairment of the hydroxylation of lysine residues correlated well with the severity of the clinical manifestations. Furthermore, cyanogen bromide cleavage of dermal collagen revealed that the hydroxylysine content was not uniformly low in the peptides examined but rather that it was zero in some peptides containing normally hydroxylatable lysyl residues and measurable, although still reduced, in others. Just one possibility to explain this is that the altered enzyme protein acts on different lysyl residues to different extents as a function of the variations in surrounding amino acid sequence [367]. Cultured skin fibroblasts from patients with EDS VI produce collagens I and III (and V), which are hydroxylated to a greater extent (~50% of normal) than their dermal counterparts formed *in vivo* [368,375,383,385,426]; overhydroxylation of collagen produced in culture is also observed in control cells [368] and may indicate that the rate of polypeptide elongation and/or helix formation in culture is delayed, thus allowing more extensive hydroxylation of lysyl residues. It is also clear that the content of hydroxylysine glycosides in collagen is likely to be markedly reduced. The ratio of glucosylgalactosyl hydroxylysine to galactosyl hydroxylysine in diseased bone appears abnormally high (1.04 and 1.24 in two cases versus 0.39 and 0.47 in two controls) [365]. However, the function of the sugar residues normally linked to hydroxylysine is not known.

The considerable extent of hydroxylation of collagen lysine residues that occurs in certain tissues in EDS VI patients may also explain why the urinary excretion of hydroxylysyl glycosides was only moderately decreased (62% of normal) in the two patients studied in this regard [362].

The above-mentioned wide variability in the extent of tissue-specific post-translational modification could be explained by several possibilities or a combination thereof:

1. Differences in the residual activity of lysyl hydroxylase in various tissues, resulting from a relative increase of either synthesis or activation of proenzyme. Krane et al. [369] reported that the ratio of lysyl to prolyl hydroxylase in dermal cells was 8–10% but that it was as high as 46–49% in bone cells of case 2.
2. Tissue-specific differences in the rate of collagen synthesis and triple-helix formation in the presence of limiting lysyl hydroxylase activity, as discussed above for the *in vitro* model.
3. Different affinities of the mutant enzyme for different collagens. Risteli et al. [388] found that the residual activity of lysyl hydroxylase in EDS VI fibroblasts (case 8) was 10% using underhydroxylated chicken collagen I as substrate but that it was as high as 35% using collagen IV from mouse sarcoma. The previously mentioned observation that the underhydroxylation of lysyl residues of CNBr-derived peptides is not uniform [367] could also be explained in this way.
4. Tissue differences in critical cofactor concentrations.
5. The existence of multiple forms of lysyl hydroxylase. This possibility may be supported by the unpublished results that lysyl hydroxylase activity in platelets from the two original patients was normal (cited in [367]) and the observation that cultured osteoblasts express a relatively higher residual activity than fibroblasts [369]. The urinary excretion of pyridinolines (see below) strongly indicates the existence of a lysyl hydroxylase activity other than the "classic type" [427]. Whether the isoform lysyl hydroxylase 2 (LH2), with its two tissue-specific splice forms, LH2a and LH2b [428], encoded by *PLOD2* located at chromosome region 3q23-q24 (MIM 601865) [429], is responsible for a substantial amount of the hydroxylysine formed is not clear because its tissue distribution has not yet been sufficiently studied, although it has been suggested that PLOD2 is associated with lysine hydroxylation in the nontriple-helical domains of collagen I in bone [430]. The same uncertainty holds true for isoform 3, lysyl hydroxylase 3 (LH3), encoded by *PLOD3* (MIM 603066) at

chromosome region 7q36 [431,432] — which has interestingly, in addition to lysyl hydroxylase activity, collagen glucosyltransferase activity [433] — and the putative lysyl hydroxylase 4 (LH4); all four isozymes are highly homologous at the C-terminal end and other parts of the molecules [431,432] and seem to be derived from an ancestral gene by two duplication events [434]. No differences in catalytic properties are found between the recombinant lysyl hydroxylase 3 and 1 isoenzymes using an artificial substrate, but the data do not exclude the possibility that differences might exist with respect to the hydroxylation of different collagen types [432]. It is possible that a deficiency of lysyl hydroxylase 2 and 3 isoforms may lead to some other variant of EDS or to some other heritable connective tissue disorder such as Bruck syndrome (see Chapter 26, Part IV, this volume).

6. The questions of why mRNA levels for LH1 do not correlate with lysyl hydroxylase activity measured in cells (R. Myllylä, unpublished data, cited in [431]) and why removal of the most conserved portion of LH1 does not totally abolish the enzyme activity [395] remain open.

The pathophysiology of this disorder is becoming clearer. Whereas early studies found no pyridinolines in normal skin [422], Pasquali et al. [435] re-examined skin, the major organ affected in EDS VI, tendon, and bone from controls and patients; the total amount of pyridinolines in patients was only ~50% of normal in skin but normal in tendon and bone, although the ratio of LP to HP was increased in the three organs. Therefore, although a qualitative abnormality in pyridinoline cross-links occurs in all tissues, only the skin of patients with EDS VI has reduced amounts of total pyridinolines, with absent hydroxylysyl pyridinoline. In long-term cultures containing ascorbic acid of fibroblasts from patients with EDS VI, pyridinium cross-links, when present, had a greatly increased LP to HP ratio (6.39 ± 3.86 versus 0.22 ± 0.10 in controls), comparable to that determined in urine from patients and controls, respectively [436] (see below)[8].

It appears that the solubility of collagen in denaturing solvents is inversely proportional to its residual content of hydroxylysine. Dermal collagen with a low (5% of normal) content of hydroxylysine is excessively soluble in 4 M $CaCl_2$ or 9 M KCSN [362,374], whereas collagen from bone (10–20% of normal hydroxylysine content) and cartilage (90% of normal hydroxylysine content) are extractable in these solvents in only moderately increased or normal amounts, respectively [362]. Because of the Amadori rearrangement and the formation of ketoamines, cross-links derived from hydroxylysine aldehydes are chemically more stable *in vitro* than those derived from lysine aldehydes, but this does not necessarily imply greater stability *in vivo*. Eyre and Glimcher [365] found an abnormal profile of reducible cross-links in skin and bone collagens, but again it is not clear how this is related to the mechanical weakness of the connective tissues because the lysine aldehyde-derived cross-links should have made equally effective intermolecular bonds. Two nonreducible trifunctional collagen cross-links, lysyl pyridinoline and hydroxylysyl pyridinoline, based on a 3-hydroxypyridinium ring, are derived from hydroxylysine and its aldehyde. Indeed, Eyre [370] has found decreased levels of the pyridinoline cross-links in the annulus fibrosus of a patient with EDS VI and the presence of a newly observed, more basic hydroxypyridinium compound that could be a lysine analog of the normal compound. It was shown that the ratio of total lysyl to hydroxylysyl pyridinolines in bone of case 8 (legend to Fig. 22) was 11.9 and 12.5 instead of 0.13 and 0.25 as in controls [389,435].

In EDS VI patients, the skin is unusually thin. This most probably is due to a reduced amount of collagen relative to elastin because the ratio of hydroxyproline to desmosine is only 1/4 of normal [365]. Why the amount of dermal collagen is reduced in these patients remains speculative but could be explained by its higher solubility, which favors rapid turnover and degradation. Bones are more radiolucent; osteoporosis seems to be a direct consequence of the qualitative change in pyridinolines and their glycosides in an as yet undefined manner and may also be enhanced by epigenetic factors such as muscular hypotonia and poor physical activity rather than to the underlying molecular cause (cases 19, 20; Fig. 23d).

Finally, it remains to be emphasized that residual enzyme activity and dermal hydroxylysine content correlate poorly with the severity of the phenotype. This is best exemplified by certain patients with EDS VIB, such as those described by Steinmann et al. [88,379].

Genetics

EDS VIA is inherited as an autosomal recessive trait. This is supported by the occurrence of affected siblings from unaffected parents (legend to Fig. 22), by the occurrence of affected children from consanguineous parents (cases 7, 8, 13, 19 and 20, 22 and 23, 24, 28 and 29, 50 and 51) and by there being intermediate enzyme activity in obligate heterozygotes who are clinically normal. However, in some parents, heterozygosity cannot be established using the usual enzymatic assay (father of cases 1 and 2, parents of case 5, father of case 11). Therefore, the disorder in the corresponding patients was thought to be most probably due to compound heterozygosity because it is the rule rather than the exception in very rare autosomal recessive disorders when there is no parental consanguinity, until it was discovered that the Alu–Alu repeats lead to frequent duplication events (legend to Fig. 22). The autosomal recessive mode of inheritance of EDS VIB is based only on formal genetic considerations [88,92,409,410] cases 4 and 5 in [383,411,440].

Diagnosis

The clinical diagnosis is still generally suspected very late and only after a negative workup of neuromuscular disorders [395,398,399]. This is mainly due to the rarity of the disease and its unfamiliarity to most physicians.

[8]Until recently, it was not known how pyridinoline cross-links are formed in cases such as cases 19 and 20 with proven absent activity of the "classical" lysyl hydroxylase [427]. Indeed, not only is lysyl pyridinoline formed — in excessive amounts, apparently in proportion to the decrease in hydroxylysyl pyridinoline — which requires hydroxylysine in telopeptides, but also some hydroxylysyl pyridinoline, which requires hydroxylysine within the triple helix, is formed as well. The most plausible explanation for pyridinoline formation is the existence of the predicted N-telopeptide-specific lysyl hydroxylase [437,438], which, however, has been shown to be bone-specific [430,439]. Furthermore, such an observation implies an alternative source of hydroxylase activity for at least some triple-helical region lysyl residues in collagen as well as the telopeptide hydroxylase activity [427] (for details regarding lysyl hydroxylase isoforms, see the text).

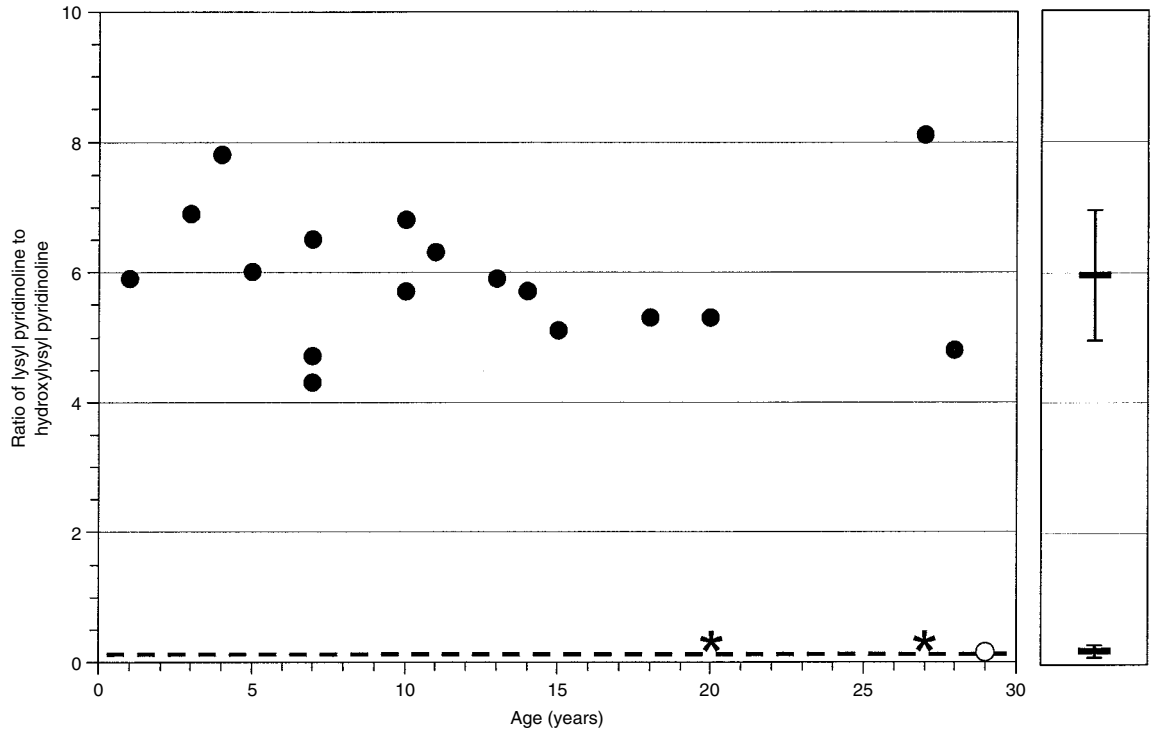

Figure 26. Urinary pyridinolines in patients with kyphoscoliotic type of EDS (EDS VI) and controls. The ratios of urinary total lysyl pyridinoline (LP) to total hydroxylysyl pyridinoline (HP) are given for each of 17 individuals with EDS VIA (•) as a function of age and compared with the mean of those of controls (▬ ▬) (**left panel**). Means of both groups of all ages are shown in the **right panel** and are 5.97 ± 0.99 (±1 SD, range 4.3–8.1) for EDS VIA and 0.2 ± 0.1 (±1 SD, range 0.1–0.4) for controls. The intraindividual variation of the ratio in 14 urinary samples collected over a time span of 7 weeks by one of the EDS VIA patients, T.O., was small (5.64 ± 0.31, range 5.21–6.22) [442]. The ratio in the female patient with EDS VIB (○, [88]), however, was 0.15 and indirectly confirmed the normal activity of lysyl hydroxylase [379]. The symbols (*) indicate two of the three patients studied with alkaptonuria.[9]

Note: the urinary pyridinoline ratio is independent of age and distinguishes both groups without overlap (for further comments, see Footnote 9).

Sometimes, confounding factors or unrelated associated diseases [398] detract from its recognition.

(1) The recommended, simple, reliable, and noninvasive laboratory test is the measurement by HPLC of total urinary lysyl pyridinoline ("deoxypyridinoline") and hydroxylysyl pyridinoline ("pyridinoline") cross-links after hydrolysis, a test that has a very high degree of sensitivity and specificity [389,427,435,441]. The ratio of the two compounds is in an abnormally high, narrow range, 5.97 ± 0.99 (mean ± 1SD; range 4.2–8.1) in 17 proven cases, as opposed to the low, narrow value of 0.20 ± 0.10 in controls, and is age-independent [442] as it is in controls [425] (Fig. 26). Obligate heterozygous parents have normal values [427]. Furthermore, this high ratio is not observed in other inherited or acquired collagen disorders, and the normal ratio is not changed by ascorbate or penicillamine and is only minimally influenced by renal dysfunction [441][9].

(2) The determination of the hydroxylysine content of dermis freed from the epidermis using an amino acid analyzer following hydrolysis [88,445] is also easy and quick, although more invasive. The results may be expressed as lysyl residues/1,000 amino acid residues (normal mean 3.85 ±

[9]The urinary total lysyl pyridinoline (LP) to hydroxylysyl pyridinoline (HP) ratio is unchanged in alkaptonuria (see Fig. 26) and under ascorbate and penicillamine treatment; however, it is abnormally low in Bruck syndrome (MIM 259450, [439]).

Purified lysyl hydroxylase has been reported to be inhibited by homogentisic acid in a linear, noncompetitive, and reversible way, with a K_i of 120–180 μM, and biosynthesis of hydroxylysine-derived intermolecular collagen cross-links in organ cultures of embryonic chick calvaria was inhibited by homogentisic acid in a dose-dependent manner [443]. The authors speculated that these results may explain the predilection of alkaptonuric complications for hydroxylysine-rich tissues such as articular cartilage, heart valve, vascular wall, and bone. To address the question of potential inhibition of hydroxylation of helical and nonhelical lysyl residues by homogentisic acid and related metabolites, we measured urinary total lysyl pyridinoline and hydroxylysyl pyridinoline in three alkaptonuric adult individuals, the oldest one symptomatic (M.Y.) and the two younger ones asymptomatic (A.A., G.A.-L.). Pyridinolines were normal in total amounts excreted and relative proportions (i.e., 0.16–0.18) [444]. These results imply that under *in vivo* conditions the claimed inhibition of lysyl hydroxylase by homogentisic acid or its derivative benzoquinoneacetate seems not to be operative, at least not in the organs that are the main source of urinary pyridinolines.

An 11-year-old girl (P.J.) with Wilson disease had an unchanged urinary LP to HP ratio of 0.22 before and after 16 months of treatment with penicillamine 3 × 300 mg daily; the ratio was 0.16 after a 12-month period in which penicillamine was replaced by oral zinc (100 mg/kg body weight) and 0.15 after a 12-month period of combined treatment with the same doses of zinc and penicillamine.

For details regarding the lack of influence of ascorbate on the urinary LP to HP ratio, see "Treatment" in EDS VI.

0.42, range 3.0–4.24, $n = 8$), as the ratio of hydroxylysine to hydroxyproline (normal mean 0.042 ± 0.006, range 0.033–0.047, $n = 8$), or as the ratio of hydroxylysine to lysine (normal mean 0.15 ± 0.02, range 0.11–0.18, $n = 8$) (values calculated from Steinmann et al. [88]).

(3) The determination of enzyme activity in cell extracts is done on a research basis only. The assay is not very sensitive and requires fresh, biosynthetically [^{14}C]- or [^{3}H]-lysine-labeled unhydroxylated collagen (protocollagen) prepared from embryonic chick calvariae or tendon cells as a natural substrate [418]. Because enzyme activity depends on cell density [367], the specific activity of the substrate, and cofactor composition, appropriate control cells have to be included in each assay. The results may be expressed as the amount of hydroxy[^{14}C]lysine formed, as the amount of tritium released, determined as [$^{3}H_2O$], or as the extent of decarboxylation of 2-oxo[1-^{14}C] glutarate, per number of cells or μg of protein in the cell extract or, preferably, as the ratio of lysyl hydroxylase activity to prolyl hydroxylase activity, the latter serving as a reference enzyme [418,432].

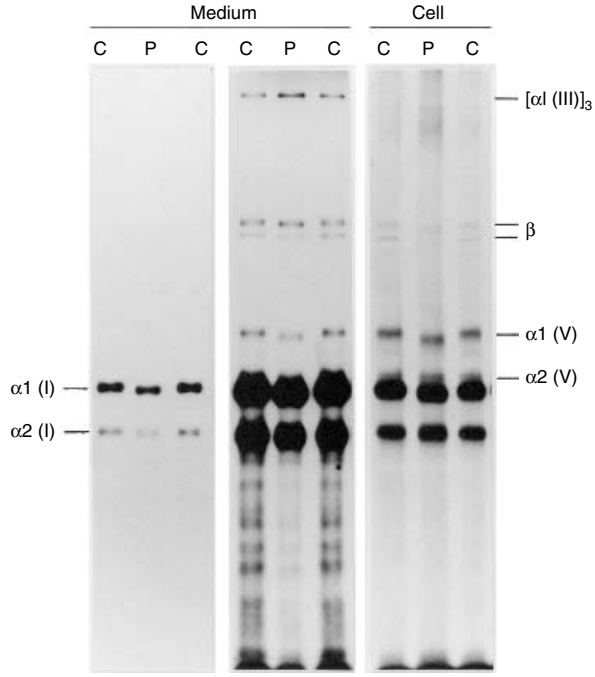

Figure 27. Lysyl residues in collagens from patients with kyphoscoliotic type of EDS (EDS VI) are underhydroxylated. Pepsin-treated radiolabeled procollagens from medium and cells synthesized by fibroblasts from case 23 with EDS VIA (P) and two controls (C) were electrophoresed on a 5% SDS-polyacrylamide gel, processed for fluorography, and exposed to x-ray films for 3 hours (**left panel**) or 7 days (**middle and right panels**). The α1(I), α2(I), and α1(V) chains and the β11 and β12 components from the patient's cells migrate slightly faster than those from the controls; the faster electrophoretic mobility is not apparent in the large collagen III molecules consisting of three disulfide-linked α1(III) chains but is obvious after reduction to free α1(III) chains (not shown). This is an indirect demonstration that collagens are underhydroxylated. Similar results were obtained after electrophoresis of collagen extracted from skin and visualized by silver staining; direct measurement of amino acids in dermis from the patient showed a marked deficiency in hydroxylysine (not shown) and proved the indirect conclusions derived from these observations. (Reprinted from Jarisch et al. [398] with permission.)

A synthetic tridecapeptide containing [^{3}H]-labeled lysine and corresponding closely to residues 98–110 of the collagen α1(I) chain has also been used as a substrate to determine residual activity in case 11 [390].

(4) It is difficult to demonstrate a decrease in the extent of hydroxylation of lysine residues in collagen produced by cultured fibroblasts from patients with EDS VI because the level of collagen hydroxylation in cultured cells is normally higher than it is *in vivo* (see above). However, a somewhat faster electrophoretic mobility of α chains on SDS-polyacrylamide gel electrophoresis is noticed due to relative underhydroxylation and underglycosylation (Fig. 27, [398]).

(5) Mutation analysis of the *PLOD1* gene will become easier and will be especially useful for prenatal diagnosis and research.

The diagnosis of EDS VIB is based so far on the typical clinical findings, together with a normal hydroxylysine content in dermis, normal lysyl hydroxylase activity, and a normal ratio of urinary pyridinolines as shown in the female of the sibs described in [88] (Steinmann et al., unpublished results) (Fig. 26).

Differential Diagnosis

EDS VI is a rare differential diagnosis in the neonate with severe muscular hypotonia; neuromuscular disorders will have to be considered first. Later, the brittle cornea syndrome [445], fragilitas oculi with joint hypermobility (MIM 229200, under which condition are included several patients also designated by McKusick [37] as having EDS VIB), and other causes of corneal rupture [410] have to be considered. Cameron et al. [446,447] reported EDS VI-like patients who presented with corneal thinning, keratoglobus, blue sclerae, corneal rupture, joint hypermobility, similarly affected sibs, and often consanguineous parents. Investigations by Steinmann et al. (unpublished results) revealed that several of the patients in these latter two reports were identical and that their normal urinary ratios of pyridinolines excluded EDS VIA. Whether this condition should be labeled as EDS VIB or instead brittle cornea syndrome, because of the fragility of the cornea as opposed to the sclera, remains open. Pemberton et al. [111] reported on six of the seven members of a three-generation family who were afflicted with retinal detachment; four of these six had features of EDS and one died of a dissecting aortic aneurysm. Biglan et al. [448] reported five patients from two families with keratoglobus, blue sclerae, hyperextensibility of the small joints, sensorineural hearing alterations, and mottling of the teeth; corneal perforations developed in seven of their ten eyes after minimal trauma.

Special Management and Genetic Counseling

Anticipatory management of individuals with EDS VI includes the following organ systems.

The musculoskeletal system. Referral to, and regular follow-up by, an orthopedic surgeon for management of kyphoscoliosis. Severe kyphoscoliosis may be resistant to bracing and require surgical intervention. Such patients may be at high risk for neurologic and vascular complications consequent upon surgery for scoliosis, necessitating careful perioperative evaluation and management [449,450]; halogravity traction may be indicated before surgery or between stages of surgery in patients with severe curves, but it must be instituted carefully to avoid brachial plexus injury and other

neurologic deficits [87]. Physical therapy should be instituted for older children, adolescents, and adults to strengthen large muscle groups, particularly at the shoulder girdle, and to prevent recurrent shoulder dislocation. Routine examination for inguinal hernia and surgical referral should be carried out as necessary. The management of other complications is similar to that in EDS I, II, and III (see above).

The eye. Routine ophthalmological examination for management of myopia and early detection of retinal detachment and glaucoma. Surgical repair of a ruptured eye globe may be difficult because of the friability of the scleral tissue (e.g., case 4). Primary vitrectomy permits the successful treatment of retinal detachment if a buckling procedure cannot be performed because of scleral atrophy. However, serious complications may occur and therefore other surgical procedures should be considered, such as pneumatic retinopexy, a temporary balloon, or a dura patch with episcleral pocket [451].

The cardiovascular system. Measurement of aortic root size by echocardiogram at the time of diagnosis or by the age of five years; it may be advisable to repeat an echocardiogram at five-year intervals even if the initial examination is normal. Patients with mitral valve prolapse or valvular insufficiency should follow guidelines for antimicrobial prophylaxis. Vigilant observation and aggressive control of blood pressure is necessary to reduce the risk of arterial rupture; vascular surgery is fraught with danger.

Others. The use of pharmacological doses of vitamin C, a cofactor of lysyl hydroxylase, has been investigated and found to result in an increased urinary excretion of hydroxylysine. Over a two-year period, one patient's wound healing and muscle strength improved and the corneal diameter increased; joint laxity, skin fragility, and the hydroxylysine content of the skin, however, did not change [381]. These results are at variance with those obtained with two pairs of sibs, cases 22 and 23, cases 26 and 27, and case 33 (legend to Fig. 22), who received vitamin C 2–4 g/day in two daily doses for two weeks. The ratio of urinary pyridinolines was indistinguishable in the six urinary specimens obtained from each during each of the periods of preloading, treatment, and washout (Steinmann et al., unpublished results)[9].

Genetic counseling and prenatal diagnosis. The parents of an affected child are obligate heterozygotes and the risk of recurrence of another affected child is 25%.

Krane et al. [33] observed that lysyl hydroxylase is readily detectable in normal cultured amniotic fluid cells, raising the possibility of prenatal diagnosis. Dembure et al. [391] found that lysyl hydroxylase activity in amniotic fluid cells, whether amniocytes (AF) or fibroblasts (F), corresponded to that in dermal fibroblasts, whereas prolyl hydroxylase activity varied markedly depending on whether F or AF cells were examined and in each case was only a fraction of that in dermal fibroblasts. This apparently differential expression of prolyl hydroxylase activity in amniotic fluid cells and dermal fibroblasts is not understood. Therefore, in a pregnancy at risk, lysyl hydroxylase activity in amniotic fluid cells was determined without reference to prolyl hydroxylase. Normal activity was found, and a healthy baby was born [391]. To our knowledge, chorionic villus biopsies, as opposed to cultured chorionic villus cells, have not been investigated as an enzyme source but have been used as a source of DNA [397].

ARTHROCHALASIS TYPE OF EDS — EDS TYPES VIIA AND VIIB (ARTHROCHALASIS MULTIPLEX CONGENITA) (MIM 130060)

Diagnostic Criteria

The arthrochalasic type of EDS is inherited as an autosomal dominant trait and is caused by mutations leading to deficient processing of the amino-terminal end of proα1(I) (EDS type VIIA) or proα2(I) (EDS type VIIB) chains of collagen I because of partial loss or complete skipping of exon 6. It is characterized as follows [39]:

- Major diagnostic criteria
  - Severe generalized joint hypermobility, with recurrent subluxations
  - Congenital bilateral hip dislocation
- Minor diagnostic criteria
  - Skin hyperextensibility
  - Tissue fragility, including atrophic scars
  - Easy bruising
  - Muscular hypotonia
  - Kyphoscoliosis
  - Radiologically mild osteopenia, occasionally fractures

Historical Introduction

Hass and Hass, in 1958 [452], suggested that there is a distinct entity of loose-jointedness, which they called arthrochalasis multiplex congenita (congenital flaccidity of the joints), which "represents, to some extent, the antithesis of arthrogryposis multiplex congenita", and which may occur with or without skin changes. This disorder was classified as EDS VII [2]. In 1973, three patients with EDS VII were reported who accumulated procollagen in their skin and tendon, and it was thought therefore that their disorder resembled dermatosparaxis in cattle (see below) [453,454]. Because it was felt that the accumulation of procollagen was most likely to be due to a defect in the conversion of procollagen to collagen, the activity of the converting proteinase was determined in the culture medium of fibroblasts from these patients and found apparently to be reduced to between 10% and 40% of normal [453,454]. However, the marked clinical and ultrastructural differences between the disorder in man and that in cattle, later reported also in sheep, led Steinmann et al. [35,36] to reinvestigate one of these patients. Analysis by SDS-polyacrylamide gel electrophoresis of collagen extracted from skin or produced by fibroblasts from the youngest of the three reported patients [453] (case 5 in Table 2) disclosed, in addition to α1(I) chains, the presence of pNα2(I)-like chains, in a 1:1 ratio with normal α2(I) chains, and an absence of pNα1(I), pCα1(I), and pCα2(I) chains. The pNα2(I) chain was resistant to pepsin, α-chymotrypsin, and N-procollagen proteinase, and, further, procollagen N-proteinase activity in cell extracts was normal. Rather than there being an autosomal recessively inherited N-proteinase deficiency as in dermatosparaxis, it was concluded that there was an extensive structural abnormality in that portion of the proα2(I) chain that is normally cleaved by N-proteinase (and other proteinases), and that the patient was a sporadic heterozygote arising from a new mutation because both parents, who were phenotypically normal, lacked the mutant pNα2(I) chain in extracts of both skin [36] and cultured fibroblasts (B. Steinmann, unpublished observations). The authors speculated further that, for sterical reasons,

molecules containing pNα2(I) chains would interfere with fibrillogenesis and cross-linking, thus leading to abnormal collagen fibrils and increased solubility of collagen. After the description of a similar patient, in whom the condition was due to a mutant pNα1(I) rather than pNα2(I) chain [455], the classification of EDS VII was subdivided into types VIIA and VIIB, respectively, depending on whether the α1(I) or α2(I) chain was affected [38]. The classification EDS VIIC (MIM 225410) is reserved for the procollagen N-proteinase deficiency analogous to dermatosparaxis in animals. Details of the patients discussed below are summarized, with case numbers and initials, in Table 2.

Clinical Findings

The hallmark of EDS VII is the involvement of ligaments and joint capsules. The disorder is characterized by severe multiple joint hypermobility, recurrent subluxations and luxations of both small and large joints, and ligamentous tears. All patients are ascertainable in the newborn period, although the correct diagnosis is still frequently only made years later. Congenital bilateral hip dislocation is the rule, and muscular hypotonia is prominent (Figs. 28–30); both factors predispose to the high incidence of breech presentation (cases 2, 7, 15, 22, 29; see Table 2) and delayed gross motor development. Short stature, if present, is due to severe thoracolumbar scoliosis and hip dislocation (cases 27, 29). In striking contrast to dermatosparaxis, the skin is only moderately affected; it is usually thin, velvety, and moderately extensible, and is occasionally affected by poor healing of wounds, with atrophic and hemosiderotic scars, especially in the adult. The facies appears to be normal, despite descriptions of a chubby appearance, epicanthal folds, hypertelorism, a depressed nasal bridge, and micrognathia (Figs. 28–30). Judging by six affected members from a three-generation family, intrafamilial variability is slight (case 1) [457].

The newly recognized occurrence of recurrent fractures, Wormian bones, and abnormally wide fontanelles (Table 2) indicates that the EDS VII phenotype includes bone changes and fragility similar to those reported in mild osteogenesis imperfecta [465]. Wormian bones were noted initially in one family (case 12), seducing the observers into calling into existence still another form of EDS [473], but have since also been observed in cases 4, 7, 16, and 23 (Table 2). X-rays of one of our patients disclosed bone changes such as discrete occipital horns, exostoses, a thickened calvarium, and Wormian bones [465] (Fig. 30; case 7).

Defect and Pathogenesis

The molecular defect in all 28 cases elucidated to date is remarkably homogeneous and results in the loss of exon 6, or part of it, of the mature mRNA coding for one of the α1(I) chains or the α2(I) chain (Table 2). The deleted peptide is the junctional segment (N-telopeptide) linking the N-propeptide to the major triple-helical domain. Loss of this short segment, 24 and 18 amino acid residues encoded by exon 6 in *COL1A1* and *COL1A2*, respectively, results in union of these latter domains and a lack of the N-proteinase cleavage site (Pro–Gln and Ala–Gln at positions 4–5), the critical cross-linking lysyl residue (at positions 13 and 9, respectively), and the cleavage sites for proteinases such as pepsin and α-chymotrypsin. The apparent paradox of a deletion yielding a larger than normal protein is thus resolved.

Studies by Wirtz et al. [476] showed that in EDS VIIB (case 17), the α1(I) N-propeptide, although cleaved from the α1(I) chain by the N-proteinase or (less likely) by nonspecific proteases, is retained by noncovalent association with the mutant pNα2(I) chain in native mutant collagen molecules, both *in vivo* and *in vitro* (Fig. 31); the α1(I) N-propeptide was readily demonstrable by western blotting of skin extracts, and rotary shadowing of pepsin-treated collagen produced in culture disclosed kinked molecules, which were longer than their normal counterparts (Fig. 31E). These data suggest that the retention of a partially cleaved but essentially intact N-propeptide in mutant collagen may play a critical role in the pathogenesis of this disease.

As a consequence of the persistence of the N-propeptide and/or the missing critical cross-linking lysyl residue, the solubility of collagen is increased three to four fold [36,453,470,477] (cases 5, 10, 17) and the ratio and pattern of β-components is abnormal [36,455,470] (cases 5, 10, 27). Only one-quarter of the normal content of histidinohydroxymerodesmosine, the major residue derived from skin collagen upon borohydride reduction, is found, but there is a similar to normal content of the mature cross-links, hydroxylysyl and lysyl pyridinoline, in fascia and bone [470]. Extracts of bone contain significantly more pNα2(I) than normal α2(I) chains. This solubility difference between bone and the soft tissues probably results from basic differences in the chemistry and molecular sites of their collagen cross-links [470].

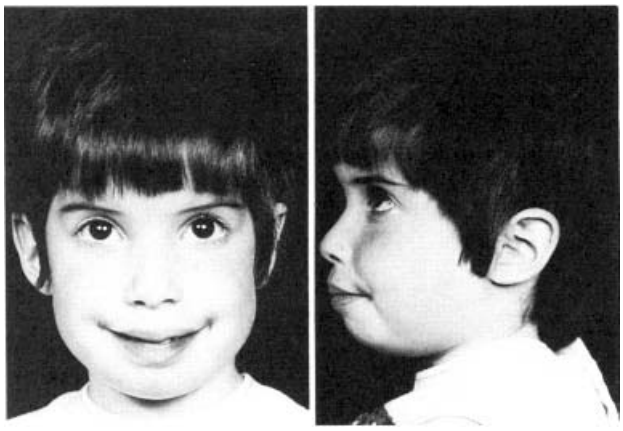

Figure 28. Arthrochalasic type of EDS (EDS VIIB). S.N. (28 Dec 1968), case 5 in Table 2, is the first patient in whom a structural mutation in proα2(I) chains was demonstrated [35,36]. At the age of 4 years, she had a ''dish-like'' face and mild retrognathia, which, however, cannot be considered typical of the syndrome because it is absent in cases 17 and 7 (Figs. 29, 30) and is not apparent in the patient herself at a later age.

She had a neuromuscular workup because of breech presentation and hypotonia at age 2 months, did not sit until age 1 year, stood with support at age 2 years, and when she began walking was noticed to have a waddling gait, which led to the diagnosis of bilateral hip luxation, necessitating several surgical interventions. The ligamentum teres of the right hip was found to be torn at surgery. She also had generalized, pronounced joint laxity.

Follow-up at age 22 years revealed an adult height of 157.5 cm (her target height was 158.5 cm); joint laxity and muscle strength had improved after puberty, whereas her skin had remained soft, velvety, and fragile and tended to form keloids. She was studying to become an elementary teacher (C. Nash, personal communication, 1991). Follow-up at age 30 years disclosed that she had had three luxations of the patella and two fractures of the femur after minor trauma in the preceding 8 years (S. Nash, personal communication, 1999).

Figure 29. Arthrochalasic type of EDS (EDS VIIB). W.A. (17 Feb 1982), case 17 in Table 2, a 12-month-old girl, born to healthy, unrelated parents from Libya. Her younger brother is healthy, and cultured amniotic fluid cells obtained during his delivery produced normal collagen I. (**a**) Subluxations of both knees, moderate thoraco-lumbar kyphosis. (**b**) Congenital hip luxations. (**c**) Marked hyperlaxity of the small joints. (**d**) Radiograph showing bilateral hip dislocation with lateralization and elevation of both femurs. (**e**) Thoracolumbar kyphosis and keloid formation at age 2.7 years, one-and-a-half years after successful operative correction of the hip dislocation. (a–c are reprinted from Steinmann and Gitzelmann [456] with permission.)

Figure 30. Arthrochalasic type of EDS (EDS VIIB). This 34-year-old subject with EDS type VIIB (M.F., case 7 in Table 2) was originally referred to us by Dr. Katarina Raslova (Bratislava, Slovakia). The patient was born from a breech presentation with dislocations of both hips and the left knee; although the hips were surgically reduced at the age of 2 years, he could not walk and had to crawl around on all fours until surgical correction of the left knee at age nine. Thereafter, he was able to walk without aid for a short period of time but soon had to use crutches because of recurrent dislocation of the right ankle, upon which surgical arthrodesis was finally performed. His skin has always been somewhat fragile, but wound healing is not delayed. His only internal complication has been a symptomatic bladder diverticulum, which was resected at age 17. In spite of these severe handicaps, he has an above-average intelligence and has led an independent life, doing much traveling; he drives an adapted car. He has had one unaffected child by a first wife and another healthy child by his second wife after negative prenatal diagnosis [260].

The photographs show the sagging skin around the eyes and mouth (**a**, **b**; the xanthoma in the left upper eyelid is probably due to coincident hyperlipoproteinemia); marked ulnar deviation of fingers II to V (which cannot be fully extended) and subluxation of the proximal interphalangeal joint of the right thumb (**c**); malposition and deformation of toes (**d**); arthrodesis has been performed on the right ankle joint. Note the normal stature (172 cm) and body proportions and the thin, hyperpigmented scars on both shins and knees (**e**).

X-rays show a peculiar combination of thickening of the calvarium with a pumice stone-like appearance, Wormian bones, calcification of the falx cerebri, and calcification of a tendon insertion in the occipital region (''occipital horns''; see arrow) (**f**, **g**); exaggerated lumbar lordosis with moderate osteoporosis of vertebral bodies (**h**); arthrotic degeneration of the knee joints with marked osteophyte formation at insertion sites on the patella (**arrows**) (**i**); reduction of articular cartilages and subluxation of several joints in both hands and feet (**j**, **k**). Note also the short metacarpals III–V, a small osteophyte (probably also in a tendon insertion) at the distal extremity of the ulna, and a previous fracture of the left fourth metatarsal.

Such radiological changes have not been observed in EDS VII so far, apart from Wormian bones (Tables 2 and 3), and may point to the natural history of the disorder as observed in this 34-year-old patient. ''Occipital horns'' and calcification of tendon insertions have been considered characteristic of EDS IX, now the occipital horn syndrome (see below and Chapter 14, this volume).

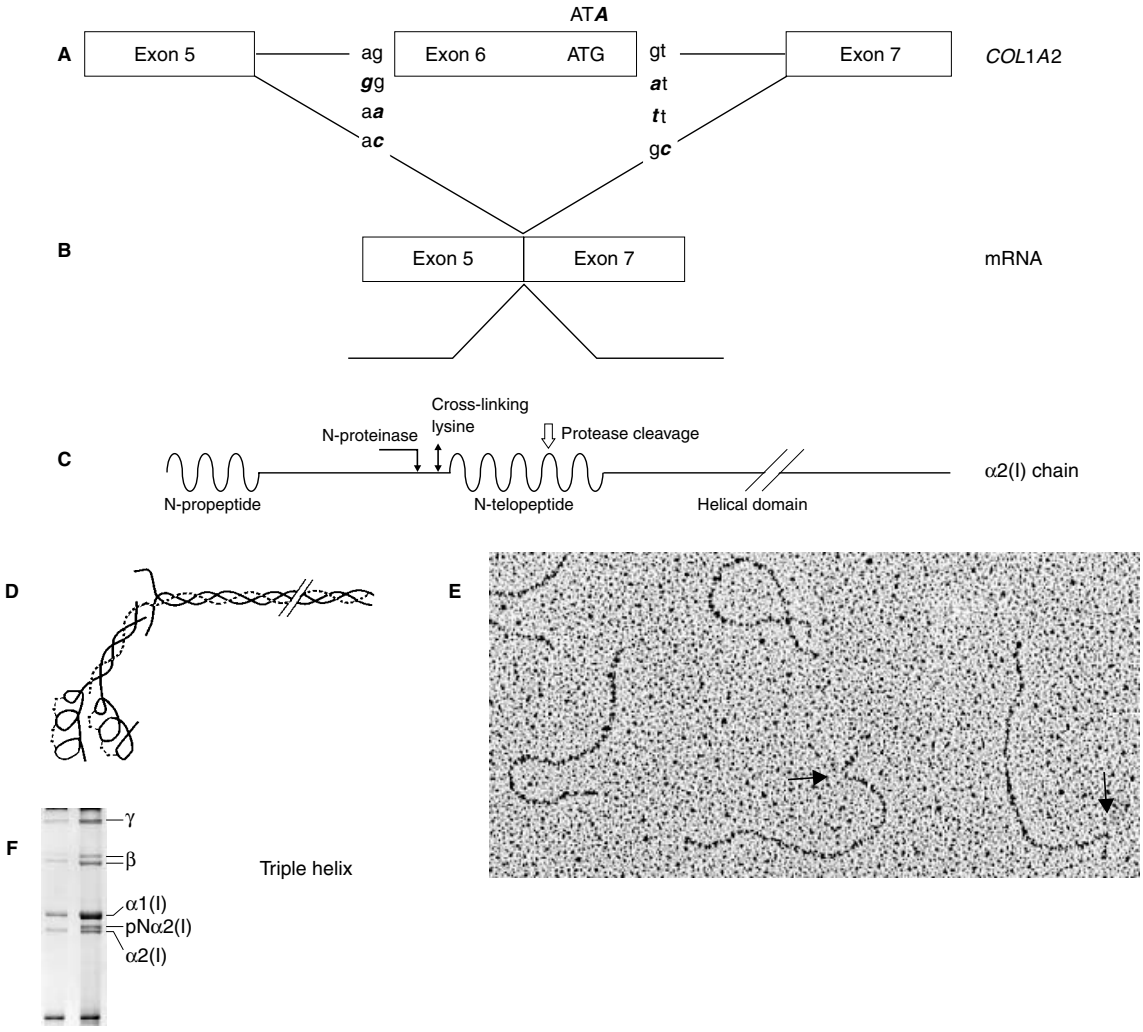

Figure 31. Schematic representation of the pathogenesis of arthrochalasic type of EDS (EDS VIIB). (**A**) Exon-intron structure of *COL1A2* with acceptor (ag) and donor (gt) splice sites adjacent to exon 6. In bold italics are mutations as listed in Table 2. (**B**) Skipping of exon 6 or deletion of exon 6 leading to fusion of exons 5 and 7 in the α2(I) mRNA. (**C**) The deletion of exon 6 removes the N-telopeptide, which contains the N-proteinase cleavage site, a lysine cross-link site, and protease cleavage sites. (**D**) Structural model of an abnormal collagen I molecule containing a mutant pNα2(I) chain, as indicated by a dotted line. Both cleaved N-terminal peptides of the α1(I) chains, as indicated by solid lines, are retained through triple-helical binding to the mutant N-terminal propeptide of the α2(I) chain and form a kink. (**E**) Rotary shadowing electron microscopy of pepsin-treated collagen produced by fibroblasts. Approximately one-half of the molecules present a kink (**arrows**) at their N-terminal ends and are somewhat longer than normal (312 vs. 297 nm). (**F**) SDS-polyacrylamide gel electrophoresis of collagen extracted by neutral salt from skin of patient S.N. [36] (**right lane**) and a control (**left lane**). The mutant pNα2(I) chain migrates more slowly than the normal α2(I) chain, and both chains are in a one-to-one ratio; pN collagen I, is more soluble than fully processed collagen I, as shown by the increased amount of its derived α, β, and γ chains. (Model in (D) adapted from experimental rotary shadowing data and reprinted from Wirtz et al. [476] with permission. (E) reprinted from Wirtz et al. [476] with permission.)

Two very interesting patients with EDS VIIB (cases 3 and 4) have been observed [458,460]. In both, a G to C change at the splice acceptor site of intron 5 activates a cryptic splice site in exon 6, removing 5 amino acid residues, including the N-proteinase cleavage site, but preserving the lysyl residue cross-link site. The fact that both mother and son, and father and daughter, respectively, were affected with typical EDS VII indicates that the persistence of the N-terminal propeptide is more deleterious than the absence of the lysyl residue or, alternatively, that in the presence of the propeptide, the lysyl residue is either not susceptible to lysyl oxidase activity or that following lysyl oxidase activity the lysyl aldehyde is unable to participate in cross-link formation for sterical reasons. However, studies of collagen solubility and cross-links have not yet been performed to answer this question.

A further instructive patient from a family with nine affected members in three generations was reported by Sippola et al. [488]. He presented features of both EDS VII and osteogenesis imperfecta (generalized osteoporosis,

platyspondyly, Wormian bones, blue sclerae, but no fractures) similarly to the patient shown in Figure 35, and carried a 19 bp deletion that caused skipping of exon 11 of *COL1A2* [489], thus deleting one of the lysyl residues involved in intermolecular cross-link formation. The presence of the shortened proα2(I) chain in procollagen synthesized by the proband's fibroblasts both lowered the thermal stability of the molecules and prevented or delayed their processing by procollagen N-proteinase [490]. The decrease in thermal stability was apparently not sufficient to produce exclusive degradation of the protein. Instead, the extreme laxity of joint ligaments in the proband was probably explained by the effect of the incompletely processed N-propeptide on fibril assembly [488]. Thus, the deletion disturbed both the helical domain and the cleavage site of the molecule, thereby resulting in the dual phenotype. The variable phenotypic expression in the proband's family was remarkable and may be explained by the possibility that the 19 bp deletion did not produce exon skipping *in vivo* with the same efficiency in everyone who inherited the defect [489], although *in vitro* the abnormal splicing was not changed by varying either the temperature of the fibroblast cultures or the salt concentration. In contrast, temperature-dependent alternative splicing has been demonstrated *in vitro* in case 5 [305] and subsequently in case 26 [484], but its significance *in vivo* remains unknown. A further case has been reported who had features of both osteogenesis imperfecta and Ehlers-Danlos syndrome [491].

We do not sufficiently understand why the abnormal collagen in humans produces major manifestations in joints and ligaments, whereas the skin, unlike that in dermatosparactic animals, is less affected; it may be that fibril formation is particularly disturbed by the pN-peptide where fibrils are tightly packed, as in tendons.

Genotype-Phenotype Correlation

Interfamilial and intrafamilial variability seems to be slight. In EDS VIIB, the heterotrimeric collagen I molecules consist of one population of normal collagen I and one population of abnormal collagen I containing the mutant α2(I) chain. In contrast, in EDS VIIA, three-quarters of collagen I molecules would be expected to be abnormal because they contain one or two mutant α1(I) chains, and thus the phenotype would be expected to be more severe than that of EDS VIIB. However, among the reported cases of EDS VIIA, three involve substitutions for the last nucleotide of exon 6 (cases 26–28, Table 2). This results in alternative splicing so that in part of the product the exon sequence from mRNA is deleted, whereas in the remainder normal splicing is permitted and the protein product contains an isoleucine rather than methionine at position 3 of the first Gly–X–Y triplet of the triple helix. The normally spliced product containing an amino acid substitution diminishes the dysfunctional effect of the three-quarters of abnormal molecules; this results in a less severe clinical phenotype that is indistinguishable from that of EDS VIIB. In contrast, in case 22, there is complete skipping of exon 6 from mutant proα1(I) chains; this leads to three-quarters of the collagen I molecules being abnormal and dysfunctional and explains the more severe phenotype, which almost resembles EDS VIIC, in which none of the collagen I molecules are processed [465].

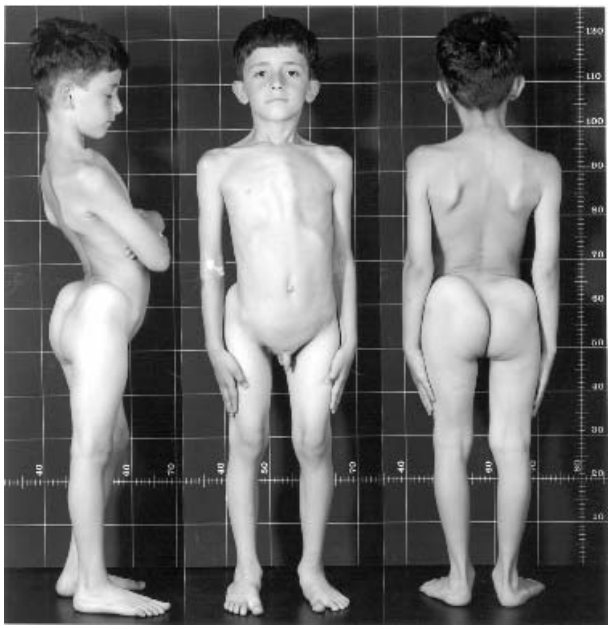

Figure 32. Arthrochalasic type of EDS (EDS VIID). A.P. (30 Sep 1993; case 31), at age 7 years, presents with bilateral hip dislocation, hyperlordosis, flat feet, pigeon-breast-like deformity, and scapulae alatae. His skin is moderately hyperelastic and soft, does not present abnormal scars, and has no tendency toward bruising. He has generalized joint laxity, muscular hypotonia, and a waddling gait due to congenital hip dislocation. The eyes and internal organs are normal, and height and weight are on the 50th centiles.

He is the fifth child of healthy, unrelated parents from Kosovo; the four older siblings are not affected. His birth and neonatal adaptation were normal, but it was noted that something was ''wrong'' with his hips; gross motor development was delayed.

Collagen fibrils in dermis were ultrastructurally normal in diameter and contour. The collagens produced by his fibroblasts were normal in amount and structure. These findings are similar to those in case 29 (see Fig. 33d) and unlike those observed in EDS VIIA, VIIB, and VIIC. He is therefore temporarily grouped as EDS VIID.

Hass and Hass [452] state that ''arthrochalasis multiplex congenita is a distinct clinical entity characterized by a multiple congenital flaccidity of the joints. It may be associated with laxity or hyperelasticity of the skin defined as Ehlers-Danlos syndrome, or it may exhibit hypermobility of the joints without involvement of the skin.''

Locus heterogeneity is exemplified by several patients (cases 29–34, Fig. 32) who are clinically similar to EDS VIIA/B but whose fibroblasts produce normal procollagen that is converted normally to collagen by pepsin or α-chymotrypsin [36]. Using the assay of Prockop and Tuderman [492], a somewhat lower N-proteinase activity has been determined, which reflects methodological problems rather than biological aberrations [36,461]. The normal structure of collagen I extracted from the skin of cases 29 and 31 and produced by fibroblasts, the absence of pNα1(I) and pNα2(I) chains in skin extracts, normal procollagen N-proteinase activity, and a normal electron-microscopic appearance of dermal collagen fibrils (Fig. 33d) clearly distinguish these patients from those with EDS VIIA and VIIB. It remains uncertain whether patients such as these are examples of EDS VII of unknown cause, temporarily called

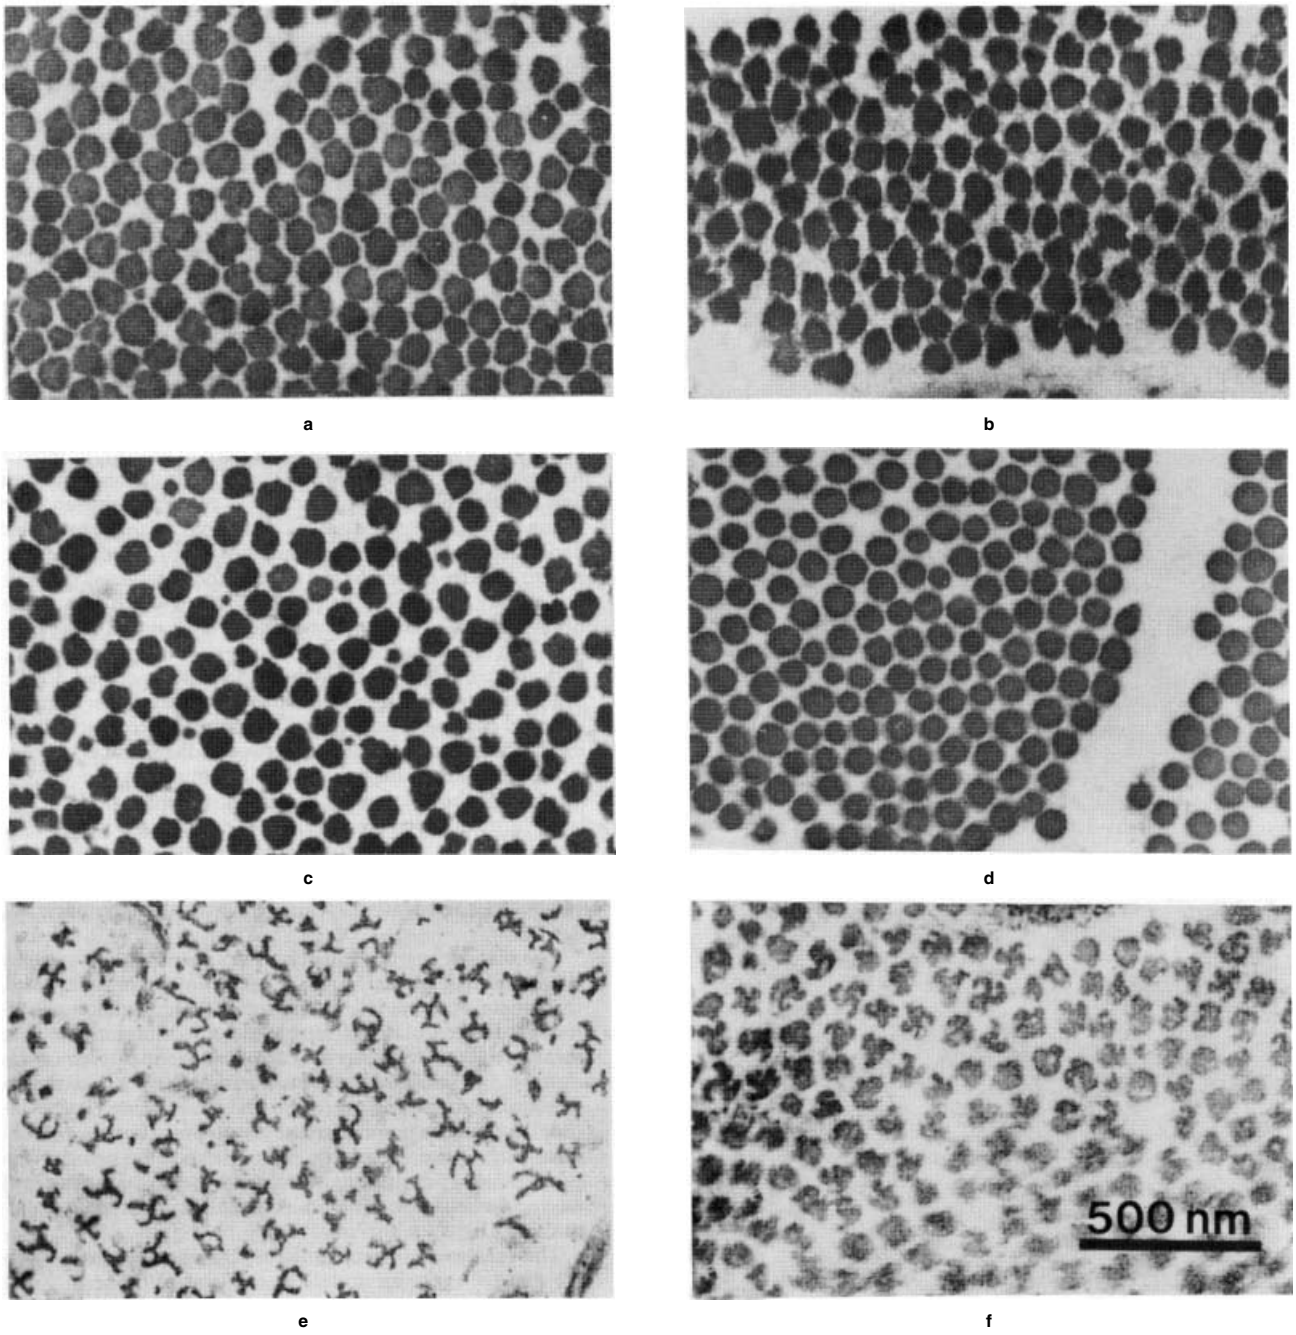

Figure 33. Ultrastructural appearance of collagen fibrils in the dermis of patients with arthrochalasic type of EDS (EDS VIIB and VIID) and in dermis and tendon of a dermatosparactic sheep. Electron-microscopic pictures of collagen fibrils in cross section from the dermis of patients with EDS VII (**a**–**d**), and the dermis (**e**) and tendon (**f**) of a dermatosparactic sheep. (**a**) Case 5, at age 10 years; (**b**) case 17, at age 1 year; (**c**) case 7; (**d**) case 29, at age 38 years (EDS VIID). Staining was with phosphotungstic acid and uranyl acetate, and the magnification is identical in all photographs. In the case of the patients, pictures were taken 0.5 mm below the epidermal-dermal junction, and the diameters of 1,000 fibrils were measured and are given below as mean ±SD.

In the three patients with defined EDS VIIB (**a**–**c**), the collagen fibrils are irregular in contour but have normal diameters with slightly increased variability: 89.0 ± 11.7 nm in (a), 86.5 ± 16.7 nm in (b); 79.5 ± 14.2 in (c). In contrast, both shape and diameter of the fibrils in the patient with EDS VIID (d) are normal and indistinguishable from controls (90.3 ± 12.4 nm).

The skin of the newborn dermatosparactic lamb was moist and thicker than normal, with a jelly-like consistency, while histologically the collagen consisted of loosely woven thin fibrils. On electron microscopy, the cross sections showed a multibranching appearance of the fibers, resembling ''hieroglyphics'' (**e**); longitudinal sections showed that the fibers had a twisted, ribbon-like appearance. In tendon, cross sections showed a more rounded appearance of the fibers with thicker and less-developed branches, particularly in areas where the fibers were packed more tightly together (**f**). (Figures a–d are unpublished pictures from Ursula Lüthi and A. Vogel, and Figs. e and f are from Fjølstad and Helle [493] with permission.)

EDS VIID, or whether they represent the extreme end of severity of EDS III. It may be of note that cases 29–31 have smooth, hyperelastic skin but without skin fragility.

Morphology

The skin collagen fibrils have a smaller and more variable diameter than normal. They are irregular in outline and also appear to be more loosely and randomly organized into fibrils resembling a loosely wound rope (Figs. 33a–c) [470,485]. A similar fibril outline is also evident in sections of fascia and decalcified bone [470]. All these changes, however, are much more subtle than those observed in dermatosparactic animals (see below) (Fig. 33e) and in cases 22 and 25, in whom three-quarters of collagen I molecules are abnormal.

Genetics

EDS VIIA and VIIB are inherited as autosomal dominant traits, and some of the sporadic cases have been shown to be heterozygous for a new mutation (Table 2). Mosaicism in the mother of case 12 is likely the cause of her milder phenotype as opposed to her affected children. The apparently higher incidence of EDS VIIB is puzzling but may have to do with differences in the structures of intron 6 in *COL1A1* and *COL1A2*.

The pedigree of case 30 (Fig. 6.15 in [2]) suggested autosomal recessive inheritance because of consanguinity of the parents and the presence of two apparently affected sisters. Re-evaluation, however, revealed that both sisters have normal joints, skin, and height and complain only about "troubles with the knees." It is therefore more likely that case 30 is a sporadic case also arising from a new mutation (B. Steinmann, own observation, May 1978).

Diagnosis and Differential Diagnosis

The diagnosis is first made on clinical grounds, supported by protein data pertaining to collagen extracted from skin or produced by fibroblasts (Fig. 31F), and proven by the demonstration of complete or partial loss of exon 6 in cDNA and of the mutation in genomic DNA. The existence of individuals with a clinical picture of arthrochalasis multiplex congenita but normal collagen I structure, normal procollagen N-proteinase activity (cases 29–34), and normal electron microscopic findings in skin (case 29, Fig. 33d) indicates further heterogeneity; these patients who do not fall into any one of the three type VII variants A, B, or C may temporarily be grouped as EDS VIID.

Congenital hip dislocation is also found in the Larsen syndrome (MIM 150250, MIM 245600), as an isolated disorder (MIM 142700), and in an as yet less well-defined disorder (i.e., dislocation of the hip, congenital, with hyperextensibility of fingers and facial dysmorphism) (MIM 601450).

The risk to healthy parents of having another affected child is small and due to the possibility of parental mosaicism. The mother of the four patients reported by Viljoen et al. [473] (case 12) was the least severely affected individual within the family and may represent a symptomatic mosaicism of the mutation in *COL1A2*, although the fibroblasts examined do not disclose any mosaicism; other of her cells, however, have not been investigated. Alternatively, her milder phenotype may simply be the expression of intrafamilial variability (G. Wallis, personal communication, 1991). The risk of an affected person transmitting the disorder is 50%, but prenatal diagnosis should be possible by either DNA or protein studies on a chorionic villus biopsy if the defect in the index case has been characterized. Biochemical analysis of a chorionic villus biopsy in a pregnancy at risk of the spouse of case 7 was normal and a healthy girl was born as predicted [260].

Management

The orthopedic outcome is often unsatisfactory because premature degenerative arthritis of the hips and other joints occurs.

The principal orthopedic problem in EDS VII patients is bilateral congenital dislocation of the hips. To gain an insight into the management of this problem, Giunta et al. [465] reviewed the treatments and their outcomes in 16 patients from 12 families. Several of the patients listed in Table 2 were not included because insufficient information was available from their published reports. Stable reductions were infrequently achieved following closed reduction with orthoses or hip spicas. Anterolateral open reductions with capsular plication, even in infancy, were also inadequate because most of the patients continued to have subluxated or dislocated hips. The poor outcome of the latter procedure is likely to be due to early stretching of the capsulorrhaphy sutures. In contrast, the addition of an iliac osteotomy of the Pemberton or Salter type with or without femoral osteotomy achieved some good results (cases 14, 17, 27).

From published results [494] and the findings of Giunta et al. [465], it appears that open reduction with capsulorrhaphy and iliac osteotomy, with the addition of femoral osteotomy in some cases, is required to achieve and maintain stable reduction. These requirements are similar to those shown to be necessary to achieve and maintain stable reduction in other laxity conditions such as Down and Larsen syndromes. As with the latter conditions, careful planning of osteotomy is required to ensure that adequate acetabular coverage of the femoral head is achieved in the functional positions of the limb [465].

Generalized joint hypermobility is worst in infancy, when marked muscular hypotonia accompanies the severe ligamentous laxity. Motor development is consequently slow, and aids such as knee-ankle-foot and ankle-foot orthoses are often required to stabilize the lower limb joints for standing and walking. As muscle tone improves, the knee-ankle-foot orthoses may be reduced to ankle-foot orthoses. Surgical procedures to stabilize the knees and the patellofemoral joints have been used occasionally. Orthotic stabilization is likely to be more reliable. Ankle or subtalar fusions have been undertaken in a few cases but, as shown in case 7, the arthrodesed joints need to be in an optimal position for this to be successful [465].

Recurrent and/or persistent dislocations, as well as hypermobility of upper limb joints, are also frequently disabling. Operative procedures appear rarely to have been undertaken in the upper limbs, and one would predict that capsulorrhaphy and osteotomy would not stabilize these joints [465]. Arthrodesis may be useful in stabilizing some small joints, such as the metacarpophalangeal joints of the thumbs, although fusion rates cannot be predicted.

Postural thoracolumbar kyphosis due to hypotonia and ligamentous laxity is a feature of infants (cases 16 and 17, Fig. 29). The spinal posture improves as the children gain in muscle power. However, structural scoliosis has been reported in eight cases (cases 2, 3, 7, 8, 9, 19, 26, 27). Spinal fusion was undertaken in cases 8 and 9, although few details are available concerning curve patterns and surgery. Spondylolisthesis of L5-S1 was noted in case 19.

The findings in the 20 molecularly proven cases of EDS VIIA and VIIB reviewed [465] show how difficult the

management is and how important early diagnosis may be. The homogeneous nature of the molecular defects allows laboratories with the appropriate expertise rapidly to establish the diagnosis, after which the clinical problems, in particular those relating to the dislocated hips, can be predicted. Adequate physical and occupational therapy and orthotic management can be given to assist with standing, walking, and activities of daily living. Appropriate surgical treatment of the dislocated hips should also diminish the frequency of hip redislocation, recurrent dislocation, avascular necrosis, and premature osteoarthritis. However, more experience correlating detailed orthopedic management and long-term outcome is needed before sound recommendations can be made [465].

Comment

In the initial study [453], it was found, and later confirmed [461], that affected fibroblasts produce more collagen in culture than normal cells. The authors speculated that the procollagen extension peptides might act as feedback inhibitors of collagen synthesis. Evidence in support of this hypothesis has been presented [495–497]. This is another example of findings in a disease leading to further general insight into biological control mechanisms.

DERMATOSPARACTIC TYPE OF EDS — EDS TYPE VIIC (MIM 225410)

Diagnostic Criteria

The dermatosparactic type of EDS is inherited as an autosomal recessive trait caused by deficiency of procollagen N-terminal proteinase as a result of homozygosity or compound heterozygosity of mutant alleles coding for the enzyme (in contrast to the arthrochalasic type, which is due to mutations involving the substrate sites of procollagen I chains) and characterized as follows [39]:

Major diagnostic criteria
- Severe skin fragility
- Sagging, redundant skin

Minor diagnostic criteria
- Soft, doughy skin texture
- Easy bruising
- Premature rupture of fetal membranes
- Large herniae (umbilical, inguinal)

Historical Introduction

Dermatosparaxis in man (see Table 3) has only recently been recognized and shown to be due to an enzyme deficiency, whereas in animals it was the first defect in collagen metabolism to be defined [507] (see "Animal Models and Lathyrism" below). An earlier suggestion of dermatosparaxis in man [453] was disproved by Steinmann et al. [36], who demonstrated a structural abnormality in the patient's proα2(I) chain, the substrate, rather than a deficiency of the enzyme, N-proteinase (see EDS VIIB above).

Clinical Findings

Clinical findings are summarized in Table 3. All six patients reported to date were born prematurely after rupture of the membranes, one of them (case 1) by Cesarean section because of breech presentation; he presented bilateral inguinal tears [498,499]. In all, the skin was soft, with a doughy feel, redundant, lax, and fragile. The skin was noted to bruise easily and avulsed from the underlying soft tissue after minor trauma; it was easily approximated, and healed well in a short time, with minimal scarring.

All patients had umbilical herniae and some dysmorphic features, consisting of micrognathia, puffy eyelids with excessive periorbital skin, sagging skin, and wide open fontanelles and osteopenia (Fig. 34). One had moderate joint laxity and had not yet walked at the age of 18 months.

Joint laxity seems to become a major clinical feature with increasing age, as illustrated by case 4, who had only a moderate degree of joint laxity as assessed over the first 3 years. Chondrodysplastic changes, however, seem not to be absent (see "Pathogenesis" below).

Genetic Defect

The defect is due to an autosomal recessively inherited deficiency of N-proteinase, as has been demonstrated by the direct measurement of enzyme activity and by indirect evidence such as pN-collagen extracted from skin or produced in fibroblast cultures, which could be cleaved by the addition of N-proteinase activity [502] or normal cell extracts [498], or, less specifically, other proteases [498,502].

Procollagen N-proteinase (ADAM-TS2, a disintegrin and metalloproteinase with thrombospondin repeats, EC 3.4.24.14, MIM 604539) is a large, neutral zinc metalloproteinase, which cleaves the amino-propeptides in the processing of pN-collagens I and II to collagens I and II, respectively. It has been isolated by affinity chromatography on immobilized collagen XIV [508]. The interaction between the enzyme and collagen XIV is highly specific, which suggests that collagen XIV might be a physiological ligand, the role of which might be to immobilize the enzyme in the close vicinity of collagen I fibers, thereby allowing the processing and subsequent polymerization of newly synthesized molecules under strict spatial control [508]. Partial amino acid sequences allowed the cDNA cloning of the enzyme. The N-proteinase consists of 1,205 amino acid residues with two sequences in the N-terminal domain that are substrates for furin-like enzymes; this suggests processing of the proenzyme to its mature form as is generally the case for metalloproteinases [509]. The enzyme is expressed in all tissues rich in collagen I [509]. The human gene is located in chromosomal region 5q35 [510].

Mutation analysis of the six cases is shown in Table 3 [500]. Five of them are homozygous for the identical mutation, although their ethnic backgrounds differ: three are Ashkenazi Jewish, one is Hispanic/Mexican, and one is from an American family of undetermined background.

Pathogenesis

Skin is more severely affected than other collagen-rich tissues (tendons, blood vessels, bones, and cartilage), and this is correlated with the extent of morphological alteration of collagen fibrils. This suggests that another enzyme, which has tissue-specific expression, can remove the amino-terminal propeptides of procollagens I and II (the latter especially in cartilage), although at a lower rate than the N-terminal proteinase.

The fragility of the skin is directly related to the concentration of precursors among the collagen polymers. The persistence of the N-terminal propeptide is known to prevent the use for intramolecular and intermolecular cross-linking of the lysyl residue located in the N-telopeptide. As a consequence, the skin collagen content in one case studied was lower than normal, and the extractability of collagen under nondenaturing conditions increased [502]; this indicates defective formation of stable intermolecular

Boy with Ehlers-Danlos syndrome type VIIC. **Top left**, groin showing bilateral fissures at birth; **top right**, profile of face at 18 months of age (note the vellus hair and micrognathia); **bottom left**, frontal view at 18 months of age showing the symmetrically shortened extremities, prominently visible vasculature, multiple ecchymoses, excess skin folds, blue sclerae, and umbilical hernia; **bottom right**, closeup of left foot showing hyperconvex nails. (Reprinted from Petty et al. [501] with permission.)

cross-links, as observed in dermatosparactic animals [511]. The pattern of collagen polypeptides extracted from the skin of cases 1–3 (Table 3) comprised a large proportion of pNα1(I) and pNα2(I) chains in a 2:1 ratio, with a small proportion of completely processed α(I) chains [498,502]. The presence of apparently correctly processed collagen I is due to either residual enzyme activity or the presence of a poorly efficient alternative proteolytic pathway. Extracted pN-collagen I treated with purified N-proteinase or pepsin can be converted to collagen consisting of normal α(I) chains [502]. Extracts of normal cells cleaved procollagen I synthesized by cells from patients, demonstrating that the enzyme, not the substrate, was defective [498]; in contrast, cultured fibroblasts from three patients studied

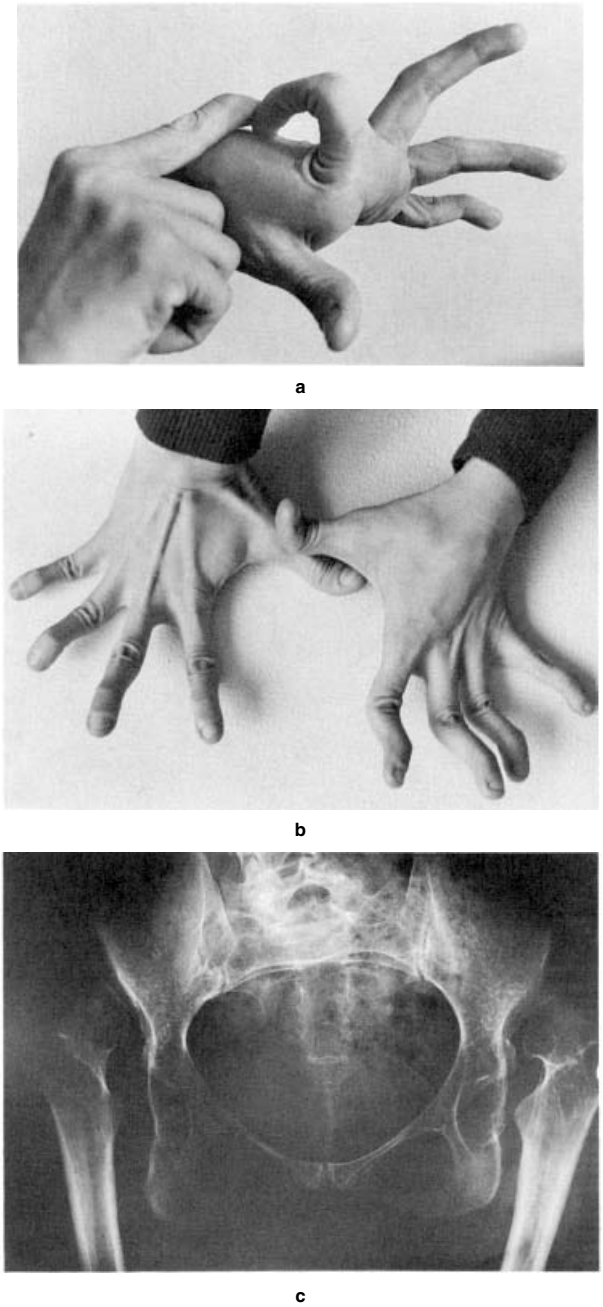

Figure 35. Marked joint laxity and osteoporosis. This female patient, in her forties, has marked joint laxity (**a**, **b**) and severe scoliosis requiring Harrington rodding. X-rays showed untreated bilateral congenital hip dislocation (**c**) and diffuse osteoporosis. She has had some fractures, suggesting that she is affected by an overlap form between EDS and osteogenesis imperfecta. She is not married and has refused a skin biopsy (own observation). Two families with similar findings have been described [488,489,491].

cleaved the N-terminal propeptides from procollagen I poorly [498,502], and collagen synthesis in cells from case 3 was increased [502], probably because of a lack of feedback inhibition by the released N-terminal propeptides, as shown in studies on cells derived from animals [495–497,512].

The accumulation of pN-collagen in tissues, mainly the skin, leads to disturbed fibrillogenesis. Instead of forming bundles of polymers running in parallel, the procollagen fibrils are poorly oriented and the space between them is much enlarged with numerous cells, among them mast cells [503], and may contain an increased amount of hyaluronate and thus water, as in dermatosparactic animals [513]. Transmission electron microscopy of the dermis reveals ribbon-like collagen fibrils and hieroglyphic profiles (Figs. 33e and 33f) characteristic of those observed in the skin of dermatosparactic animals [498,502,505,506,514]; (for a scanning electron micrograph of dermal collagen, see [498]). Collagen fibrils of the sheets around vessels, nerves, and adnexa are similarly affected, whereas the dermo-epidermal junction basement membrane and anchoring fibrils appear normal, indicating that collagens IV and VII are not involved [498], thereby indicating substrate specificity of the N-proteinase.

Watson et al. [474] have proposed a model of fibril formation in EDS VIIC in which the intact N-propeptides are located at the surface of the hieroglyphic fibrils. Partial cleavage of the *in vitro*-synthesized abnormal collagen by N-proteinase allows the N-propeptide to be incorporated within the body of the fibrils with conversion of the hieroglyphic outlines to the ragged outlines characteristic of EDS VIIA and VIIB.

Skin fragility seems to decrease as a function of age, as exemplified by case 4, a tendency also observed in animals. This may be explained by the increasing density of collagen fibers in skin during development and the slower collagen turnover as observed at a more advanced age in animals [515].

Diagnosis and Differential Diagnosis

The diagnosis is suspected clinically. The ultrastructural findings of skin collagen fibrils are typical but may be almost indistinguishable from those in certain patients with EDS VIIA (see case 22 in Table 2). It must be emphasized that light microscopy does not allow detection of these changes. This is well-demonstrated by case 4 (Table 3), where routine paraffin sections of samples of skin and tendon taken on several occasions showed no remarkable features, whereas later, samples reprocessed for electron microscopy from paraffin blocks showed hieroglyphic collagen fibrils in dermal samples and, to a lesser extent, in tendon [506]. Biochemical confirmation is based on the electrophoretic demonstration of pNα1(I) and pNα2(I) chains of collagen I extracted from dermis in the presence of protease inhibitors or detected in fibroblast cultures in the presence and/or absence of added dextran sulfate [487]. Determination of N-proteinase activity is performed on a research basis only. However, direct mutation analysis has become feasible (Table 3) [500] and will allow prenatal diagnosis.

Comment

Dermatosparaxis represents a good example of the unity of biomedical research. The study of dermatosparaxis was initiated by clinical veterinarians, taken up by biochemists and cell biologists with the help of physical chemists, and continued by clinicians and molecular biologists to determine the cause of the disease in man. This collaboration has also largely contributed to the better understanding of the physiologic processes involved in collagen fibrillogenesis and the regulation of collagen biosynthesis.

OTHER TYPES OF EHLERS-DANLOS SYNDROME

The number of distinct types of EDS that have already been identified indicates great heterogeneity, but clearly that heterogeneity is not exhausted by the most widely used classification and presents a pasture for splitters — although the most recent classification reverses that trend. There is no place for the passionate defense of a purely clinical classification, which can only provide the framework for a further investigation of clinical problems. The question is whether a particular set of findings represents merely a chance association or whether they can be understood either as having a cause-and-effect relationship or as sharing a common pathogenesis.

Ehlers-Danlos Syndrome Type V — X-Linked EDS (MIM 305200)

The existence of EDS V (Table 1) as a separate entity is more than questionable [39]. Its phenotype is not well-defined because it is based on only eight members of two British families demonstrating apparent X-linked inheritance [136] and one additional case traced during a follow-up of these two families [129]. All nine patients had marked dermal extensibility but only mild to moderate tissue fragility and mild scarring and bruising. Spheroids and molluscoid pseudotumors were also found. The skin was of a soft and doughy consistency. Articular laxity was mild and most evident in the digits, yet orthopedic complications (effusions, recurrent sprains, arthritis) were frequent. It may have been noteworthy, at least to the authors, that all affected persons in both families had red hair [129]. In one 53-year-old affected man, a skeletal survey excluded occipital horns and other skeletal abnormalities, and serum copper and ceruloplasmin in affected males and obligate carrier females were normal [129]. The disorder is thus clearly different from the occipital horn syndrome (EDS IX) and is a nuisance rather than a handicap to the affected persons [129].

Di Ferrante et al. [516] reported a 9-year-old boy and two maternal cousins as having EDS V. All had congenital heart disease, floppy mitral valve syndrome, which in one of them progressed to severe insufficiency and death, herniae, short stature, stretchable skin, moderate joint hypermobility, musculo-skeletal weakness with dorsal kyphosis, genu valgum, and flat feet. An atrial septal defect with left-to-right shunt, and floppy mitral and tricuspid valves with significant regurgitation, were present. The nosology of this disorder remains uncertain, but in our view it more likely belongs to an X-linked cardiovascular disease type (MIM 314400; [517]).

Other patients with EDS V have been mentioned [518], but no clinical or genetic data were given, and probably more sporadic cases have also been reported uncritically and erroneously as EDS type V [519–521].

The distinction of EDS V from autosomal dominant EDS is based solely on its apparently X-linked recessive mode of inheritance in two pedigrees. However, pedigree 2 [129,136] could be explained, as originally critically discussed [136], by autosomal dominant inheritance with incomplete penetrance in the supposed carrier female (II/5 in [129,136]). This view is fostered by the follow-up revealing that her affected son (III/1) has two children with minor stigmata of the syndrome: the 21-year-old daughter has generalized joint laxity and normal skin, the 19-year-old son has soft, extensible skin but no scars or joint laxity. In pedigree 1, the putative heterozygote mother (III/2 in [129,136]), when re-examined at the age of 60 years, had recently undergone surgery for degenerative arthropathy of the knee, which had been ascribed to articular instability. This problem, together with slow healing at the operation site, could represent minor syndromic manifestation in a female heterozygote or, again, incomplete penetrance. Close linkage to Xg blood groups and color blindness was excluded in the two families [136], and cytogenetic investigation, including high-resolution banding, yielded normal results [129]. X-linked inheritance therefore remains questionable, and thus the existence of this disorder as a distinct entity remains to be proven.

The biochemical defect was thought to be a deficiency of lysyl oxidase (protein-lysine 6-oxidase, EC 1.4.3.13; MIM 153455), the gene for which was later shown to be located on chromosome 5q23.3-q21.2 [522], a finding that is at variance with claimed X-linked inheritance of the disorder. The observation of low levels of lysyl oxidase in skin and other tissues from mice with an X-linked connective tissue disorder [523,524] was the stimulus for Di Ferrante et al., who reported a deficiency of lysyl oxidase in one patient [516]. However, methodological flaws make their measurements unreliable; lysyl oxidase, which is almost entirely secreted in culture, was estimated in fibroblast cell layer homogenate; furthermore, the activity in culture medium was measured after lyophilization and "redissolution" of the enzyme, which, however, is poorly soluble in buffers lacking urea; in the absence of any clinical or biochemical follow-up report, there remains a conspicuous silence about the nature of the disease in their patient, who also had two maternal cousins similarly affected. Siegel et al. [525], using appropriate techniques, could not confirm this result in four of the original patients reported [136]. They found greater than normal activity of lysyl oxidase and no diminution in the amount of immunologically cross-reacting material in extracts of skin from patient J.W. (subject III/2 in family 2 [136]), normal proportions of reducible cross-links in skin from all four patients studied (III/1 and III/2 of family 2 and IV/1 and IV/4 of family 1 [136]), and normal amounts of thermally stable cross-links as judged by the normal proportion of high-molecular-weight chains on SDS-polyacrylamide gel electrophoresis. Siegel et al. [525] also pointed out that an absence of cross-links would lead to continuous extension of the fibers as they slipped past each other under tension until rupture occurred and that in this situation there would be no restoring force, in contrast to what is found in EDS. Ultrastructural studies showed changes that were not qualitatively different from those in the skin of patients with EDS I or II [183]; other changes in undefined patients have been reported [518,519]. Note that Fig. 7 in [526] refers erroneously to a patient with EDS V instead of EDS IX, the occipital horn syndrome (K. Holbrook, personal confession, 1990).

Because there are no distinct clinical characteristics and no biochemical marker for EDS V, diagnosis depends solely on the mode of inheritance. In every sporadic male EDS patient, the family history should be carefully evaluated, with special emphasis on the males of the maternal tree (such as maternal uncles and maternal cousins). EDS V is readily differentiated from the X-linked EDS IX, the occipital horn syndrome, by the absence of cutis laxa and exostoses such as occipital horns and by the presence of normal amounts of serum ceruloplasmin and copper and from an X-linked congenital heart disease (MIM 314400) [517] by other criteria.

Beighton and Curtis [129] state that "the disorder is undoubtedly very uncommon; nevertheless, it has gained the asterisk of syndromic respectability in the catalogue of Mendelian inheritance in man." We feel that this is unjustified and would question the existence of this disorder as a separate entity despite the asterisk attributed to this entry in "Mendelian Inheritance in Man" [37].

Ehlers-Danlos Syndrome Type VIII — Periodontotic Type of EDS (MIM 130080)

The existence of EDS VIII (Table 1) as a separate entity is questionable [39]. On the last page of the chapter on the Ehlers-Danlos syndrome in "Heritable Disorders of Connective Tissue," McKusick [2] writes: "A condition unique in my experience, and apparently in the literature as well, is demonstrated by the wife of a colleague of mine and several of her relatives. Lesions on the shins suggest those of EDS, and slow-healing breaks in the skin at that site have occurred after blunt trauma. The skin is not generally fragile, and no unusual bruisability or stretchability of the skin has been noted. The joints are not hyperextensible. A second feature, apparently syndromally related to the lesions on the shins, is absorptive periodontosis, with early loss of the teeth. The dental and skin changes are present also in the proband's father, in several sibs of her father, and in a cousin. The lesions on the shins suggested necrobiosis diabeticorum on histologic study.... The small scars on the knees are somewhat like those of EDS, and the skin of the lateral aspect of the soles is wrinkled in the manner demonstrated by EDS-patients."

The description of this "unique condition," together with a second family, prompted Stewart et al. [527] to classify this new variant as EDS VIII. More cases have since been reported [528–533; D. Hollister, personal communication, 1990; K. Hinkel, personal communication, 1990] or have just been mentioned without clinical description [518]. In all, joint laxity, especially of the fingers, is mild to moderate, hyperextensibility is mild or absent, fragility of the skin is mild to severe, the scars are "cigarette-paper"-like, the palms and soles are excessively wrinkled [528], and there is no evidence of visceral involvement [529]. A Marfanoid habitus with arachnodactyly and slim limbs and fingers was noticed in two families [527,528]. Minor trauma produced ecchymoses that resolved normally except on the shins, where the pretibial skin healed with distinct hyperpigmented atrophic scars. Hoffman et al. [534] described a sporadic patient with EDS VIII in whom autoimmunity to collagen I appeared to be responsible for unusual features such as intractable vasculitis and resorptive arthritis and osteolysis.

Dental disease begins with numerous caries of the deciduous teeth, which are shed prematurely or normally; the permanent dentition erupts at the usual time. The onset of gingival inflammation in the second decade, and the progression of periodontal disease, leads to a generalized alveolar bone loss around all teeth, which results in the premature loss of all permanent teeth during the third decade. The teeth are morphologically normal [530]. A propensity for the rapid and extensive formation of calculus, particularly around the gingival portions of the posterior teeth, was noted [527].

In one sporadic case, histology of the gingiva exhibited the presence of peculiar, previously unidentified, cell-poor homogeneous masses underneath the epithelium with staining properties resembling those of fibrin. Whether these gingival fibrinoid deposits are a typical feature of EDS VIII will remain uncertain until similar studies in other cases have been performed [531]. Ultrastructural studies have shown a mixed population of large- and small-diameter fibrils with altered packing into fibers and fiber bundles in the reticular dermis [192,532].

EDS VIII seems to be a rare, dominantly inherited disorder of unknown cause. In three patients from a family with eight affected individuals over six generations (K. Hinkel, personal communication, 1990), collagen studies were normal (M. Raghunath, personal communication, 1991). In the large Dutch kindred reported by Hollister [530], linkage to *COL3A1* has been excluded [535]. Ultrastructural examination of skin from two patients did not show any abnormalities in the cells or matrix, and the collagen bundle architecture appeared normal [530].

Absorptive periodontosis occurs also in EDS IV. Therefore, collagen studies should be performed to exclude the latter condition with its dismal prognosis. The father of the initial propositus reported by Stewart et al. [527] died at the age of 39 years of an apparently spontaneous rupture of the duodenum with subsequent overwhelming peritonitis [530]. However, studies of fibroblasts from the propositus performed later showed normal collagens I and III (D. Cohn, personal communication, 1991), indicating that he may not have suffered from EDS IV. On the other hand, an initial diagnosis of EDS IV based on preliminary biochemical data in a separate case had to be revised following more careful studies [533].

The gene for an autosomal dominant form of juvenile periodontitis (MIM 170650) is located on chromosome 4 and linked to the trait for dentinogenesis imperfecta type III [536]; a recessive form may also exist (MIM 260950). Early loss of teeth occurs also in the Papillon-Lefèvre syndrome with keratosis palmoplantaris (MIM 245000), hypophosphatasia (MIM 146300 and MIM 241500) (see Chapter 18, this volume), and Werner syndrome (MIM 277700). Because periodontal ligaments are rich in collagen XII [537], the gene *COL12A1* could be a candidate for the disorder.

Occipital Horn Syndrome (Formerly Ehlers-Danlos Syndrome Type IX) (MIM 304150)

The phenotypic manifestations of the occipital horn syndrome (OHS) were first described by Lazoff et al. [538] in an 11-year-old boy and his two maternal uncles. The child presented with diarrhea, recurrent urinary tract infections, bladder diverticula, inguinal herniae, and peculiar "occipital horns." All three had educational problems but were not mentally retarded. One year later, a new form of X-linked cutis laxa with bladder diverticula and skeletal anomalies was reported [539]. The phenotype was associated with a deficiency of lysyl oxidase that was later inferred to result from disordered copper metabolism [540]. The condition was renamed Ehlers-Danlos syndrome type IX [126], but because of the skin laxity it was later withdrawn from the EDS nosology [38] and the accepted term is now the occipital horn syndrome. The proper term indeed should be mild Menkes disease with occipital horns (see Chapter 14, this volume, and Table 1).

Menkes disease (MD) is an X-linked inborn error of copper metabolism affecting several body systems, including the connective tissues. The clinical manifestations of MD can be quite variable, and both severe and mild forms exist. In the milder forms, the neurological symptoms are less severe, whereas connective tissue findings remain prominent. This group is likely underdiagnosed. The

classical, severe form of MD comprises 90–95% of all cases, and its clinical manifestations include progressive neurological degeneration, seizures, growth failure, arterial aneurysms, and skeletal defects, as well as characteristic hair changes (pili torti) and hypopigmentation, and death results in early childhood. The occipital horn syndrome is the mildest form of MD. Remarkable changes are inguinal herniae, bladder diverticula, skin laxity, and skeletal abnormalities, including a short trunk, deformed elbows, and genu valgum. A diagnostically important feature is the occurrence of bony protuberances on the occiput, the so-called occipital horns. Chronic diarrhea and orthostatic hypotension are other characteristic features.

MD and the occipital horn syndrome are allelic, X-linked, and due to mutations in the Menkes gene, *ATP7A*, which codes for a P-type ATPase, an enzyme located in the *trans*-Golgi network, where it transports copper into the lumen for incorporation into secreted and vesicular copper-requiring enzymes (see Chapter 14, this volume).

Ehlers-Danlos Syndrome Type X (MIM 225310) — Fibronectin-Deficient EDS

The existence of EDS X (Table 1) as a separate entity is questionable [39]. The problem of defining a new type of EDS is well-illustrated by the single family with EDS X to which McKusick has assigned a separate entry in the catalog, although without the "quality label" of the asterisk [37]. Arneson et al. [541] described four of six sibs born to apparently unaffected, unrelated parents with a mild form of EDS and dysfunction of plasma and cellular fibronectin, which was confirmed independently [542]. The proband, a 28-year-old female physician, had joint hyperextensibility, most prominently of the hands and feet and to a lesser extent of the elbows and shoulders, thin but not velvety skin with "fish-mouth" scars that was easily bruisable, petechiae, a positive Gorlin sign, mitral valve prolapse, an aortic root diameter at the upper limit of normal, and, surprisingly, striae distensae. She had once had a knee dislocation that reduced spontaneously (D. Hammerschmidt, personal communication, 1990). Electron-microscopic studies showed a lack of cohesion between collagen fibers within bundles in skin, where there was an unusually loose organization of the deep reticular dermis. Cauliflower collagen fibrils and large fibril diameters were also observed (Fig. 7a in [192]; Fig. 10 in [543]). The proband has had two uncomplicated pregnancies (D. Hammerschmidt, personal communication, 1990).

The platelet aggregation defect was correctable *in vitro* by the addition of normal human fibronectin; on the other hand, the patient's plasma failed to support the aggregation of gel-filtered platelets from controls in response to collagen. Because the measured level of immunoreactive fibronectin in plasma was normal and immunohistochemical studies have shown fibronectin to be present in the platelet α-granules, the authors assumed a minor structural or post-translational abnormality of the fibronectin molecule. In a preliminary experiment, the fibronectin was found to have an abnormal isoelectric behavior (D. Hammerschmidt, personal communication, 1990).

The inherited connective tissue disorder segregated with the platelet aggregation defect, and, since fibronectin is an important adhesive glycoprotein in connective tissues, the authors proposed that both the platelet malfunction and the mild EDS in this kindred might be explained by a defective fibronectin. This relationship, it seemed to them, was further supported by the observation that during the first pregnancy the ability of the proband's plasma to support collagen-induced aggregation of normal platelets markedly improved [544], which may have contributed to the surprising fact that hemostasis was normal, while the somewhat dilated aorta remained constant through both pregnancies and even episiotomy was needed, and healed normally (D. Hammerschmidt, personal communication, 1990). Plasma obtained six months postpartum behaved as did pregravid and first-trimester plasma samples [544].

The proband has two children, a girl and a boy. However, the girl had had approximately 75 luxations of the head of the radius by the time she was 8 years old but had no more in the subsequent two years. Her brother, as well as their two maternal cousins, has also had a luxation of the radius at least once. Studies of platelet aggregation or skin morphology have not yet been performed in them (D. Hammerschmidt, personal communication, 1991). Since no further cases have been observed and no biochemical or genetic studies have been performed, the primary defect and its mode of inheritance remain unclear. The linkage of two separate disturbances and a common underlying cause are both possible, and autosomal recessive or autosomal dominant inheritance, transmitted by one parental carrier of a gonadal mosaicism, are also both possible. If one considers the proband's daughter and son, as well as their maternal cousins, to be affected, dominant inheritance seems more likely.

Regarding the proposed association between the platelet aggregation disturbance and this mild form of EDS, it should be noted that altered production, assembly, and distribution of fibronectin has been observed in cultured fibroblasts from patients with several different types of EDS [545–547]. It is further appropriate to mention that in eight members of a three-generation family, half-normal levels of plasma fibronectin, which has a normal electrophoretic mobility, do not result in abnormalities of platelet aggregation or clinical signs of a connective tissue disorder [548].

Furthermore, there are numerous reports of EDS associated with more or less well-characterized platelet or coagulation dysfunctions [549–557]; most probably, these findings are simply coincidental, but they may have added to the bleeding tendency of the underlying EDS, thus prompting clinical investigation. In summary, the causal association between EDS, dysfibronectinemia, and platelet dysfunction remains to be established and thus we question the existence of EDS X as a separate entity in this single family.

Familial Joint Hypermobility Syndrome (Formerly EDS Type XI) (MIM 147900)

Familial joint laxity with recurrent luxations of the shoulder and patella, often with congenital hip dislocation, has been reported as an autosomal dominant condition [2,59,62,558–560]. Because of the lack of skin involvement, it has been recommended that this entity, formerly EDS XI (Table 1), be classified as a separate entity, familial articular hypermobility syndrome [37–39].

Progeroid Form of Ehlers-Danlos Syndrome (MIM 130070)

Hernandez et al. [561–563] described five sporadic male patients with mental retardation, short stature, a progeroid appearance with wrinkled facies, curly and fine hair, scanty eyebrows and eyelashes, and periodontitis in addition to typical signs of the EDS. Increased paternal age suggested to

them *de novo* mutations. A similar case has been reported by DeLozier-Blanchet et al. [564].

Kresse et al. [565] have described a five-year-old sporadic patient, born to nonconsanguineous parents, who represented a progeroid variant with signs of the EDS (hyperelastic skin and atrophic scars), developmental delay, dwarfism, craniofacial disproportion, osteopenia of all bones and dysplasia of some, and defective wound healing. Later, at age 8.4 years, it was noted that his growth rate had been normal during the last years and that he had made steady intellectual progress [566]. His fibroblasts were defective in the biosynthesis of the ubiquitous proteoglycan small dermatan sulfate proteoglycan (DS-PG II), or decorin, which consists of a core protein of M_r 36,319, with a single glycosaminoglycan chain on the serine residue at position 4, and either two or three asparagine-bound oligosaccharides (see Chapter 4, this volume). The fibroblasts synthesized normal amounts of core protein but converted it into mature proteoglycan only in reduced amounts; the remainder was secreted in a glycosaminoglycan-free form, the tyrosine residues of which were normally sulfated [567]. This abnormality is explained by the marked deficiency (~5% residual activity) of galactosyltransferase I (xylosylprotein 1,4-β-galactosyltransferase, XGALT1; EC 2.4.1.133) as measured in cell homogenates using artificial substrates [568]. This enzyme normally catalyzes the second glycosyl transfer reaction in the assembly of the xylose/serine-linked proteoglycans. The mutant enzyme was thermolabile and had K_m values different from normal for several substrates. Because the parents have intermediate enzyme levels, the disorder seems to be inherited as an autosomal recessive trait. The disorder has been shown by two groups to be due to compound heterozygosity for two mutant alleles, Ala186Asp and Leu206Pro, of β4Gal-T7 (*XGalT-1*), and enzymatic measurements in expression systems of both cDNAs showed 10–50% and 0% activity, respectively [569,570]. Why the activity of galactosyltransferase II (galactosylxylosylprotein 3-β-galactosyltransferase, EC 2.4.1.134) is reduced to ~20%, and whether the large dermatan and heparan sulfate proteoglycans are also affected, remains to be determined [568]. Quantitative immunogold electron microscopy of a skin biopsy revealed that the collagen fibrils of the patient were decorated with much less decorin than those from an age-matched control [566]. It was suggested that the glycosaminoglycan-free core protein present in the patient's tissues is more rapidly metabolized than intact proteoglycan. Unfortunately, no information is available about the thickness and morphology of the patient's skin. Further studies on this and future cases will certainly provide important insights into physiological and pathophysiological roles of decorin.

Reduced transcription and expression of decorin mRNA has been observed in conditions that have in common muscle hypotonia, little subcutaneous fat, joint and skin laxity, easy bruisability, and poor mineralization of bone, as observed in progeroid and progeria patients, and the neonatal Marfan syndrome (MIM 1154700) [604], as well as in the Wiedemann-Rautenstrauch syndrome (MIM 264090). However, in this last condition, such a defect was present only during infancy and hence should be considered as a secondary phenomenon, which leads to a fault in the regulation of decorin gene transcription [571].

Another example of a disturbance in proteoglycan synthesis is given by Fushimi et al. [572], who describe a sporadic case of isolated adrenocorticotrophic hormone deficiency with features characteristic of the EDS (fragility, hyperextensibility and easy bruisability of the thin skin with easily visible veins, molluscoid pseudotumors, but an absence of hypermobility of any joints). Immunohistochemical analysis using anti-dermatan sulfate-proteoglycan antibodies and studies of the biosynthesis of glycosaminoglycans in cultured fibroblasts suggested a defect either in the synthesis of a proteoglycan core protein or in the synthesis of dermatan sulfate side chains in the patient's skin. These results suggested that the dermal findings were due to a lack of dermatan sulfate proteoglycans. The reason for the thinness of the skin, and hence deficiency of collagen, in spite of the normal amounts and proportions of collagen produced by the fibroblasts, is unknown, but the findings suggest that dermatan sulfate proteoglycans play an important role in the formation, function, and maintenance of the structural integrity of the skin. The absence of joint laxity may be explained by the fact that the core proteins of dermatan sulfate proteoglycans in tendon and skin are genetically different [573], but dermatan sulfate in tendon could not be analyzed in this case. This report also illustrates that in the absence of joint laxity the nosology of the EDS itself becomes loose.

Unspecified Types of the EDS and Chance Associations

There are many enthusiastic claims reporting "new forms" of the EDS, such as that of Viljoen et al. [473] in members of a family later shown to have EDS VII [474] (see above), among others [104,109 (MIM 225320), 574,575 (MIM 130090)] waiting to be confirmed clinically and/or characterized biochemically or to be withdrawn because of a recognized chance association with EDS, such as occurred in cases of, for example, neurofibromatosis [576], α2-macroglobulin deficiency [577], α1-antitrypsin deficiency [578], epidermolysis bullosa [579], cystic fibrosis [398], and bilateral focal polymicrogyria [580]. Other authors have been caught in semantic traps of different syndromes [581].

ANIMAL MODELS AND LATHYRISM

The advantages of studying animals with heritable disorders of connective tissue are obvious: (1) they provide adequate quantities of material from different tissues for morphological, biochemical, and biomechanical studies and the establishment of cell cultures; (2) they allow the comparison of paired affected and unaffected littermates at all stages of embryonic, fetal, and postnatal development, with the assessment of early consequences of lethal mutations, as well as during aging within a reasonably short time period; (3) they allow experimental mating for prospective genetic studies to produce heterozygous, homozygous, and compound heterozygous animals; (4) they allow the comparison of similar diseases in different species. Although the eponyms of human diseases are not strictly applicable to the analogous diseases in animals, the causes and effects of these diseases appear to be directly comparable. For an overview of animals with dermatosparaxis or EDS-like conditions, see Table 4.

Dermatosparaxis

Dermatosparaxis in cattle was the first "true" collagen disease to be elucidated. Its characterization greatly stimulated research on the conversion of procollagen, led to the isolation, characterization, and sequence determination of the N-terminal propeptide extensions of proα1(I) and proα2(I) chains, and enabled the study of the regulation

TABLE 4. Natural Animal Models of EDS

Disorder and Species	Inheritance[1]	Defect	Phenotype	References (Selected)
Dermatosparaxis				
Cattle from Belgium	AR	Procollagen N-proteinase deficiency	Severe	464,500,507,511,513, 582–593
from Texas (Hereford)	AR (?)		Severe/moderate	594
Sheep from Norway (Dala)	AR	Defective conversion of pN-collagen		464,493,512,595–599,
from Australia	AR	Procollagen N-proteinase deficiency (25%)	Mild	487,600–605
from Finland	AR		Severe	606
from South Africa (white Dorper)	AR		Moderate	607
Cat	?		Mild	608–610
Dog	AR		Severe	611;G.D. Hegreberg, personal communication, 1991
Ehlers-Danlos syndrome-like conditions				
Dog	AD			612–618
	?			442,619–621

[1] Inheritance: AR, autosomal recessive; AD, autosomal dominant; XL, X-linked recessive; ?, sporadic case; ND, autosomal recessive or dominant inheritance possible but more likely paternal mosaicism of an AD trait.

of fibrillogenesis and cross-link formation by the precursor peptide and the function of the cleaved peptide in the control of procollagen synthesis. Although it had been speculated for some time that high-molecular-weight precursors of collagen might exist [637,638], the actual demonstration of such molecules in tissue cultures of human fibroblasts [639], and in both rat calvariae [640] and chick embryo tendon cells [641], by three independent laboratories occurred at about the same time that dermatosparactic cattle were recognized to have an abnormal high-molecular-weight collagen precursor in skin. This immediately made it possible to prepare and purify the precursor chains in sufficient amounts and to gain the above-mentioned insights at a much higher speed.

The hallmark of dermatosparaxis (“torn skin”) is the excessive fragility of the skin with only mild or absent involvement of tendons and ligaments, which distinguishes this disorder from EDS VIIA and VIIB in man. In affected calves from Belgium, lambs from Norway, sheep from Australia, and cats, the conversion of pN-collagen to collagen seems to be disturbed, either because of a deficiency of procollagen N-proteinase activity [507,600,608] or possibly because of an absence of the collagen-binding protein annexin V (anchorin CII), which could function as a “presenter” of procollagen to the enzyme [595]. The amount of pN-collagen in skin roughly correlates with the extent of the enzyme deficiency, the clinical severity, and morphological abnormalities; for example, skin from the severely affected lambs contained almost exclusively pN-collagen [582], whereas skin from the less severely affected Australian sheep contained only approximately one-third of the collagen as pN-collagen [600]. The relatively low amount of pN-collagen in these latter sheep is due to a less severe reduction (~25% of normal) in procollagen N-proteinase activity as measured in skin extracts [600]. Within one animal, variable degrees of involvement of different organs are reflected in differences in their content of pN-collagen (70% and 15% in skin and tendon, respectively; [596]) and ultrastructure (Figs. 33e and 33f).

As a consequence of the persistence of the N-propeptide, collagen fibril formation is disturbed. This is reflected by the ultrastructural changes observed in all dermatosparactic animals. In cross-section, the fibrils have a spider-like or hieroglyphic-like appearance or a markedly serrated contour; longitudinally, the fibrils resemble ribbons twisting in both directions [493,583,594,601,609,611]. Abnormal cross-link formation [511], increased solubility of collagen, and, ultimately, decreased tensile strength are the consequences of disturbed fibril formation. *In vitro* experiments show that with increasing pN-collagen content, cross sections of the formed fibrils are progressively distorted from circular to

lobulated to thin and branched structures [642,643], which indicates that there is a dose-dependent relationship. Watson et al. [474] have proposed a model of fibril formation in EDS VIIC in which the intact N-propeptides are located at the surface of the hieroglyphic fibrils. Partial cleavage of *in vitro*-synthesized abnormal collagen by N-proteinase allows the N-propeptide to be incorporated within the body of the fibrils, with conversion of the hieroglyphic outlines to the ragged outlines characteristic of EDS VIIA and VIIB.

The variability of different organ involvement has not been adequately studied. It may be influenced by differences in local residual procollagen N-proteinase activity, collagen turnover, stringency in collagen packing, or a combination thereof. The fact that with aging there is an improvement in various properties of the skin may point to an influence of collagen turnover; Piérard and Lapière [515] observed several differences between two calves 3 and 6 months old. The sheet-like arrangement of the polymers was replaced by a bundle-like organization, the ratio of collagen to procollagen increased, and the biomechanical properties of the dermatosparactic skin also tended to become more normal.

In one strain of dermatosparactic calves in which the disease was first observed [584], the mutation consists of a 17 bp deletion that changes the reading frame of the message [500], and would, if the mRNA were stable, result in the synthesis of a truncated protein. Because the mutation would prevent the synthesis of active procollagen N-proteinase, the fact that different tissues contain variable amounts of processed procollagen I suggests that another enzyme, tissue-specifically expressed, can remove the N-terminal peptide of procollagen I, although at a lower rate than the N-proteinase. Two proteins that have a high sequence homology with the N-proteinase and contain similar domains, including properdin repeats, have been described (for references, see [500]). Their physiological roles have not yet been determined. However, the regulation of their expression and their tissue-specificity suggest various functions for members of this new subfamily, which are candidates for an alternative pathway of processing procollagens I and II [500].

Ehlers-Danlos Syndrome-like Conditions

All animals with "generalized cutaneous asthenia," "conditions resembling the EDS," or "fragility and hyperextensibility of the skin" seem to inherit these as autosomal dominant traits. Most reports focus on the description of the skin, others (e.g., [619]) mention also profound joint laxity, subluxations, and osteoarthritis; radiographic and microradiographic studies have revealed subclinical involvement of bone [617]. In all animals, the defect remains unknown. Ultrastructurally, abnormalities in the packing of collagen into fibrils and fibers have been noted [617,620,624,625]. Differences in the solubility and cross-linking of collagen have occasionally been reported [612,625], but these may also be accounted for by an increased rate of collagen turnover and thus be secondary to some other primary change.

In pregnancies resulting from matings between two heterozygous cats [624], the litter size was reduced and only 12 of 34 offspring were affected; furthermore, uterotomy at gestational days 20 and 44 (normal duration is 63 days) revealed that approximately one-quarter of the placental sacs were abnormally small and contained no embryo. It was concluded therefore that the homozygous state of the "defect in collagen fibrillogenesis" would be lethal during early embryonic development [618], perhaps shortly after implantation or during early gastrulation (R. Minor, personal communication, 1990). The apparently homozygous EDS cases in man [29,134] seem therefore to be basically different from those in this animal model.

Kobayashi et al. [644] reported a 4-month-old Holstein calf with soft and hyperextensible skin, skin fragility, and a history of delayed wound healing, but without joint hypermobility. Electron microscopy showed rarefaction of collagen fibers and an increased amount of dermal ground substance. Tajima et al. [645] showed that there was a deficiency in dermatan sulfate proteoglycans in skin caused by a presumably new heterozygous mutation, a G to A transition at nucleotide position 254, which resulted in a Ser-to-Asn substitution at amino acid position 85 of the bovine proteoglycan core protein. This substitution occurred in the highly conserved Ser–Gly dipeptide repeat sequences suspected to be the O-glycosylation site of dermatan sulfate side chains. The sire and grandsire did not carry the mutation, and the dam and granddam were not available for analysis but did not present these skin manifestations. It therefore appears that the calf was affected due to a newly occurring heterozygous mutation of the gene coding for the proteoglycan core protein.

Transgenic Animals

The use of gene targeting as a means of assessing the biological function of a protein is a powerful tool, although there are certainly many instances in which overlapping functions or gene compensation can obscure the function of the missing or defective protein under study, often making comparison between affected individuals and experimental animals difficult. Some examples are given here which illustrate that certain transgenic animals were seminal in the characterization of the human counterpart, while others should prompt research into the elucidation of hitherto unknown basic defects of diseases in man.

Targeted Mutation of the Col5a2 Gene in Mice — A Model of the Classical Type of EDS

This animal model was seminal in the elucidation of the classical type of EDS in man. Homozygous mice (pN/pN) with an in-frame exon 6 deletion in *Col5a2* survive poorly, possibly because of complications from spinal deformities, and exhibit skin and eye abnormalities caused by disorganized collagen I fibrils [150]. The deletion is outside the major helix of the collagen V molecule and does not alter the reading frame of the *Col5a2* transcript but prevents normal processing of the proα2(V) chains. It results in a heterotrimeric $[\alpha1(V)]_2\alpha2(V)$ that is assembled, secreted, and integrated normally into heterotypic collagen fibrils. The abnormal collagen V is structurally defective due to an alteration in the conformation of the N-globular domain, a region thought to play a key role in the interaction between collagen V and collagens I and III [149].

Heterozygous animals (pN/+) were phenotypically normal and fertile. Likewise, the homozygous mutant mice (pN/pN) appeared normal at birth. Soon after, however, many of them were cannibalized and the remaining ones began to show a progressive hunching of the back that affected mobility and respiration. By weaning age (~3 weeks), the survival rate was 5% and their weight was ~50% of normal. Radiology revealed varying degrees of spinal lordosis and kyphosis in all. The normal morphology of the vertebrae suggested that spinal deformity was probably secondary to loss of tensile strength of the ligaments. On the other hand, intravital

double-tetracycline labeling demonstrated that bone in the mutant mice grew at a slower than normal rate.

Skin was much more fragile and stretchable upon physical examination and biomechanical testing. The amount of collagen in the dermis of mutant mice was markedly reduced, whereas the hypodermis was 4–6-fold thicker and contained a large number of hair follicles not normally localized in this layer. Ultrastructurally, the collagen fibrils were more disorganized, less tightly packed, and more heterogeneous in size. Collagen fibrils in the cornea were disorganized and thicker: mean fibril diameters were estimated to be 25 nm in controls, 35 nm in heterozygous mutants, and 50 nm in homozygous mutants. Consistent with the ultrastructural findings, the stroma but not the epithelium of the cornea appeared collapsed and was thinner than that of controls.

The lack of an apparent phenotype in the heterozygous mice is consistent with the stoichiometry of collagen V, which predicts that only half of the trimers will have an abnormal conformation. This could also explain why size differences in fibrils were noted only in the cornea, a tissue that contains fibrils of equal size and with the largest proportion of collagen V. Alternatively, heterozygous animals were not examined with more stringent analyses and were under greater physiological stress, so clinical signs may have been missed.

In summary, the deletion of the α2(V) N-telopeptide leads to a change in the conformation of the collagen V heterotrimer and the elimination of the hinge-like region. This conformational change abrogates the collagen V regulation of the growth of collagen fibrils and their subsequent packing into fibers, affecting the spatial arrangement of the fibers into tissue-specific macroaggregates [150].

The tight skin mouse (TSK/+), a naturally occurring mutant, develops a generalized connective tissue abnormality that is transmitted as an autosomal dominant trait and is caused by a large duplication in the fibrillin1 gene (see Marfan syndrome, Chapter 12, this volume). The phenotype is characterized by marked hyperplasia of loose connective tissues, thickening of the skin, pulmonary emphysema, and cardiac hypertrophy. Although both pN/pN and TSK mice exhibit cutaneous thickening, there are striking differences between the two mutant strains. However, crossing TSK/+ mice with pN/pN mice resulted in an F1 progeny without cutaneous hyperplasia [646]. This interesting example of genetic complementation may serve as a model to explain lack of penetrance in double heterozygous individuals.

Tenascin-X Knockout Mouse — A Model of the Classical Type of EDS

Mao et al. [647] have produced a *Tnx* knockout mouse. The skin of TN-X-deficient mice becomes clearly hyperextensible at about 2 months of age, and hyperelasticity is progressive with advancing age. The best phenotypic indication, beginning at about 3 months of age, is that when such mice are held by the skin of the neck, they are still able to twist around to bite the investigator due to the hyperelasticity of their skin. The joints show no obvious hypermobility.

Biomechanical studies demonstrate reduced tensile strength (60% of that of age and sex-matched unaffected littermates) and hyperextensibility of skin. The dermis is less dense and thinner in TN-X-deficient animals than in normal littermates. Ultrastructurally, dermal collagen fibrils have a normal contour and a normal mean diameter, which is, however, more variable. The most striking finding is that the density of the collagen fibrils is reduced by 40% and that the alignment of fibrils with respect to one another appears to be less perfect. These data suggest that TN-X has a role in regulating collagen fibril architecture and that its lack can cause the skin manifestations of EDS with minimal alteration of fibrillogenesis.

Decorin Knockout Mice — A Model of EDS?

To study the function of decorin in collagen fibrillogenesis, Danielson et al. [179] created mice with a targeted disruption of the decorin gene. The decorin null mice presented no gross anatomical anomalies, were normal in size, fertile, without radiologically overt bone abnormalities, without obvious behavioral deficiencies, and with normal routine chemistry.

The skin was hyperelastic, thin, and fragile, with detachment of the tail skin, not unlike in dermatosparaxis (heterozygotes were indistinguishable from control animals). Histology showed a thin dermis, a loose connective tissue in the hypodermal layer, and a sharp detachment of the skin between the deeper dermis and the fascia, with clean, sharp edges along the dissection. Electron microscopy revealed less orderly packed collagen fibrils with a much larger diameter and irregular coarse outlines in cross section. Electron microscopy of longitudinally sectioned collagen fibrils from tendon showed that the typical 67 nm periodicity of collagen I was maintained; however, numerous d bands of the D-periodicity were not occupied by orthogonally arranged proteoglycan granules as in controls. The absence of overt abnormalities in the cornea of null mice, a tissue in which decorin is normally expressed, may be explained by the larger requirement for keratan sulfate in this transparent structure and by the presence of at least five members of the small leucine-rich proteoglycan family, which could control more tightly the fibril diameter necessary for transparency.

Dermatosparaxis and decorin knockout mice. A contributing factor to the skin fragility in dermatosparaxis was thought to be the steric exclusion of a factor from the gap zone of collagen fibrils by the N-terminal propeptide, which forms a hairpin and thus blocks this region [179]. In dermatosparactic skin, several proteoglycan filaments are not closely bound to collagen fibrils but rather float freely in the interfibrillar spaces [593]. Thus, dermatosparactic animals, through the presumed exclusion of access to decorin, and decorin null animals, through a lack of decorin, were assumed to share a common pathogenetic mechanism (i.e., the obstruction/deficiency of a key regulatory molecule in collagen fibrillogenesis). Further support for this concept was provided by the lowered dermatan sulfate to hydroxyproline ratio from 4.7 in normal skin to 3.6 in dermatosparactic skin [513]. However, later experiments showed that in dermatosparactic calf fibrils the equilibrium between fibrillar and soluble decorin was shifted in favor of enhanced fibril-associated decorin [648]. Thus, the results showed that N-propeptides can distort the morphology of fibrils, that they do not inhibit the binding of gap-associated macromolecules (such as decorin), and that normal mechanical properties of skin are strongly dependent on the close association of near-cylindrical fibrils, thereby enabling maximal fibril-fibril interaction [648].

Lumican-Deficient Mice

Mice homozygous for a null mutation in lumican display skin laxity and fragility with easy bruising resembling certain types of EDS [180]. In addition, mutant mice develop bilateral corneal opacification. Skin has a markedly increased compliance and reduced tensile strength independent of any differences in skin thickness. Its fibroblasts and collagen fibers are poorly aligned. There is a significant proportion of abnormally thick collagen fibrils in skin and cornea.

Thus, lumican, a prototypic leucine-rich proteoglycan (LRP) with keratan sulfate side chains that colocalizes with fibrillar collagens, has a crucial role in the regulation of collagen assembly into fibrils in various organs, especially the cornea [180]; other LRP members, such as biglycan, fibromodulin, epiphycan, osteoglycin, and keratocan, may have similar functions.

Thrombospondin-2-Deficient Mice — a Model of Ehlers-Danlos Syndrome

Thrombospondin-2 (TSP-2) is a member of a family of five secreted, modular glycoproteins whose functions in the extracellular matrix are diverse and poorly understood. TSP-2 is predominantly expressed in dermis, tendon, ligament, perichondrium, and pericardium; it is also present in smooth muscle cells and endothelial cells. In an attempt to determine the function of TSP-2, Kyriakides et al. [181] disrupted the *Thbs2* gene by homologous recombination in embryonic stem cells and generated TSP-2-null mice by blastocyst injection and appropriate breeding of mutant animals.

Thbs2 − /− mice are normal in size and overt appearance and reproduce normally. Juvenile mice often have subtle bends in their tails that become less distinct as they mature, but the tail becomes more flexible, enabling the investigator to tie its end into a knot, a manipulation that is not possible in normal mice. The phenotype of adult mice is characterized by increased laxity and fragility of skin, tendons, and ligaments, an increase in total bone density and cortical thickness, an increased density of medium and small blood vessels, and a bleeding diathesis.

These abnormalities in structure and function are supported by anatomical analysis and mechanical testing. The weave of dermal collagen fibers in the knockout mouse is disorganized, and collagen fibrils in skin and tendon are abnormally large and irregularly contoured when examined by electron microscopy. Tensile strength measurements of skin from mutant mice support indications of increased fragility, first suggested by the tendency of skin to tear. The skin ruptures at lower loads and has increased ductility; these findings explain its increased stretchability.

A possible clue to the pathogenesis of these findings lies in the decreased attachment of skin fibroblasts from these animals to various substrata and their increased sensitivity to trypsinization. Although the binding of TSP-2 to collagens has not been studied, defective cell adhesion to a suitable substratum through lack of TSP-2 may be the primary cause. This would explain abnormal collagen fibrillogenesis, osteopetrosis-like features through abnormal osteoclast adhesion to bone or failure to form a bone-resorbing ruffled border, and the bleeding diathesis through defective adhesion of platelet aggregates to the injured subendothelium. TSP-1 has been shown to bind to von Willebrand factor (vWF), and it is possible that TSP-2 is also required, either directly or indirectly, for the binding of vWF to one or more collagens in the subendothelium. The increase in blood vessel density in mutant mice is a strong argument for the function of TSP-2 as an inhibitor of angiogenesis *in vivo*. It is of interest that findings intermediate between those in wild-type and mutant animals are observed in skin from heterozygous *Thbs2*+/− mice; this suggests haploinsufficiency for the function of TPS-2, at least in skin [181].

Fibromodulin-Null Mice — A Model of Abnormal Fibrillogenesis as in the Ehlers-Danlos Syndrome

Homozygous mice lacking a functional fibromodulin gene do not show any gross anatomical defects, grow to normal size, are fertile, and have a normal life span. In fibromodulin-null animals, virtually all collagen fiber bundles are disorganized and have an abnormal morphology; also, 10–20% of the bundles in heterozygous mice are similar to those in homozygous null mice. Electron microscopy shows that the fibrils are thinner, with irregular and rough outlines. They have a fourfold increase in the content of lumican despite a decrease in lumican mRNA; this suggests that lumican and fibromodulin, both of which belong to a family of extracellular matrix glycoproteins/proteoglycans sharing a leucine-rich repeat (LRR), have the same binding site on collagen fibrils [649].

Procollagen N-Proteinase Knockout Mice — A Model for Dermatosparaxis

Transgenic mice that are homozygous for inactive alleles coding for procollagen N-proteinase (ADAM-TS2) have fragile skin, as expected; however, surprisingly, adult homozygous males are sterile and have a marked decrease in sperm count in semen and fluid expressed from the epididymis and in mature sperm in cross sections of the testes [650]. At the moment, it is unclear whether male sterility is confined to these transgenic mice or whether the enzyme is necessary for the modification of some other and still unknown substrate because three of the six reported cases of human dermatosparaxis (Table 3) have not reached the age of reproduction and because dermatosparactic sheep and calves did not reach puberty. Male individuals with EDS VIIB, however, were fertile and produced one affected and two unaffected children (father of case 4 and case 7, respectively).

Targeted Mutations of the Col3a1 Gene in Mice — A Model of the Vascular Type of EDS

To define the role of collagen III in fibrillogenesis, Liu et al. [334] generated *Col3a1*−/− mutant mice by gene targeting. Most homozygous mutants died in the perinatal period. The precise cause of neonatal lethality was not clear because the dead pups were cannibalized before they could be examined, and light microscopic histologic analysis of live newborn homozygous mutants did not detect any gross abnormality.

The phenotype of surviving homozygous mutant mice resembled the clinical manifestations of patients with EDS IV, whereas heterozygous mice appeared phenotypically normal. Mutant mice (−/−) displayed an average survival rate of 5% at weaning age (~3 weeks), with most deaths occurring within the first 48 hours after birth. Adult homozygous mutant mice appeared normal except that they were about 15% smaller than their wild-type littermates of the same sex. Their average life span, however, was about 6 months, or one-fifth of normal.

Autopsy showed that blood vessel rupture was the major cause of death of these mice. The sites of ruptured arteries with or without aneurysm were random. In addition, mutant mice showed frequent intestinal enlargement and occasional intestinal rupture. Two-thirds of −/− mice displayed spontaneous skin lesions. Light microscopy of skin, intestine, and internal organs, including liver and lung, did not detect any overt abnormalities.

Electron microscopy showed that collagen fibrils normally located between smooth muscle cells, or between smooth muscle cells and elastic fibers, were absent or severely reduced in the media of the aorta as well as in the intestinal submucosa and serosa. Most strikingly, in the adventitia of the aorta, skin, lung, and liver, where collagen I fibrils predominate,

the number of fibrils was reduced to approximately one-third and their mean diameter was approximately twofold and highly variable.

These studies show that collagen III is not only an essential component in tissues rich in collagen III but that it also plays a critical role in collagen I fibrillogenesis and thus in maintaining the functional integrity of the organs [334]. Also, heterozygous mice with a *Col3a1* null allele are phenotypically normal under the conditions examined and, as in putative EDS IV patients with a nonfunctional allele, a milder or late-onset visceral involvement may yet be found under stress conditions (see EDS IV above).

Targeted knock-in mutation in *Col3a1* in mice with defective cross-linking of collagen III. Toman et al. [651] generated transgenic mice by microinjection of a mutated mouse *Col3a1* harboring a Lys>Met substitution at the amino acid 939 cross-linking site within the triple-helical region of the α1(III) chain. Pregnant female mice expressing the transgene at levels of >30% in relation to the normal endogenous procollagen III showed greatly diminished ability to deliver pups at time of labor. Analysis of the uterine smooth muscle function of pseudopregnant transgenic mice showed an abnormal contraction pattern upon stimulation with oxytocin, and electron-microscopic analysis of the uterus indicated a marked disorganization of the collagen bundles disrupting the normal architecture of the myometrium. The authors concluded that the mutation that prevents cross-linking of the collagen III alters the normal functioning of smooth muscle in the uterus.

Mottled Mouse Mutants

Of the series of mouse mutants involving the X-linked locus mottled (Mo), so named because of its effect on coat color, the brindled (Mo^{br}) and blotchy (Mo^{blo}) variants have been studied particularly. The nature of the basic defect is a disturbance in copper handling as a result of mutations in *Atp7a*, the murine homolog of *ATP7A*, which codes for ATP7A, a member of the copper ATPase family, and is known to be affected in Menkes disease and the occipital horn syndrome. Consequently, intracellular copper is unavailable for enzymes requiring copper [632,633,652]. For a more detailed consideration, see Chapter 14 of this volume.

Hemizygous brindled mutant males normally die at 10–14 days of age with severe neurological deterioration without showing any signs of connective tissue disorder [523,653]. Although lysyl oxidase in extracts of skin is secondarily reduced to about 60% of normal [524,654], there is perhaps insufficient time for effects on connective tissue to manifest themselves before the neurological involvement takes its toll. The brindled mutants are considered to be a model of Menkes disease in the human [633], in severe cases of which connective tissue abnormalities may be prominent [655].

The blotchy male mutant, on the other hand, shows a variety of connective tissue features, including emphysema [656], and tends to die from aortic aneurysm at about 150 days of age [523,657]. The connective tissue defects appear to be secondary to deficient cross-linking of collagen [658] and elastin, consequent on inadequate activity of the copper-dependent lysyl oxidase which functions to initiate the process and is present in the tissues at only about one-quarter of normal levels [524,654,659]. The blotchy mutant has been suggested as a model of EDS IX [633], now reclassified as the occipital horn syndrome (see Chapter 14, this volume).

Experimental Animals for the Study of Tissue Fragility

Lathyrism

The condition in which deleterious effects in connective tissues are caused by chronic ingestion of the sweet pea *Lathyrus odoratus* is called lathyrism and is due to the inhibition of lysyl oxidase by β-aminopropionitrile (β-APN), with consequent inhibition of cross-link formation in both collagen and elastin. β-APN, the toxic agent, is released *in vivo* by an amidase or protease from the precursor, β-(γ-glutamyl)aminopropionitrile, present in the legumes, and is a potent and irreversible inhibitor of lysyl oxidase, with I_{50} values of 3–5 μM (for a review, see Kagan [660]).

Lathyrism has been reviewed by Levene and Gross [661] and Barrow et al. [662]. Geiger et al. [663], by feeding growing rats with sweet pea, were the first to describe dramatic malformations of mesenchymal tissues, termed osteolathyrism as opposed to neurolathyrism [664], which included kyphoscoliosis, exostosis of the long bones, marked periosteal new bone formation, weakening of the tendinous and ligamentous attachments and of the epiphyseal plates, skin, cartilage, and healing wounds, dislocation of joints, loss of teeth, and herniae. Later, dissecting, diffuse, or saccular aneurysms of the aorta were reported (angiolathyrism) [665], and teratogenic effects such as cleft palate [666] and ectopia cordis and gastroschisis [667] were observed in 1968 and 1971, respectively. In 1954/1955, β-APN was found to be the toxic factor in *Lathyrus odoratus* causing osteolathyrism [668]. Using chick embryos, Levene and Gross [661] showed that both tissue fragility and the amount of extractable collagen were dose- and time-dependent and speculated that normal intermolecular cross-linking was affected by the lathyrogenic agent. Martin and co-workers reported that the interference by β-APN in collagen cross-linking, and in the biosynthesis of desmosine and isodesmosine, was through the specific inhibition of lysyl oxidase, the enzyme used in the first step of cross-linking of collagen and elastin [669]. Lathyrogenic compounds were shown to fall into four major groups, in order of diminishing potency: nitriles > ureides > hydrazides > hydrazines [670].

β-APN has proved to be a useful agent to administer to growing animals, or to add to organ and cell cultures, to block collagen cross-linking and thus allow the extraction in large amounts of newly formed collagen which is amenable to characterization. It is also required in the preparation of biosynthetically labeled substrate for the assay of lysyl oxidase [418]. The successful use of β-APN in the prevention of esophageal strictures after lye injury and in overcoming the restrictive effects of peritendinous adhesions in animal experiments [671] led to human clinical trials. Results with β-APN in the treatment of patients with ureteral strictures and tendon adhesions [672] indicate that the physical properties of scar tissue may be amenable to biochemical control. However, the therapeutic value of β-APN as an antifibrotic agent is, unfortunately, outweighed by its damaging systemic side effects [673].

Copper Deficiency

Because copper is a cofactor of lysyl oxidase, its dietarily induced deficiency has effects that strongly resemble those of lathyrism. Common to both conditions are the following: (1) the disease is readily inducible only in the young; (2) vascular rupture is the cause of mortality; (3) aortic tensile strength is reduced, and there is a decrease in aortic elastin; (4) elastic fiber alterations are the cardinal histopathologic

and ultrastructural vascular lesions; (5) bone deformities occur in both conditions; (6) increased solubility of elastin and collagen are due to deficient cross-linking. Lysyl oxidase activity is not detectable, or is grossly reduced, in extracts of tissues from copper-deficient animals, a fact that originally suggested copper as the naturally occurring cofactor for the enzyme. Indeed, copper-deficiency states enabled the early isolation and characterization of tropoelastin [674].

D-Penicillamine

D-penicillamine (β, β-dimethylcysteine), according to the conventional view, inhibits collagen cross-linking by interacting with the lysine-derived aldehydes, rendering them unavailable for cross-link formation, although there is evidence that its principal effect might be to block the synthesis of polyfunctional cross-links from bifunctional Schiff base precursors [675]. D-Penicillamine acts preferentially on collagen cross-linking in soft tissues, while the hydroxylysine-derived aldehydes present in bone are much less affected. At high concentrations, it also chelates copper and reduces the activity of lysyl oxidase [675] (see also Footnote 9).

The overall effectiveness of the drug in reducing the structural stability of collagen *in vivo* is well-documented in animal experiments. It has also been used to reverse collagen accumulation in patients with hepatic fibrosis and progressive systemic sclerosis, but side effects, reviewed by Steinmann et al. [676], have prevented its use in such high concentrations as in animal experiments. Side effects of penicillamine in the treatment of cystinuria and Wilson disease have been reported and include symptoms reminiscent of EDS [676] and pseudoxanthoma elasticum [677] as well as ultrastructural changes in dermal collagen and elastin [678].

In conclusion, studies using lathyrogens have been instrumental in demonstrating that the ability of collagen and elastin fibers to function is primarily dependent on a system of covalent cross-links between the polypeptide chains of the respective proteins.

CONCLUDING REMARKS

Mutations that give rise to the several different phenotypes of EDS affect collagen structure (some cases of EDS I and II, EDS VIIA and VIIB), expression (a few cases of EDS I and III), maturation (EDS VI, VIIC, occipital horn syndrome), and fibrillogenesis (EDS I/II, VII), noncollagenous proteins, such as proteoglycans (progeroid form of EDS) and tenascin-X, and potentially many more proteins of the extracellular matrix in the vast majority of cases. The EDS phenotypes reflect both disturbances in the intermolecular cross-linking of collagen (EDS VI, VII, and occipital horn syndrome) and the lack of an appropriate scaffold (EDS IV, progeroid form of EDS) on which to build the major components of the skin. The precise phenotypic findings therefore depend on the nature of a mutation and the molecule in which it occurs. Despite such a wide genetic heterogeneity, the organism has only a limited repertoire for functional and morphological changes.

RECENT DEVELOPMENTS

EDS Types II and III

Clinical Features

Absence of the inferior labial and lingual frenula has been reported in 12 patients, four with EDS II and eight with EDS III, with a mean age of 29.7 years (range 15–45 years), and suggested to be a highly specific and sensitive marker for these disorders [679]. It will remain uncertain, however, whether this is a congenital anomaly or rather an acquired trait due to tissue fragility, until prospective, longitudinal observations have been performed and the natural history is known. It is further unknown whether this clinical finding also occurs in other types of EDS.

Vascular Type of EDS (EDS Type IV)

Genetics and Pathogenesis

Because EDS IV has hitherto been associated exclusively with dominant negative *COL3A1* mutations, it has been unclear whether any *COL3A1* haploinsufficiency mutation would cause an EDS IV-like phenotype differing in severity or symptomatic range from usual, or indeed any phenotype, and therefore have escaped analysis. This uncertainty was reinforced by the finding that heterozygous *Col3a1* knockout mice are phenotypically normal [334], although late onset signs would have been missed if they had occurred after the 18 months follow-up period.

Schwarze et al. [680] have now presented data on four patients with EDS IV with *COL3A1* haploinsufficiency mutations. Three of them had frameshift mutations that led to premature termination codons in exons 27 (1832delAA), 6 (413delC), and 9 (555delT), respectively, and to allele product instability. In the fourth patient, a point mutation introduced a premature stop codon in the most 3′ exon (4294C>T; Arg1432Ter), resulting in the synthesis of truncated proα1(III) chains that were not incorporated into procollagen III molecules. All four index patients had vascular aneurysms or ruptures, and the phenotype of family members presumed to be affected was reported to be within the range of "classical EDS IV" due to structurally abnormal collagen III. Surprisingly, biochemical evidence of reduced synthesis of procollagen III was limited to dermal fibroblasts from a single patient, procollagen III synthesis in cell strains from each of the other three patients being normal. The authors concluded that a 50% reduction in the amount of structurally normal procollagen III is as deleterious to the vascular system as the biosynthesis of collagen III, seven-eighths of which is structurally abnormal, that occurs as a consequence of the more than 200 other reported mutations. However, their conclusions have some limitations in that the probands had been ascertained because of "typical" EDS IV signs and symptoms and on average they, as well as their relatives presumed to be affected, were older than the reported median age of survival for EDS IV [256]. The probands may thus simply represent the more severe range of a milder phenotype characterized by the attainment of a greater age before symptomatic arterial events occur and by longer survival.

The report by Schwarze et al. [680] gives rise to the following considerations in relation to the diagnosis of EDS IV: (1) The cornerstone of the diagnosis should remain suggestive clinical findings in the proband and similarly affected family members in conjunction with detailed medical histories; by this approach alone, however, sporadic cases are less likely to be detected. (2) In fibroblast strains with *COL3A1* haploinsufficiency, the relative proportions of collagens I and III secreted into the medium and retained by the cells do not constitute a reliable diagnostic indicator because they depend on such parameters of culture conditions as cell density [218,342]. It must also be stressed that the ratio of $[\alpha1(III)]_3$ molecules to combined α1(I) and α2(I) chains after limited proteolysis with pepsin provides a more accurate measure of synthesis of the two collagen types than may be achieved by determining the relative proportions of reduced

proα1(III) and proα1(I) chains, as done in the study under discussion [680]. Furthermore, subtle structural alterations in type III collagen are more readily detectable in $[\alpha1(III)]_3$ molecules than in proα1(III) chains. (3) Mutation analysis in individuals in whom the diagnosis of EDS IV has been made on clinical grounds has been successful in those whose cultured cells have synthesized a cohort of structurally abnormal procollagen III molecules. Now that a clinical phenotype due to haploinsufficiency has been recognized, direct genomic analysis is likely to be a more efficient way of identifying cell strains from individuals so afflicted. (4) Because the role of *COL3A1* mutations in other conditions such as isolated cerebral aneurysm [272] and abdominal aortic aneurysm [271] has been explored only at the cDNA level, non-expressed alleles or unstable mRNA products might not have been detected in a minority of individuals homozygous (or hemizygous) at known polymorphic sites; retesting of such individuals at the genomic level might therefore be warranted.

Kyphoscoliotic Type of EDS (EDS Type VI)

Clinical Features

Pregnancy in EDS VI. There remain no published reports on pregnancies of individuals with EDS VI. Two affected women are known to have delivered normally after 36 weeks without untoward consequences (R. Wenstrup, personal communication, 2001). Another affected woman with a moderately severe phenotype (case 55, see legend to Fig. 22) had an early abortion and later delivered a boy at term (B. Steinmann, personal observation).

Differential Diagnosis

Infants with Ullrich disease (MIM 254090; see Chapter 26, Part VI, this volume) may present with severe muscular hypotonia, marked joint laxity, Marfanoid proportions, and autosomal recessive inheritance, and thus may expand the differential diagnosis of EDS VI. Children with the autosomal recessively inherited Nevo syndrome (MIM 601451) have tall stature at birth, muscular hypotonia, joint laxity, kyphoscoliosis, a Marfanoid habitus, wrist drop, long spindle-shaped fingers, osteopenia, and dural ectasia, and may be confounded with EDS VI (B. Steinmann, personal observation).

Therapeutic Approaches

With the aim of local gene therapy, Rauma et al. [681] cloned human lysyl hydroxylase 1 cDNA into a recombinant adenoviral vector (Ad5RSV-LH). Transfection of human EDS VI fibroblasts from case 3 (see legend to Fig. 22) with the vector increased lysyl hydroxylase activity in these cells in a dose-dependent manner from residual values of 20% of normal to levels greater than in control cells. The adenoviral vector also successfully transfected rat fibroblasts *in vitro*, and intradermal injections of the vector in rats produced human lysyl hydroxylase 1 mRNA and elevated lysyl hydroxylase 1 activity *in vivo*. This study suggests the feasibility of gene replacement therapy to modify skin wound healing in EDS VI patients.

ACKNOWLEDGMENTS

The authors acknowledge the many patients for their cooperation, sharing of their experiences, and giving permission for the reproduction of photographs. The preparation of this chapter was largely supported by the Swiss National Science Foundation (grant nos. 32-42198.94 and 32-59445.99 to B.S.) and the 1997 Award of the Swiss Bone and Mineral Society to B.S., sponsored by Merck Sharp & Dohme-Chibret AG, 8152 Glattbrugg. B.S. thanks the Ehlers-Danlos National Foundation (USA) for the invitation to the meeting "The Clinical and Biological Basis of the Ehlers-Danlos Syndrome" held at the Banbury Center, Cold Spring Harbor Laboratory, Cold Spring Harbor, New York, 18–21 April 1999.

Chapter 10

Cutis Laxa and Premature Aging Syndromes

Jeffrey M. Davidson[1] and MariaGabriella Giro

Department of Pathology, Vanderbilt University School of Medicine and [1]VA Medical Center, Nashville, TN 37232-2561

SUMMARY

- **Cutis laxa is characterized by deep wrinkling or sagging of skin, predominantly due to defects in the elastic fiber system. Elastin may be reduced, absent, fragmented, or dissociated from the microfibrillar components of the elastic fiber. Congenital forms of the disease occur with autosomal dominant and autosomal recessive inheritance patterns, whereas acquired cutis laxa usually has a later onset that is associated with collateral inflammatory aspects.**
- **Progerias are accelerated aging syndromes involving many organ systems, in which effects on connective tissues are most likely secondary to global, metabolic defects in processes such as DNA repair. In many forms of progeria, such as Hutchinson-Gilford progeria and Werner syndrome, the *in vitro* life span of cultured fibroblasts is reduced.**
- **Autosomal dominant cutis laxa and supravalvular aortic stenosis are linked to the elastin locus. Both diseases involve skin and other elastic tissues, but there are selective effects on the designated tissue compartments. Supravalvular aortic stenosis is due to functional or actual hemizygosity at the elastin locus, a deficiency that affects the elastin-rich aortic root most profoundly. Other elastic tissues, such as skin, are less affected. Williams syndrome is due to a large-scale chromosomal deletion that usually encompasses the elastin locus; thus, most affected individuals exhibit supravalvular aortic stenosis. In autosomal dominant cutis laxa, point mutations in the 3′-coding region of the elastin transcript can affect synthesis and perhaps assembly of mutant protein. Elastic tissues throughout the body are affected to a variable extent.**
- **Autosomal recessive cutis laxa is usually more severe, with major effects on the pulmonary elastic network that lead to death in infancy. Although elastic fibers are malformed, no specific genetic defect has been identified. Findings in Costello syndrome suggest a linkage between altered metabolism of dermatan and chondroitin sulfate, the 67 kDa elastin/laminin-binding protein, and elastic fiber assembly.**
- **Cutis laxa is a trait that is associated with the phenotype of many other syndromes, including Wiedemann-Rautenstrauch syndrome, Hallerman-Streiff syndrome, Cantu syndrome, Meretoja syndrome, and others. Bone and skin are affected, but there does not appear to be a selective effect on connective tissues. Intrauterine growth retardation may occur.**
- **The copper-transport defects now known as occipital horn syndrome and Menkes disease are allelic and due to mutations in *ATP7A*. Cutis laxa arises as a result of defects in copper transport that have significant effects on the cross-linking of collagen and elastin by lysyl oxidase.**
- **Acquired cutis laxa usually arises from postinflammatory elastolysis, and it is manifest in Sweet's syndrome, Marshall syndrome, and mid-dermal elastolysis.**
- **Hutchinson-Gilford progeria is the most striking form of progeria, with early childhood signs of reduced stature, cutaneous atrophy, alopecia, and micrognathia. Fatal complications of atherosclerosis and respiratory failure occur in the second and third decades of life. Biochemical evidence of altered elastin and hyaluronan metabolism are associated with the disease but not known to be causative.**
- **Werner syndrome manifests in adolescence as a lack of the typical growth spurt, lack of subcutaneous fat, skin wrinkling with scleroderma-like changes, hyperkeratosis, and premature arteriosclerosis. Malignancies develop in the third and fourth decades. Although connective tissue metabolism is altered in several ways, the primary defect is in RecQ DNA helicase at the WRN locus. Cockayne syndrome is another late-onset form of progeria that is associated with mutations in two genes that lead to defective DNA excision repair.**

INTRODUCTION

The clearest and most inevitable signs of aging are the changes in the appearance of the skin and the shape of the craniofacial skeleton. These are due to alterations in the structural components of the dermis, bone, and cartilage, and there are several striking disease states or syndromes in which the skin, fat, and bone changes that signify advanced age appear

Connective Tissue and Its Heritable Disorders, pages 525–560

prematurely. More importantly, the altered arrangement and abundance of skin and bone macromolecules are often signs of internal connective tissue changes that can impede organ function and increase morbidity. As will be discussed, the etiologies of these syndromes can be quite diverse, although two themes predominate: alterations to elastic tissue and defective DNA repair mechanisms. In the latter case, it should be clear that effects on connective tissue will be secondary to actual genetic mechanisms.

DEFINITIONS AND NOMENCLATURE

Cutis Laxa and Slack Skin Syndromes

Cutis laxa (see Table 1) is characterized by loose and inelastic skin and can be inherited [1,2] or acquired [3–5]. It was first described in the early 19th century by Graf [6]. Inherited forms of cutis laxa are characterized by generalized cutaneous laxity that is present at birth or develops soon afterward. Other organs, such as the lungs, aorta,

TABLE 1. Cutis Laxa and Slack Skin Syndromes

Disease	Inheritance	MIM	Skin Phenotype	Other Clinical Manifestations
Cutis laxa/slack skin				
Cutis laxa	AD	123700	loose, sagging skin lacking elastic recoil	pulmonary emphysema
CL type I	AR	219100	loose skin; deficiency of elastic fibers in the skin	Pulmonary emphysema; diaphragmatic hernia; diverticula of the gastrointestinal and urinary tracts
CL type II	AR	219200	markedly wrinkled and lax skin	mental retardation
CL type III	AR	219150	lax skin; defective elastic fibers	cloudiness of the cornea; mental retardation
CL X-linked (OHS)	AR	304150	defective collagen and elastin; reduced lysyl oxidase activity; poor wound healing	occipital osseous projection; ligament laxity; poor wound healing; abnormality of copper metabolism
Menkes disease	AR	309400	skin laxity and hyperextensibility	skeletal abnormality; vascular complication; mental retardation
SCARF	X-linked	312830	lax skin	joint hyperextensibility; mental retardation; facial abnormality
Deficiency of lysyl oxidase	AR	153455	skin with fewer elastic fibers	
SVAS	AD	185500	premature aging of the skin	Narrowing of aortas; heart failure
Williams syndrome		194050	premature aging of the skin	congenital heart disease; mental retardation
Patterson pseudoleprechaunism		169170	cutis gyrata in hands and feet	hyperadrenocorticism; diabetes mellitus; bladder diverticula
Wrinkly skin syndrome		278250	wrinkled skin of hands and feet	skeletal musculature poorly developed
Costello syndrome		218040	areas of redundant skin; elastic fiber degeneration	growth and mental retardation
Elastosis				
Actinic (solar) elastosis			aged skin; accumulation of elastotic material	fibrillin accumulation
Buschke-Ollendorf syndrome	AD	166700	dermal papules	osteopoikilosis
Elastoderma			skin laxity with accumulation of dermal elastin	
Elastosis perforans serpiginosa	AD?	130100	transepidermal elimination of abnormal elastic fibers	
Pseudoxanthoma elasticum	AR (AD)	264800 177850	skin laxity; calcified elastic fibers	cardiovascular complications; aneurysm; retinopathy

TABLE 1. (*Continued*)

Disease	Inheritance	MIM	Skin Phenotype	Other Clinical Manifestations
Cantu syndrome	AD or X-linked	114620	wrinkled palms and soles	joint hyperextensibility; cardiac anomalies; mental retardation
Aging Syndromes				
Progeria	AD;AR	176670	cutaneous atrophy; loss of facial and scalp hair	arthritis; respiratory complications; atherosclerosis with angina
Wiedemann-Rautenstrauch syndrome	AR	264090	progeroid appearance	intrauterine growth retardation; natal teeth
Werner syndrome	AR	277700	wrinkled skin; hyperkeratosis; atrophy of subcutaneous fat	short stature; arteriosclerosis; frequent malignancies
Cockayne syndrome		216400	lack of subcutaneous fat; senile appearance	dwarfism; retinal atrophy; deafness; mental retardation
Xeroderma pigmentosum		194400		
Mandibulo-acral dysplasia		248370	progeroid features	alopecia; postnatal growth retardation
Gerodermia osteodysplastica	AR	231070	lax skin	joint hyperextensibility; osteoporosis
Hallerman-Streiff syndrome		234100	skin atrophy; progeroid features	cataract; microphthalmia; dysmorphology of airways
Acrogeria		201200	wrinkled skin of feet and hands	joint hypermobility; mental retardation
Metageria			generalized form of 201200; loss of subcutaneous fat; thinning of skin	
Down syndrome		190685	prematurely aged skin	degenerative vascular disease; increased tissue lipofuscin; precocious aging
PAS, Okamoto type		601811		microcephaly; osteosarcoma; osteoporosis
PAS, Penttinen type		601812	hard confluent skin lesions	prematurely aged appearance; acrosteolysis; brachydactyly
Lenz-Majewski hyperostotic dwarfism		151050	skin hypoplasia; loose, wrinkled, and atrophic skin	dental enamel dysplasia; joint laxity
ROMBO syndrome		180730	lack of elastin or elastin in clumps in affected areas	
Acquired Forms				
Cutis laxa acquisita			fragmented, disorganized, and scarce elastic fibers	emphysema; aortic aneurysm; bowel diverticula
Postinflammatory elastolysis			atrophy, wrinkling, and disfigurement of the skin	
Mid-dermal elastolysis			absence of elastic fibers in mid-dermis; wrinkling	
Sweet syndrome			destruction of dermal elastin	
Anetoderma	a few congenital	250450 133690	localized sac-like skin lesions with reduced and fragmented elastic fibers	

gastrointestinal tract, and genitourinary systems are generally involved. Inheritance patterns include autosomal dominant, autosomal recessive, and X-linked recessive. In the inherited forms, the defect seems to be in the synthesis and/or assembly of elastic fibers [7–10], whereas the acquired forms result from the destruction of normal elastic fibers and are often associated with preceding inflammatory reactions, such as urticaria, eczema, or erythema, or as a reaction to penicillin, penicillamine, or other drugs. Histologically, all types of cutis laxa have decreased numbers or an absence of elastic fibers in the dermis [11–13].

Cutis laxa can often be confusing to the clinician because of its heterogeneity and varying etiology. For the purposes of this discussion, cutis laxa is defined as a condition in which the skin, in whole or in part, is inelastic and remarkably wrinkled or sagging. This is in striking contrast to the hyperextensible, hyperelastic skin seen in patients with classical Ehlers-Danlos syndrome (EDS) (see Chapter 9, this volume). Other elastic tissues are affected to a varying extent. Many terms have been used to describe this syndrome in the past, such as dermatochalasis, chalazodermia, Schlaffhaut, and cutis pendula [2]. In contrast to the Ehlers-Danlos syndrome, joint mobility in autosomal forms is usually reduced rather than increased, and the skin does not show increased fragility or a propensity to heal poorly with scarring.

Autosomal Dominant Cutis Laxa

Congenital cutis laxa with no evidence of consanguinity and milder, cutaneous manifestations is often considered to arise from (new) dominant mutations. A clear inheritance pattern has been documented in a number of cases [1,14]. Elastic fibers are either sparse or disorganized. The skin is loose, wrinkled, and lacking in elastic recoil. At least three cases with these criteria have been shown to be due to mutations in the elastin gene [15,16].

Autosomal Recessive Cutis Laxa

The autosomal recessive form of the syndrome displays a more severe phenotype than the dominant form and is often accompanied by aortic aneurysm and pulmonary emphysema. Classification is further subdivided into type I (MIM 219100), fatal in the first year of life [17]; type II (MIM 219200), associated with bone dystrophy, joint laxity, and developmental delay [18]; and type III (De Barsy syndrome; MIM 219150), which presents very severe symptoms, with ocular involvement and mental retardation [19].

In addition to the more typical forms of the syndrome, Rogers and Danks [20] reported a form of cutis laxa with intermediate severity, probably autosomal recessive, which was associated with mental and growth retardation. A unique form of autosomal recessive cutis laxa with cutaneous and systemic involvement presents with severely fragmented elastic fibers in early childhood [21]. This form of the disorder is thought to involve the overexpression of a neutral proteinase with elastolytic activity [22].

Two case reports describe another form of cutis laxa with recessive inheritance presenting with skin and joint laxity at birth and Wormian bones. Lysyl oxidase (MIM 153455) activity is reportedly reduced, but ceruloplasmin and serum copper levels are reportedly normal, and the authors propose a mechanism distinct from the X-linked form of the syndrome that involves copper transport (see below) [23].

X-Linked Recessive Cutis Laxa (MIM 304150)

In the X-linked, recessively inherited form of the syndrome, the cutis laxa phenotype is accompanied by effects on collagenous tissues (ligamentous laxity) and poor wound healing. The underlying mechanism is a copper-transport deficiency leading to reduced activity of lysyl oxidase, an enzyme that is essential to cross-linking of both collagen and elastin. This disorder is discussed more extensively under its new designation, the occipital horn syndrome, in Chapter 14 of this volume.

Acquired Cutis Laxa

Postdevelopmental loss of skin elasticity characterizes acquired cutis laxa, but internal organs, including the respiratory and cardiovascular systems, may become involved. The condition is rare in childhood, and elastic tissue destruction can be generalized, with a craniocaudal progression, or it may be more focal, as in the case of Marshall syndrome (focal elastolysis following Sweet syndrome) [24]. This syndrome should not be confused with the heritable disorder also named Marshall syndrome (MIM 154780). Patients with acquired generalized elastolysis reportedly have a local increase in granulocyte elastase [25].

Progeria

Progeria and accelerated aging syndromes (see Table 1) are a collection of syndromes that manifest several features of accelerated aging, including cutaneous changes such as thin, wrinkled, or sagging skin, premature atherosclerosis, early onset of tumor growth, and bone dystrophy [26,27]. Early-onset forms of progeria include geroderm(i)a osteodysplastica (Bamatter-Franceschetti syndrome), Hallermann-Streiff syndrome, and Wiedemann-Rautenstrauch syndrome, or neonatal progeroid syndrome. Among the forms that show postnatal onset are Cockayne syndrome, Hutchinson-Gilford progeria syndrome, Werner syndrome, and mandibuloacral dysplasia [28]. Skin fibroblasts from progeria patients show a limited *in vitro* life span [29], and faulty DNA repair mechanisms are implicated in several instances [30,31]. Although skin atrophy is common to several subtypes, skin recoil is not altered in progeroid syndromes. Many of the progeroid syndromes show postnatal skeletal and developmental abnormalities that involve connective tissue, but no single matrix component has been implicated. The distinct forms of cutis laxa are excluded from the progeria category (autosomal recessive cutis laxa (MIM 219100), De Barsy syndrome (MIM 219150)) because elastic tissue is selectively affected.

MATRIX COMPONENTS INVOLVED IN CUTIS LAXA AND PREMATURE AGING

Elastic Fibers

Elastin and elastic fibers are reviewed extensively in Chapter 3 of this volume. The elastic properties of nearly all connective tissues are provided by the unique vertebrate structure, the elastic fiber. This is a composite structure that is abundant in the extracellular matrix of dermis, large and medium blood vessels, the lung interstitium and pleura, the vocal folds, the intervertebral ligaments, and elastic cartilage. Elastic fibers are a minor component of many other tissues, including Bruch's membrane of the eye, the cornea [32–34], and the periosteum [35]. The principal component of the elastic fiber is elastin, comprising 70–90% of the peptide material, and the remainder is a mixture of microfibrillar proteins organized into the 15 nm microfibril. The predominant molecule in this latter structure is fibrillin.

Elastin (MIM 130160)

Genetic organization. The single *ELN* (elastin gene locus) resides at 7q11.23 as a highly dilute, multiexon structure spanning more than 40 kb. Individual exons

encode hydrophobic or cross-link domains. Alternative splicing commonly excludes several exons. A 6 kb promoter region has been identified [36,37], and there is a large conserved (1.6 kb) 3′ untranslated region [38] that may regulate mRNA stability [39]. In addition, mRNA stability and TGF-β response elements have been identified within exon 30 of rat elastin mRNA [16].

Biosynthesis. The only intracellular, post-translational modification is the occasional hydroxylation of proline when this amino acid occurs in the appropriate position to act as a substrate for prolyl hydroxylase. Nevertheless, ascorbic acid, a cofactor of prolyl hydroxylase, can antagonize elastin synthesis, probably through an oxidative stress mechanism [40].

Tropoelastin appears to become associated with a molecular chaperone, s-galactosidase (an alternatively spliced, inactive form of β-galactosidase), in the secretory pathway. This lectin may play a dual role as both a means of preventing spontaneous self-aggregation of the hydrophobic monomer before secretion and as part of a cell-surface recognition mechanism [41–43]. Altered proteoglycan catabolism in Hurler syndrome appears to affect elastogenesis via interactions with the 67 kDa elastin/laminin-binding protein [44]. The most crucial modification of elastin is the oxidative deamination of lysyl residues by the copper-dependent lysyl oxidase in the extracellular space to catalyze the condensation of the interchain, tetrafunctional cross-links desmosine and isodesmosine. Several new lysyl oxidase genes have been identified [45–47].

Degradation. The bulk of elastin is accumulated during late fetal life and rapid growth, and turnover of the molecule is exceptionally low. Under normal circumstances, the turnover of elastin can be measured in months to years. Thus, degradation of elastic fibers, particularly in the skin, can lead to irreversible loss of these structures and loss of skin elasticity. Elastin accumulation can rapidly be reactivated in other tissues, however. In blood vessels, neosynthesis is readily brought on by injury or hypertension [48,49], and lung fibrosis can also sharply up-regulate elastin gene expression and accumulation [50].

Breakdown of (cutaneous) elastic tissue is characteristic of intrinsic and accelerated aging. A number of proteinases can degrade elastin (see also Chapter 7, this volume), although the specific term elastase is reserved for neutrophil elastase, a serine proteinase with broad substrate specificity, and a member of the matrix metalloproteinase family, MMP-12 [51]. This zinc metalloenzyme is predominantly produced by macrophages [52]. Both of the gelatinases, MMP-2 and MMP-9, are also relatively efficient elastases that can be secreted by fibroblasts and other mesenchymal cells [53]. Matrilysin (MMP-7) can also degrade elastin. Smooth muscle cells appear to express a unique elastase related to adipsin [54]. As discussed below, many of the acquired forms of cutis laxa appear to arise from either localized or generalized elastin destruction.

Given the high potency of neutrophil elastase, multiple defense mechanisms are normally in place to limit proteolytic action. The most specific and effective inhibitor is α1-antiproteinase (see also Chapter 17, this volume). However, α_2-macroglobulin can certainly block elastase access to macromolecular substrates [55], and secretory leukocyte proteinase inhibitor has significant anti-elastase activity [56].

Microfibrillar Proteins

Microfibrils form the core of the elastic fiber, eventually becoming obscured to microscopic detection as elastin is deposited around them during development. In addition to fibrillin-1 and fibrillin-2, microfibrils contain the microfibril-associated glycoproteins MAGP-1 and MAGP-2, fibulin-1 and fibulin-2, emilin, and LTBP-2 (see also Chapter 3, this volume). In certain sites, such as the dermal-epidermal junction and the trabecular meshwork of the eye, diminishing proportions of elastin transform the tinctorial properties of the elastic structures, leading to the designations elaunin and oxytalan fibers. These microfibrillar components can be affected to a limited extent in acquired forms of cutis laxa. There is a loss of microfibrils perpendicular to the epidermis in cutis laxa acquisita, although fibrillin (MIM 134797) persists in the middle and deep dermis [57], but fibrillin has not been linked genetically to cutis laxa [58]. The fibrillins are closely related to latent TGF-β binding proteins (LTBPs), and the elastic fiber may serve as a reservoir for this potent cytokine [59].

Proteoglycans and Hyaluronan

Proteoglycans and hyaluronan (see Chapter 4, this volume) are crucial to maintaining the hydration state of many connective tissues, and proteoglycan destruction is frequently associated with the age-related degeneration of the joint. In the skin, turgor is regulated, at least in part, by proteoglycan content. These large, negatively charged, hydrophilic macromolecules are not associated with normal elastic fibers, but they can be detected in several pathological conditions affecting elastic fibers. From fetal life onward, the content of the glycosaminoglycan, hyaluronan, diminishes in skin. In addition to changing the mechanical properties of skin, hyaluronan is reported to affect the quality of wound healing. A lower hyaluronan content and a higher hyaluronidase content are associated with a granulation and scarring response, while the converse is characteristic of a fetal regenerative response. Age-related losses are noted in the articular cartilage proteoglycan, aggrecan. The principal proteoglycan found in association with aggrecan is the small proteoglycan, decorin, comprising a 28 kDa polypeptide core and a single dermatan sulfate side chain. Interestingly, an abnormality in small proteodermatan sulfate biosynthesis was reported by Quentin et al. [60,61] in a patient presenting with features of Ehlers-Danlos syndrome and progeria (MIM 130070) (see Chapter 9, this volume). There were multiple abnormalities of connective tissue, including short stature, loose but elastic skin, osteopenia of all bones, delayed wound healing, defective deciduous teeth, and hypermobile joints. The primary defect appeared to be a deficiency of galactosyltransferase I that normally catalyzes the second transfer reaction to xylosyl acceptors on decorin. Two mutations have been identified [62]. As a result, decorin was secreted as an unmodified core protein.

Collagen

Many of the age-related changes in connective tissue are due to altered collagen function; (for a detailed review of collagen biochemistry and molecular biology, see Chapter 2, this volume). Osteoarthritis, osteoporosis, and cutaneous atrophy are hallmarks of aging. They are thought to be due, at least in part, to imbalances between the synthesis and degradation of collagen and other connective tissue components. Senile purpura is consistent with a weakened collagenous structure in the microvasculature.

Biosynthesis. The quantity and quality of collagen production are affected by age. One of the most notable developmental changes is the switch from type III to type I collagen

during perinatal maturation of the skin, but this decline continues for some time. Type III collagen is thought to regulate the form and extensibility of the collagen fiber [63]; thus, reduced elasticity of connective tissues can arise from a lack of type III molecules in both the human disease Ehlers-Danlos syndrome type IV and the *Col3A1* null mouse (see also Chapter 9, this volume). Blood vessels and other extensible structures are most severely affected by overt deficiencies in type III collagen. Fiber diameter is altered in skin and blood vessels. The synthetic rate of collagen in skin fibroblasts shows a moderate decline with age, but this decline is not sufficient to account for phenomena such as cutaneous atrophy or susceptibility to trauma.

Degradation. Collagen destruction is a hallmark of joint and skin aging. The extent of cutaneous atrophy in human skin is correlated with elevated expression of matrix metalloproteinases, including MMP-1 and MMP-2 [64]. Many forms of skin ulceration are coupled to the aging process, and these chronic lesions call into play inflammatory cell proteinases, including neutrophil collagenase (MMP-8) and elastase, among others [65]. It is likely that a modest decline in synthetic activity, when coupled to an exaggerated expression of proteolytic enzymes, can lead to the slow, progressive loss of dermal connective tissue. Although the age-related synthetic capacity of cartilage is less well-characterized, the poor reparative potential of cartilage, once damaged, is well-known.

CUTIS LAXA AND ELASTIC TISSUE DISEASES

Cutis laxa is a relatively rare connective tissue disorder characterized by genetic heterogeneity and clinical variability [12,14–16,66]. The common trend is loose skin with reduced elasticity and a prematurely aged appearance.

Clinical Classification

Cutis laxa (slack skin syndrome) is a collection of diseases that are typified by loose and/or wrinkled skin that imparts a prematurely aged appearance [1]. Various classification schemes have been applied, including distinction based on apparent pattern of inheritance: autosomal recessive, autosomal dominant, X-linked, sporadic, and acquired. More recently, one group of investigators [18] suggested a segregation of the recessive forms into type I (MIM 219100; skin laxity without bone involvement) and type II (MIM 219200; skin laxity with bone involvement) and further amended the McKusick classification [67] to include type III (MIM 219150; skin laxity with mental retardation; De Barsy syndrome). Unfortunately, none of these classifications provides insight into differential mechanisms, although the autosomal dominant forms (MIM 123700) are linked to elastin gene mutations [15,16]. Among the acquired forms, the syndrome has been subdivided.

Common Features

All forms of cutis laxa exhibit clear involvement of the skin, although face, hands, feet, joints, and torso may be differentially affected. Unlike the Ehlers-Danlos syndrome, cutis laxa syndrome always involves elastic tissue, although various organs may be relatively spared.

Cutaneous aspects. The typical aspect of the cutis laxa patient is loose, sagging skin lacking elastic recoil [68]. This is in marked contrast to the hyperelasticity apparent in classical Ehlers-Danlos syndrome (see Chapter 9, this volume). These properties are nearly always attributable to loss, fragmentation, or severe disorganization of dermal elastic fibers [8,69] (Fig. 1). Some, but not all, forms of congenital cutis laxa exhibit reduced elastin production by skin fibroblasts, some of which are due to missense frame shift mutations in the elastin gene [15,16]. Other congenital forms show an abnormal structural arrangement of elastin and its improper association with the microfibrillar component of the elastic fiber [8]. In one familial form of cutis laxa [70] and many forms of cutis laxa acquisita, elastin degradation and increased elastolytic activity can be seen to progress as affected areas or lesions enlarge.

Pulmonary aspects. Despite the heterogeneity of cutis laxa, many forms of the syndrome include pulmonary complications, especially emphysema [1,71–76]. This emphasizes the convergent effects of cutis laxa on the form and function of elastic fibers. Emphysema is most prevalent in the severe, autosomal recessive form of the syndrome. Milder changes, sometimes described as chronic obstructive pulmonary disease, are described in autosomal dominant [1,72,77] and acquired [3,25,78–80] forms of cutis laxa. Cutis laxa patients are often reported to have altered voice characteristics, which are particularly noticeable in acquired forms. Voice alteration (hoarseness) is consistent with deterioration of the rich bed of elastic fibers present in the vocal folds [81–83].

Vascular aspects. Cases of congenital cutis laxa with dilatation of the ascending aorta and hypoplasia of the pulmonary arteries have been reported [1,84]. Aneurysm has been noted in both recessive and acquired forms.

Other organ involvement. Other common abnormalities in cutis laxa include bladder and gut diverticula, diaphragmatic and inguinal hernias, and changes in joint mobility. With the exception of type II and type III autosomal recessive cutis laxa (De Barsy syndrome), bone involvement is not remarkable.

Autosomal Cutis Laxa

Clinical aspects of the syndrome and its heritable pattern were described by Graf as early as 1836 [6], and the predominant patterns of inheritance were described clearly by Beighton [1,2]. The morbidity of the syndrome is related to the pattern of inheritance, the recessive forms being much more severe.

Autosomal Recessive Cutis Laxa

Autosomal recessive cutis laxa was described in the earlier literature by several investigators and reviewed by Beighton [2]. In the type I form (MIM 219100), the phenotype of loose, wrinkled skin, a consequent prematurely aged appearance (Fig. 2), and cardiopulmonary complications is recognized at or shortly after birth. The consequences of internal organ involvement are often fatal in infancy [85]. Beighton noted the frequent association of the syndrome with consanguinity and/or in multiple offspring of the same parents, and characteristic kindreds were described in his 1972 publication [2]. Although elastic fibers and elastic tissues are clearly involved in this condition, the biochemical basis is as yet unknown. Examination of fibroblast strains and dermis from some cutis laxa patients revealed lower elastin expression and ultrastructural findings consistent with defects in elastic fiber assembly [8]. Other congenital cases of cutis laxa show reduced elastin mRNA levels in cultured fibroblasts [7], although lower elastin mRNA levels are not universally associated with these severe forms.

Type II cutis laxa (MIM 219200) is an additional autosomal recessive form of the syndrome that is accompanied by bone dystrophy that was originally described in an affected

Figure 1. Ultrastructural heterogeneity of elastic fiber morphology in dermal biopsies from cutis laxa patients. All micrographs are at an original magnification of 10,000. **A**: small elastic fibers are indicated by arrows. Elastin and microfibrillar components are present but in markedly reduced amounts. **B**: another patient with reduced abundance and altered morphology of elastic fibers in the reticular dermis. The arrow points to elastic fibers. **C**: elastic fibers from the reticular dermis of a patient with autosomal dominant cutis laxa with a 2132delC missense mutation. Note the marked absence of amorphous elastin (arrows) in these fibers. **D**: another cutis laxa patient with abundant elastin but high levels of intrafibrillar microfibrils (arrows). **E**: in this patient, elastic fibers are marked by an excess of microfibrillar material (arrows) and a paucity of amorphous elastin. **F**: a cutis laxa patient who exhibited separate elastin (heavy arrow) and microfibrillar aggregates (fine arrow) as well as an overall reduction in the abundance of each component. Figure 2. S.A. (d.o.b. 4 Oct 96), a 1.5-year-old girl with severe cutis laxa. She was the first and only child of consanguineous Turkish parents. Birth was normal after an uncomplicated pregnancy at term and neonatal adaptation was good; the child at birth had weight 3410 g, length 49 cm, and head circumference 34.5 cm. Both parents are unaffected, although the mother carried a Gly610Arg polymorphism in one *ELN* allele.

S.A. had numerous hospitalizations and the following cumulative diagnoses and complications of severe cutis laxa: upside-down stomach, which was successfully operated upon with ensuing gastroesophageal reflux; pseudodiverticulosis of the colon; diverticulae of the bladder with recurrent urinary tract infections; mitral valve prolapse and insufficiency of the mitral and aortic valves; recurrent respiratory infections; respiratory failure, oxygen-dependent pneumopathy, and pulmonary hypertension; bilateral inguinal herniae; anal prolapse; progressive short stature. (Courtesy of Dr. B. Steinmann.)

female [86]. Japanese investigators described a male patient and reviewed the literature [87]. Unlike type I cutis laxa, hip dislocation is accompanied by growth retardation. Hatamochi et al. [88–90] reported elevated levels of MMP-1, MMP-3, and MMP-9 expression in autosomal recessive cutis laxa fibroblasts and suggest that the pathology of this disease may be due to excess proteinase activity, possibly due to elevated levels of an AP-1-binding transcription factor.

De Barsy syndrome, the type III form of autosomal recessive cutis laxa (MIM 219150), is a progeroid syndrome first described by De Barsy et al. [91] in an infant girl who had cutis laxa with defective development of elastic fibers in the skin. The phenotype is not restricted to elastic tissue, however. The patient presented with cloudiness of the cornea and mental retardation (Fig. 3). Karnes et al. [19] extended these observations by describing a case with aged appearance, dwarfism, mental retardation, right esotropia and myopia, lax skin, lax joints, and elastic fiber deficiency. These authors studied elastin gene expression in cultured skin fibroblasts and observed reduced elastin mRNA steady-state levels compared with age-matched control skin fibroblasts. Stanton et al. [92] presented two cases characterized by severe cutis laxa, growth and mental retardation, a characteristic facies, and joint hypermobility. Jung et al. [93] reported that congenital cutis laxa type III also involves collagen fibers. They described a 6-year-old girl presenting aberrations of collagenous and elastic tissues, increased collagen type I mRNA expression associated with increased protein synthesis, and increased collagenase gene expression in cultured fibroblasts.

Autosomal Dominant Cutis Laxa (MIM 123700)

Dominantly inherited forms of cutis laxa (MIM 123700) were definitively documented in two kindreds by Beighton [2], although earlier citations support this categorization. Loose skin hanging in folds is obvious in infancy (Fig. 4), and elastic fibers are reduced in number. Beighton suggested that the dominant pattern was consistent with a mutation in the structural protein elastin [1]. Molecular and cellular investigations by Tassabehji et al. [15] and Zhang et al. [16] have confirmed dominant inheritance in affected kindreds, although a lack of elastase inhibitors has been suggested as an alternative explanation [94]. Corbett et al. [77] reported two cases (mother and daughter) with a benign

Figure 3. de Barsy syndrome. The 22-month old patient shows laxity of abdominal, thoracic, and facial skin. The patient could not sit up unaided. She showed characteristic facial grimacing and clenching of the hands and wrist. (Reprinted from [19] with permission.)

form of autosomal dominant cutis laxa, confined to the skin, with early onset of emphysema. This classification is probably erroneous, because both patients were heterozygous for α1-antitrypsin mutations as well as being smokers.

Biochemical Findings

Although patterns of inheritance were not clearly described in initial studies, several strains of skin fibroblasts derived from autosomal dominant cutis laxa patients demonstrated low elastin production accompanied by low or undetectable elastin mRNA levels [7,8]. Subsequently, Zhang et al. [9] demonstrated that reduced mRNA levels in cells from two kindreds with autosomal dominant cutis laxa were attributable to mRNA instability, an abnormality that could be reversed by TGF-β.

Type VI collagen. A 1985 *in vitro* study of one cutis laxa fibroblast strain implicated type VI collagen overproduction [95]. Gene expression and protein production of type VI collagen were studied in fibroblasts from patients with congenital cutis laxa and compared with normal strains. Increased quantities of collagen type VI and microfibrils were noted in the strain of skin fibroblasts derived from a 2-year-old patient [95]. In a follow-up study, both collagen type VI mRNAs and corresponding proteins were increased in four other cutis laxa cell strains, and this phenomenon may have been secondarily related to skin changes in the patients from whom the cell strains were derived [96].

Other matrix molecules. Laminin deficiency has been reported in one case of congenital cutis laxa that presented also cardiovascular abnormalities, emphysema, and a diaphragmatic hernia [97]. The same investigators cited an additional 17 cases that may encompass a new disease class.

Proteinase involvement. Increased elastase activity has been reported in cultured dermal fibroblasts from lesional skin of cutis laxa patients [98]. In one report, an Italian family had three of four siblings affected with hemolytic anemia and pulmonary emphysema, and the only sib to survive into adolescence exhibited cutis laxa together with elevated serum elastase activity [99]. A patient with Marshall syndrome combined with α1-antiproteinase (α1-antitrypsin) deficiency exhibited both cutis laxa and pulmonary emphysema [24]. Cathepsin G expression has been implicated in cutis laxa with possible involvement in two generations [100].

Genetic Basis

Both Tassabehji et al. [15] and Zhang et al. [16] have described mutations in the elastin gene in autosomal dominant cutis laxa (Fig. 5). The cellular consequences appear to be different in the three cases. In the study by Zhang et al., decreases in elastin protein production and

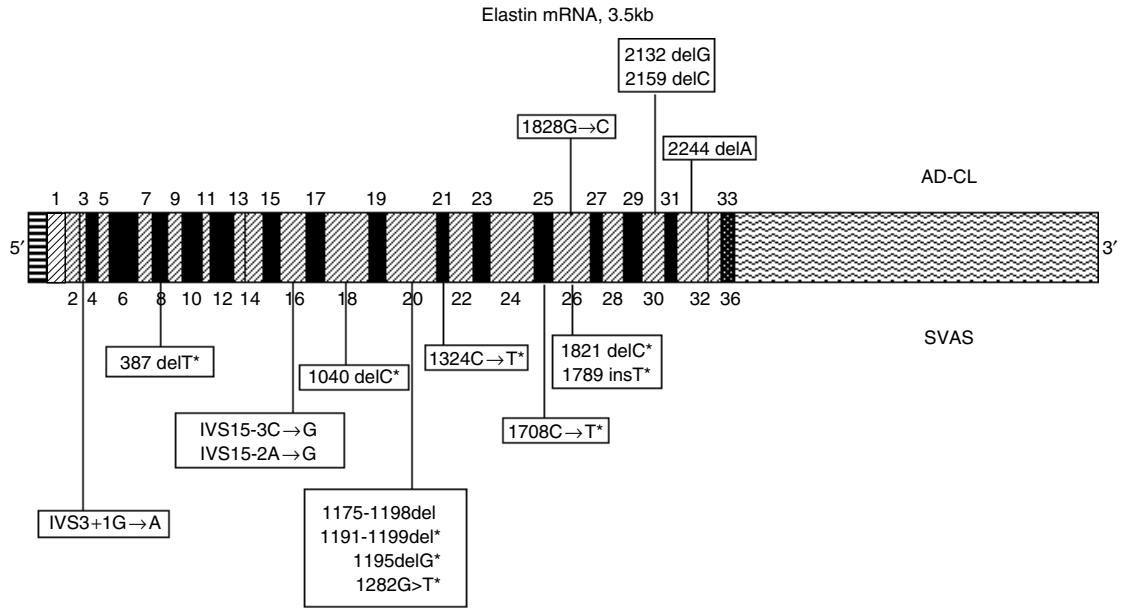

Figure 5. Mutations in the elastin gene. The entire coding sequence of 3.5 kb is depicted in relation to exon notation and domain structure as follows: 5′UTR ▤; signal peptide ▨; cross-linking domains ■; hydrophobic domains ▨; C-terminal region (exon 36) ▩; and 3′ UTR ▤. Mutations in supravalvular aortic stenosis (SVAS) are shown below the cDNA structure, while mutations in cutis laxa (AD-CL) are shown above. In one instance, the same mutation has been documented in two separate cases. A number of the SVAS mutations shown below the graph involve splice sites. In general, SVAS mutations tend to be located toward the 5′ end of the gene and generally result in premature termination codons (asterisks), while the cutis laxa mutations are confined to exons 30 [16] and 32 [15] in the 3′ region and encode missense C-termini. The nonconservative 1828G → C mutation in exon 26 (Gly610Arg) is reported to be polymorphic with a 7% allelic frequency in a Caucasian population and has been identified in one severely affected cutis laxa patient (Fig. 2). These data and a compilation of known polymorphisms have been summarized by Urban et al. [189].

unstable elastin mRNA in skin fibroblasts from two kindreds were linked to two distinct point deletions in the 5′ portion of exon 30 (2132delG; 2159delC), an exon that encodes a typical hydrophobic domain in elastin. The presence of either mutation and the observed alternative splicing of exon 32 led to a missense translation product extended by 25 amino acids; however, no significant elastin protein was produced by cultured fibroblasts from either patient in the absence of TGF-β. The structure of the mutant mRNA or protein led to instability of both normal and mutant transcripts, possibly related to a negative feedback regulation [101] or the alteration of mRNA stability sequences present in exon 30 [16]. In contrast, the mutation described by Tassabehji et al. [15] (2244delA) had no apparent effect on elastin production or mRNA stability and occurred in exon 32. This deletion resulted in a missense translation product in which the 37 C-terminal amino acids of tropoelastin were replaced with a novel sequence of 62 amino acids. Although exon 32 is frequently absent from mature elastin mRNA, transcripts from both mutant and normal alleles were present in cultured skin fibroblasts, and an abnormally large form of tropoelastin was detected in culture supernatants. Thus, in this case, mutant protein may act dominantly to alter elastin assembly. One implication of these studies is that truncations or extensions near the C-terminus of the protein may have limited consequences on elastin function in organs other than the skin. On the other hand, the findings from both of these studies suggest that phenotypic rescue by alternative splicing of mutant exons could spare other organs [15,16].

X-Linked Recessive Cutis Laxa (MIM 304150)

X-linked cutis laxa has had a complex history. It was first described by Byers et al. [102] as a cutis laxa syndrome, while a similar disease had previously been identified as a novel syndrome presenting, among other features, occipital horns [67,103]. Subsequently, Taieb et al. [104] reported that the X-linked cutis laxa described by Byers et al. was the same entity as that referred to at that time as Ehlers-Danlos syndrome type IX (see Chapter 9, this volume) by other investigators [105]. This syndrome is no longer classified as EDS type IX but now corresponds to the occipital horn syndrome, a disorder of copper transport (see Chapter 14, this volume). In this syndrome, the cutis laxa phenotype is accompanied by effects on collagenous tissues (ligamentous laxity) [106] and poor wound healing. Occipital horn syndrome and lysyl oxidase are closely interrelated by the dependency of this enzyme on tissue copper availability. The underlying disease mechanism is a copper-transport deficiency leading, among other effects, to reduced activity of lysyl oxidase, an enzyme essential to cross-linking of both collagen and elastin [106–108] (see Chapters 2 and 3, this volume). The specific genetic lesion results in the deficiency of a Cu^{2+}-ATPase located on the X chromosome (MIM 300011; *ATP7A*). Similarly, direct deficiency of the enzyme, resulting from either toxic inhibition through the ingestion of lathyrogens such as β-aminopropionitrile, or dietary copper deficiency, has an effect on the degree and extent of collagen and elastin cross-linking that can manifest, in part, as cutis laxa.

Menkes Disease (MIM 309400) and the Occipital Horn Syndrome (MIM 304150)

Menkes disease and the occipital horn syndrome (see also Chapter 14, this volume) are allelic variants of X-linked cutis laxa [109–112], being X-linked recessive disorders of copper transport with a reduction in fibroblast lysyl oxidase activity due, in part, to a pretranslational mechanism [113] as well as to dependence of the enzyme on copper for catalytic activity. Increased skin laxity is accompanied by skin hyperextensibility, joint hyperextensibility, skeletal abnormalities, neurologic degeneration, mental retardation, and vascular complications [105]. Unlike the occipital horn syndrome, Menkes disease is usually a lethal condition, although it can exist in a milder form [114–116]. There are two highly polymorphic CA repeats that should be useful for prenatal diagnosis and carrier detection in Menkes disease and the occipital horn syndrome [117]. Martins et al. [118] have reported ultrastructural findings concerning elastic fiber alterations of the skin in three patients with this syndrome. The elastic fibers of the reticular dermis presented a paucity of the central amorphous component whereas the microfibrillar component looked normal. Elastic fiber disruption and dye and antibody binding suggest an abnormal association of elastin with glycosaminoglycans [119].

SCARF Syndrome (MIM 312830)

Koppe et al. [120] described two male maternal cousins with lax skin and joint hyperextensibility, skeletal abnormalities, retardation, and facial abnormalities. The fact that the two young patients were related through their mothers may suggest X-linked recessive inheritance. The acronym SCARF stands for skeletal abnormalities, cutis laxa, craniostenosis, ambiguous genitalia, retardation, and facial abnormalities. This rare form only differs from the occipital horn syndrome in terms of the genital ambiguity and dental abnormalities.

Deficiency of Lysyl Oxidase

Lysyl oxidase, an extracellular, copper-dependent enzyme located on chromosome 5 (MIM 153455), has been reported, without supporting data, to be deficient in two cases of congenital cutis laxa with an autosomal recessive inheritance [23]. Cutaneous elastic fibers were diminished, and the symptoms declined with age. Spinal osteoporosis and joint laxity were present. Serum copper and ceruloplasmin levels were normal in the affected individuals. A family with several affected offspring showing mild cutis laxa, emphysema, and joint laxity of variable penetrance may fall into this category [121].

Cutis Laxa Acquisita

Clinical Aspects

Perhaps even more heterogeneous than the inherited forms of cutis laxa is the collection of acquired conditions that lead to late (adult) onset of elastic fiber destruction. Though genetic associations are lacking, knowledge of these forms can be useful in differential diagnosis. The disorders can be generalized and progressive or may be localized to the face or digits. Cutis laxa acquisita has been associated with multiple myeloma [5], altered antiproteinase status [100], and a wide variety of inflammatory conditions [24,122–135]. Tsuji provides a good summary of earlier cases [136].

Postinflammatory Elastolysis

Elastolysis and cutis laxa as a consequence of inflammation (Fig. 6) has been described by Lewis et al. [132]. This form of acquired cutis laxa has a childhood onset, and its characteristics are malaise, fever, and the presence of large urticarial or papular eruptions that evolve to bring about the destruction of elastic tissue, resulting in areas of atrophy, wrinkling, and severe disfigurement of the skin. Its course is relatively benign, and it is distinguishable from anetoderma with cutis laxa and other forms of elastolysis by its clinical features. It was first described in children from Africa and South America living in tropical or subtropical climates; Lewis et al. [132] reported the first case in a white child.

Other Forms of Elastolysis

Mid-dermal elastolysis. This form of cutis laxa acquisita [137] is a rare, acquired condition presenting as erythematous patches, an absence of elastic fibers in the mid-dermis, and wrinkling [123]. The condition has been compared and contrasted with other elastic tissue abnormalities such as solar elastosis, anetoderma, postinflammatory elastolysis, and heritable forms of cutis laxa [131,138]. As may be true for other acquisita forms, this condition may have an inflammatory pathogenesis [138].

Sweet syndrome with acquired cutis laxa. This rare pediatric skin disease starts with an acquired neutrophilic dermatosis (Sweet syndrome) that is followed by the destruction of dermal elastin producing acquired cutis laxa [139–142]. In one case, inflammation and destruction extended to the aorta [140]. The original reports were

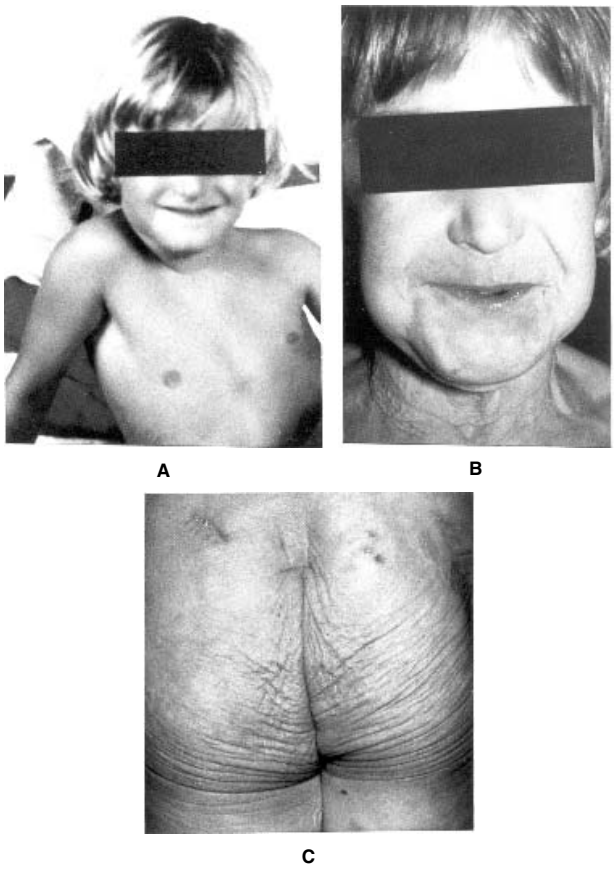

Figure 6. Postinflammatory elastolysis and cutis laxa. Face before (**A**) and after (**B**) development and resolution of urticarial lesions in a five-year-old male. Panel **C** illustrates the buttocks region. (Reprinted from [132] with permission.)

based on observations by Marshall on African children in whom lesions were possibly created by insect bites [143,144]. Hwang et al. [24] reviewed several cases of Sweet syndrome and presented a novel case with classic signs and also α1-antitrypsin deficiency. The cause of Sweet syndrome is unknown, but the α1-antitrypsin deficiency may have allowed the unregulated destruction of dermal elastin by neutrophil elastase.

Anetoderma. In this disorder, localized flaccid, sac-like skin lesions develop over several years. Within the lesions, elastin fibers are reduced in number and fragmented. This has been determined in studies using both radioimmunoassay of desmosines, elastin cross-links [145], and light and electron microscopy [146]. Both macrophages and lymphocytes with plasma cells have been localized in the affected areas [147] and, more recently, image analysis has demonstrated a reduced number of elastic fibers in tensional skin of three patients [148]. This last study also reported an increase in the activity of progelatinases A and B (MMP-2 and MMP-9) in tissues and the activation of progelatinase A in organ cultures from explants of affected skin [148]. Another case study suggested that autoimmunity could be involved [149], which is a common thread in many cutis laxa studies. Other cutaneous insults such as the application of leeches can incite similar lesions [150]. Histologic examination of areas so treated showed a deficiency of elastic fibers, probably due to the release of elastase from leukocytes.

A few cases of congenital anetoderma have been reported (MIM 250450; MIM 133690), some in association with skeletal abnormalities [151,152]. Michaelsson [153] described the Rombo syndrome (MIM 180730), a familial disorder with vermiculate atrophoderma, and other cutaneous abnormalities. This dominant, four-generation disorder showed histological features during the early stages that included irregularly distributed and atrophic hair follicles, milia, dilated dermal vessels, and lack of elastin or the presence of elastin in clumps. Related localized elastolysis and cutis laxa also occur in annular atrophic lichen planus [154].

Localized loss of elastic fibers can also occur in atrophoderma, which presents as circular, depressed lesions in the dermis [155]. Elastin production was reduced and elastase levels increased in cultured skin fibroblasts from affected sites in one patient with a diagnosis of atrophoderma that was based on similar perivascular infiltrates of mononuclear cells [156]. The more recent case report describes similar lesions in a 61-year-old black female, and the authors suggest the term atrophoderma elastolytica discreta for this entity [155].

Pathogenesis

Role of the neutrophil. Because the neutrophil represents the richest source of elastolytic enzymes, including elastase and cathepsin G, involvement of this cell type might be expected. Several instances of neutrophil involvement in acquired cutis laxa may be found in the literature [139–141,157,158]. In a number of cases, generalized elastolysis associated with IgA deposits and infiltrates of eosinophils and neutrophils has been described [125,128,138]. Marshall syndrome shares this pathogenetic mechanism. A genetic component was excluded in one study of identical twins [159].

Role of the lymphocyte. Elastic tissue breakdown and disappearance often begins with an inflammatory episode. This may be accompanied by an obvious source of irritation, but this is not always the case [138]. The immune system shows multiple connections with acquired forms of cutis laxa, but autoimmunity is rarely implicated. A number of cases of multiple myeloma show association with cutis laxa acquisita as a paraneoplastic syndrome [3,5,160–164], but the accumulation of IgG on elastic fibers has only been noted in one such instance [3]. IgG associated with elastic fibers was noted in a case of plasma cell dyscrasia [126], and Tsuji suggested a possible autoimmune component [136]. Acquired cutis laxa has been reported in association with cutaneous T-cell [124] and B-cell lymphoma [127].

Blood vessels. Vascular involvement has been noted in acute neutrophilic dermatosis (Sweet syndrome) [165]. Vascular damage is clear in pseudoxanthoma elasticum (PXE; see Chapter 11, this volume), although the typical abnormality of elastic fibers in this instance is calcification rather than degradation [166]. Pseudoxanthoma elasticum can exhibit signs of cutis laxa [167], and multiple alterations to the elastic fiber have been noted [168–170]. Congenital vascular abnormalities may be present [84,171].

Lungs. Pulmonary involvement is occasionally found in association with cutaneous manifestations of cutis laxa acquisita [5,100,136]. Although not truly representing an acquisita form of the syndrome, one family with generalized elastolysis and elastic fiber fragmentation exhibited clear and early signs of pulmonary emphysema [22,99]. Pulmonary artery stenosis may also be present in acquired cutis laxa [28,84,104,172].

Supravalvular Aortic Stenosis (SVAS; MIM 185500) and Williams syndrome (MIM 194050)

SVAS is an autosomal dominant condition that presents as narrowing of the ascending aorta and other arteries, which can lead to elevated intracardiac pressure, myocardial hypertrophy, heart failure, and death. It can be inherited as an isolated trait [15,173–177] or as part of a second disease, Williams syndrome, which is a developmental disorder involving the vasculature, the central nervous system, and connective tissue. SVAS is due to functional hemizygosity at the elastin locus, whereas Williams syndrome deletions encompass a much larger segment of chromosome 7 [178]. The SVAS patient described by Tassabehji et al. [15] presented at birth with a heart murmur. At the age of 3 years, echocardiography suggested SVAS on the basis of narrowing of the ascending aorta and poststenotic dilatation. A brother had died suddenly in the first year of life and at autopsy had been noted to have had spontaneously repaired SVAS, repaired central pulmonary artery stenosis, and marked ventricular hypertrophy. The aortic valve and proximal aorta were markedly dysplastic, with extreme thickening beyond the valve. The proband's mother had presented to cardiologists in childhood with a murmur, and a clinical diagnosis of aortic stenosis had been made.

Some of the main features of Williams syndrome are congenital heart disease, premature aging of the skin, and poor visual-motor integration [178–185]. Williams syndrome patients have a remarkable spectrum of cognitive alterations, including mental retardation that is accompanied by unusual musical and linguistic skills and an outgoing personality [186]. There are also connective tissue changes, including vascular involvement, hypertension, and premature aging of the skin, but other significant features such as mental retardation and an unusual set of behaviors are consistent with the deletion of a larger block of genetic information.

Moderate changes in skin texture that may relate to elastic fiber architecture have been reported [187].

Molecular Genetics

Since 1993, a number of investigators have defined SVAS as a group of mutations at the elastin locus (7q11.23) [173–175,179,181,188,189]. In the study reported by Ewart et al. [174], the disease phenotype was linked to gross DNA rearrangements (35 and 85 kb deletions and a translocation in chromosome 7) in three SVAS families. However, large-scale rearrangements of the elastin gene have not occurred in the majority of autosomal dominant SVAS cases examined to date. A number of point mutations that support functional hemizygosity have been defined in SVAS (Fig. 5). Li et al. [177] showed that *ELN* point mutations cosegregated with SVAS in four familial cases and were correlated with SVAS in three sporadic cases. Two of the mutations were nonsense mutations causing premature termination in exons 21 (1324C → T) and 25 (1708C → T), respectively, one was a single base pair deletion (1821delC), and four were splice site mutations in introns. In one sporadic case, an *ELN* deletion arose *de novo* and caused a frame shift, resulting in a premature stop codon in exon 28. In one patient with SVAS, Tassabehji et al. [188] identified the insertion of a T in codon 606 of exon 26 of the *ELN* gene (1814insT), which produced a frame shift predicted to cause premature termination 10 codons downstream. Thus, mutations in SVAS that do not ablate large portions of the *ELN* locus are likely to create functional hemizygosity through the generation of translation products that undergo premature termination and, at least in some cases, nonsense-mediated decay. Six new SVAS mutations and 11 new single-nucleotide polymorphisms (SNP) have been identified [189]. Five SNPs were intronic, and five of six expressed SNPs were from a single individual. Interestingly, three of the SVAS kindreds had mutations in exon 20. Compound heterozygosity was suggested in one proband, with one apparently normal parent carrying a frame shift mutation (387delT) and the other a short, in-frame deletion in exon 20 (1175-1198del). The one broadly expressed polymorphism, 1828G → C in exon 26, had a prevalence of 7% and predicts a Gly610Arg amino acid change that could have functional consequences. In contrast to pure SVAS, Williams syndrome involves the deletion of a large (100 kB) region at the 7q11.2 locus that nearly always encompasses the *ELN* locus and that includes the deletion of at least five other structural genes [178,180,182,190].

Messenger RNA levels and levels of tropoelastin expression have not been determined in most cases of SVAS. A C to G transversion at the acceptor splice site of exon 16 was shown to create a truncated elastin transcript that was expressed at very low levels [191]. Urban and colleagues demonstrated that one mutation, 1195delG, leads to haploinsufficiency due to nonsense-mediated decay that is reversible by cycloheximide treatment of cultured fibroblasts. These cells also produced reduced amounts of tropoelastin [189]. *ELN* (elastin gene) haploinsufficiency appears to affect the ascending aorta selectively, most likely due to the high concentration of elastin in this tissue as a result of the selective expression of the elastin gene during perinatal development and the high mechanical load placed on the tissue by cardiac output. Other elastic tissues are affected to a lesser extent, if at all. Although penetrance of the mutation is complete, there is very wide variability in the extent and severity of mutational consequences, confirming the important influence of other genes and environmental influences on the expression of this defect.

Relationship to Other Elastin Gene Defects

Molecular genetic findings have now shown that autosomal dominant cutis laxa is allelic with SVAS at the elastin locus. Although there are cutaneous manifestations in SVAS, the predominant pathology is severe, progressive disorganization of the arterial wall. In contrast, the autosomal dominant cutis laxa mutations identified to date are all predicted to encode peptides that are extended at their C-termini and whose C-termini contain missense sequences. The only confirmed cutis laxa mutations occur in the 5′ region of the transcript (exons 30 and 32) [15,16].

Other Congenital Forms or Syndromes with Features of Cutis Laxa

Patterson Pseudoleprechaunism Syndrome (MIM 169170)

Patterson and Watkins [192] described a 10-month-old boy with marked cutis gyrata (deeply furrowed skin) of hands and feet and a generalized skeletal disorder. He developed hyperadrenocorticism, diabetes mellitus, and bladder diverticula and died at age 7.5 years from gram-negative sepsis. Enlargement of the zona fasciculata of the adrenal glands was found at autopsy [193].

Wrinkly Skin Syndrome (MIM 278250)

Wrinkly skin syndrome is characterized by wrinkled skin on the hands and feet, with an increased number of wrinkles on the palms and soles, poorly developed skeletal musculature, and a prominent venous pattern over the anterior thorax [194]. The syndrome may occur together with mental retardation and microcephaly, in one such case of which there was a decrease in the number and length of elastic fibers in a skin biopsy from a wrinkled area [195]. Likewise, a mother and two sons with wrinkly skin syndrome presented with wrinkling of the abdominal skin as well as that of the dorsum of the hands and feet, decreased elastic recoil of the skin, an increased number of palmar and plantar creases, musculoskeletal anomalies, microcephaly, mental retardation, and an aged appearance. Fragmented elastic fibers were evident in the dermis [196]. These last authors reported an interstitial deletion involving band q32 of chromosome 2 and also noted that two collagen genes, *COL3A1* (MIM 120180) and *COL5A2* (MIM 120190), located in the same general region of 2q, may be candidate genes for wrinkly skin syndrome. They compared the phenotype of their patient with those of 20 previously reported individuals with the same deletion and emphasized the overlapping features of del 2q and wrinkly skin syndrome. The co-occurrence of mental retardation and elastic fiber deficiency is shared with DeBarsy syndrome and Costello syndrome, perhaps suggesting a common mechanism.

Other Syndromes

Other congenital anomalies that exhibit cutis laxa features include ablepharon-macrostomia syndrome (MIM 200110) and the related, possibly allelic condition, Barber-Say syndrome (MIM 209885) [197,198]. There is marked wrinkling and laxity of the skin and a prematurely aged appearance in both syndromes, and elastic fiber abnormalities have been noted in several cases [199,200]. However, there were no ultrastructural abnormalities of either elastic fibers or microfibrils at the electron-microscopic level in one case in which an 18q deletion was present [201]. Furthermore, hyperelastosis was reported in the index case of the Barber-Say syndrome [197]. Because of distinctive

clinical manifestations that are shared by the ablepharon-macrostomia and Barber-Say syndromes, it has been suggested that they may represent defects in the same gene [198].

Another syndrome, the arterial tortuosity syndrome (MIM 208050), presents with arterial tortuosity and alteration of the vascular elastic fibers accompanied by skin hyperelasticity, which may be confused with cutis laxa. It has been suggested to be an autosomal recessive connective tissue disorder [202]. The latter authors reported histologic findings at autopsy of one affected child showing arterial changes involving disruption of elastic fibers of the media and fragmentation of the internal elastic lamina. Other reports suggest an association with Ehlers-Danlos syndrome, based on skin and joint hyperextensibility [203,204].

Costello Syndrome (MIM 218040)

This condition was first described in 1977 [205]. Children with this syndrome present with short stature; redundant skin of the neck, palms, soles, and fingers; curly hair; papillomata around the mouth and nares; and mental retardation [205,206]. Further review of several cases [207] and a ten-year follow-up [208] of previous cases [209,210] led to the conclusion that Costello syndrome should be included in the differential diagnosis of cutis laxa in association with postnatal growth retardation and developmental delay. A further case described clinical findings that included loose skin of the neck, hands, and feet; deep palmar and plantar creases; a typical coarse face with thick lips and macroglossia; relative macrocephaly; mental retardation; short stature; arrhythmia; a large size for gestational age; and poor feeding [211]. The infant died of rhabdomyolysis at the age of 6 months. The major pathologic findings were fine, disrupted, and loosely constructed elastic fibers in the skin, tongue, pharynx, larynx, and upper esophagus, but fibers were normal in the bronchi, alveoli, aorta, and coronary arteries. The degeneration of elastic fibers was confirmed in the skin of another, previously described patient from Japan [212]. Autopsy also showed degeneration of the atrial conduction system, calcification and ballooning of skeletal muscle fibers with infiltration of macrophages, and myoglobin deposits in the collecting ducts of the kidney, consistent with rhabdomyolysis. Clinical findings in 14 cases showed increased elastic fiber fragmentation. Lack of elastic fiber attachment was observed in one patient [213]; however, normal elastin fibers have been reported by other authors [207,214–216].

Although the cause of Costello syndrome remains unknown, possible autosomal recessive inheritance [217–219] and an autosomal dominant, *de novo* mutation to explain the sporadic occurrence of the syndrome [220] have been suggested. An underlying metabolic defect, possibly a lysosomal storage disorder, has been proposed [217].

Defects in elastic fiber assembly may be coupled to mental retardation and other abnormalities in Costello syndrome through an excess level of galactosyl sugars, derived from chondroitin sulfate proteoglycans such as biglycan and CD44, that interfere with the action of the 67 kDa elastin/laminin-binding protein [221]. This study showed that six strains of Costello syndrome skin fibroblasts secreted normal levels of tropoelastin but that they failed to incorporate the precursor into insoluble elastin or immunoreactive elastic fibers. The elastin-binding protein appeared to be shed from the cell surface at an abnormally high rate, and intracellular pools of biglycan and CD44 appeared elevated. The cellular phenotype was reversed by addition of chondroitinase ABC. This concept has been reviewed [222].

Trisomy 7p

This disorder can include cutis laxa as part of the spectrum of multiple congenital anomalies [223]. Redundant skin at the neck and joints as well as cardiovascular abnormalities have been reported. Because the elastin locus is on the 7q arm of chromosome 7, elastin gene dosage would be unaffected.

Recurrent ctb(7)(q31.3)

This syndrome consists of one case that presented as neonatal cutis laxa with a Marfanoid phenotype. The child died of severe cardiovascular problems at 22 weeks. There was a chromosomal break (ctb) at 7q31.3 that led to an examination of laminin status. Fibroblast strains could not be established. The investigators proposed either an absence of, or an abnormality in, the B1 chain of laminin as a consequence of the chromosomal anomaly [97].

Meretoja Type Amyloidosis (MIM 105120)

Neurologic signs in this disorder (also known as amyloidosis V or Finnish type amyloidosis) derive from an inheritable systemic amyloidosis (amyloid deposition in the perineurium and endoneurium) that affects facial muscle tone and causes a bloodhound-like facies that could be confused with cutis laxa. In several Japanese cases, the phenotype is due to a mutation in gelsolin that results in extracellular deposition of the protein as amyloid material [164,224,225]. Cutis laxa with typical dermal elastolysis can also be associated with amyloid deposits [162,164,226–228].

Cantu Syndrome (MIM 114620)

Cantu et al. [229] reported four unrelated girls with an apparently identical syndrome consisting of mild mental retardation, short stature, macrocranium, a prominent forehead, hypertelorism, exophthalmos, cardiac anomalies, cutis laxa, wrinkled palms and soles, joint hyperextensibility, wide ribs, and small vertebral bodies. Each was the product of nonconsanguineous parents and appeared to be sporadic cases. In each case, the age of the father was advanced. The authors suggested the possible presence of a *de novo* autosomal or X-linked dominant mutation. Further reports suggested an autosomal recessive pattern based on affected sibs [230–232], but the most recent analysis has once again favored the concept of new, dominant mutations [233].

Congenital Hemolytic Anemia with Emphysema and Cutis Laxa (MIM 235360)

This syndrome presented in three of four sibs from a consanguineous mating as severe congenital hemolytic anemia and early onset of pulmonary emphysema. One of the probands demonstrated at age 15 severe pulmonary emphysema and cutis laxa [99]. These cases can be considered a unique form of cutis laxa.

Elastoses

Excessive elastin accumulation (elastosis) can arise from both genetic and environmental causes. The examples discussed below do not include common pathological states that involve elastin, such as hypertension and other fibroproliferative disorders.

Actinic (Solar) Elastosis

The sun is a major cause of dermal alteration in photoaging. Chronic exposure of the skin to UV leads to the accumulation of so-called elastotic material in the mid- and deep dermis. This material is formed by the

generation of large and irregular clumps of elastin together with other poorly defined extracellular matrix components by an unknown mechanism. Elastin expression is increased, and fibrillin expression and accumulation are also elevated [234]. Elastic fiber accumulation appears both to displace and mask collagen accumulation at affected sites [235], leading to altered appearance and biomechanical properties. In transgenic mice harboring an elastin promoter linked to β-galactosidase, UV activation of the promoter correlates with elastosis [236–238]. In contrast to the situation in photoaged skin, elastic fiber content tends to diminish with chronological age in nonsun-exposed areas [239].

Buschke-Ollendorff Syndrome (Osteopoikilosis; MIM 166700)

Buschke-Ollendorff syndrome is an autosomal dominant disorder characterized by uneven osseous formation in bone (osteopoikilosis) and yellowish, fibrous skin papules containing elastic fibers (dermatofibrosis lenticularis disseminata). This disease is not characterized by a prematurely aged appearance. Collagen and elastin fibers appear thickened and distorted by electron microscopy, and *in vitro* production of these proteins by skin fibroblasts is elevated [240]. Osteopoikilosis may occur independently of skin lesions. Although bone involvement may suggest a nonelastin etiology, elastic fibers are a component of the periosteum, and their abundance is elevated during fracture repair [35].

Elastoderma

Elastoderma is a very rare acquired syndrome, involving skin laxity and excessive accumulation of dermal elastin without calcification, in contrast to the calcification seen in pseudoxanthoma elasticum. Only two cases have been described. The first, a 29-year-old female, showed the development of loose and pendulous skin over the trunk and right arm with a superficial resemblance to acquired cutis laxa [241,242]. Although excessive elastin accumulation was noted, the skin lacked normal recoil. Elastic fibers were reportedly pleiomorphic. The etiology is unknown. The second case was a 27-year-old man with a 2-year history of prematurely aged skin localized to the anterior and posterior of his neck, accompanied by a marked accumulation of thin, intertwined elastic fibers, particularly in the papillary dermis [243].

Elastosis Perforans Serpiginosa (MIM 130100)

Elastosis perforans serpiginosa is a rare skin disease characterized by transepidermal elimination of abnormal elastic fibers [244]. Elastic material can be organized as large fibers or as infiltrating material with an inhomogeneous organization. It is a rare disease, found principally in young individuals, and is characterized by keratotic papules clustered in an arcuate arrangement. Histologically, the lesions show a hyperkeratotic and acanthotic epidermis, communicating channels extending from the dermis to the surface, and increased dermal elastin. It is occasionally associated with Marfan syndrome, pseudoxanthoma elasticum, Ehlers-Danlos syndrome type IV, osteogenesis imperfecta, and Down syndrome. The pathogenesis of the condition remains unclear. One family with isolated elastosis perforans serpiginosa has been reported in which inheritance was autosomal dominant with variable expression [245].

Pseudoxanthoma Elasticum (PXE; MIM 264800,177850)

The prime characteristic of pseudoxanthoma elasticum (see also Chapter 11, this volume) is the accumulation of calcified, fragmented elastic fibers in flexural skin. Skin laxity may be present. Effects extend to other elastic tissues, including Bruch's membrane of the eye (forming angioid streaks), and cardiovascular complications due, at least in part, to calcification and cracking of vascular elastic laminae [168,169,246]. Patients are at risk of blindness and gastrointestinal hemorrhage. A consensus conference reviewed the features and classification of PXE [247]. Lax or redundant skin is part of a distinctive constellation of signs that strongly implicate elastic tissue as a primary target. Elevated fibroblast elastase activity has been reported [98]. Elastin has been excluded as a candidate locus [246]. Linkage of both autosomal recessive and dominant PXE to a locus at 16p13.1 has been shown [248–252], and PXE-causing mutations have been identified at the locus of the ABC transporter gene (*ABCC6*), the product of which is associated with multidrug resistance [253,254].

PREMATURE AGING SYNDROMES

Premature aging disorders can be divided into several groups, depending on the time of onset, which can be prenatal, neonatal, postnatal, or postadolescent. Many of these syndromes exhibit connective tissue changes common to innate aging, including wrinkling and atrophy of skin, loss of subcutaneous fat, bone fragility, advanced atherosclerosis, and skeletal deformities. In most cases, the biochemical and genetic bases of the pathology are unknown. Many of the premature aging syndromes show evidence of possible convergent mechanisms in the sense that signs such as micrognathia, alopecia, and a beaked nose are common among many of the progeroid forms.

A hallmark of many of the aging syndromes is atrophy and wrinkling of the skin. The skin may have a parchment-like texture, and there is often an absence of subcutaneous fat. Unlike cutis laxa, loose, sagging skin is a rarer observation. The collagen content of the skin is reduced as determined by histological evaluation. Muscle development can be poor or atrophic, and many of the syndromes show micrognathia and/or facial hypoplasia. Growth may be mildly to severely retarded. Atherosclerosis is accelerated and advanced. Most severely affected individuals die of complications of coronary artery disease.

Hutchinson-Gilford Progeria (MIM 176670)

This form of progeria was independently described by Hutchinson in 1886 [255] and Gilford in 1904 [256,257]. It is the rare but classical archetype of premature aging syndromes (Fig. 7). Although patients may not exhibit growth retardation at birth, this problem is evident within the first few months of life, and growth rapidly falls below the 10th percentile, often ceasing after the fifth year. Patients have striking features of segmental aging, including cutaneous atrophy, micrognathia, a beaked nose, a large cranium, corneal clouding, loss of facial and scalp hair in the first years of life, crowding of teeth, and a narrow chest. Mental retardation is absent. Arthritis and respiratory complications arise in the first decade, and atherosclerosis with angina is prevalent. Life span ranges from 7 to 27 years, with coronary artery disease being the most common cause of death [258]. Both autosomal dominant [259,260] and autosomal recessive inheritance patterns [261–263] have been suggested. Germline mosaicism has been suggested in a few familial cases, one of two brothers [264], another of nine offspring of two sisters [265], and a consanguineous Libyan family [266]. Maciel [262] reported a Brazilian family with

Figure 7. Characteristic facial features of a patient with Hutchinson-Gilford progeria. This 10-year-old female shows classic craniofacial disproportion, loss of hair and subcutaneous adipose tissue, absent earlobes, and irregular skin pigmentation. She died three years later of congestive heart failure. (Reprinted from [260] with permission.)

clear autosomal recessive inheritance, but McKusick [67] questions the authenticity of the diagnosis (MIM 176670). Brown et al. [267] described identical twins with progeria who died of heart failure a month apart at age 8 years. There was evidence for a possible deficit in growth hormone and a suggestion that a gene for progeria could be located on chromosome 1 [267]. On the other hand, a common trait of high elastin production as observed in fibroblasts from one mother and her progeroid child could indicate an autosomal recessive inheritance [263].

Biochemical Findings

Progeroid fibroblasts in culture have a very limited life span [268]. Histologically, Colige et al. [269] have reported the presence of abundant and abnormal elastic fibers as well as thickening of basement membrane in the skin of one patient. In fibroblasts from some patients, elastin mRNA expression and elastin synthesis are elevated [269,270]. Unlike normal skin fibroblasts, the addition of TGF-β does not affect these parameters, suggesting that elastin production is already maximally stimulated [263] (Fig. 8). Likewise, collagen type IV production was high in cultured fibroblasts from one patient as well as steady-state levels of elastin and type IV mRNA [269]. While fibroblasts from affected individuals responded to the addition of EGF by a decrease in the level of mRNA for fibrillar collagens and elastin, collagen type IV remained highly expressed [271].

In addition to abnormalities in matrix proteins, reduced antioxidant protection by vitamin E was suggested by Ayres and Mihan as a cause of the disorder [272], while Goldstein and Moerman showed increased thermolability of fibroblast and erythrocyte enzymes [273,274]. A recessive inheritance pattern was suggested on the basis of intermediate thermolability values in both parents. Brown and

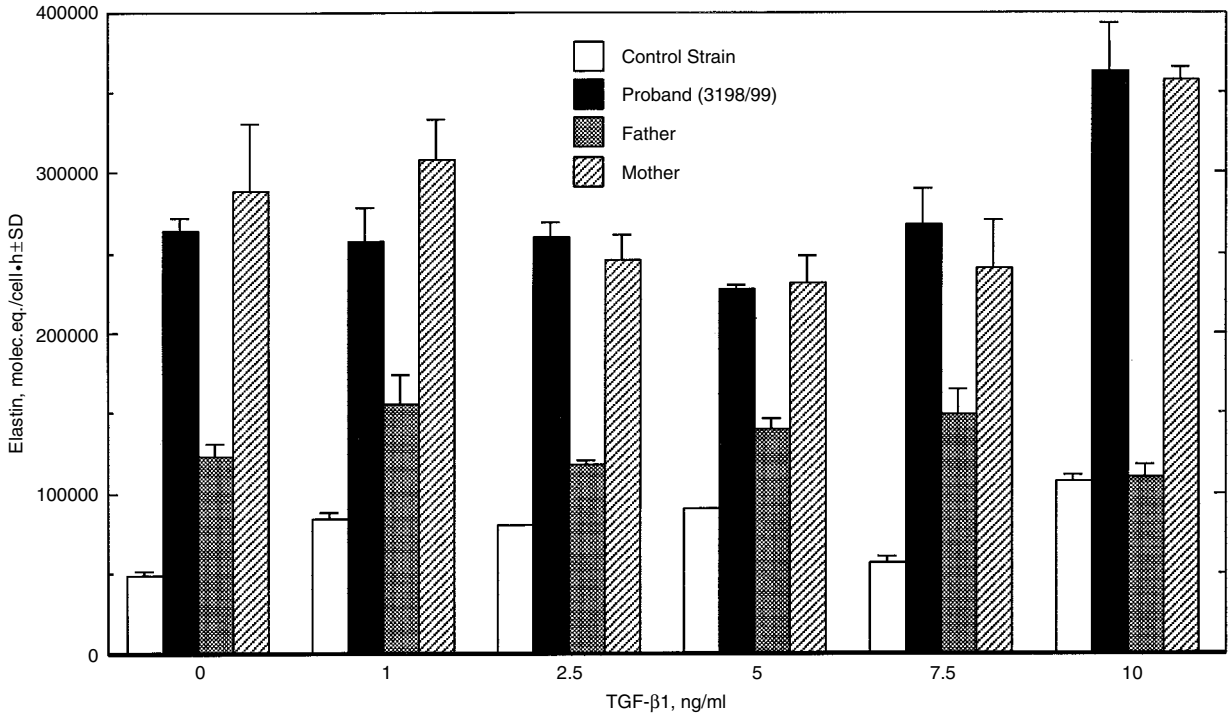

Figure 8. Elastin production in progeria fibroblasts. Evidence for dominant inheritance of high production and lack of a TGF-β response. Skin fibroblasts were cultivated to confluence in 5% fetal calf serum, and elastin production was analyzed by competitive ELISA over the next 48 hours. Production was expressed on a per cell basis in a control strain as well as in fibroblasts from a progeroid patient and the two parents. Basal elastin production is illustrated at the 0 ng/ml dose of TGF-β1. While elastin production in control cells was doubled by the highest dose of TGF-β1, production appeared to be constitutively elevated, at least under standard cell-culture conditions, in the proband and mother. The father's production level was intermediate. Ordinate: elastin production expressed in molecular equivalents per cell •h $\times 10^{-5}$, ±SD. (Reprinted from [263] with permission.)

Darlington [275] reported contrary evidence using glucose-6-phosphate dehydrogenase (G6PD) and 6-phosphogluconate dehydrogenase (6PGD) as markers. Fibroblasts from patients with Hutchinson-Gilford progeria and several other progerias show greatly reduced *in vitro* life spans that could be consistent with defects in an error correction mechanism. However, the DNA helicase mutations reported in Werner syndrome [276] have not been identified in progeria [277].

Brown reported reduced IGF-1 but normal growth hormone levels and very high basal metabolic rates in several progeria patients [259]. Interestingly, growth hormone therapy reduced metabolic rates. Brown and his colleagues have also identified excess urinary excretion of hyaluronan as a common feature of Hutchinson-Gilford progeria and Werner syndrome, suggesting that excess hyaluronan synthesis is associated in each case with a lack of vasculogenesis [278,279]. Hyaluronan is certainly a key factor in the hydration of many connective tissues, including cartilage and skin. Another study reported increased secretion of fibronectin and collagen by cultured skin fibroblasts from a patient with Hutchinson-Gilford progeria [280]. An unusual aspect of connective tissue metabolism in progeria is the paradoxical overexpression of elastin [263,270] and collagen IV [281] by progeroid skin fibroblasts. The familial segregation of elastin overexpression may suggest a recessive aspect to the syndrome [263] (Fig. 8). Colige et al. [271] have also reported a reduced mitotic responsiveness of progeroid cells to EGF, and Giro and Davidson [263] noted a diminished response of elastin synthesis to TGF-β, although elastin production may have already been maximal. Quentin-Hoffmann et al. [61] reported that several patients with progeroid-like symptoms presented abnormalities in the biosynthesis of chondroitin/dermatan sulfate proteoglycans. It has also been shown that in infantile progeroid patients there is deficient expression of decorin [282]. Another study has suggested that polymorphisms in signal peptide sequences may be linked to premature aging [283].

Age-related atrophy of skin and other connective tissues is consistent with excessive matrix catabolism. Studies by Millis et al. [64,284] have illustrated the overexpression of several matrix-degrading enzymes by aging fibroblasts. Our own studies with the aged rat reflect this as an overexpression of MMP-2 (72 kDa gelatinase) in skin. Indeed, the screening of an expression array with mRNA from normal and Hutchinson-Gilford progeria fibroblasts provides unequivocal evidence for overexpression of several MMPs in these strains (Davidson, Giro, and He, unpublished findings). As part of a gene-chip-based screen of alterations common to progeria and intrinsic aging, it has been suggested that aging involves the accumulation of errors in the mitotic machinery of cells. These studies also detected altered expression of a number of matrix molecules and MMPs [285].

Wiedemann-Rautenstrauch Syndrome (Pseudohydrocephalic Progeroid Syndrome; MIM 264090)

This neonatal progeroid syndrome is a rare, autosomal recessive disorder first reported by Rautenstrauch and Snigula in 1977 [286] and Wiedemann in 1979 [287]. Affected children have intrauterine growth retardation, a progeroid appearance at birth and during infancy, and natal teeth. Death occurs in infancy or early childhood [28,288,289]. Hou and Wang described a Chinese girl without intrauterine growth retardation [290]. Arboleda et al. [291] found disturbance of bone maturation as well as of lipid and hormone metabolism. Key findings include prenatal growth deficiency, a lack of subcutaneous fat except in the flanks, buttocks, and anogenital area, sparse scalp hair, beaking of the nose, a persistent anterior fontanelle, macrocephaly, and congenital heart defects. Sudanophilic leukodystrophy is a common laboratory finding, consistent with a generalized abnormality of lipid metabolism. One case report describes another patient and compares the findings among six individuals [292], and a further report describes five additional cases [293].

Werner Syndrome (MIM 277700)

Werner syndrome is a rare, autosomal recessive progeria with substantial connective tissue involvement [294]. An important difference in comparison with other progerias is the later onset of symptoms. These begin during the second decade with a lack of the typical adolescent growth spurt. Consequently, Werner syndrome patients have short stature, slender limbs, and a stocky trunk. In common with other progeroid syndromes, the nose is beaked and there is atrophy of subcutaneous fat. There are scleroderma-like skin changes, especially over the extremities, bilateral cataracts, subcutaneous calcification, hyperkeratosis, hoarseness, a high-pitched voice, and premature arteriosclerosis. These features progress over several decades. Wrinkled skin, a wizened appearance, and premature graying of the hair are other significant features (Fig. 9). Affected patients frequently develop malignancies in the third and fourth decades [295]. Death usually occurs in the fourth or fifth decade from malignancy or cardiovascular disease.

Connective Tissue Abnormalities

Classical signs of Werner syndrome include diffuse osteoporosis and calcification of the soft tissues and blood vessels as well as calluses or deep ulceration of the skin over the lower extremities [295]. A few specific biochemical abnormalities have been noted: elevated urinary excretion of hyaluronan [296,297]; a diminished response of collagenase expression to stimulation by PDGF or basic FGF; increased basal expression of collagenase by fibroblasts [298]; increased fibroblast expression of collagen I [299]; and decreased expression of collagen VI [300]. Several matrix genes were found to be overexpressed in a Werner syndrome cDNA library that was used in a candidate gene approach; these were *COL1A1* (collagen α1(I) chain), *COL1A2* (collagen α2(I) chain), *FN1* (fibrillin 1), *THBS1* (thrombospondin 1), *ON/SPARC* (osteonectin/SPARC), *HSPA1-1* (heat shock protein 70 1A), and *IGF-BP3* (insulin-like growth factor binding protein-3) [301]. Interestingly, many of the products of these genes are induced by TGF-β. Unlike Hutchinson-Gilford progeria fibroblasts, elastin production in Werner syndrome fibroblasts is normal; it is slightly increased by TGF-β and slightly decreased by bFGF (M.G. Giro and J.M. Davidson, unpublished observations) (Fig. 10). Increased collagenase expression is consistent with the behavior of normal fibroblasts near the limits of their replicative life spans [64]. None of these defects can be directly linked to the known molecular defect in Werner syndrome, decreased activity of a RecQ DNA helicase [276,302].

Molecular Genetics

Although there had previously been a number of genetic hypotheses concerning Werner syndrome [303], positional cloning firmly and finally established the basis

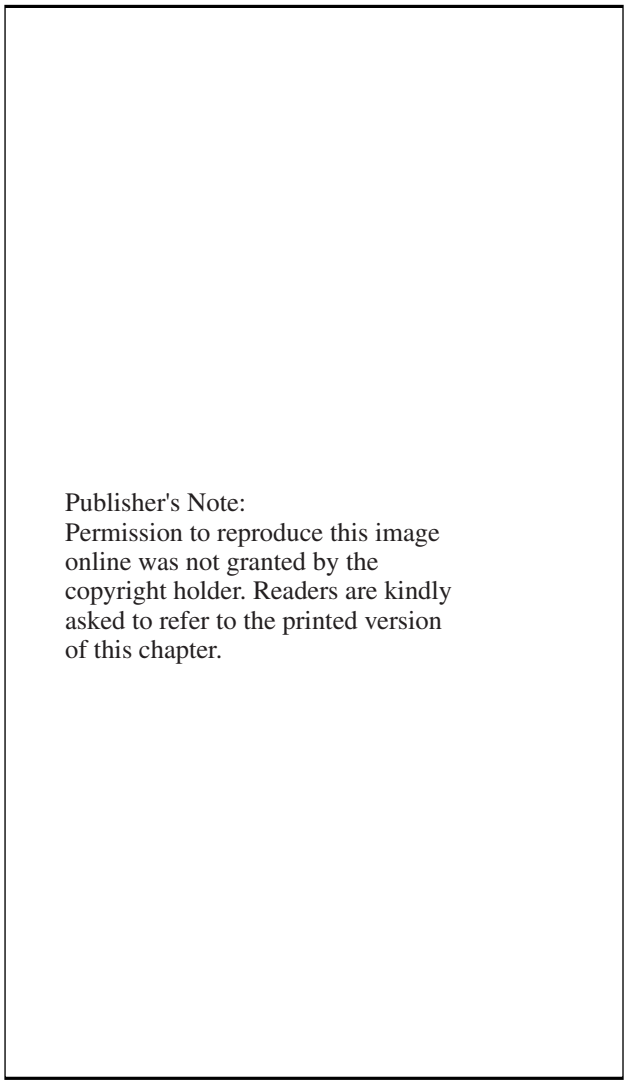

Figure 9. Clinical features of the Werner syndrome. **A**: This 54-year-old man demonstrates a characteristic bird-like facies with a beaked nose and premature graying of hair. **B**: The patient demonstrates scleroderma-like features of the feet, with acrosclerosis and recalcitrant ulcers. (Reprinted from [377] with permission.)

of the disease in 1996 [276,302,304–306] and a large number of publications have ensued that describe mutations within the Werner (*WRN*) gene locus [307]. Most of the reported mutations predict premature truncation in the C-terminal region of the *WRN* gene product, a region that contains helicase activity [276,308,309] as well as a nuclear translocation signal [310,311]. In the case of one mutation, the mRNA product is unstable [312]. Defects in RecQ helicase activity could account for chromosomal instability [313,314] and high mutation rates [315].

Cockayne Syndrome (MIM 216400)

In 1936, Cockayne described two siblings with dwarfism, retinal atrophy, deafness, and mental retardation. A precociously senile appearance due to lack of subcutaneous fat and sunken eyes gives the syndrome progeroid aspects; sensitivity to sunlight was also described [316]. No abnormality was observed in fibroblast collagen synthesis from one patient [317]. In our own studies of elastin synthesis in three strains of cultured skin fibroblasts, we found that elastin production was reduced in two cases and could be highly stimulated by the addition of 10 ng/ml of TGF-β, while 100 ng/ml of bFGF reversed this effect (Fig. 10). Two major subtypes have been described within the syndrome — type I (type A) and type II (type B) [318] — both of which exhibit defective repair of UV-mediated DNA damage [319]. Cockayne syndrome type I is due to mutations in the *CKN1/CSA* gene [320], the product of which contains so-called WD40 domains, and has been implicated as a transcription-repair coupling factor [321] in studies with mutant yeast homologs; however, the gene appears to function in the context of other RNA polymerase II transcription factors [322]. Cockayne syndrome type II is due to mutations in the *ERCC6* (*CKNB/CSB*) gene, the product of which is a DNA-dependent ATPase [323] that appears to function, at least in part, as an RNA polymerase II transcription factor [324,325]. The consequence of the CSA and CSB mutations, as in xeroderma pigmentosum (MIM 194400), is defective nucleotide excision repair.

Other Progeroid Syndromes

Mandibuloacral Dysplasia (MIM 248370)

The progeroid features in this syndrome appear 1–2 years after birth and include hypoplasia of the jaw and clavicles, late closure of cranial fontanelles and sutures, a thin, beaked nose, prominent eyes, alopecia, short stature, and postnatal growth retardation [326,327]. Changes in the fingertips, including shortened terminal phalanges and atrophic skin, may be indicative of a diffuse connective tissue involvement. This very rare disease occurs mostly in families of Italian origin [328]. A lethal, neonatal form of the disorder has been described [329].

Gerodermia Osteodysplastica (MIM 231070)

This condition was first described by Bamatter in 1950, and the author called affected individuals "Walt Disney dwarfs" [330]. Hunter et al. [331] reported that this autosomal recessive condition exhibited lax but not hyperelastic skin, most markedly over the extremities, joint hyperextensibility, osteoporosis, which may be associated with fractures, vertebral collapse, and Wormian bones. The cutaneous features are illustrated in two siblings and another proband (Fig. 11). Three key findings are severe osteoporosis, joint hyperextensibility, and cutis laxa. Eich et al. [332] described two sibs with gerodermia osteodysplastica who, in addition to the characteristic manifestation of the disease, presented a metaphyseal peg indenting the epiphyses of the long bones, particularly at the knees. The peg was only visible from the age of 4 to 5 years to epiphyseal closure, and the authors proposed that it could be a new bone marker specific to gerodermia osteodysplastica. Al Torki et al. [333] described the disease in a Bedouin family in which two sisters had the disorder and the older sister had a prematurely aged face with loose and wrinkled skin, joint laxity, and osteoporosis involving the thoracolumbar vertebrae.

Acrogeria (MIM 201200)

Gottron [334] first reported two cases of acrogeria in whom hands and feet had appeared aged since infancy because of thin skin. The same disease has also been called metageria when more generalized [335] and acrometageria

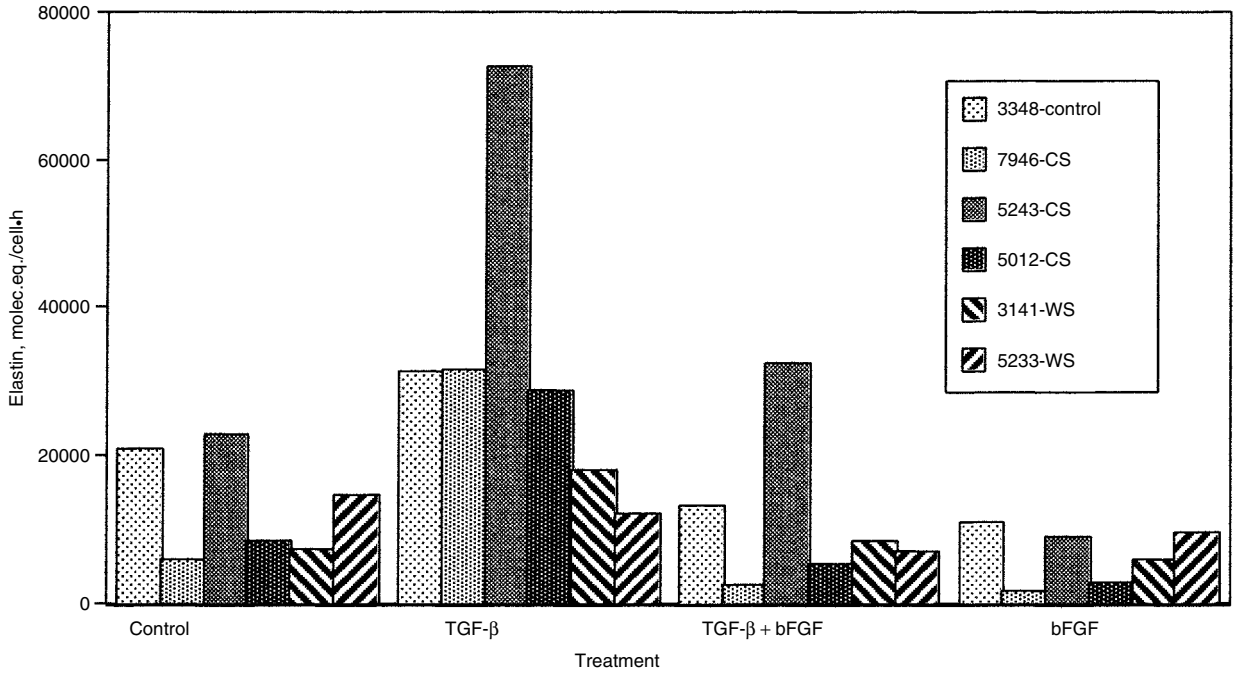

Figure 10. Elastin production in Cockayne syndrome (CS) and Werner syndrome (WS) fibroblasts and their cytokine responses. Normal (National Institute of General Medical Sciences Human Genetic Mutant Cell Repository (NIGMS) strain GM3348), Cockayne syndrome (National Institute on Aging Cell Repository (NIA) AG7946, AG5243, AG5012), and Werner syndrome fibroblasts (NIA AG3141, AG5233) were treated with serum alone, TGF-β1(10 ng/ml), TGF-β1 (10 ng/ml) plus basic FGF (100 ng/ml), or basic FGF alone (100 ng/ml). Culture supernatants were analyzed for elastin production as described in Figure 8. Werner syndrome strains were only slightly affected by the growth factors. Cockayne syndrome fibroblasts increased elastin production nearly fourfold in response to TGF-β1. This effect was attenuated by bFGF, and bFGF alone inhibited elastin production in Cockayne syndrome fibroblasts.

by Greally et al. [336]. In addition to wrinkled skin of feet and hands, patients with this disorder have joint hypermobility and mental retardation.

Metageria, the more generalized form of acrogeria, is characterized by loss of subcutaneous fat, thinning of the dermis, multiple telangiectasias, and mottled hyperpigmentation. In cultured fibroblasts from the skin of a patient and his sister, Hunzelman et al. [337] found some decrease in the production of type I collagen, which was reversed when TGF-β was added to the culture medium. De Groot et al. [338] described an affected mother and son with conspicuous vessels over the trunk and elastosis perforans serpiginosa, which was also a feature of the female described by Gottron as well as two other patients, but this rare inherited form lacks the characteristic scarring or arterial and intestinal rupture characteristic of Ehlers-Danlos syndrome type IV. No defects in type III collagen have been noted, but the reader should refer to the chapter on EDS (Chapter 9, this volume) for a discussion of possible phenotypic overlap.

Hallermann-Streiff Syndrome (MIM 234100)

This is a sporadic syndrome with major craniofacial and ocular abnormalities, including dyscephaly, cataracts, microphthalmia, and dental abnormalities. Stature is short but proportionate. Skin atrophy is reported in 60–70% of cases [339,340]. Mandibular hypoplasia and a beaked nose are features shared with many other progeroid syndromes [341]. Major complications relate to airway and respiratory mechanics, probably related to dysmorphology of these structures.

Down Syndrome (MIM 190685)

Down syndrome has features of a "segmental" progeroid syndrome, meaning that tissues and organs are differentially affected. Patients present with degenerative vascular disease, premature hair loss and graying, increased tissue lipofuscin, and markedly reduced life expectancy. Neuropathological changes include precocious aging and dementia [342]. These features are apparently the result of overexpression of genes located on chromosome 21. Down syndrome fibroblasts have a reduced *in vitro* life span [343].

Premature Aging Syndrome, Okamoto Type (MIM 601811)

Severe growth and developmental abnormalities were noted in the 15-year-old daughter of unrelated parents. Microcephaly, osteosarcoma, and osteoporosis were significant connective tissue findings in this condition [344].

Premature Aging Syndrome, Penttinen Type (MIM 601812)

A 10-year-old Caucasian male presented a prematurely aged appearance with pronounced acroosteolysis and brachydactyly [345]. Distinctive cutaneous findings included hard, confluent skin lesions that clinically and histologically resembled those of juvenile hyaline fibromatosis (MIM 228600).

Lenz-Majewski Hyperostotic Dwarfism (MIM 151050)

Patients with this disorder exhibit a progeroid appearance that includes dental enamel dysplasia, skin hypoplasia, and joint laxity. Gorlin and Whitley [346] reported a patient with strikingly loose and wrinkled atrophic skin of the

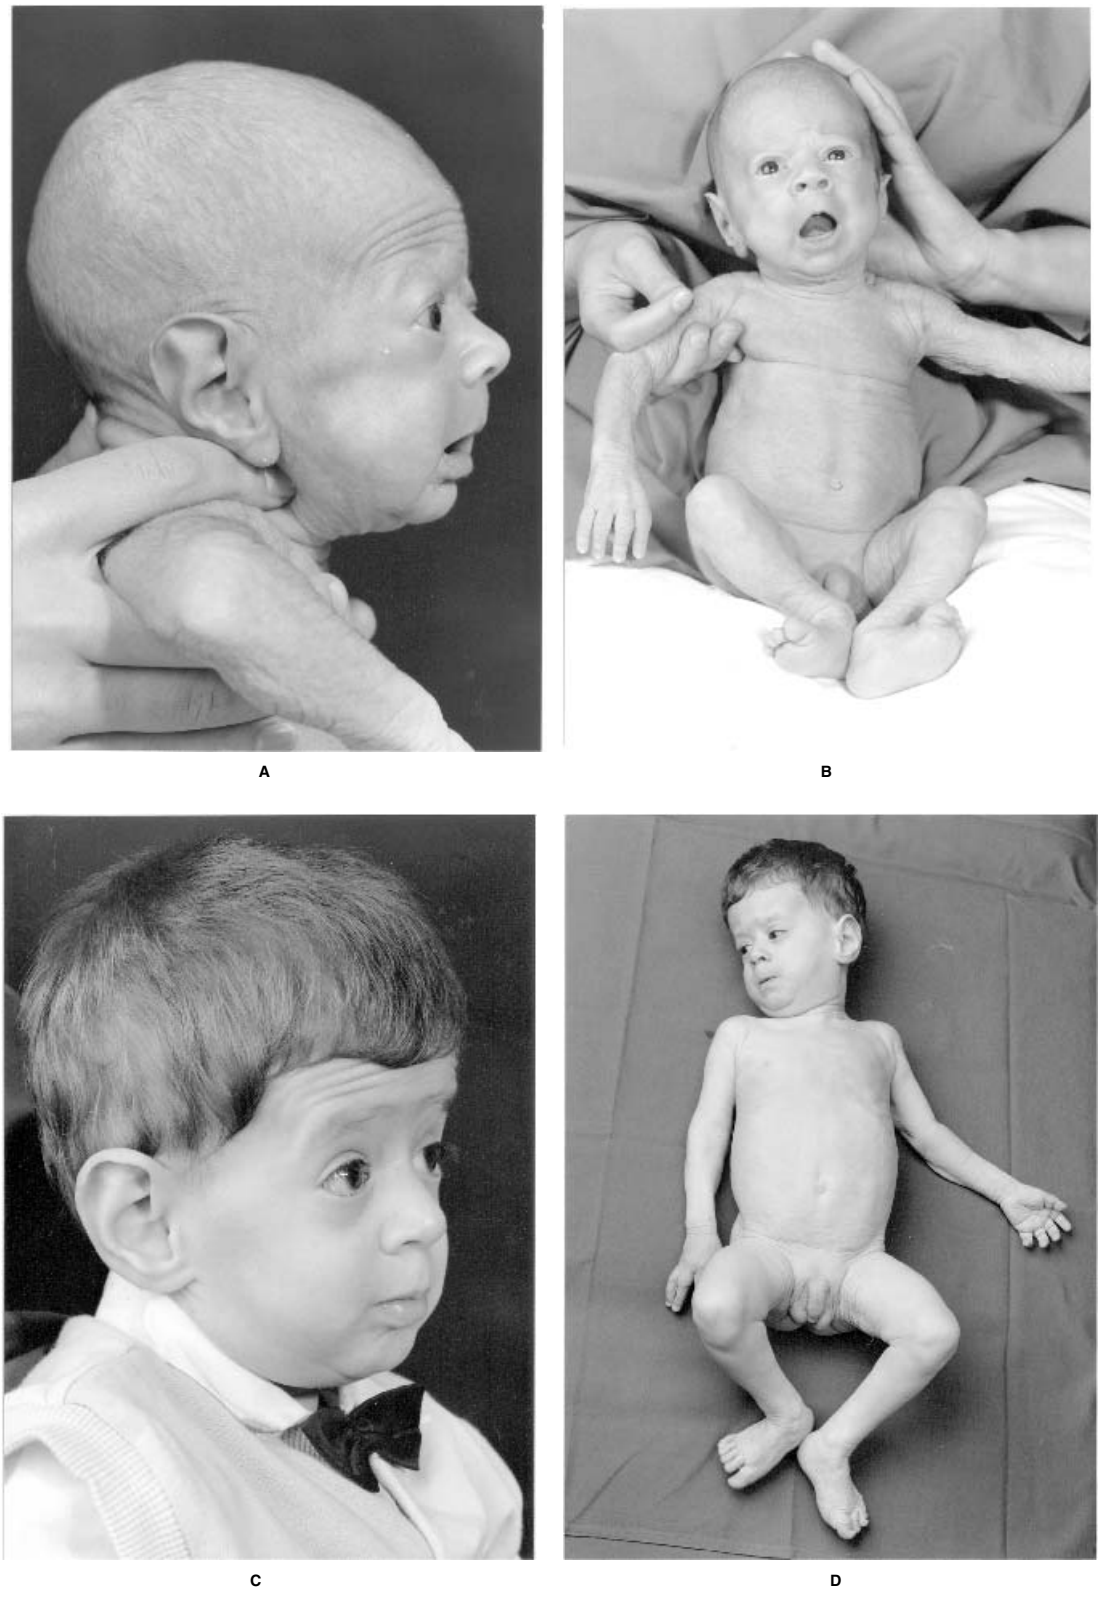

Figure 11. Gerodermia hereditaria osteodysplastica. V.R. (d.o.b. 20 May 90) at 3 weeks of age (**A** and **B**), at 2 years (**C** and **D**), and at 6 years (**E**), and his older sister M.R. (d.o.b. 14 Nov 79) at 12 years (**F** and **G**). Extensive wrinkling and an aged facies are especially obvious at younger ages. Congenital hip dislocations, multiple spontaneous fractures, marked osteopenia, Wormian bones, and short stature are common to both, findings that were initially interpreted as osteogenesis imperfecta in the sister. The parents are healthy and unrelated but originate from the same region in Italy. (All illustrations courtesy of Dr. B. Steinmann).

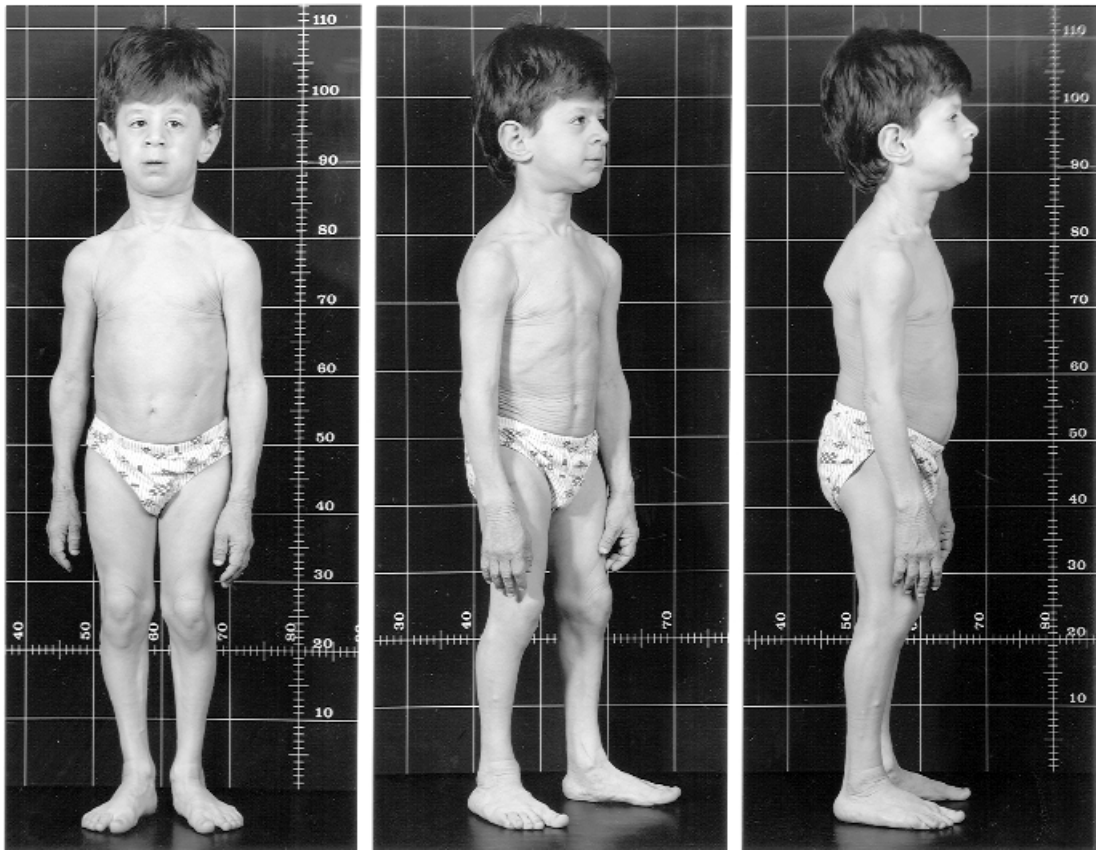

E

F G

Figure 11. (*Continued*)

hands with short digits and partial syndactyly. Scalp veins were prominent through thin, wrinkled, and atrophic skin. There was bilateral narrowing of the nasal choanae and nasolacrimal duct obstruction. Skeletal maturation was retarded, with progressive sclerosis of the skull, facial bones, and vertebrae, broad clavicles and ribs, and short or absent middle phalanges. Chrzanowska et al. [347] described the 10-year-old son of young, healthy, unrelated parents, who had a progeroid appearance, bilateral symmetrical shortening of the fingers and metacarpals, short toes, and loose, thin skin with marked hyperlaxity.

MURINE GENETIC MODELS

Experimental models can provide substantial insight into the etiology and pathogenesis of cutis laxa and premature aging. Transgenic and recombinant mouse models have proven to be extremely informative in understanding certain aspects of connective tissue biology. This volume contains numerous examples representing the remarkable rate of advancement offered by genetic manipulation of whole animals. Although the microfibrillar proteins are intimately related to elastogenesis, other chapters discuss fibrillin and other elastin-associated proteins in detail. This discussion will be more restricted.

Elastin

Mammalian elastin promoter sequences have been defined by combining sequence and functional studies of the upstream regions of the elastin gene of man [36,348–350], cow [351–353], and rat [354,355]. Uitto et al. have developed a transgenic mouse that expresses the human elastin promoter (6 kB) linked to the *CAT* gene. This has proven to be a useful model for evaluating molecules that regulate elastin accumulation in photodamaged skin, such as glucocorticoids, TGF-β, and psoralens [236,356–359]. Elastin null mice have been produced by homologous recombination [360]. It was hypothesized that heterozygotes would present a phenotype resembling that of SVAS. Interestingly, however, mice hemizygous for elastin show a compensatory increase in the number of elastic lamellae despite a reduction in aortic elastin mRNA and protein [361]. The murine model does not completely parallel the response in the human aorta to SVAS mutations. Essentially the same genetic lesion manifests in man as severe disorganization of the vessel wall as well as there being effects on other elastic tissues. Mice that are homozygous for the elastin gene deletion exhibit a lethal, obstructive arterial disease, the development of which is not dependent on hemodynamics, thrombosis, or interactions with circulating cells [360]. These latter findings underscore a critical role for elastin in the homeostasis of the arterial wall.

Premature Aging

A number of animal species have been used to examine the relationship between intrinsic aging and connective tissue, but only recently have new strains been identified that exhibit phenotypes akin to progeroid syndromes.

Klotho: A Prematurely Aging Mouse Strain

A new murine gene locus has been defined by a targeted deletion that leads to many signs of premature aging, including atherosclerosis, emphysema, hypogonadism, skin atrophy, and calcification of soft tissues [362]. Mice homozygous for the mutation die within 3–4 months. The mouse *Klotho* gene encodes a novel, single-pass transmembrane protein with homology to β-glycosidases [363], which is predominantly expressed in kidney and amplified by renal stress [364]. There also appear to be effects on bone metabolism in the Kl^{-}/Kl^{-} mutant mouse that resemble osteopenia [365]. The human gene has been localized to chromosome 13q12 and, as does the mouse gene [366], expresses two transcripts as a result of alternative splicing [367]. It is not known how the status of *Klotho* gene expression relates to normal or accelerated aging in man.

Senescence-Accelerated Mouse

This term covers a widely studied group of inbred mouse strains that has undergone extensive selection for reduced life span [368]. Strains with a shortened life span exhibit many manifestations of accelerated aging, including atherosclerosis [369], reduced life span of dermal fibroblasts [370,371], and bone loss [372–376].

RECENT DEVELOPMENTS

Cutis Laxa

A two- to threefold increase in elastolytic activity in lesional skin fibroblasts from a 21-year-old female with acquired cutis laxa has been reported [378]. No significant mutations could be detected in the coding region of the *ELN* gene in five further cases of apparent autosomal recessive cutis laxa, nor was elastin production by dermal fibroblasts found to be markedly altered *in vitro*. Although polymorphisms in exons and introns could be detected, none can definitively be linked to disease (X. Zhao and J.M. Davidson, unpublished observations).

A further patient with the wrinkly skin syndrome has been described, in whom there was a considerable loss of elastin and fragmentation of microfibrils associated with wrinkly features and poor elasticity over the abdomen and the dorsum of the hands and feet [379]. Loss of mid-dermal elastic fibers has also been reported in two cases of lupus erythematosus [380]. In addition to forms of cutis laxa acquisita being associated with cutaneous lymphoma, T-cell lymphoma, and myeloma, it has been suggested that anetoderma can arise in cutaneous B-cell lymphoma [381]. One of the acquired forms, granulomatous slack skin disease, has been reported to have been treated successfully with systemic, recombinant interferon-γ [382]. Although decreased elastin expression in Costello syndrome fibroblasts has been reported [383], the *ELN* locus has been excluded in a separate study [384].

Supravalvular Aortic Stenosis

The analysis of new cases of SVAS has reinforced the concept that mutations toward the N-terminus of elastin lead to functional haploinsufficiency, while C-terminal missense or truncation mutations can lead to the cutis laxa phenotype [385]. Metcalfe et al. have reported 35 mutations associated with SVAS [386], and many more are likely to exist (Z. Urban, personal communication). The predominant mechanism for haploinsufficiency appears to be nonsense-mediated decay. A small fraction of the SVAS mutations result in the production of mutant tropoelastin molecules, the coacervation properties of which are altered *in vitro* [387]. Exon 26 is reported to contain crucial sites for coacervation [388,389]. A novel 1281delC mutation with variable penetrance is the fifth example of an SVAS mutation in exon 20 [390]. Skin elastic fibers have been suggested to be a useful diagnostic feature for Williams syndrome, and, by analogy, SVAS [391]. The clinical relevance of mouse models of elastin haploinsufficiency has been reviewed [392].

Premature Aging Syndromes

Hutchinson-Gilford Progeria

There are a number of further, descriptive studies of Hutchinson-Gilford progeria [393–397]. An additional reported pathologic feature of the condition is an expansion of the mesangial matrix, leading to glomerulosclerosis [398]. Of interest, are the scleroderma-like features of several patients [394,395]. Unlike the situation in some cases of Hutchinson-Gilford progeria, telomere shortening was not a feature in a newly identified case of Wiedemann-Rautenstrauch syndrome [399]. On the other hand, two studies in gene profiling have led to the suggestion that there are genes altered in common in progeroid and elderly skin fibroblasts, but not in *in vitro* aged skin cells [400]. Furthermore, the expression of MMPs 1, 2, and 3, is commonly elevated in aged and progeroid fibroblast cultures (L. He and J.M. Davidson, unpublished findings). A more detailed profile by Ly et al. [401], suggests that genes associated with the mitotic machinery may be selectively prone to error, leading to chromosomal abnormalities.

Werner Syndrome

It has been suggested that defective helicase domain-containing proteins represent a common mechanism leading to the aging phenotype, not only in Werner and Cockayne syndromes, but also in other conditions such as xeroderma pigmentosum, trichothiodystrophy, Bloom syndrome, X-linked α-thalassemia/mental retardation syndrome, and Juberg-Marsidi syndrome [402–404]. In Werner syndrome, the enzyme RecQ is distinguished from other helicases by a physically separable and functionally distinct 3′-5′ exonuclease activity [405,406]. Although there are examples of WRN mutants lacking either 3′-5′ exonuclease or helicase activity, the preponderant genotype is thought to be consistent with a functionally null phenotype, since the WRN protein is generally absent in affected individuals [404,407]. Possibly, genetic instability arises in *WRN* mutants through an interaction of WRN protein with DNA polymerase-δ, an enzyme involved in DNA replication and repair [408]. WRN protein has also been shown to interact with the catalytic subunit of a DNA-dependent protein kinase, and its activity to be regulated by phosphorylation-dependent complex formation [409]. Glycophorin A mutation rates show an age-dependent increase in the development of variant sequences, and there is also evidence for genetic instability in mutant WRN heterozygotes [410]. In a murine model of Werner syndrome expressing a helicase from which the C-terminal region had been deleted, dermal fibroblasts derived from homozygous null mutants showed a very mild phenotype *in vitro*, and fibroblasts derived from a double null mutant lacking also p53 exhibited an increased mortality rate [411]. The WRN protein seems to interact with telomerase, although their actions can be separated. The introduction of telomerase activity into Werner and other progeroid fibroblast strains can certainly extend the replicative lifespan of these cells [412], but genomic instability persists [413]. Perhaps the best explanation for tissue-specific effects of *WRN* mutations derives from studies of T lymphocytes which, unlike fibroblasts, are able to upregulate telomerase activity independently of the presence or absence of functional WRN protein, and thereby maintain some resistance to the lifespan shortening effects of the genetic defect [414]. However, lifespan extension is not sufficient to overcome important aspects of WRN function; lymphoblasts from Werner syndrome patients are indeed long-lived, but there is still a marked elevation of genetic instability. Such studies do emphasize the differential effects of the *WRN* mutation on different cell populations [415], and they may help to explain some of the selective effects on connective tissues.

SUMMARY

- **Pseudoxanthoma elasticum (PXE) is a heritable systemic disorder that affects elastic tissue and is characterized by systemic manifestations, typically first in skin and then in the eyes and cardiovascular system. There is consensus about the diagnostic criteria defining the disease.**
- **The disorder manifests primarily as an autosomal recessive disease, and is caused by mutations in the *ABCC6* gene encoding the transmembrane transporter protein ABCC6, situated at chromosome 16p13.1. The heterozygous carrier may express a forme fruste. Although familial clinical PXE in three consecutive generations with apparent disease transmission from diseased parent to child has been reported, genetic haplotype analysis in 81 families did not identify affected sib pairs as heterozygotes at the locus. Although this finding does not absolutely exclude the existence of a dominant PXE trait, it clearly indicates its rarity, if it exists at all.**
- **The prevalence of PXE is approximately 1 in 75,000, but this could be an underestimate due to some affected individuals having only mild manifestations and unawareness among physicians of the disease. There is an unexplained 2:1 predominance in females.**
- **The diagnostic and histopathological hallmark of PXE is degenerative calcification with subsequent disintegration and destruction of the elastic tissue of the body. Elastic tissue is involved in the mid- and deep dermis of the skin, in Bruch's membrane of the eye, in the endocardium of the heart, and in the lamina elastica interna and externa of arteries. The pulmonary elastic tissue is spared. An increased content of glycosaminoglycans in affected elastic tissue has been demonstrated.**
- **The clinical spectrum of the disease ranges from mild manifestations to severe, occasionally lethal cardiovascular complications. The skin typically shows yellow-orange papules and plaques symmetrically in flexural sites, with gradual extension, and subsequent loss of elasticity with redundant folding of the skin. While the skin lesions are cosmetic in nature, the eye manifestations begin with angioid streaks and progress to macular degenerative retinopathy complicated by retinal bleeding and central visual field blindness. Cardiovascular disease encompasses a wide spectrum from mental fatigue syndrome to early cardiovascular death due to myocardial infarction or, very rarely, gastrointestinal hemorrhage. Typically, it manifests with hypertension, intermittent claudication, mitral valve prolapse, and angina pectoris.**
- **The cardiovascular phenotype may manifest as a dominant trait and show striking histomorphological similarities to idiopathic arterial calcification of infancy (IACI). Although IACI is most likely an independent heritable disease, its potential clinical overlap with PXE, its comparatively earlier manifestation, either intrauterine or typically within 6 months of birth, and its lethal course give some justification for hypothesizing IACI as the homozygous, potentially lethal manifestation of the dominant cardiovascular PXE trait.**
- **Although there is no treatment for the basic defect, a prophylactic lifestyle, prophylactic medical monitoring, and genetic counseling are highly recommended to prevent complications from arising.**

INTRODUCTION

Definition

Pseudoxanthoma elasticum (PXE) is a hereditary, systemic disorder of connective tissue. Its transmission is primarily autosomal recessive (MIM 264800). A possible dominant inheritance pattern (MIM 177850) has been described. The elastic fibers of the skin, eyes, and cardiovascular system degenerate and slowly become calcified, subsequently losing their structural integrity and elastic function. This causes a clinical spectrum of disease involving these three organ systems. The disease shows considerable clinical heterogeneity, independent of the mode of inheritance. There is a 2 to 1 female predominance. A gene locus for both the recessive and dominant forms of the disease has been mapped to chromosome 16p13.1, suggesting allelic heterogeneity, by which different molecular mutations of the same gene give rise to recessive and dominant variants of the same disease [1–3]. Mutations in the gene *ABCC6* encoding the transmembrane transporter protein ABCC6 have been shown to cause PXE (see Recent Developments).

Connective Tissue and Its Heritable Disorders, pages 561–583

History

First Description

PXE is probably as old as mankind, although there is no documentation of the disease before the nineteenth century. The first description of the clinical signs and symptoms of PXE appeared in the medical literature in 1884 as a case report by Balzer [4]. However, he did not recognize the involvement of the elastic tissue and its aberrant calcification in the pathogenesis of the clinical features he described and attributed them to xanthomas instead. Some of the histological features of the disease had already been described before Balzer's clinical description by Rigal in 1881 [5], but Rigal also attributed the skin lesions to xanthomas.

Recognition as an Independent Disease Entity

The case presentation by Balzer in 1884 [4] and a clinically similar one by Chauffard in 1889 [6] were reviewed by Darier and others from 1891 [7] to 1896 [8,9] with regard to their clinical and histological similarities and compared with the known clinical and histological characteristics of xanthomas. Darier recognized these cases as representing a unique and independent disease entity of the elastic tissue with clinical and histological features distinct from xanthomas and, perhaps in an overzealous effort to distinguish the two different disease entities, coined the term "pseudoxanthome élastique." This term remains the most widely accepted name for the disorder. The fundamental histological feature of PXE — namely, calcification of the elastic fiber — was first described by von Tannenhain in 1901 [10] and further verified by Finnerud and Nomland [11], who used microincineration methods to establish the fact that the minerals in the elastic fibers were calcium salts. Multinuclear giant cells in close proximity to vessels in the periphery of typical histological skin lesions were first recognized by Balzer [4] and confirmed by Bodin in 1900 [12]. De Schweinitz, at the time in all likelihood unaware of PXE as a new disease entity, had first described in 1897 the familial occurrence of angioid streaks in family members most likely suffering from PXE [13]. It was then Werther, in 1902, who was probably the first to observe familial aggregation of PXE cases and who suggested the cause of the disease to be congenital, pioneering the idea of a genetic cause underlying PXE [14].

Recognition as a Systemic Disorder of Connective Tissue

The nosologic position of PXE continued to unfold in the later nineteenth and early twentieth centuries as angioid streaks were first described by Doyne [15] in 1889, named by Knapp [16] in 1892, and recognized by Kofler [17] in 1917 as originating from crazing of Bruch's membrane. Thirty-three years after Darier's initial recognition of PXE, a Swedish ophthalmologist, Grönblad [18], and her colleague Strandberg [19], a dermatologist, in 1929 made the first unequivocal connection between the skin and eye manifestations of PXE. The recognition of PXE as a general disorder of the elastic tissue was imminent and resulted in a new eponym, the Grönblad-Strandberg syndrome. Giesen [20] confirmed the involvement of the mucosal membrane, which had first been described by Balzer [4], in a typical case of PXE in 1936.

The cardiovascular aspects of PXE were studied by Carlborg et al. [21–23], Scheie [24], and Touraine [25,26] from the 1940s on. They were the first to comprehensively describe the cardiovascular manifestations of PXE and therefore to complete the full canonical triad of skin, eye, and cardiovascular aspects of PXE, which has remained essentially unchanged ever since.

Many reports of individuals and large cohort groups and literature reviews were published between 1950 and 1990 and served to outline in greater detail variations in the natural course of PXE and identify environmental risk factors that can alter the natural course. Major clinical reviews have been conducted by Eddy and Farber [27], Goodman et al. [28,29], McKusick [30], and Neldner [31].

Eponymous Designations

Typically for the descriptive medical science of the late nineteenth and early twentieth centuries in Europe, new discoveries were named after their discoverers. Arbitrary examples of eponymous PXE designations are: Grönblad-Strandberg syndrome, Darier-Grönblad-Strandberg syndrome, and Grönblad-Strandberg-Touraine syndrome. The most common of these is the Grönblad-Strandberg syndrome. Today, these eponyms are still used in the European medical literature. In view of the more common international use of the term pseudoxanthoma elasticum to describe not only the skin involvement but also the inherited systemic connective tissue disorder, with additional retinal and cardiovascular manifestations, and its convenient abbreviation, PXE, it is recommended that the use of eponyms be discontinued.

EPIDEMIOLOGY

The prevalence of PXE in the general population is estimated to be approximately 1 in 75,000. It is believed that many cases may go undiagnosed for the lifetime of an affected individual so that the exact prevalence may be more common. Because genetic linkage analysis is now available and the gene will be identified in the near future (see Recent Developments), more examples of minimal or forme fruste expression will be detected, which can represent disease expression in the heterozygote. Therefore, the true incidence will become known with greater accuracy.

There seems to be no geographic or racial predilection for PXE. All studies of large cohort groups of individuals with PXE or literature summaries of individual case reports have shown an approximate 2 to 1 female-to-male ratio [30,31].

The mean age of clinical onset is 13 years. There are rare reports of the onset of skin lesions at age 2 or 3 years and even more rare reports of their being present at birth [28], although none of the latter were biopsied for proof. Delayed onset in the fifth or sixth decade of life has been reported. Such cases may simply have gone undetected for many years. In very mild cases, skin lesions are most likely present but so minimal as to be overlooked, even by physicians, unless there is a specific request to look for minimal PXE and to biopsy any suspicious areas. Such cases represent the far end of the clinical spectrum of PXE.

CLINICAL ASPECTS

Skin

The most apparent clinical feature of PXE is the skin involvement, which in most cases is the first clinical manifestation and the one on which the diagnosis is based. If systemic involvement does antedate the skin lesions, it is seldom recognized and can at best be considered a presumptive diagnosis, which needs further confirmation. Whereas previously the diagnosis of PXE in such cases could only be confirmed after the appearance of pathognomonic

skin signs, the discovery of the gene locus now allows diagnosis through linkage analysis in families with proven clinical disease in at least one other family member for both recessive and dominant forms of the disorder.

Clinical Signs and Symptoms

The primary cutaneous expression of PXE is small, 2–5 mm, yellow-orange papules of rhomboidal or irregular shape, bounded by normal skin, which coalesce into larger plaques. These yellow-orange papular lesions with a rough, cobblestone-like, Moroccan leather or chicken skin texture are highly characteristic. They usually first come into view on the lateral neck and gradually appear, over several years, in the more distal flexural sites. They develop symmetrically and are initially confined to flexural areas (lateral neck, axillae, antecubital fossae, groins, and popliteal spaces) of the body, although they may gradually encompass larger areas (Figs. 1–4). In a clinically heterogeneous fashion, the skin lesions in some patients may extend well beyond the flexural sites. Anogenital and oral mucous membranes are affected in some, but not all, patients. The oral mucosal lesions are usually confined to the inner aspect of the lower lip. There are also rare cases with normal skin appearance on visual inspection but with minimal diagnostic histological changes in skin biopsies taken from predilection sites [32–35]. This finding can be interpreted both as representing preclinical disease and as minimal disease expression in a heterozygous individual. About 2–3% of individuals with PXE will develop small circles of 2–3 mm diameter, encrusted papules called elastosis perforans serpiginosa (EPS) or perforating PXE. EPS is not unique to PXE, although in other disorders with EPS, the extruded elastic fibers will not be calcified. The long-term cutaneous changes are diffuse thickening, loss of elasticity, and loss of the early surface signs, resulting in sagging and/or redundant folding of the skin, particularly in the axillae. This may appear 20–40 years after the initial onset of the disease and may interfere with clothing. In some cases with facial involvement, this phenomenon may produce a "hound-dog" look. Solar elastosis can give a similar appearance but usually occurs at a later average age and is confined to the face and lateral neck. Except

Figure 1. Close-up photograph of typical and pathognomonic early skin lesions on the lateral neck of a 21-year-old female with PXE. This is the most common site of origin of PXE skin involvement and always presents in a symmetrical distribution.

Figure 2. Posterior neck lesions of a more advanced case in a 30-year-old female.

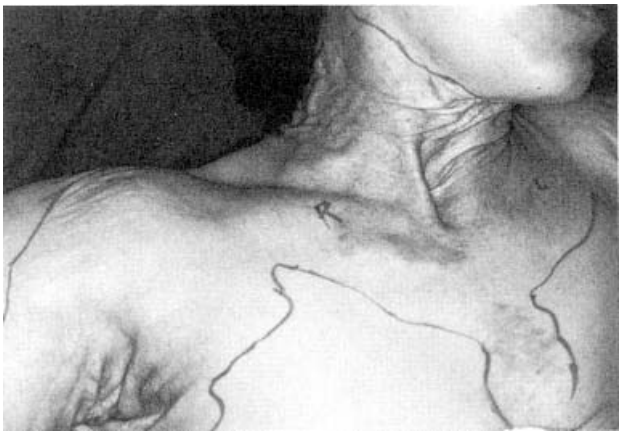

Figure 3. Advanced PXE in a 45-year-old female with extensive neck lesions that have joined with the axillary lesions. Thickened, folded, affected skin, most pronounced in the axillae, is a sign of PXE of long duration.

Figure 4. Axillary involvement producing deep folds when the arm is lowered. The surface features of PXE skin are often lost in such areas.

for mild itching in some individuals, the skin lesions are asymptomatic.

Eyes

The PXE retinopathy, clinically demonstrated by funduscopic examination, follows a somewhat predictable course but also one with great clinical heterogeneity.

Clinical Signs and Symptoms

The retinopathy of PXE consists of the following findings:

- Mottled *peau d'orange* hyperpigmentation
- Angioid streaks
- Atypical (Bruch's membrane) drusen
- Subretinal membranes (nets) with neovascularization
- Retinal hemorrhages with macular scarring
- Central vision loss with "legal blindness" (20/200 visual acuity OU [both eyes])
- Preservation of peripheral vision

The mottled *peau d'orange* hyperpigmentation (Fig. 5) is probably the earliest retinal finding, but it is seldom recognized until there is a medical indication for a retinal examination later in life. Its most common time of origin is unknown; it is, however, present in most cases when the earliest angioid streaks are found. Its specificity to PXE is unknown. The mottled hyperpigmentation is best seen at the periphery of the retina on funduscopic examination. At times, the pigment may form clumps of dark-staining material scattered throughout the retina. The reason for, and significance of, this clumping is also unknown.

Bruch's membrane is the retinal layer that contains elastic fibers and is therefore a potential site for calcification. It usually becomes sufficiently calcified about two to five years after the skin lesions first appear (at an average age of 13 years) and subsequently develops cracks or splits, called angioid streaks (Fig. 6). Angioid streaks are totally asymptomatic, and their presence often remains undetected until later in life (past age 40 years), when retinal hemorrhages begin to occur, unless a retinal examination has been performed earlier. They usually appear as irregular, often jagged, pigmented lines radiating out from the disk, like spokes on a wheel, but may also encircle the disk as peripapular streaks. At times, they develop white borders,

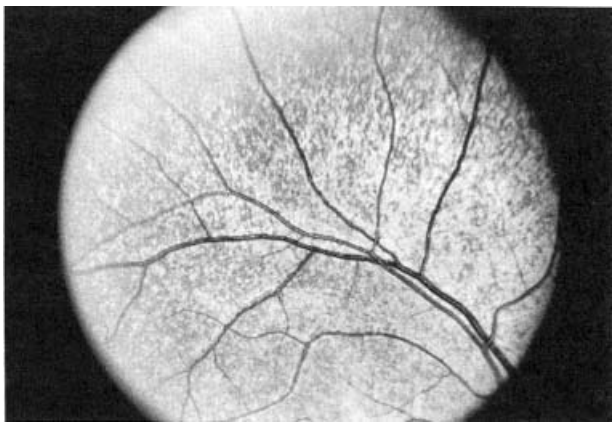

Figure 5. Mottled *peau d'orange* hyperpigmentation of the lateral margin of the posterior pole of the retina. Such pigmentation is nearly always more pronounced peripherally.

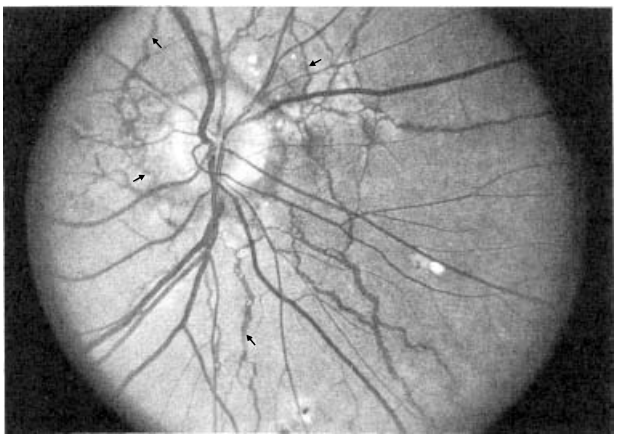

Figure 6. Multiple angioid streaks (small arrows), some radiating outward from the disk and others in a peripapillary distribution around the optic disk. Note the whitish "rock-like" drusen.

suggesting scar formation around the streaks, although the exact etiology of these white borders is unknown. Some streaks will develop paired pigmented spots on either side, which have been called "owl's eyes" and are again of unknown etiology and significance. There are at least 17 other conditions in which angioid streaks have been observed (see Table 1), so they cannot be considered pathognomonic for PXE, but, sooner or later, essentially 100% of individuals with PXE will develop streaks. The most notable examples of disorders other than PXE in which angioid streaks occur include Marfan syndrome, Ehlers-Danlos syndrome, β-thalassemia, Paget disease of bone, and sickle cell anemia [36,37].

The drusen bodies appear as small, shiny, white, "rock-like" deposits scattered throughout the retina, with no particular pattern or distribution. They are seen in about half of all patients, and their numbers will vary from one or two spots to large "showers" of drusen. Their etiology is unknown.

With time, small vascular loops grow up through the cracks in Bruch's membrane (angioid streaks) from the underlying choroid vessels by the process of neovascularization. As the vessels enlarge, particularly if the eye is traumatized,

TABLE 1. Disorders Other than PXE in Which Angioid Streaks Have Been Observed

Paget disease (Osteitis deformans)
Marfan syndrome (MIM 154700)
Ehlers-Danlos syndrome (see Chapter 9, this volume)
β-thalassemia
Sickle cell hemoglobinopathies
Hereditary spherocytosis (MIM 182900)
Idiopathic thrombocytopenic purpura (MIM 188030)
Tumoral calcinosis (MIM 211900)
Lead poisoning
Cowden syndrome (MIM 158350)
Pituitary tumors
Acromegaly
Familial polyposis (MIM 175100)
Nevus of Ota (oculodermal melanocytosis)

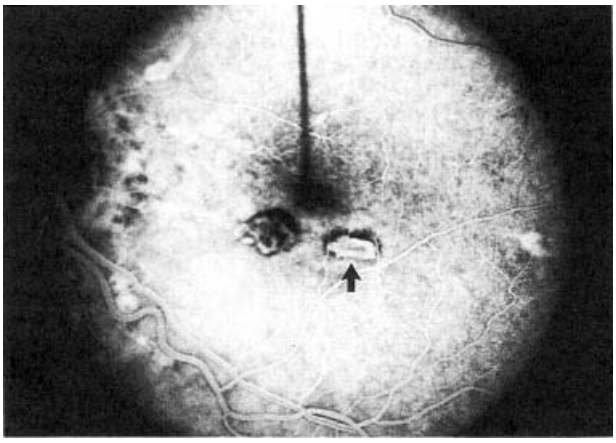

Figure 7. Example of a fluorescein angiogram. A typical subretinal net (membrane) is shown (arrow).

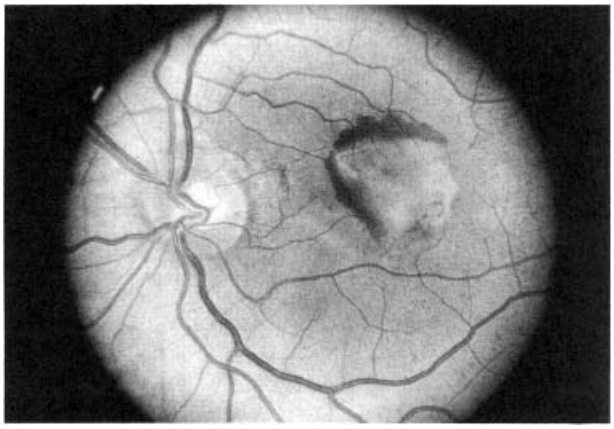

Figure 9. A healed retinal hemorrhage (4 months after the event) with the resulting white gliotic scar in the macula resulting in loss of central vision.

they may begin to leak clear serous fluid and form a so-called subretinal membrane or net (Fig. 7). At this juncture, the patient will notice wavy lines at the subretinal net site on an Amsler grid examination. Once this stage is reached, a frank retinal hemorrhage is imminent and usually occurs within days or a few weeks. Retinal hemorrhages (Fig. 8) most commonly seek out the macula and leave a white opaque scar (Fig. 9) as they heal over a period of several weeks. The end result is a loss of central vision, much the same as in the wet form of age-related macular degeneration (AMD), but through a different mechanism.

When a retinal hemorrhage occurs in one eye in an individual past age 40 years, a second hemorrhage in the same or opposite eye will commonly occur within one to five years, although longer intervals have occurred [31]. By the sixth decade of life, nearly 100% of affected individuals will have had a retinal hemorrhage of some degree. Retinal hemorrhages may occur before age 40 years, but, if so, they usually follow blunt trauma to the eye. It is important to emphasize to patients that, even if multiple retinal hemorrhages occur, peripheral vision will be preserved to the extent that they will be able to get around on their own, although they will be unable to drive a car or read standard-sized print. This will usually reach the point of 20/200 visual acuity, which is the definition of beginning legal blindness.

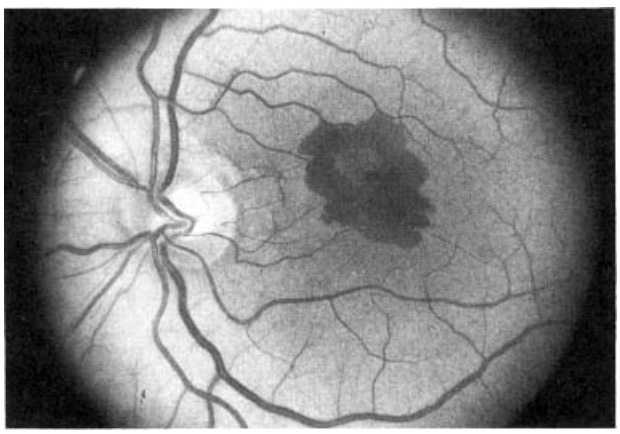

Figure 8. A fresh retinal hemorrhage, several days old, in the macular area, which is the most common site for retinal hemorrhages in PXE.

Cardiovascular System

General Considerations

The cardiovascular manifestations of PXE result from characteristic degenerative changes that occur in the elastic tissue of the endocardium and all arteries, although they are predominantly seen in arteries of the muscular type. Secondary aberrant calcification of the arterial internal elastic lamina and myoelastic tissue (media and external elastic lamina), with their subsequent fragmentation and proliferative destruction and continued calcification (Fig. 10), therefore primarily affects the peripheral (femoral, external iliac, renal, splenic, and coronary) arteries [21,24,28,31,38]. This may be accompanied by various degrees of intimal thickening due to a patchy proliferation pattern of the fibroelastic components [38].

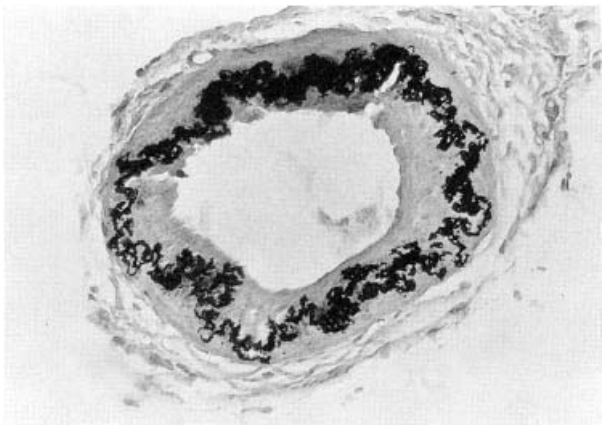

Figure 10. Medium-sized artery from a deep breast biopsy showing calcification of the elastic media. Elastic tissue stain (Verhoeff-van Gieson) shows dark irregularly shaped, fragmented calcified elastic fibers. ×225.

Comparison with Similar Cardiovascular Phenotypes

The medial calcification in Mönckeberg-type arteriosclerosis resembles that seen in PXE [21,38]. This form of focal calcific arteriosclerosis in the elderly is primarily characterized by widespread medial calcification particularly in the arteries of the lower limbs [39,40], but it has also been described in the arteries of the upper extremities, the splenic and renal arteries [41], and the mesenteric and coronary arteries [42]. Although medial calcification can be extreme, leading to circumferentially arranged rings of calcium within the arterial wall, Mönckeberg sclerosis does not usually cause cardiovascular complications unless an independently occurring process of intimal sclerosis with luminal narrowing accompanies it. This is usually not documented before the seventh decade of life. Intimal proliferation and calcification is, by definition [39], not an integral part of Mönckeberg calcinosis. The lamina elastica interna remains intact.

In PXE, cardiovascular complications can occur as early as within the first decade of life [23,43–45] but, in general, do not do so earlier than the end of the third or the beginning of the fourth decade [21,31,46]. Death at an early age due to cardiovascular complications in PXE has rarely been reported [47], or PXE may not have been recognized as the underlying disorder causing early cardiac death [45]. In any case of unexplainable early cardiac death with histopathological features of generalized calcification of the arterial myoelastic tissue, PXE has to be considered as one of the differential diagnoses.

The idiopathic type of generalized arterial calcification in infancy (IACI) (MIM 208000) is a third, clinically dramatic variant of arterial myoelastic degenerative tissue calcification, which can affect all arteries [48–50]. It is rare, of unknown etiology, and morphologically characterized by diffuse, degenerative calcification of the arterial internal elastic lamina. This is usually associated with fragmentation of the internal elastic lamina and a locally prominent, occasionally obliterative, patchy fibroelastic intimal proliferation pattern. The clinical course of IACI may lead to intrauterine death [51–53] or premature delivery around 32 weeks of gestation [54]. In live births, it is usually lethal in 85% of cases within the first 6 months (range 1 day to 27 months) [55,56], in most cases as a result of coronary artery occlusion due to excessive fibroelastic hyperplasia of the intima [48,55–57]. Prolonged survival, in one case up to adulthood, has been reported [58–61]. Based on its familial aggregation [54,62–74], it has been considered to be an independent congenital disease entity, most likely with an autosomal recessive inheritance pattern [60,74]. A comparison of different clinical features of cardiovascular manifestations in IACI, PXE, and Mönckeberg sclerosis of the elderly is given in Table 2.

It is important to emphasize that PXE and IACI differ with regard to their individual time courses of the typical clinical onset of cardiovascular complications, whereas the histopathological features of both disease entities show striking similarities [57,75]. Moreover, morphological changes similar to those described in PXE skin and endocardium at the ultrastructural level [76–78] were recognized within the internal elastic lamina of the coronary artery of an infant who died from IACI [75]. In fact, there is one reported case of a baby with IACI born to a mother with PXE [79]. To the extent that IACI most likely represents an independent disease entity in which the morphological similarities to PXE as regards structural changes within the elastic tissue are caused by a different etiological factor and the familial association of PXE and IACI in one case [79] is just a coincidental occurrence, these findings, however, still raise the intriguing question of whether IACI could represent at least in part, due to the overlap of its clinical spectrum with PXE, the extreme of the earliest fatal cardiovascular manifestations of PXE. Considering the recessive mode of inheritance of IACI, parents, as heterozygous carriers, would most likely not have clinical signs and symptoms of PXE if IACI were the earliest manifestation of any PXE abnormality. Because their children with IACI die of cardiovascular complications before the development of classical signs and symptoms of PXE, the diagnosis of PXE in these families cannot be established. Even if parents of babies with IACI did have signs or symptoms of PXE, these would most likely remain unnoticed because PXE is not generally considered as a potential differential diagnosis in relation to IACI.

Clinical Signs and Symptoms

Vascular morphological changes in PXE produce symptoms of intermittent claudication, coronary artery disease, hypertension, stroke, gastrointestinal hemorrhage, and abdominal angina. Aberrant calcification of the degenerated elastic tissue of the heart may result in diffuse endocardial

TABLE 2. Comparison of Clinical Characteristics of Cardiovascular Disease in PXE with Histopathologically Similar Vascular Phenotypes of Degenerative Aberrant Calcification Involving Primarily the Myoelastic Tissue of Arteries

Disease	Typical site of arterial manifestation	Typical age range of disease onset	Prognosis of clinical course of disease
Idiopathic arterial calcification of infancy (IACI) MIM 208000	Predominantly lamina elastica interna	0–2 yr,	Typical course: lethal
		Delayed onset up to 22 yr of age	Delayed onset: coronary artery disease (CAD), hypertension
PXE MIM 264800 MIM 177850	Predominantly lamina elastica interna and media but also lamina elastica externa	35–50 yr	Typical course: peripheral vascular disease and/or CAD
		Progressive course: 0–20 yr	Progressive course: lethal due to CAD (in the majority of reported lethal cases) or, rarely, other vascular complications
Mönckeberg's arteriosclerosis	Predominantly media	60–80 yr	Typically benign

fibroelastosis of the atria, ventricles, and atrioventricular valves [38,80,81] with clinical manifestations of mitral valve prolapse [82] or other forms of valvular heart disease [83] or restrictive cardiomyopathy [80,84].

Intermittent claudication of the lower extremities is the most common cardiovascular symptom of PXE, occurring in 30% of patients [31], usually from 30 years of age and older [31,85] and ultimately in nearly all patients to some degree, although it may occasionally be observed as early as 9 years of age [43]. The peripheral artery calcification is usually patchy such that the ischemia produced progresses slowly enough to allow for the development of collateral circulation in the extremities [85–87]. Therefore, the serious consequences of gangrene and total loss of an extremity are rare in PXE and usually coincide with other risk factors of vascular disease [85]. Severe stenosis and occlusion of the ulnar, radial celiac, splenic, renal interlobar, and femoral arteries have been observed angiographically and/or Doppler ultrasonographically [21,28,34,43,85,88]. Symptoms of intermittent claudication of the upper extremities are rare, but early fatigability has been reported. The rarity of intermittent claudication in the upper extremities may result from the development of an obviously sufficient arterial collateral blood supply to the radial and ulnar vascular bed originating from the interosseous artery and is related to the lesser muscular mass of the upper extremity [30].

Abdominal angina results from celiac artery stenosis [88] and is the second most frequent abdominal complaint in PXE [30]. Hypertension, an additional risk factor for vascular disease and hemorrhage, was observed in 8–22% [27,31] of patients studied. Hypertension has also been observed as the presenting manifestation of PXE in childhood [88–90].

Involvement of the major vessels and the heart does occur but is rare. More severe cardiovascular complications can occur. Myocardial infarction has been reported only rarely, but examples of very young patients 13 years [44], 18 years [47], and 19 years old (unpublished data) who succumbed to myocardial infarction have occurred. There is also an uncertain number of cases of early cardiac death due to PXE in whom the diagnosis of PXE as the causative underlying disorder had not been established at the time of death [45]. The incidence of strokes is rare [31]. A more common, potentially serious complication is gastric hemorrhage, with hematemesis as the presenting sign. This complication has been reported variously in from 8% to 19% [31,91] of patients. Gastric hemorrhage is slightly more common during pregnancy and in younger patients (under age 29 years). Death due to gastrointestinal hemorrhage in PXE has been reported [91].

Pathophysiology

Comparable to the loss of elasticity in skin, the gradual loss of arterial elasticity secondary to the gradual destruction of the vascular myoelastic tissues with subsequent calcification is the most obvious and logical pathophysiologic mechanism for the cardiovascular manifestations in PXE. This mechanism has a continuous, potentially "vicious cycle" effect on the arterial vascular system and the heart with unphysiologically increasing vessel stiffness (vascular impedance) and subsequent hemodynamic complications. Although increasing arterial impedance is, to some extent, a physiological process occurring with increasing age, there has been no doubt since the original and groundbreaking hemodynamic studies of Carlborg in 1944 [21] that the physiological process of age-related increased vascular stiffening is accelerated in PXE beyond the physiological pace.

Carlborg demonstrated in two morphologically distinctly structured arterial segments, elastic conduit vessels and arteries of the muscular type, different hemodynamic effects which were specific for the morphological type of arterial segment. Elastic conduit vessels showed a significant premature increase in arterial stiffening in PXE in comparison with normal controls, as documented by an increased pulse wave velocity and an increased pulse pressure amplitude. Increased vascular stiffness may be associated with hypertension. The functional impairment of the elastic properties of the conduit vessels is related to the histomorphological findings of destruction of the arterial myoelastic tissue (Fig. 10). The impaired compliance of the arterial conduit in storing and transforming the intermittently ejected left ventricular stroke volume into a continuous flow toward the periphery increases the left ventricular workload, resulting in left ventricular hypertrophy. Increased left ventricular muscular mass and wall tension may functionally enhance the morphological changes within the coronary artery system toward an early manifestation of coronary insufficiency in PXE, with angina pectoris or myocardial infarction, among others, as possible clinical manifestations. Elevated pulse pressure has been suggested to be involved in the development and progression of large vessel atherosclerosis [92] and small vessel disease [93–96]. In fact, pulse pressure, although not an ideal measure of conduit vessel function, has been shown to be an important determinant of cardiovascular and, in particular, coronary events [97–103].

Carlborg's functional findings in the peripheral arteries of the muscular type were different from those observed in the elastic conduit vessels. As the functional result of the morphological changes in muscular arteries that cause diminished arterial elasticity in PXE, he found symmetrically in the radial artery (arteria radialis) and the anterior tibial artery (arteria tibialis anterior) characteristically changed sphygmograms and a symmetrically abnormally low pulse wave velocity in comparison with healthy subjects.

The sphygmograms showed a prolonged crest time, a very low height and amplitude of the pulse curve, and a prolonged and convex shape of its descending limb. These findings were in accordance with his clinical findings of a weakened peripheral pulse with a low and slowly increasing amplitude in patients with PXE. In arteries of the muscular type, the amount of elastic tissue is considerably less than in the elastic conduit vessels. The elastic properties of the muscular arteries are therefore noticeably influenced by the natural viscoelasticity of the arterial smooth muscle layer. The effect is pronounced in PXE due to the destruction of the elastic laminae and the medial calcification. The PXE sphygmograms of peripheral arteries therefore suggest a marked arterial smooth muscle hysteresis effect in these vessels. This effect is characterized by a reduced elastic modulus of the vascular smooth muscle and its decreased distensibility within the arterial wall at a given pressure over a given time interval. The normal pulse duration is too short to fully distend the arterial smooth muscle layer, resulting in diminished arterial wall oscillations. The pathophysiological consequences are the same as have been described for the changes within the elastic conduit vessels — that is, loss of energy during the continuous propagation and transformation of the pulse wave into continuous blood flow and nutrient supply along the arterial bed to the end organs,

with the subsequent, potentially "vicious cycle" adaptations of the cardiovascular system.

In contrast to the peripheral muscular arteries of the extremities, comparable morphological changes in the submucosal gastric arteries result in increased vascular fragility, with subsequent gastrointestinal hemorrhage. Other etiological factors, such as increased gastric acidity with mucosal erosions and subsequent damage to the submucosal arteries, may also be involved. The retinal arteries in PXE also show increased fragility, leading to retinal hemorrhage.

Pregnancy

Pregnancy in PXE has been studied, but further long-term assessment in a larger number of patients is warranted. Viljoen et al. [104] found a slightly higher first-trimester abortion rate compared with the general population and a slightly greater incidence of hypertension. In general, pregnancy was well-tolerated and uncomplicated — an observation confirmed by Neldner and Yoles [31,105]. There are two reports of normal infants from mothers with PXE being "small for age", but a direct relationship with PXE is unverified [106]. A long-term assessment of the effect of pregnancy on the natural course of PXE did show a positive correlation between pregnancy and the long-term overall severity of the disease, which also correlated with the number of pregnancies [31]. If this result is confirmed in a larger number of patients, it would be prudent for women with PXE to limit their number of full-term pregnancies. The unusually high quantities of calcium ingested by many pregnant women (up to 2–3 g daily) may be a contributing factor and should be limited to 1200 mg daily, the RDA (recommended daily allowance) for pregnancy. Calcification of the placenta is known to occur in PXE but also occurs in other conditions. Its frequency and potential significance are unknown.

DIAGNOSIS

Clinical Diagnosis

The initial diagnosis of PXE is based, in most cases, on the presence of the highly characteristic yellowish, cobblestone-like papular skin lesions in bilaterally symmetrical flexural sites (neck, antecubital spaces, axillae, groins, popliteal spaces) (Figs. 1–4). The lateral neck is usually the first site to be involved, and the trained eye can make the diagnosis instantly. A small 3 mm punch biopsy from an affected site is adequate to give positive histological confirmation of calcified elastic fibers in the mid- and deep dermis. (See "Diagnostic Tests" below and also Figs. 11, 12).

The retina is the second place to look for signs of PXE by funduscopic examination. It must, however, be stressed that the characteristic angioid streaks (Fig. 6) may not be present in the early stages of the disorder; therefore, early skin lesions may be present while the retina appears normal. Angioid streaks most commonly first appear a few years after the onset of the skin lesions.

The initial clinical assessment of cardiovascular involvement in PXE includes taking a thorough history for symptoms of intermittent claudication, angina pectoris, gastrointestinal bleeding, hypertension, and exercise-related fatigue of the upper and lower extremities and making a comparative evaluation of the pulse status at different peripheral locations. With the manual measurement of the blood pressure in both upper and lower extremities, the arterial pulse pressure should also be recorded separately for each of the extremities.

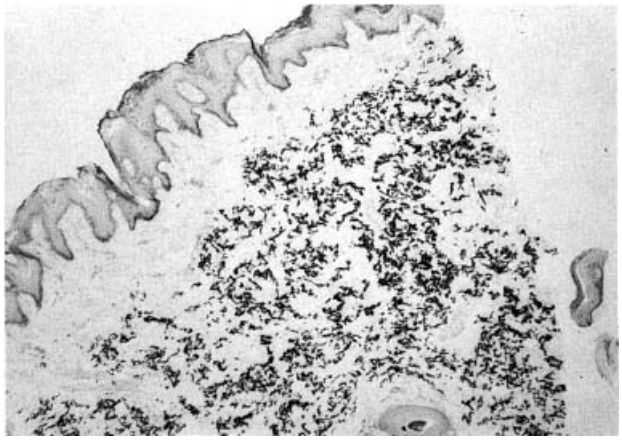

Figure 11. PXE-affected skin. Von Kossa stain. The black staining fibers in the reticular dermis are elastic fibers filled with calcium salts. ×20.

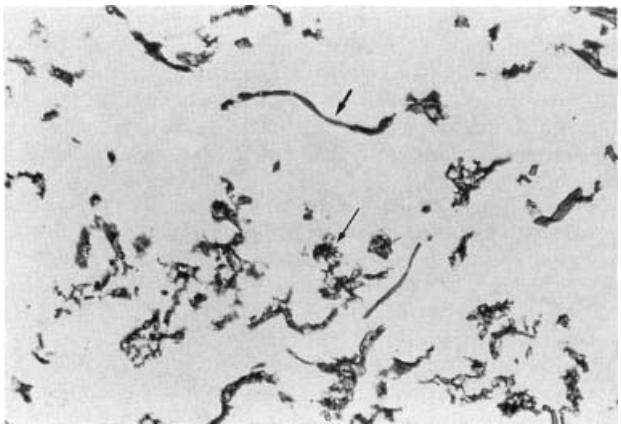

Figure 12. Von Kossa stain. Higher magnification (×250) of sample shown in Figure 11. At this magnification, elastic fibers with early calcification (shorter arrow) and also severely mineralized and ruptured (long arrow) elastic fibers are visible.

It is important to realize that at the time of the first diagnosis of PXE not all three sites of disease expression will necessarily show clinical manifestations of the disease. It is, however, certain that with increasing disease duration all sites will manifest clinical signs and symptoms of the disease but with considerable clinical heterogeneity. Regularly obtained cardiovascular parameters will allow a prospective evaluation of the development of cardiovascular disease in PXE patients.

Prenatal Diagnosis

The identification of the gene locus on chromosome 16 [1,2] permits the prenatal prospective diagnosis of the mutation through linkage analysis in families with a proven case of PXE in at least one other child.

Diagnostic Classification

Historical aspects. Pope's individual and historically justified attempt to describe a wide spectrum of clinical manifestations of PXE, with their subsequent classification into

different diagnostic and potentially etiological and prognostic subclasses [107–109], became obsolete with increasing knowledge about the disease over time. Pope's classification was replaced [110] because his clinical observations had not been made in earlier investigations [27,28] and could not be confirmed in later studies [31]. An additional systematic shortcoming of this classification had been the inevitability of needing to reclassify patients during their individual natural disease course.

Current consensus. At the consensus conference in 1992 [110], it was concluded that all patients seem eventually to merge into a single classic phenotype of the disease, which involves the skin, the eyes, and the cardiovascular system, although considerable clinical heterogeneity of individual expression of the disease at various points in time can be observed. This conclusion, based on clinical observations, implied the concept of pleiotropy of PXE to explain the many different clinical facets of the disease. To guide, facilitate, and unify the diagnostic process for PXE, three major diagnostic criteria (characteristic skin involvement, characteristic histopathological features of lesional skin, characteristic ocular disease) and two minor diagnostic criteria (characteristic histopathological features of nonlesional skin, family history of PXE in first-degree relatives) were defined (Table 3) [110]. This categorization, although not perfect, has proven to be a clinically useful diagnostic aid in evaluating the disease status of different family members because it has become clear that category I defines not only the full-featured clinical syndrome of PXE but also characterizes at the molecular level the genetic homozygote or compound heterozygote for *PXE* on chromosome 16. Category II with its subcategories (a–d) defines at the molecular level the heterozygous carrier state, which may be clinically associated with angioid streaks and/or the minor diagnostic criteria. (For more details, see "Genetics" below.)

Future consensus. Although the diagnostic criteria and their categorization in combination with molecular haplotype data are helpful, although incomplete, in diagnosing PXE and counseling families with PXE, this classification will be replaced with a molecular classification. Now that the PXE gene has been identified, different mutations may be associated with different phenotypic patterns of the disease.

Diagnostic Tests

Light microscopy. The presence of fragmented and calcified elastic fibers in the mid- and lower dermis of affected skin is essentially pathognomonic for PXE (Figs. 11, 12). The only exceptions are the rare acquired forms of localized acquired cutaneous PXE (LAC-PXE), for which the history and clinical presentation are vastly different from classical hereditary PXE. (For further details, see "Histopathology," below.)

Electron microscopy. Although electron microscopy is not routinely used for the diagnosis of PXE, the ultrastructure of calcified elastic fibers is also highly characteristic and pathognomonic for the disorder and may therefore be used if confirmation of the diagnosis is needed. Ross et al. [111] demonstrated that calcified elastic fibers can be detected in skin biopsies of clinically unaffected relatives, such as parents and siblings of patients in families with a recessive mode of inheritance. This morphological finding thus characterized those relatives as heterozygous carriers of *PXE*. (For further details, see "Histopathology" below.)

Ultrasonography. The following tests are recommended as an integral part of a standard clinical workup for each patient with PXE.

1. Doppler ultrasound. The ankle/brachial index (or A/B ratio) compares the arterial occlusion pressures of the upper and lower extremities on each side of the body. The occlusion pressure for the brachial arteries is measured with a sphygmomanometer and that for the dorsalis pedis and posterior tibial arteries in both ankles is measured by Doppler ultrasound. This is a fast, inexpensive, and noninvasive means of determining the competency of the vasculature and blood supply of the lower extremities for screening purposes. The A/B ratio usually correlates quite well with the presence or absence of intermittent claudication and is therefore useful for initial baseline data and follow-up studies.
2. 2-D color-coded ultrasound. This technique is excellently suited to screening for peripheral vascular disease in general and has been used for the diagnosis of vascular disease in PXE [34]. Its high resolution allows the evaluation of arteries, particularly with regard to

TABLE 3. Consensus Diagnostic Categorization of PXE Enhanced by Haplotype Analysis Data for the Chromosome 16 Locus in 81 Families

Category I (three major criteria)	Category IIa (one major criterion and two minor criteria)	Category IIb (one major and one minor criterion)	Category IIc (one major and one minor criterion)	Category IId (two minor criteria)
characteristic flexural skin lesions				
ocular disease in adults	angioid streaks	angioid streaks	angioid streaks	
elastic fiber calcification, lesional skin	elastic fiber calcification, nonlesional skin	elastic fiber calcification, nonlesional skin		elastic fiber calcification, nonlesional skin
	family history of PXE in first-degree relatives		family history of PXE in first-degree relatives	family history of PXE in first-degree relatives

Family members in category I invariably carry two disease alleles. In contrast to those in category I, family members in all subclasses of category II invariably carry one disease allele and one normal allele, as defined by the combined genotypic and phenotypic observation in each family. Genetically, this characterizes family members in this diagnostic category as heterozygous carriers of a disease allele.

morphological changes of the arterial wall structure (thickness and degree of calcification). The color-coded Doppler signal allows a functional assessment of local vessel patency and stenotic or obliterative processes along the vascular bed. In skilled hands, this technique is highly accurate and the first choice for a prospective diagnostic assessment of vascular disease in virtually any location, although peripheral arteries are particularly easy to access.

3. Abdominal ultrasound. With this diagnostic screening tool, Garel et al. [112] demonstrated a pattern of increased echogenicity at the renal corticomedullary junction in six children with renovascular hypertension. Two of these children had PXE. The hyperechogenicity pattern was considered to be due to a diffuse calcification process involving the elastic tissue of the small arteries (interlobar and/or arcuate arteries of the kidney). These patterns of kidney hyperechogenicity have been confirmed in other PXE patients [88,113–115] and also shown to occur in pancreas [88,114] and spleen [114] in these patients. Although this pattern is not pathognomonic for PXE [112,115], it is highly suggestive of vascular changes due to PXE in members of a family with inherited PXE.
4. Echocardiography. This method is indispensable in cardiology and, in PXE, is particularly useful and necessary in evaluating and monitoring cardiac function foremost with regard to morphological changes of the endocardium and potentially subsequently developing valvular heart disease (valve thickening, stenosis, and insufficiency, such as mitral valve prolapse). Diagnosis of these changes makes an antibiotic endocarditis prophylaxis necessary shortly before dental or surgical treatment. Excessive thickening of the endocardium may result in a restrictive cardiomyopathy, which can be diagnosed by echocardiography. Reduced ventricular contractility and local wall mobility, suggestive of myocardial ischemia due to coronary insufficiency, can also be visualized.

Prognostic Laboratory Tests

The prognosis for the progression of cardiovascular disease in PXE is not controlled solely by the defective PXE gene but is additionally influenced by general polygenic risk factors for cardiovascular disease. Therefore, the following tests are recommended for the detection of additional risk factors for vascular disease in PXE.

Lipid profiling. A complete lipid profile (cholesterol, triglycerides, HDL-C, and LDL-C) is most important and should be obtained initially and then followed from time to time over the lifetime of the patient. Abnormal lipid values portend more severe cardiovascular adverse effects.

Fasting glucose test. Any evidence of familial diabetes mellitus, the most common endocrine disease with vascular complications similar to those seen in PXE, should be thoroughly evaluated. Although there is no causal relationship with PXE, the independent, considerable additional risk of vascular disease as a long-term complication of an unrecognized fasting hyperglycemia and the high frequency of diabetes mellitus in western societies make every effort necessary to diagnose abnormal glucose metabolism in PXE patients. This will prevent additional vascular complications through the early recognition of an additional common vascular risk factor and its subsequent therapeutic control.

Specialized Procedures

Endoscopy. Esophageal endoscopy is not indicated unless there are signs of acute gastrointestinal bleeding. Gastrointestinal tract bleeding can occur anywhere in the gastrointestinal tract; however, the stomach is almost always the site of the bleeding. Even with active bleeding, the endoscopic findings are usually nonspecific, showing only a diffuse oozing of blood, without specific focal bleeding points. In some patients, a submucosal, yellowish cobblestone-like pattern can be observed [116,117].

Angiography. Invasive arteriography is indicated for the planning of invasive treatment of severe vascular disease that cannot be managed by conservative procedures.

Magnetic resonance imaging (MRI), computed axial tomography (CAT). These tests are not routinely indicated but have been used on occasion to document aberrant intracranial calcification in PXE patients with symptoms most likely ascribed to a neurological category.

Differential Diagnosis

The differential diagnosis of classical hereditary PXE is usually not difficult. Characteristic skin lesions in the typical flexural sites will, in all likelihood, represent hereditary PXE, which can be confirmed histologically by a skin biopsy (Figs. 11, 12). There are, however, a number of disorders in which angioid streaks have been reported (see Table 1) such that their presence cannot be considered pathognomonic for PXE, although in most instances they are highly suggestive. There are also a number of conditions in which there are skin lesions that superficially resemble PXE and must therefore be considered in the differential diagnosis (see Table 4).

The occasional association of PXE with other hereditary disorders of connective tissue is well-documented, particularly Marfan syndrome, Ehlers-Danlos syndrome, and Paget disease of bone. Less common associations have been reported with tumoral calcinosis and congenital hyperphosphatasia.

Conditions with Histological but no Clinical Resemblance to Hereditary PXE

Localized acquired cutaneous PXE (LAC-PXE). LAC-PXE [118], also called "periumbilical perforating PXE" [119,120], is the best-known example of such a condition. We prefer the former term to emphasize the nonhereditary nature

TABLE 4. Conditions that May Be Associated with or Resemble PXE

Marfan syndrome
Ehlers-Danlos syndrome
Idiopathic hyperphosphatasia
Hyperphosphatemia
Tumoral calcinosis
Vitamin D toxicity
Renal disease with elevated Ca × P product
Penicillamine therapy
Milk-alkali syndrome
β-thalassemia
Localized acquired cutaneous PXE
Saltpeter contact
White papulosis
Papillary dermal elastolysis
Buschke-Ollendorf syndrome

of the disorders included in LAC-PXE. Furthermore, the skin lesions in LAC-PXE are not always strictly periumbilical and do not always show examples of perforating lesions. LAC-PXE has been reported most commonly in black, multiparous, hypertensive, obese females. Type II diabetes has also been described in some. Most such patients do not have angioid streaks; however, one reported patient [120] did do so, which raised the question of a possible hereditary component, although the streaks could also have been acquired. The patient was a 77-year-old, multiparous, obese female with hypertension and severe renal disease with an elevated Ca × P product. After 6 months of hemodialysis and with a normalized Ca × P product, her skin lesions decreased markedly in size, indicating the reversible nature of the basic, *acquired* process. In an example of typical *hereditary* PXE, a reduction in diameter of the lateral neck lesions was seen after several months of a low (400 mg per day) calcium diet [76], again indicating the possible reversible nature of the skin lesions in their early stages and suggesting calcification of elastic fibers in PXE to be a secondary effect.

Saltpeter contact. Contact with saltpeter in farmers with forearm skin exposure from carrying fertilizer bags represents another entity of acquired, highly localized cutaneous patches with a histologically PXE-like appearance [121]. The skin contact areas usually remain localized to the forearms without any of the stigmata of hereditary PXE. Such localized lesions have been reported to last up to 50 years [122].

Conditions with Clinical but no Histological Resemblance to Hereditary PXE

White papulosis of the neck, acquired elastolysis of the papillary dermis. There are several connective tissue disorders that have been described with a PXE-like appearance. These include "white papulosis of the neck" and "acquired elastolysis of the papillary dermis," which is also called "PXE-like papillary dermal elastolysis" [123,124]. Both conditions present flesh-colored papules that commonly occur on the neck but also in other nonflexural sites. They display none of the other signs of hereditary PXE, and the elastic fibers show varying degrees of elastolysis or collagen fibrosis but no calcification. The collagen fibers usually show fibrotic changes.

Penicillamine. Long-term penicillamine therapy can also lead to the production of skin lesions similar to those of hereditary PXE as one of its adverse side effects [125,126]. Again, however, histology shows no calcification of elastic fibers but does show a degenerative alteration of them, called a "bramble bush" deformity.

Hyperphosphatemic tumoral calcinosis (MIM 211900). This condition is, in some patients, associated with angioid streaks of the retina and may also show skin lesions clinically similar to those of PXE. The histological findings in this disease are quite distinct from those in PXE.

Familial hypoalphalipoproteinemia (MIM 107680). This disease, particularly the Detroit type of high-density lipoprotein deficiency (combined deficiency of apolipoproteins A-I and C-III), has been shown to be associated with infiltrative xanthoma of the neck and antecubital fossa [127–129]. These skin features may be misinterpreted clinically as signs of PXE, but the distinct histological appearance of the lesions, the extremely low plasma level of HDL cholesterol, and other distinct clinical manifestations (xanthelasma, arcus cornealis) allow the unequivocal differential diagnosis of hypoalphalipoproteinemia from PXE.

Buschke-Ollendorf syndrome (osteopoikilosis) (MIM 166700). This disease (see also Chapter 10, this volume) manifests skin lesions that can look strikingly similar to the skin appearance in PXE. They also show a symmetrical distribution on the forearms, but are commonly found on the trunk, buttocks and feet, where PXE does not occur. Although the skin disturbance may resemble signs of PXE, the differentiation of both diseases is easy because in osteopoikilosis there is in most cases typical bone involvement, no ocular disease, and a different histopathology.

Conditions with Both Clinical and Histological Resemblance to Hereditary PXE

β-thalassemia. In recent years, there has been an increasing number of reports of cases of β-thalassemia resembling the clinical manifestations of PXE [37,130–133]. Some patients have histological changes in skin biopsies similar to those seen in PXE but do not show angioid streaks, while others have angioid streaks and minimal or no skin involvement. Aessopos et al. [133] found that six of eight patients studied with β-thalassemia had positive skin biopsies with PXE-like lesions and that 52% of a larger group ($n = 40$) had angioid streaks. Cardiovascular manifestations have been mild or have not been detected. β-thalassemia patients commonly have iron overload with high serum ferritin levels, raising the additional interesting question of a possible role for iron in a calciphylaxis-type reaction.

GENETICS

Mendelian Inheritance

Pedigree analysis of families in which PXE occurs demonstrated that PXE is, unequivocally, a genetically predetermined disorder [28,30,31,107–109,134–136]. The disease, although highly variable in its clinical expression in different individuals, nevertheless cosegregates as a Mendelian trait. This means that a particular genotype at one locus is both necessary and sufficient for the trait to be expressed. This definition takes into account that the expression of a Mendelian trait or character most likely involves a large number of genes and environmental factors. (See also "Diagnosis-Current Consensus" above.) "Sporadic" cases, which are also commonly observed, usually represent the autosomal recessive form of the disease or could be new dominant mutations.

Autosomal Recessive Trait

The disease presents primarily and in the majority of families (greater than 90%) as an autosomal recessive trait. This requires that those who are affected according to the diagnostic criteria of category I (see Table 3) be homozygotes or compound heterozygotes at the gene locus. Large, genetically isolated, consanguineous families displaying cosegregation of the PXE trait through multiple generations have been described [137,138].

Autosomal Dominant Trait

Individuals heterozygous at the gene locus express a disease phenotype that is, in principle, indistinguishable from that seen in recessive PXE. Families manifesting PXE in three consecutive generations have occasionally been described in the literature [109,134]. Clinically detected disease expression in three consecutive generations of a family, with transmission of the trait from an affected parent to a child in at least two successive generations,

makes the existence of dominantly inherited PXE possible. Nevertheless, it must be rare (less than 10%) compared with the number of reported families with a most likely recessive inheritance of the disease. The mode of inheritance can clinically be defined unambiguously in only a small number of pedigrees, thereby leaving a certain margin of error, even in the assessment of pedigrees with the occurrence of a PXE affection status in three consecutive generations. The situation may be complicated further by issues of penetrance, late disease onset, or the occurrence of new mutations.

Penetrance

The degree of penetrance of PXE has never been formally investigated. Preliminary analyses in the families we have studied [1–3] indicate that penetrance of the recessive disease may actually be complete or close to complete by the fourth decade of life because almost all individuals that eventually develop PXE do so by their early thirties. In fact, the problem appears more to be late recognition of a manifest illness by physicians not fully aware of the disorder. A reliable estimate for the penetrance of potentially dominantly inherited PXE cannot be given due to the small number of families comprising three or more generations with clinically detectable disease in at least two of them.

Molecular Genetics

Candidate Gene Studies

The first molecular studies to investigate the genetics of PXE were undertaken in 1992 [139] and 1994 [140] and used the candidate gene approach. These studies were either inconclusive or negative. In the former investigation, which examined the possible role of lysyl oxidase in some ten families, genetic linkage to this enzyme was excluded; likewise, no evidence for linkage was demonstrated for the gene encoding fibrillin-2 (*FBN2*) in a family with six affected members, although the power was naturally insufficient to exclude linkage [139]. The latter study investigated the elastin gene as a potential cause of PXE through cosegregation analysis of a gene-inherent RFLP (restriction fragment length polymorphism) in one family with PXE [140].

Identification of the Gene Locus

Applying a two-stage strategy, our group performed, as a first step, a genome-wide screen of 73 affected sib pairs from 38 families with PXE using a commercially available set of single-sequence-length polymorphisms (SSLPs) to identify the chromosomal location of the causative gene, designated *PXE*. Sib pair genotype data analysis with nonparametric allele-sharing algorithms identified a significant excess of allele sharing for three markers on the short arm of chromosome 16 [1,2]. In a second step, we mapped *PXE* to a 3 cm interval on chromosome 16p13.1 by linkage analysis in all available members of 50 families with PXE using a highly polymorphic high-resolution panel of SSLPs and calculating linkage twice: first under the assumption of a recessive, and second under the assumption of a dominant mode of inheritance in all families [1,2].

Heterogeneity

The linkage results with multipoint lod score values of greater than 21 assuming a recessive model and of greater than 16 assuming a dominant model of inheritance suggest considerable homogeneity of the study sample. Further heterogeneity analysis confirmed this suggestion and predicted allelic heterogeneity at the chromosome 16 locus, where allelic variants of a single gene most likely account for recessive and dominant forms of PXE [1,2]. Although possible because it cannot be definitely excluded, there is no convincing evidence in our set of family data for locus heterogeneity of the disease. In fact, others have confirmed our mapping data in different collections of families [141].

High-Resolution Mapping and Genomic Structure of the 500 kb PXE Locus

Haplotype analysis of informative PXE families narrowed the locus to an interval of less than 500 kb [3]. This interval is defined by the markers *D16B9621* and *D16B764*. This region could be covered by three overlapping YAC clones, and a second-layer BAC contig was constructed.

Candidate Genes at the Locus

Two multidrug resistance protein genes, *MRP1* [142] and its homolog *MRP6* [143], represent two possible candidate genes within the *PXE* region on chromosome 16p and belong to the gene superfamily of ATP–binding cassette (ABC) polytopic integral membrane transport proteins. Members of this gene superfamily are also involved in the transport of proteins, amino acids, inorganic ions, large polysaccharides, and peptides in prokaryotes and eukaryotes [144]. Many known ABC genes cause heritable human diseases such as cystic fibrosis (MIM 219700) (*CFTR*) [145] and recessive Stargardt macular dystrophy (MIM 248200) (*ABCR*) [146]. Typically, mutations in ABC genes, which have been shown to be responsible for specific genetic disorders, cause defects in the energy-dependent transport of specific substrates. Therefore, mutations in drug resistance genes of the ABC superfamily could cause PXE through a transport defect eventually leading to the accumulation of substrates such as calcium and/or glycosaminoglycans within the extracellular matrix. Both genes are currently under investigation for PXE-specific mutations by our group due to their physical location within the *PXE* locus on chromosome 16p13.1.

An expressed sequence tag (EST) of a transcript named *pM5*, of unknown function but with domains homologous to those of metalloproteinases, was mapped close to the locus of *PXE* on chromosome 16 by radiation hybrid mapping and into the locus by genetic mapping. This gene had been identified while screening a melanoma cDNA library on the basis of homology to the metal-binding domain of human fibroblast collagenase and had the anticipated function of coding for a serine protease [147]. The physiologic function of this gene has not been determined. Its domain homology to metalloproteinases makes it a potential candidate for *PXE*.

Three similar copies of a novel gene, with different predicted splicing forms, are found in the *PXE*-relevant region [3,148]. This gene has been characterized as encoding a nuclear core complex interacting protein (NPIP). Additional paralogs of this gene are present in several duplicons [148] on chromosome 16 outside the immediate region of interest for PXE, raising the possibility of a novel gene family.

Editors' note added in proof: The genetic basis of PXE is now known to reside in the gene *ABCC6*, as described in the section "Recent Developments", below.

Molecular Analysis of Mendelian Inheritance Patterns

When Mendel introduced the qualitative terms "recessive" and "dominant" to describe inheritance, he intended to reduce the very complex and quantitative phenomenon of allelic control of phenotypic traits to the two extreme ends of a continuous spectrum. At the "dominant" end of the spectrum, one mutated allele of a gene is necessary and sufficient to result in expression of the Mendelian trait, whereas at the "recessive" end of the spectrum, two

allelic variants are needed to express the same trait. This reductionist approach was very helpful to Mendel to convey a revolutionary concept that has proven to be useful in clinical medicine for a coarse and greatly simplified categorization of different inheritance patterns for the same disease. This is important for the individual and familial risk assessment applied in genetic counseling.

Correlating the consensus diagnostic criteria [110] and their subsequent arbitrary, diagnostic categorization of the PXE trait with our familial haplotyping data, it is evident that all sib pairs fulfilling the diagnostic criteria of category I (Table 3) invariably share two alleles and are homozygotes or compound heterozygotes at the locus. These individuals show the full clinical picture of the disease and therefore carry the recessive trait. Siblings with signs of PXE according to category II diagnostic criteria share with siblings belonging to category I only one allele and are heterozygotes as defined by the combined genotypic and phenotypic observations in each family. We were unable to identify sib pairs who belonged to category I and shared only one allele at the locus. We did not detect PXE as defined by diagnostic category I in three consecutive generations of any family in our study. Therefore, most family members with signs of PXE according to diagnostic category II and with a single disease allele at the locus are heterozygous carriers of the recessive trait. At this time, there is no positive confirmation by haplotype analysis for the existence of a dominant PXE trait. Although the haplotype data in our families cannot definitely exclude the existence of a dominant PXE trait at the molecular level, they do provide further evidence, in addition to the rarity of families with unequivocal category I disease in three consecutive generations that are not consanguineous, that a dominant PXE trait must be rare, if it exists at all. The haplotype data further confirm that those heterozygous for the recessive trait may develop angioid streaks or a positive skin biopsy over time. At the time of the consensus conference, it was not clear whether the diagnostic criteria of category II defined the heterozygous carrier of the dominant or recessive disease.

Molecular Genetic Considerations in Relation to Cardiovascular Disease

It is important to note that, in contrast to other polygenic diseases associated with increased vascular impedance, accelerated arterial stiffening in PXE has a broad hereditary base; in other words, it is predominantly influenced by allelic variants of a single gene. PXE could therefore develop as a "monogenic model disease" for the analysis of the molecular pathways and the identification of genes responsible for the development of premature vascular aging and subsequent cardiovascular complications. Moreover, it has been observed that although the canonical triad of clinical PXE is predominantly a recessive trait, the vascular disease can manifest as a dominant trait [149]. This identifies heterozygotes as susceptible to early clinical manifestations of cardiovascular disease. It remains to be seen whether heterozygotes in PXE families show an increased risk of early manifestation of cardiovascular disease in general or whether such risk is associated with certain allelic variants of *PXE*.

The vascular histomorphological similarities of idiopathic arterial calcification of infancy (IACI) with the vascular and skin lesions in PXE, the association of PXE with at least one case of IACI, and the comparatively extremely early manifestation of cardiovascular death in IACI in the majority of cases raise the intriguing question of whether IACI is the homozygous lethal manifestation of a dominant cardiovascular PXE trait associated with specific allelic variants of *PXE*. Because this remains a speculative question for the time being, *PXE* will, after its identification, be a prime candidate for exclusion as the molecular cause of IACI, particularly in consideration of the obvious difficulties in undertaking a gene mapping study in this disease.

HISTOPATHOLOGY

Light Microscopy

By light microscopy, fragmented and calcified elastic fibers in the mid- and lower dermis of affected skin can be demonstrated as the essential pathognomonic finding in hereditary PXE. These findings may also be observed to a lesser extent in carriers of the disease. As discussed under "Differential Diagnosis" above, the two exceptions to this are the rare acquired forms LAC-PXE and "contact–PXE" through saltpeter, which show a similar histopathology. In well-established lesions, the diagnosis can be made with ordinary hematoxylin and eosin or elastic tissue stains; however, the von Kossa stain (Figs. 11, 12) is the "gold standard" in that it stains specifically for calcium salts and dramatically shows the calcified elastic fibers that confirm the diagnosis. Calcified and fragmented elastic fibers can also be demonstrated in the myoelastic tissue of arteries (Fig. 10). Uncalcified elastic fibers appear essentially normal with elastic tissue stains before their mineralization. The dense deposits of glycosaminoglycans (polyanions) in the dermis can usually be demonstrated with alcian blue stain. The numerical increase in elastic fibers in the dermis may or may not be detectable by light microscopy. Although of unknown significance, it is common to see many mast cells in the PXE dermis. They may be concentrated in perivascular locations or scattered throughout the dermis. As many as 12–15 mast cells per high-power field may be seen.

Electron Microscopy

The ultrastructure of calcified elastic fibers, particularly the initial observation that calcium salts are confined to the central core of the fiber, is also highly characteristic and pathognomonic for the disorder [31,150] (Fig. 13).

There is always a darker, more electron-dense band surrounding the central calcified core, which is of unknown

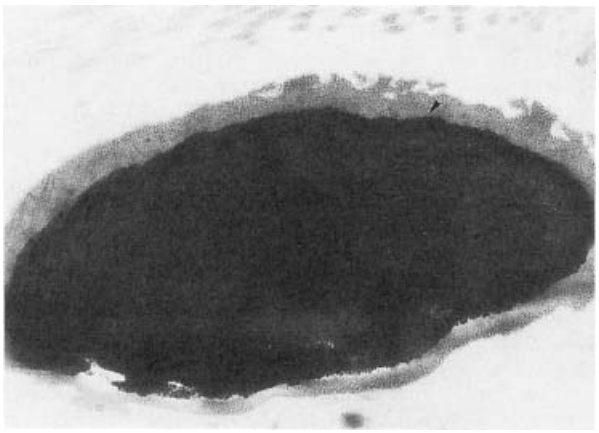

Figure 13. Electron micrograph (×30, 000) of an early mineralized elastic fiber. Note the band of normal-appearing elastic fiber and microfibrils at the periphery and the solid electron-dense, calcified core. A discrete, sharp peripheral margin to the mineralized elastin is commonly seen (arrowhead).

significance (Fig. 13). As the process evolves, the core calcification of some fibers seems to clear, leaving an electron lucent area, but with the peripheral dark band remaining. The natural course appears to be a gradual complete calcification of the fiber, with only tiny sites of normal-appearing elastic fiber at the periphery remaining. The fiber then seemingly "bursts," leaving a totally fragmented structure (Figs. 14, 15).

Collagen fibers, especially those adjacent to calcified elastic fibers, occasionally show partial or total calcification. Interference with fiber formation to produce so-called flower figures is also common [78] but not specific for PXE. Less often, masses of fine filaments (microfibrils?) and amorphous granular material are seen in the same area and described as granulofilamentous material. Such masses are of unknown origin but are thought possibly to represent an abortive effort to make new elastic fibers.

Figure 14. Electron micrograph (×12, 000) of a more advanced stage of calcification showing nearly total involvement with beginning fragmentation of the elastic fiber.

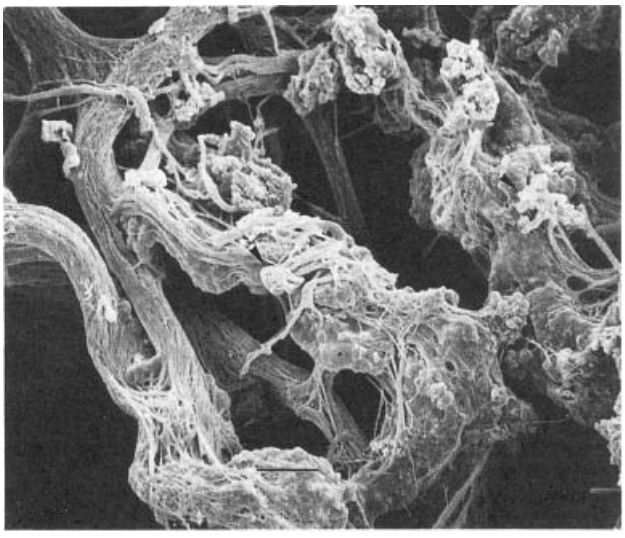

Figure 15. Scanning electron micrograph of elastic fibers showing the abrupt sites of mineralization. Bar = 1 μm. (Courtesy of Dr. Takuo Tsuji.)

BIOCHEMISTRY

There are three unequivocal biochemical abnormalities recognized in PXE:

- Elastic fiber mineralization predominantly by calcium carbonate and calcium phosphate, although other elements, especially magnesium and possibly iron, aluminum, and copper, may also be involved.
- Increased deposition of glycosaminoglycans in the affected dermis.
- Increased production of elastic fibers in affected skin.

Cutaneous Elastic Fibers and Amino Acid Composition

Only a few attempts have been made to isolate and analyze PXE elastic fibers for amino acid content, and these have yielded varying results. This is due, at least in part, to the difficulty of extracting pure elastic fibers from skin. Different extraction methods yield different concentrations of amino acids from the same dermis. Increases in the content of polar amino acids (aspartic and glutamic acids, lysine, arginine) have been observed somewhat more consistently than others [31]. The significance of this is unknown other than there being a possible theoretical role for glutamic acid as a precursor of γ-carboxyglutamic acid, which has a specific affinity for calcium and has been implicated in bone mineralization.

Glycosaminoglycans

After the seminal observation that elastic fibers were the target in PXE, the next observation at the molecular level was that there was an increase in glycosaminoglycans (GAGs), formerly known as mucopolysaccharides (MPS), throughout the affected dermis [151]. The excessive deposition of GAGs in affected skin has led to speculation that these compounds might be involved in the pathogenesis of PXE [152]. As previously noted, most observers have held the view that elastic fibers are morphologically normal before mineralization; however, one report [77] suggested that they appear more granular than normal, and that this granularity is secondary to an increased content of polyanions within the fiber, on the basis of increased staining with osmium-ruthenium red following EDTA demineralization.

Earlier studies in PXE [151] showed the GAGs to be mainly hyaluronan and chondroitin sulfate (mainly chondroitin 4-sulfate B). More recent studies by Longas et al. [153] showed relatively large amounts of dermatan sulfate in addition to hyaluronan and chondroitin 4-sulfate B in the skin and urine of PXE patients. These authors also reported an altered form of chondroitin 6-sulfate in urine. This observation was confirmed by Walker et al. [154], who identified chondroitin 6-sulfate using immunohistochemical staining. Tiozzo Costa et al. [155] found decreased amounts of sulfated glycosaminoglycans in cultured PXE skin fibroblasts compared with normal controls and increased production of a high-molecular-weight fraction of sulfated proteoglycans.

Two multidrug resistance protein genes, *MRP1* [142] and its homolog *MRP6* [143], are located within the *PXE* locus on chromosome 16p. Apart from their specific protective function of preventing cytotoxicity through transmembranous transport of cell toxic substances, they may also be nonspecifically involved in the transport of inorganic ions, large polysaccharides, and peptides in prokaryotes and eukaryotes [144]. The unspecific transport

function of these genes and their localization within the *PXE* locus are the reasons for their consideration as candidate genes for PXE (see "Candidate Genes at the Locus" under "Molecular Genetics" above).

Proteinases, Elastases, and Elastogenesis

The possibility of the elastic fibers in PXE being uniquely sensitive to enzymatic degradation by proteinases has been considered as a factor in the pathogenesis of the disorder but no conclusive link has yet been established.

Various species of elastase are produced by the pancreas, polymorphonuclear leukocytes, platelets, macrophages, fibroblasts, smooth muscle cells, synovial membranes, and bacteria. However, these and serum elastase inhibitors, such as α1-antitrypsin and α2-macroglobulin, have been sparsely studied, and no clear implication for a role in pathogenesis has yet emerged. Pasquali Ronchetti et al. [156] reported that both the calcified and uncalcified elastic fibers in PXE had a normal lytic response to porcine pancreatic elastase and that the dermal granulofilamentous material described by Danielsen [157] was sensitive to degradation by elastase and hyaluronidase. It was also partially removed by trypsin and chondroitinase but not by collagenase. The great stability and resistance of normal elastic fibers to chemical destruction and normal catabolism suggests that an abnormal elastolytic enzyme might be required to alter a fiber and specifically create a highly localized environment in or around it that would allow the mineralization process to proceed without initially destroying the fiber.

The elastic fiber precursor, tropoelastin, is known to be highly sensitive to degradation by proteinases, including leukocyte and pancreatic elastases at physiologic pH and ionic strength, and therefore might be uniquely sensitive to an abnormally active PXE proteinase. The age of an individual fiber may also be important. The more rapid destruction of elastic fibers could also be the feedback stimulus to synthesize more elastic tissue, which is known to occur in PXE. Perhaps the granulofilamentous material represents an abortive attempt by the fibroblast to synthesize new elastic tissue but one that is at least partially blocked at a post-translational stage such that tropoelastin becomes the granular portion of the granulofilamentous material rather than moving on to become mature elastic fibers.

Schwartz et al. [158] demonstrated an elastase-like proteinase that degraded a synthetic substrate, succinyl-trialaninyl-p-nitroanilide (SANA), in cultured PXE lesional fibroblast medium and was not found in normal control fibroblast cultures. The nature of the proteinase and its kinetics however, were, not studied.

Gordon et al. [159,160] studied proteoglycanase activity in the medium of cultured PXE fibroblasts. They found a cysteine proteolytic enzyme with proteoglycanase activity, which was markedly (500-fold) enhanced by the addition of zinc and, to a much lesser degree (70-fold), by the addition of $CaCl_2$. Normal control fibroblasts did not produce this enzyme. The authors did not further purify or study the enzyme.

A gene named *pM5*, with homology to metalloproteinase domains, was identified at the *PXE* locus [3,141,147,148]. Its homology to metal-binding domains of human fibroblast collagenase, a matrix degrading metalloproteinase, suggests it as a potential candidate for *PXE*.

Calcium, Phosphorus, and Vitamin D Metabolism

There is good evidence that any condition resulting in an elevated Ca × P product can present as a complication aberrant calcification in the skin, arteries, and other organs, causing large necrotic ulcers and arterial occlusion secondary to vascular calcification [161]. There are also reported examples of unusual combinations of PXE with an elevated Ca × P product, which appears to accelerate greatly the natural course of PXE. Elevated serum phosphorus is usually associated with high levels of alkaline phosphatase, which is normally involved in calcification and remodeling of bone. Chronic renal disease and hyperparathyroidism are two conditions that commonly display a high Ca × P product, usually in excess of 60. Alkaline phosphatase activity is high during childhood and adolescent growth spurts, which is also the average time of onset of PXE and its most rapid period of progression.

Some of the rare congenital and idiopathic disorders of calcium and phosphorus metabolism at least suggest a possible aggravating role of aberrant calcium and phosphorus metabolism in the pathogenesis of PXE. In rare instances, PXE has been noted in association with chronic idiopathic hyperphosphatasia, which is characterized by high levels of serum alkaline phosphatase activity and with elevated levels of serum calcium and phosphorus. One such case was followed by Mitsudo [162] from age 6 years to death at 18 years. This individual had moderately elevated levels of serum total calcium (10.7 mg/dl) and phosphorus (5.8 mg/dl) with a Ca × P product of 62. At death, his alkaline phosphatase was very high. All aspects of his PXE progressed with great speed, resulting in hypertension at age 6 years, retinal hemorrhages at age 9 years, and a fatal stroke at age 18 years.

Tumoral calcinosis (MIM 211900) is predominantly an autosomal recessive disorder of children and young adults in which large localized soft tissue calcium deposits occur, most commonly around major joints. Several cases have been reported in association with PXE in which the PXE had an early-childhood onset and progressed more rapidly than usual [163]. Most of these patients also had elevated serum phosphorus levels with a high Ca × P product.

Self-induced dietary disorders, such as the milk-alkali syndrome or hypervitaminosis D, will result in hypercalcemia. Prolonged hypercalcemia impairs renal function, which, in turn, causes hyperphosphatemia. When the Ca × P product reaches critical levels, soft tissue calcification commonly occurs but not specifically affecting elastic fibers or in a PXE distribution. Mallette and Mechanick [163] reported a 60-year-old white male with PXE, hyperphosphatemia, and elevated 1,25-dihydroxyvitamin D levels. His clinical course was complicated by severe, occlusive peripheral vascular disease, retinal hemorrhages, and hypertension. His milk intake had exceeded 4.5 liters per day for many years.

The Fibroblast

Because the fibroblast is the source of all the extracellular matrix of the skin, it is most likely the origin of any abnormal tropoelastin, GAG, or proteinase, although aberrant post-translational modification of any otherwise normal extracellular connective tissue matrix component cannot be ruled out. Much more is known of collagen synthesis and turnover, in which at least ten specific enzymes are required for synthesis and degradation, many of which require additional cofactors and cosubstrates (see also Chapter 2, this volume). With electron microscopy, PXE fibroblasts appear metabolically active with a large, rough endoplasmic reticulum filled with granular material. However, they are morphologically indistinguishable from fibroblasts in any non-PXE healing or rapidly growing site.

MANAGEMENT

There is currently no specific or causal treatment available for the disease.

Prophylactic Lifestyle

Prophylactic measures can be taken by any patient with PXE in an attempt to prevent, or at least postpone, known complications of the disease as long as possible. Most physicians, unfortunately, neglect the prophylaxis of complications of hereditary disorders. There are many recommendations, and the earlier in life they are started, the more effective they will be. The recommendations outlined below are primarily designed for the prevention of adverse effects rather than for the treatment of an existing complication.

General:

- A proper attitude toward any chronic disorder is important. A healthy balance between excessive concern on one hand and a denial or disregard of preventive measures on the other is important. Learning to cope with PXE may take many years, especially for adolescent and younger individuals.

Activities:

- A regular exercise program at a level that is well-tolerated should be developed. If nothing more, it should involve a vigorous daily walk.
- Head trauma can cause retinal hemorrhages. Sports involving potential head trauma or very heavy lifting should be avoided, especially in the adolescent years. These include such activities as boxing, soccer, football, rugby, hockey, heavy weight lifting, and so forth. Sports such as track, swimming, or bicycling are recommended.

Tobacco Use:

- The use of tobacco in any form should never be started. If it is being consumed, it should be stopped immediately.

Dietary:

- A normal weight for age and height should be maintained.
- A dietary calcium intake at or slightly below the recommended dietary allowance (RDA) of 800 mg per day should be maintained, even during the childhood/adolescent years. A well-balanced diet, rich in antioxidants, is also recommended. A good starting point is to follow the current recommendation of eating five servings of fruit and vegetables each day.

Prophylactic Medical Care and Symptomatic Treatment

- Any slight vomiting of blood or the appearance of black tarry stools can be a sign of stomach bleeding. This is a medical emergency and requires immediate attention.
- Routine eye examinations should be carried out by a retinal specialist, preferably with experience in treating PXE and a conservative attitude toward laser treatment of retinal hemorrhages. The value of laser therapy for retinal hemorrhages in PXE is controversial and believed indicated only in very selective situations. Excessive ultraviolet light exposure should be avoided by wearing good UV-filtering sunglasses when outdoors in the bright sun for prolonged periods.
- The complete lipid profile should be checked regularly (cholesterol, triglycerides, HDL-C, and LDL-C). An abnormal result in any of the four categories is cause for concern and should be vigorously treated by dietary means and, if necessary, with medication.
- Blood pressure should be checked regularly. If elevated, an initial effort should be made to control it through diet, weight loss, and exercise. Drug treatment should be added if necessary.
- Echocardiography should be carried out at regular time intervals. If endocardial thickening of the heart valves has been diagnosed, which may result in functional valve impairment causing mitral valve prolapse (MVP), antibiotics should be taken before surgical or dental procedures.
- The long-term daily use of aspirin or any other substance of the ibuprofen group of analgesics should be avoided. They are also good anticoagulants and could precipitate or aggravate a retinal or gastrointestinal hemorrhage. Occasional use is safe. In the case of cardiovascular complications that require the long-term use of anticoagulants, a specialist should be consulted.

ANIMAL MODELS

There are no known animal models of pseudoxanthoma elasticum.

RECENT DEVELOPMENTS

Beat Steinmann and Peter M. Royce

Identification of the PXE Gene

Four groups have reported independently, within a short time of each other, that mutations in the *ABCC6* gene (formerly known as *MRP6* or *eMOAT*) are responsible for causing PXE [164–167]. A historical account of the events leading to discovery of the gene has been given by Pennisi [168].

ABCC6 — The Gene Encoding a Transporter for an Unknown Substrate

The *ABCC6* gene is located on chromosome 16p13.1, spans approximately 73 kb, containing 31 exons, and codes for an mRNA approximately 6 kb in size with an open reading frame of 4.5 kb. The polypeptide ABCC6, also called MRP6 (multi-drug resistance protein 6), is a member of the ATP-binding cassette (ABC) transmembrane transporter subfamily C, and comprises 1503 amino acid residues with a calculated molecular mass of 165 kDa. It is located in the plasma membrane, has 17 membrane-spanning helices, grouped into three transmembrane domains (TMD1-3), and two intracellular nucleotide binding domains NBD1 and NBD2 (see Figure 1 in [169]), each of which is built of approximately 200 highly conserved amino acid residues containing the Walker A and B domains that bind and hydrolyze ATP, as well as a C-terminal motif that is critical for the function of the protein as a transmembrane transporter [170]. ABCC6 is highly homologous to ABCC1, with a sequence identity of 45%, and the respective genes, *ABCC6* and *ABCC1*, both containing 31 exons, are located in the same region, being orientated in opposite directions.

The 4.5 kb ABCC6 mRNA is expressed in several secretory tissues, but primarily in kidney and liver. Immunolocalization studies have identified a basolateral location of ABCC6 in both hepatocytes and renal epithelial

cells [171]. ABCC6 is a transporter for an as yet unidentified physiologic substance, although experimentally it is known to transport a non-physiologic substrate, the cyclopentapeptide Trp–Asp–Pro–Val–Leu, the endothelial receptor antagonist BQ-123, and amphipathic anion conjugates.

Mutations in the *ABCC6* Gene (MIM 603234)

Le Saux et al. [169] studied 122 unrelated patients with PXE and compiled all 43 *ABCC6* mutations known to date. Thirty-six *ABCC6* mutations were characterized in their population, among which 28 were novel variants. Twenty two alleles have been missense variants, nine have had small insertions or deletions, six have contained nonsense mutations, two have contained mutations likely to result in aberrant mRNA splicing, two have had large deletions, and one has had a contig deletion comprising both flanking genes, *ABCC1* and *MYH11*del [169].

Although most mutations appeared to be unique variants, two disease-causing alleles occurred frequently in apparently unrelated individuals. One, Arg1141Ter was found at a frequency of 18.8% and was preponderant in European patients. The other, a large deletion, *ABCC6*del exons 23-29, occurred at a frequency of 12.9% and was prevalent in patients from the United States. This latter 16.5 kb *Alu*-mediated deletion was described in four multiplex families with PXE inherited in an autosomal recessive pattern by Ringpfeil et al. [172], and in a further such family by LeSaux et al. [169]. In each of the families the proband was a compound heterozygote for a nonsense mutation and the approximately 16.5 kb deletion mutation spanning the site of the nonsense mutation in *trans*. The nonsense mutation was thereby reduced to hemizygosity in these patients. The deletion mutation was shown to extend from intron 22 to intron 29, resulting in an out-of-frame deletion of 1213 nucleotides from the corresponding mRNA, and causing the elimination of 505 amino acid residues from the ABCC6 polypeptide. The deletion breakpoints were precisely the same in all families, which were of different ethnic origins, and haplotype analysis suggested that the deletions had occurred independently. Deletion breakpoints were embedded within *Alu*Sx repeat sequences, suggesting *Alu*-mediated homologous recombination as a mechanism.

The distribution pattern of *ABCC6* mutations showed a cluster of disease-causing variants in a region of the gene encoding the C-terminal end of the protein, in contrast to the neutral variants, in which alterations appeared to be evenly distributed. Indeed, most mutations (36 of 43), including deletions, were located in the 3′ portion of the gene, and, remarkably, 24 (56%) mutations were located in exon 24 and exons 28-30, the latter of which encode the NBD2 domain. The fact that only a few mutations affect NBD1 indicates that the two nuclear binding domains are functionally nonequivalent [169]. This supposition is supported by the fact that in the case of *ABCC1*, which is highly homologous to *ABCC6*, mutations affecting NBD2 abolish its function whereas those affecting NBD1 decrease transport activity by about 70% [173]. In keeping with this, homozygous or compound heterozygous mutations in the region of *ABCC6* encoding NBD1 may not contribute significantly to the development of the PXE phenotype, because an intact NBD2 could sustain residual activity (approximately 30%) which could be comparable to the overall transport capacity (50%) of an asymptomatic individual carrying a single disease-causing allele.

Among the 122 patients studied by Le Saux et al. [169], putative disease-causing mutations were identified in approximately 64% of the 244 chromosomes studied, and 85.2% of them were found to have at least one disease-causing allele. The mutation detection rate achieved in the study indicated that a significant number of mutations escaped detection by SSCP (single-stranded conformation-dependent polymorphism) and CSGE (conformation sensitive gel electrophoresis); the results also suggest that a fraction of undetected mutant alleles could be either genomic rearrangements or mutations occurring in non-coding regions of the gene [169].

Genetics

Nonsense, missense, deletion, and insertion mutations are associated with sporadic, autosomal recessive and autosomal dominant forms of PXE. Large deletions may lead to haploinsufficiency. The molecular mechanisms associated with both autosomal recessive and autosomal dominant PXE due to missense mutations are not clear, but a number of similar phenomena have been described. For instance, glycine substitutions in *COL7A1* severely affect folding of collagen VII, causing dominant dystrophic epidermolysis bullosa (DEB), whereas similar glycine mutations which have little effect on the folding of collagen result in autosomal recessive DEB [174].

Pathogenesis

The pathogenesis of PXE remains unknown. It is possible that, because of an aberrant transport function of ABCC6 in the kidney and/or the liver, the lack of an unknown substrate(s) in the blood could lead to secondary changes in the dermis and the arterial wall that lead to calcification of elastic fibers and the development of PXE. Indeed, for these reasons, Bergen [166] commented that the molecules presumably transported by ABCC6 may be essential for extracellular matrix deposition or the turnover of connective tissue at specific sites, and Uitto et al. [175] have suggested that perhaps PXE is more a heritable metabolic disorder than a primary connective tissue disease. In this respect it would be akin to alkaptonuria. In keeping with this concept, acquired PXE-like symptoms have been associated with altered renal function; elastic fiber calcification has been shown, for example, in a patient with chronic renal failure and periumbilical PXE [120], in another with calciphylaxis and renal failure [161], and in many with β-thalassemia and sickle-thalassemia after prolonged transfusion and chelation therapy [130–133], treatments that are known to influence renal function. It is possible, therefore, that abnormal renal function in patients with the acquired disorder results in altered levels of ABCC6 which, in turn, lead secondarily to symptoms of PXE.

Alternatively, subtle changes in the expression of the ABCC6 transporter in affected tissues in patients with PXE may be instrumental in inducing an inappropriate extracellular matrix environment for the correct assembly of elastic fibers. However, by RT-PCR analysis using RNA isolated from tissues affected by PXE, Bergen et al. [166] detected expression of ABCC6 in retina, skin, and vascular tissue, but only in very small amounts, which makes the pathogenic role of this route less likely.

No significant correlation could be established between the disease-causing alleles and the clinical manifestations in the 26 patients for whom the pertinent information was available [169]. However, the small size of the cohort may have been a factor in the lack of any obvious genotype-phenotype relationship. Although the severity of the phenotype seemed to be related to the age of the patients, it appeared not to be mutation dependent because the

mutations identified in them (premature termination codons and missense mutations located in NBD2) all predict the complete loss of ABCC6 function. It is therefore reasonable to assume that PXE mutations predispose carriers to the typical PXE clinical lesions, but that the contribution of other factors — such as trauma in the case of ocular lesions, and, perhaps, diet or lifestyle — may determine the age of onset of clinical manifestations and their severity.

Further functional studies of the substrate specificity of ABCC6 and the effect of its reduced capacity are needed to elucidate its role in maintaining elastin fiber integrity and its role in the development of PXE.

FUTURE INVESTIGATIONS

The next step will be the identification of further disease-causing mutations and their correlation with the clinical spectrum of the disease. To create a *PXE* knockout mouse, the murine homolog needs to be identified. The generation of a knockout or knockin mouse will allow the experimental study of gene function in relation to cardiovascular, ocular, and dermal phenotypes of the disease. It will be intriguing to study whether non-*PXE* allelic variants of *PXE* can be associated with early manifestations of cardiovascular disease or with the occurrence of early macular degeneration in the general population. All of these investigations will eventually provide potential molecular targets for the design of forms of treatment that either prevent or alleviate potential complications of the disease in patients.

ACKNOWLEDGMENTS

We thank the members of many PXE families for their continued support of PXE research. Most of the North American families included in the mapping study were identified from the database of the National Association for Pseudoxanthoma Elasticum (NAPE) (http://www.napxe.org). This work was supported by Project Grant 695-0209 from the March of Dimes Birth Defects Foundation, White Plains, NY (http://www.modimes.org), and by a Pilot and Feasibility Grant from the Harvard Skin Disease Research Center at Brigham and Women's Hospital. B.S. is the recipient of a National Research Fellowship Award from the Association of Clinical Pharmacology Berlin/Brandenburg and from the Ministry of Education, Science, Research, and Technology of the Federal Republic of Germany.

SUMMARY

- **Marfan syndrome (MFS) is a pleiotropic, autosomal dominant disorder of connective tissue that affects 1–3 per 10,000 individuals, regardless of ethnicity. The condition is characterized by abnormalities in the ocular, skeletal, and cardiovascular systems. The eye shows lens dislocation and early myopia. Retinal detachment, early glaucoma, and cataract are occasional findings. The skeleton demonstrates overgrowth of the bones and joint hypermobility. The cardiovascular system shows enlargement of the aortic root with a predisposition for dissection or rupture. Mitral valve prolapse is common. Aortic or mitral valve regurgitation can cause myocardial dysfunction.**
- **MFS can cause major morbidity and mortality if untreated. The average age of death, usually due to aortic dissection, for affected individuals who receive no treatment is in the fourth decade. Left ventricular failure due to mitral valve regurgitation and volume overload is the leading contributor to mortality in young children with a severe variant of MFS.**
- **Improvements in diagnostic, medical, and surgical practices have resulted in an extension of life expectancy in MFS to near normal. Close echocardiographic follow-up of aortic root size, the use of medications to decrease hemodynamic stress, and prophylactic surgical repair of the ascending aorta are mainstays of the therapeutic protocol.**
- **All cases of MFS for which a basic defect has been defined demonstrate heterozygosity for a mutation in the *FBN1* gene, which is located at 15q21.1 and encodes the extracellular matrix component fibrillin-1. This glycoprotein is the major constituent of extracellular microfibrils, which are abundant in both elastic and nonelastic tissues.**
- **The diagnosis of MFS remains based largely on clinical criteria. Molecular adjuncts to diagnosis are applicable in selected circumstances. Conditions that show clinical overlap but do not meet criteria for the diagnosis of MFS have been grouped separately. Included among these are the MASS phenotype, familial thoracic aortic aneurysm or dissection, familial ectopia lentis, and familial tall stature. Defects of *FBN1* have only been found in a minority of patients and families warranting a diagnosis of one of these conditions.**
- **Congenital contractural arachnodactyly (CCA) affects predominantly the skeleton and is caused by mutations in the *FBN2* gene, which is located at 5q23-q31 and encodes fibrillin-2.**
- **The fibrillins are structurally related proteins that are both incorporated into microfibrils but show divergent temporal and spatial patterns of expression. Current evidence suggests that perturbation of both the structural and regulatory roles of microfibrils underlies the phenotypic abnormalities in MFS and selected related disorders.**

INTRODUCTION

Marfan syndrome was one of the charter members of Victor McKusick's initial compilation of Mendelian conditions that he termed "heritable disorders of connective tissue" [1]. This initial nosology encompassed six syndromes that shared little in common other than the presumption that different defects in components of the extracellular matrix were at fault. Because this category of human disease has expanded to over 200 phenotypes, the nosology has continued to be based largely on phenotypes, despite the growing knowledge about causation at the biochemical and genetic levels.

The disorders discussed in this chapter, with MFS being the most prominent and best-understood example, share many phenotypic features and have as the cause of at least some cases of each abnormalities of one or another of the components of the extracellular microfibril, hence the term "microfibrillopathies" used by some. Fibrillin-1 and fibrillin-2 are the best-studied components of the microfibril, and a subset of the microfibrillopathies has been called "fibrillinopathies" by some.

Connective Tissue and Its Heritable Disorders, pages 585–626

MARFAN SYNDROME

Historical Introduction

> I present to the Society a little girl five and one-half years old, suffering from a congenital deformation of the four limbs, for which I have not found a precedent from the authors whom it was possible for me to consult.
> A.-B. Marfan, 1896 [2]

Among the heritable disorders of connective tissue, Marfan syndrome is especially noteworthy because of its worldwide distribution and relatively high prevalence, its clinical variability, and its pleiotropic manifestations, some of which are life-threatening. Marfan syndrome is second only to osteogenesis imperfecta with regard to when the phenotype was first described, when even earlier literature references occurred, when it was correctly interpreted as a generalized disorder of mesenchyme, and in the number of published articles addressing various aspects of the condition. The most extensive critical review of the literature of the first half of the twentieth century is in McKusick's monograph [3].

Antonin-Bernard Marfan (1858–1942) was Professor of Pediatrics in Paris; little could he have suspected that his name and interest in him as a physician would persist because of a brief case presentation made to the local medical society [2]. At the Société Médicale des Hôpitaux de Paris on February 28,1896, he described a 5-year-old girl, Gabrielle P., who had disproportionately long, thin limbs and digits, the latter so remarkable that he termed them *pattes d'araignée*, or spider fingers [2]. Her musculature was sparse, but on numerous examinations, including electromyography, no myopathy was evident. She had fibrous contractures of the fingers and knees, a long, narrow skull (dolichocephaly), and tall stature. Her eyes, heart, and intellect were normal, or at least aroused no clinical suspicion. She was the last of five children of a father in his early thirties, and the family history, sketchy as it was, did not suggest similarly affected relatives. Marfan was baffled as to causation and concluded with a plea, the sense of which is frequently uttered at gatherings of clinical geneticists today: "Above all, I have intended to present a case which seemed exceptional to me. I beg my colleagues to tell me if they have seen analogous cases" [translated by E. L. Fox].

A brief follow-up report of Gabrielle at age 11, including skeletal radiographs, revealed thoracolumbar kyphoscoliosis, perhaps an anterior chest deformity, and the first signs of the tuberculosis that was to end her life a few years later [4]. By 1938, when Marfan [5] reviewed the subject of dolichostenomelia, meaning excessively long limbs (the term he preferred), more than 150 similar cases had been reported, congenital displacement of the lens (ectopia lentis) [6] and disease of the mitral valve [7,8] had been associated with the skeletal phenotype, the concept of the *forme fruste* had (unfortunately) been introduced, and Gabrielle P. had died at 16 years of age, apparently without an autopsy. Furthermore, Marfan knew that both sexes and sequential generations in families were affected, which he recognized as being consistent with a Mendelian dominant trait. The idea of genetic mutation was quite clearly stated. In terms of pathogenesis, Marfan considered several possibilities, including Weve's [9] concept of a developmental defect of mesodermal tissues and an abnormality of pituitary function. The chief detraction of the mesodermal hypothesis was the apparent involvement of the ocular lens, which is ectodermal; the pathologic involvement of the zonules in ectopia lentis and their ectodermal embryologic origin had not been described. However, neither was Marfan particularly enamored of an endocrine pathogenesis.

More than 40 years after he had described Gabrielle P., Marfan understood a great deal about "his" syndrome, although his only reference to the eponymous designation, made without evident favor or disfavor, was to cite Weve's [9] suggested designation, "dystrophia mesodermalis congenita typus Marfan." The only major breakthroughs missed by Marfan, who died in 1942, were the recognition of aortic involvement in 1943 [10], the creation of the heritable disorders of connective tissue nosology, with Marfan syndrome a charter member, by McKusick in 1955 [11], and the discovery of the nature of the basic defect in 1991 [12]. Marfan never hinted that the mass of clinical information about dolichostenomelia in his day prompted a reconsideration of the diagnosis in his first patient. Thus, one could imagine the senior pediatrician in France bristling a bit had he heard the notion, first suggested in 1971, that Gabrielle P. did not have what we understand today as being Marfan syndrome but congenital contractural arachnodactyly [13,14]. Of course, Marfan's young patient may have had subtle lens dislocation, mitral valve prolapse, and aortic root dilatation, with all of these manifestations never looked for because of her premature death from an infectious disease. In 1938, Apert [15], a student of Marfan's and a definer of syndromes himself, codified use of the eponymous designation "Marfan syndrome," and the term may well still be in common use 50 years from now.

Phenotype, Natural History, and Prognosis

Marfan syndrome (MIM 154700) is a *pleiotropic* condition, meaning that diverse and even seemingly unrelated manifestations stem from a single mutation. The range of pleiotropism has largely been a function of the industriousness of the clinician and the sensitivity of the methods of analyzing the phenotype. As a result, the number of abnormalities in MFS has steadily increased. In addition, pleiotropism is expanding because affected individuals are living longer, and both primary and secondary evidence of the underlying connective tissue abnormality is emerging in mid- and late adulthood.

Most textbook descriptions of the phenotype and diagnostic criteria focus on the three organ systems prominently involved: the skeleton, the eye, and the heart and aorta. However, the skin, fascia, lungs, skeletal muscle, and adipose tissue are also clearly involved, and occasionally one of these areas constitutes the principal clinical concern. In this section, the clinical involvement (see also Table 1) and natural history of each area are discussed.

The Skeletal System

Height and proportions. In some respects, little improvement can be made to Marfan's description of the typical skeletal changes in a child with "dolichostenomelia." The birth length is long, and the stature is tall, mostly due to disproportionately long legs (Fig. 1), although the height of vertebrae is increased to some extent. Growth curves based on cross-sectional and longitudinal observations (Fig. 2) [16] have been constructed for affected Caucasians and show that height tends to increase parallel to, and on average slightly above, the 97th percentile. Skeletal maturation is not markedly different from that of unaffected children and

TABLE 1. Diagnostic Criteria for Marfan Syndrome

Summary: For the *index case*, two systems must qualify as ''major criteria'' and a third must be ''involved.'' Alternatively, if a mutation in *FBN1* is present, then one system must qualify as a ''major criterion'' and a second must be ''involved.''
For a *near relative of an index case*, one system and the family history must each qualify as a ''major criterion'' and a second organ system must be ''involved.''

Skeletal System
A ''major criterion'' is defined by the presence of at least four of the following:
- pectus carinatum
- pectus excavatum severe enough to require surgery
- reduced upper-to-lower segment ratio *or* arm span-to-height ratio ≥ 1.05 (both in the absence of severe scoliosis)
- positive wrist *and* thumb signs
- reduced extension of the elbows ($\leq 170^{\circ}$)
- medial displacement of the medial malleolus associated with pes planus
- protrusio acetabuli of any degree (ascertained on radiographs, CT, or MRI)

''Involvement'' of the skeletal system is defined by the presence of two of the preceding features *or* the presence of one of the preceding features and two of the following: pectus excavatum not requiring surgery; joint hypermobility; high-arched palate; facial features—at least two of dolichocephaly, malar hypoplasia, enophthalmos, retrognathia, down-slanting palpebral fissures.

Ocular System
A ''major criterion'' is defined by ectopia lentis of any degree.
''Involvement'' of the ocular system is defined by the presence of at least two of the following:
flat cornea; increased axial length of the globe (>23.5 mm); hypoplastic iris or hypoplastic ciliary muscle causing decreased miosis.

Cardiovascular System
A ''major criterion'' is defined by either dissection of the ascending aorta *or* dilatation of the ascending aorta with or without aortic regurgitation and involving at least the sinuses of Valsalva.
''Involvement'' of the cardiovascular system requires the presence of at least one of the following: mitral valve prolapse with or without mitral regurgitation; dilatation of the main pulmonary artery, in the absence of valvular or peripheral pulmonic stenosis, under the age of 40 years; calcification of the mitral annulus under the age of 40 years; dilatation or dissection of the descending thoracic or abdominal aorta under the age of 50 years.

Pulmonary System
''Involvement'' is defined by either spontaneous pneumothorax or radiographic evidence of apical blebs.

Skin and Integument
''Involvement'' is defined by either striae atrophicae or a recurrent or incisional hernia.

Dura
A ''major criterion'' is the presence of lumbosacral dural ectasia.

Family/Genetic History
A ''major criterion'' is defined by one of the following: a first-degree relative who independently meets these diagnostic criteria; the presence of a mutation in *FBN1* that is likely to be pathogenic; or the presence of a haplotype around the *FBN1* locus inherited by descent and unequivocally associated with diagnosed Marfan syndrome in the family.

adolescents, in keeping with apparently normal homeostasis of the endocrine system. Height may be extreme with occasional males exceeding 2.1 m; however, most adult men are less than 1.95 m and most adult women do not reach 1.85 m.

The arm span is exaggerated. A span greater than 1.05 times the height, provided vertebral deformity has not foreshortened stature, is considered abnormal. However, if the span is measured as a straight line from fingertip to fingertip, then flexion contractures of the elbows will underestimate the true length of the long bones of the arms. The dolichostenomelia of the legs has traditionally been expressed by the upper-to-lower segment ratio (US/LS), in which LS is measured from the top of the symphysis pubis to the floor and subtracted from stature to obtain US. The ratio is abnormally low in most patients with the Marfan syndrome but can reflect more than long legs if the upper segment is reduced by vertebral column deformity. The major limitation of the US/LS is its dependency on age, sex, and race. The only standard curves were developed years ago [3] and are somewhat cumbersome to use. Regression of US on LS produces a tight relationship that is independent of these confounding factors [16]

$$\frac{\text{US (cm)} - 24}{\text{LS (cm)}} = 0.6$$

but the equation has not been tested for its ability to discriminate between normally and abnormally proportioned people.

Exaggerated length of the bones of the hands and feet results in several striking manifestations. Arachnodactyly is best left a subjective impression and is shown by the Walker-Murdoch wrist sign — the combination of thin wrist and long digits results in the overlap of fingers I and V when the wrist is grasped (Fig. 1h). Attempts to objectify the measure, based on finger length or radiographs (the metacarpal index [17] or metacarpophalangeal pattern [18]), put more weight and importance on the finding than is warranted by its specificity.

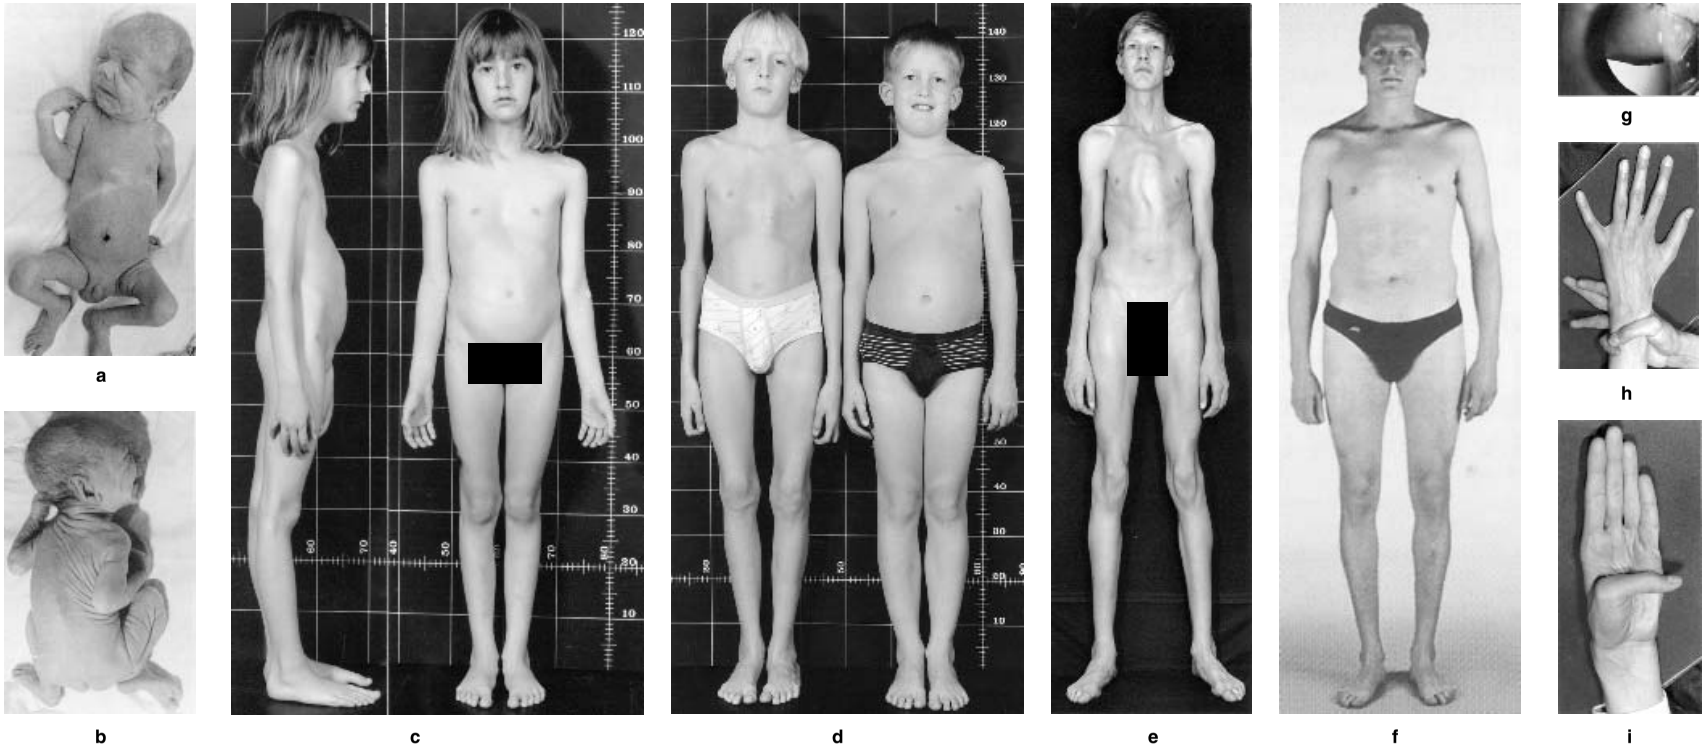

Figure 1. Marfan syndrome (MFS) and congenital contractural arachnodactyly (CCA). a, b: One-week-old patient with **neonatal lethal MFS** who died at age 10 weeks from global valvular insufficiency. Note the old-appearing expression, cutis laxa, the large and soft ears, and contractures of the elbow, hip, wrist, and knee joints. **c**: Girl with **classical MFS**, age 5.5 years, with an earnest and older-looking facial appearance, mild pectus excavatum, a flat thoracic cage, and height 4 cm above the 97th centile. **d**: 9-year-old boy with **CCA** and his healthy dizygotic twin brother. Note dolichostenomelia, asymmetric pectus carinatum, and contractures of the fingers (''arachnodactyly'') and elbows. **e**: **Classical MFS.** 15-year-old youth with nonfamilial tall stature (213 cm), an older-appearing facial expression, long limbs, especially the distal portions, asymmetric pigeon breast, sparse subcutaneous fat, and poorly developed muscles. He had several surgical repairs of diaphragmatic herniae and died at age 23 years of pericardial tamponade after dissection of the ascending aorta. **f**: 28-year-old man with no apparent external stigmata of **MFS**; his height is 192 cm, the aorta is dilated, and both lenses are luxated. **g**: **MFS.** Luxation of the lens to the temporal upper side. Note the parallel aligned zonular fibers that deform the edge of the lens. **h**: Positive Murdoch or wrist sign: the small finger and the thumb of one hand touch each other or overlap while encircling the opposite wrist. **i**: Steinberg or thumb sign: the thumb when folded across the palm extends beyond the ulnar edge of the hand. (Courtesy of Dr. B. Steinmann, Zurich.)

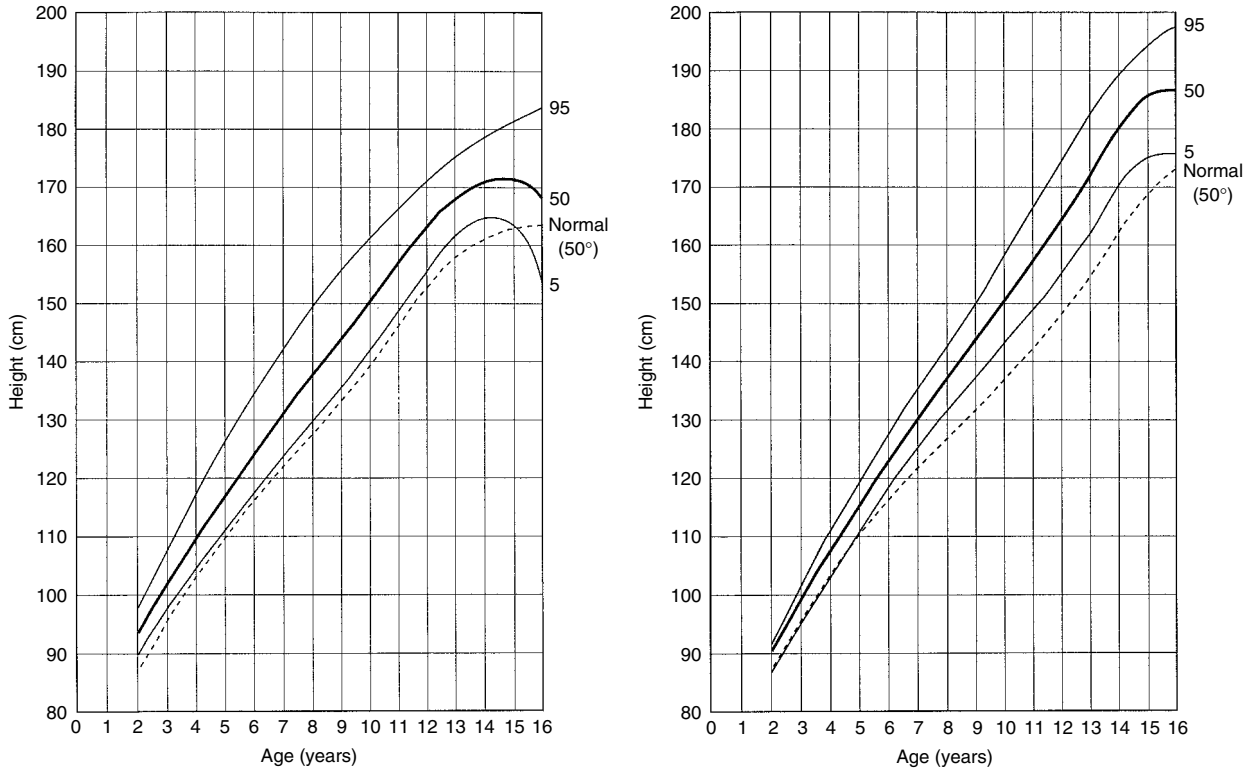

Figure 2. Growth curves for height in girls and boys with Marfan syndrome. **Left panel**: girls; **right panel**: boys.

The elongated foot often requires AA or narrower shoes; the narrow heel is particularly difficult to fit properly.

Weight. Most children and adolescents with MFS weigh less than the 50th percentile for age, which gives them a strikingly low weight/height ratio. When adipose tissue is accumulated in adulthood, it is usually central, especially around the hips. Weight is also reduced because of decreased skeletal muscle mass and occasionally, in severely affected children, by feeding difficulties or cardiac cachexia.

Craniofacies. The skull is long and narrow (dolichocephaly), the palate high and narrow, and the mandible hypognathic, retrognathic, or both. The eyes are usually deeply set (enophthalmos), in part due to a deficiency of retro- and peri-orbital fat. The brow appears prominent, whereas the malar region is hypoplastic and flat. The overall appearance can be "myopathic." McKusick [3] has described the facial expression as "lugubrious," and it is the facies, coupled with the tall stature, that explains why young children seem older than they are (Fig. 1c). The ears are normally placed, but the helix may be soft, simple, or crumpled, the latter occasionally as striking as described in contractural arachnodactyly [13,19,20]. The teeth show malocclusion on account of both crowding and overbite.

Anterior chest. The ribs, being tubular bones, tend to overgrow and in doing so push the sternum posteriorly, anteriorly, or both. The result is a funnel chest (pectus excavatum), pigeon breast (pectus carinatum), or a combined defect (Fig. 1c, e). The last is quite typical of MFS; the left costochondral junctions usually protrude, presumably because the underlying heart buttresses the ribs. The shape of the thorax may change dramatically during childhood; on several occasions, we have witnessed a deep pectus excavatum evolve over the course of a decade into a pectus carinatum. Until maturation of the skeleton, alteration in the contour of the rib cage should be anticipated.

Vertebral column. Abnormal curvature of the spine is common and may begin at any time before skeletal maturity; depending on severity, it may progress at any age [21–23]. However, estimates of prevalence, especially those emanating from orthopedic centers, must be interpreted with caution because of bias of ascertainment favoring severe cases. A reduction in the usual high thoracic kyphosis to a "straight back" or an outright reversal is most prevalent and need not be associated with scoliosis; accentuated high thoracic kyphosis is less frequent. Scoliosis typically begins in childhood and progresses most rapidly during growth spurts. Single or multiple curves affecting any level of the vertebral column may occur. A spine not deformed beyond about 10° by late adolescence is unlikely to become distorted. However, for severe curves (40° or more), completion of linear growth is no guarantee of future stability. The consequences of marked thoracic spinal deformity in MFS are little different from those of idiopathic scoliosis (i.e., restrictive pulmonary disease and cor pulmonale). Severe scoliosis of the lumbar spine may lead to chronic back pain subject to acute exacerbation.

Spondylolisthesis is relatively more common than normal in MFS, but a true prevalence is unknown [24]. Typically, the lower lumbar levels are affected. Instability of the cervical spine is also of unknown prevalence and occasionally causes clinical problems [25]; anesthesiologists should be aware of potential laxity before attempting endotracheal intubation.

A common skeletal manifestation in the spine is secondary to dural ectasia. The radiologic findings, often incidentally noted, include thinning of the laminae of L4 through S2 and widening of the neural foraminae.

Pelvis. Congenital dislocation of the hip occurs infrequently but at an increased incidence compared with the general population [26]. Protrusio acetabuli is much more frequent than in the general population, is more common in MFS than appreciated [27], can be evident in children, and is progressive but generally asymptomatic through young adulthood [28]. The findings are often incidentally noted on plain radiographs or CT scans. However, as with most of the skeletal manifestations mentioned thus far, the extended natural history of protrusio acetabuli is unknown because until recently most adults did not survive their cardiovascular problems.

Joints. Although the appendicular joints of MFS patients are commonly perceived as being lax, normal mobility and even outright contractures are frequent. During early life, little disability usually results from laxity of the hands, wrists, elbows, shoulders, hips, and knees. Occasionally, acquisition of motor skills is delayed, but this is often impossible to separate from muscular hypoplasia. Similarly, handwriting may suffer from weakness and instability of the wrist and fingers. The patella may dislocate repeatedly, causing pain, transient locking of the knee joint, and chondromalacia. In general, however, repeated dislocations are uncommon. Longitudinal laxity of the hand is responsible for the positive "thumb sign," also known as the Steinberg sign, in which the thumb, when apposed across the palm, extends well beyond the ulnar border of the hand (Fig. 1i). Laxity of the ankle and foot produces the most common problems. Although the arch of the foot may be normal, or even exaggerated (pes cavus), a "flat foot" (pes planus) is one of the most common skeletal manifestations. At its most mild, pes planus is due to stretching of the plantar fascia and other ligaments of the midfoot. At its worst, calcaneoplanovalgus exists, and the medial malleolus is displaced medially; as a result, body weight is not centered over the foot, and secondary disturbances of knee and hip function develop, especially during childhood. Later in adulthood, degenerative arthritis often develops, especially in the hips and knees [29]. Osteoporosis is more common in MFS and at earlier ages than in the unaffected population [30,31].

The Ocular System

The first description of ectopia lentis with joint laxity may well have been recorded two decades before Marfan [32]. The most comprehensive studies have been those of Cross and Jensen [33] and Maumenee [34]; both of these series consisted largely, but not exclusively, of patients referred to the Johns Hopkins Hospital for other than ophthalmic concerns.

The globe. Typically, the globe is elongated, a feature that can be defined by the axial length as determined by ultrasound [34]. Exaggerated axial length contributes to myopia, is a risk factor for retinal detachment, and is more likely to be present in association with ectopia lentis. The sclera may be thin, and thereby appear blue, but this is not a consistent finding.

The cornea. The distribution of corneal diameters is shifted upward in Marfan syndrome, with some in the megalocornea range. Corneal clouding is not a feature. Study of the radius of curvature (keratometry) has proven useful from the diagnostic, pathogenetic, and management perspectives [34]. The cornea tends to be flatter than normal; the degree of reduction in curvature is positively associated with the presence of ectopia lentis but bears little relation to the severity of astigmatism. Keratoconus is distinctly uncommon.

The iris. The iris is often homogeneous or "velvety" in appearance. Transillumination is possible in ~20% of patients. Dilation of the pupil is often difficult with standard mydriatics because of hypoplasia of the dilator pupillae muscle.

The lens. Adequate evaluation for ectopia lentis requires optimal pupillary dilatation and slit-lamp examination. Under these circumstances, and with bias of ascertainment minimized, about 60% of patients have some degree of lens displacement by age 4 years (Fig. 1g). Dislocation can be in any direction, with superior, superotemporal, and backward preferred. Ectopia lentis is often congenital and may be detected first by a parent or grandparent through iridodonesis, or fluttering of the iris as the eye attempts to accommodate. Some progression of displacement can occur, being most common during periods of rapid growth. The ocular zonules tend to be normal in appearance, both in number and organization. In a minority of cases of clear MFS, the zonules break, as is the rule in homocystinuria. This distinctive behavior of the zonules accounts for the lens tending to fall inferiorly and lodge in the anterior chamber in homocystinuria, whereas both behaviors are much rarer in MFS. Microspherophakia is uncommon. Development of cataracts is accelerated in MFS, especially in displaced lenses. Cataract is one of the pleiotropic manifestations that will become more prevalent and better understood as patients live longer.

The retina. Changes associated with myopia, such as thinning of the choroid, retinal holes, and lattice degeneration, are the most common findings. Detachment occurs in a small minority and used to be predisposed by intraocular surgery, especially lensectomy. Newer surgical techniques have greatly reduced this risk.

Visual acuity. Most patients with MFS attain corrected visual acuity of 20/40 or better in at least one eye [34]. This optimistic prognosis even pertains in the presence of ectopia lentis. The most common cause of poor vision in one or both eyes is amblyopia, nearly always secondary to inattention to conservative methods of improving acuity during infancy and early childhood. Retinal detachment usually impairs acuity to some further extent and can cause blindness.

The Cardiovascular System

Life expectancy. A preponderance of clinical attention in the person with MFS is directed at the aorta. The reason for this bias is readily evident from the important study by Murdoch and associates [35] of life expectancy and causes of death. By the early 1970s, when the retrospective review of medical records on which Murdoch based his conclusions was conducted, medical and surgical therapy had had no beneficial impact on survival. The causes and ages of death of 270 patients were ascribed, and the latter were compared with age-adjusted mortality rates for the United States population. On average, men and women survived about two-thirds as long as expected, although the life-table mortality curves began to deviate unfavorably in infancy. When the cause of death was known, the cardiovascular system was the culprit in over 90% of cases, with aortic dissection, aortic regurgitation, and congestive heart failure (presumably from chronic valvular regurgitation) the leading

conditions. A more recent assessment of outcome in Marfan syndrome suggests that life expectancy now approximates that for the general population [36]. Advances in the management of cardiovascular complications were cited as primary contributors to improved prognosis.

The heart. The first reported cardiovascular manifestation of MFS involved the mitral valve [7]. Early in the twentieth century, the thought emerged that septal defects were common, but this has not been confirmed by later, less biased experience. Cardiomyopathy, out of proportion to valvular problems, appears occasionally, and some have speculated that a primary defect in cardiac muscle occurs [37]. Whether this is a widespread but generally subclinical tendency, a manifestation of only some biochemical defects, or a chance association of idiopathic dilated cardiomyopathy, which is not rare, with MFS remains to be explored. The most consistent manifestations in the heart involve the atrioventricular valves and the conduction system [3,11,38–42].

The earliest clinically evident changes occur in the mitral valve [43–47]. The patients affected most severely are often burdened with a severe phenotype [45,46,48]; severe mitral regurgitation may lead to early congestive heart failure, failure to thrive, pulmonary hypertension, and demise in infancy. However, children with MFS less severe in the skeletal and ocular systems may still have severe mitral regurgitation develop before adulthood [47,49]. The underlying connective tissue disturbance is reflected in redundancy of the atrioventricular valve leaflets, stretching of the chordae tendineae, and dilatation of the valve annulus; in brief, these are the same features as in mitral valve prolapse in its nontrivial form [40,50]. The mitral valve is invariably more severely affected than the tricuspid valve, presumably because of its location in a higher-pressure system. Physiologically, the prolapsing mitral valve in MFS behaves as in the idiopathic variety.

The clinical findings vary with both physiologic maneuvers and pathophysiologic alterations [51]. The prevalence of mitral valve prolapse, defined by either auscultation or echocardiography, increases with age through young adulthood and, during at least that age range, is more common in women than in men. Both of these characteristics are qualitatively similar to mitral valve prolapse in the general population. However, there are several important departures in MFS. First, more than one-quarter of people with MFS have progression of the prolapse to mitral regurgitation, and worsening of the valvular leak, by adulthood [49]. Second, a much higher percentage have marked redundancy of the valve leaflets detected on echocardiography (Fig. 3) [52]. Third, calcification of the mitral annulus accompanies mitral valve prolapse in a higher proportion of patients with MFS [3,40,53]. Remaining questions include whether the risk of endocarditis is higher in all patients with MFS or just those with mitral valve prolapse, how often mitral valve prolapse is associated with dysrhythmia, and what the long-term course of mitral valve prolapse will be as patients with Marfan syndrome survive to advanced ages because of aortic surgery.

The aortic valve is often thinned and myxomatous. Although these changes are intrinsic to the fundamental connective tissue defect, they become exaggerated as the three valve cusps are stretched by the expanding sinuses of Valsalva. Aortic regurgitation is occasionally due to cusp prolapse, a fenestrated cusp, or valvular endocarditis. Acute aortic leaks are usually due to aortic dissection. However, the vast majority of aortic regurgitation is due to progressive dilatation of the upper attachments of the cusps at the sinotubular ridge [51].

Electrical disturbances are common in MFS and a not infrequent cause of sudden death. Unfortunately, few extensive or unbiased studies of ambulatory electrocardiographic recordings have been done [41]. There is a predilection for both supraventricular and ventricular dysrhythmia as primary disturbances (i.e., unassociated with valvular regurgitation, electrolyte disturbance, cardiac surgery, or the like). Occasional patients have primary conduction delay or aberrant pathways. Both atrial and ventricular dysrhythmia are often associated with mitral valve prolapse.

No electrocardiographic changes can be considered typical of MFS. Patients with mitral valve prolapse often have the inferior T wave inversions seen in that condition [54]. A personal impression is that limb lead aVL often shows a Q wave, usually interpreted even in young children as suggestive of anterior ischemia, although patients almost never have any reason to suspect inadequate myocardial perfusion. Development of anterior electrical forces across the precordium is delayed (i.e., does not appear until V4–5) in patients with pectus excavatum and leftward rotation or shift of the heart.

The aorta. Dilatation of the sinuses of Valsalva often begins *in utero*, as evidenced by neonates having enlargement of the aortic root on echocardiography [3,45,47,55]. This fact has several implications. First, dilatation initially affects the most proximal portion of the aorta. Second, in some patients the aortic wall is so intrinsically abnormal that the relatively minor hemodynamic stresses of fetal life are sufficient to promote irreversible stretching of the wall. Third, if therapy to prevent dilatation is to be effective, it must be started early, at least in some cases; this point is discussed in the section on management.

The rate of dilatation is unpredictable. In general, children with considerable dilatation are more likely to develop clinically important aortic root aneurysms sooner than other children with MFS. Echocardiography and β-adrenergic blockade therapy arrived on the scene at about the same time, so that large, unbiased longitudinal studies of untreated patients have never been performed; hence, the detailed natural history of ascending aortic involvement has been gleaned from small series and case reports [42,56–59].

A recurring problem is how to interpret the aortic root dimension of an echocardiogram (Fig. 4). At least three issues must be addressed. The first concerns which dimension to use for diagnostic purposes. The size of the ascending aorta clearly depends on age and body size; sex and blood pressure are not important determinants in children [60,61]. Devereux and colleagues [62] have examined the ascending aorta by cross-sectional echocardiography and measured the dimensions at four levels: the annulus, midsinuses of Valsalva, supraaortic ridge, and proximal ascending aorta. Measurements obtained solely by M-mode echocardiography (in widespread use until the early 1980s) may approximate the annular diameter rather than that of the sinuses of Valsalva. These days, the cross-sectional echocardiogram in the parasternal long-axis view should be used to generate an M-mode tracing or directly measure the point of maximal dilatation at the sinuses of Valsalva. Thus, the nomograms, and graphs that related aortic dimensions obtained by the earlier M-mode technique to body size [60,61], may underestimate the diameter of the sinuses and if relied on may produce a false-positive diagnosis of aortic

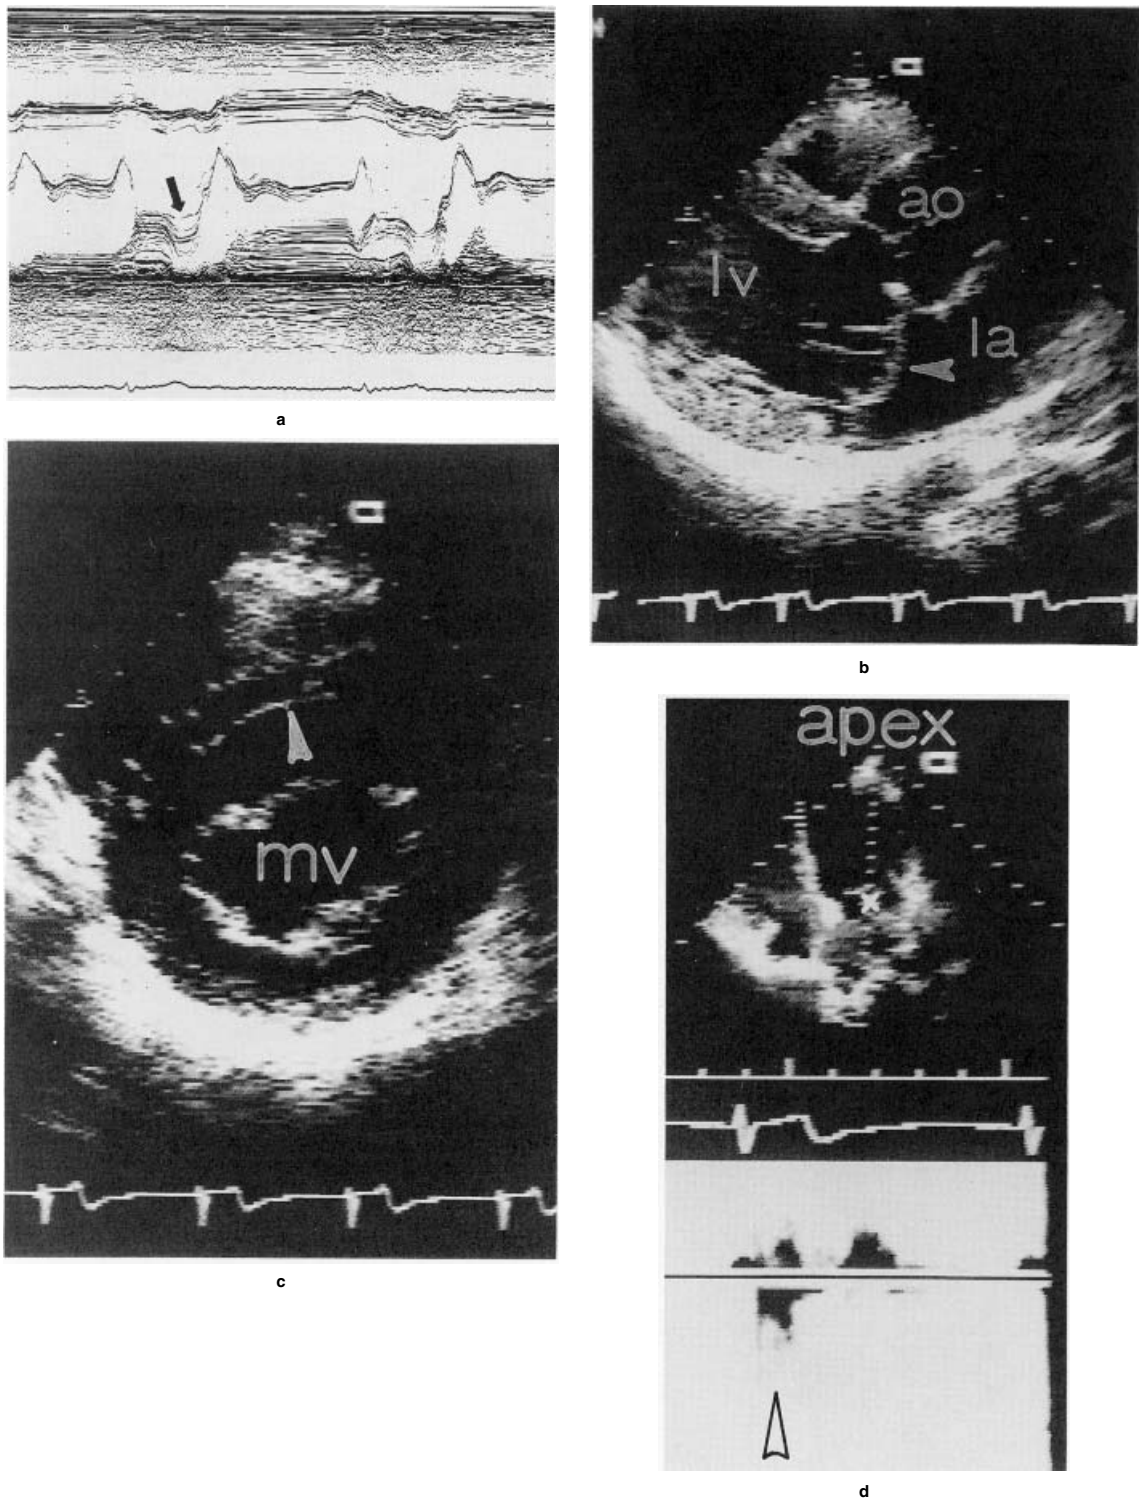

Figure 3. The mitral valve in Marfan syndrome as viewed by echocardiography. **a**: A one-dimensional (M-mode) tracing; the arrow points to the mid-systolic prolapse. **b**: A cross-sectional (two-dimensional) scan in the parasternal long-axis view; the arrowhead points to the prolapsing mitral leaflets. la, left atrium; lv, left ventricle; ao, aortic root. **c**: A cross-sectional parasternal short-axis view of the left ventricle. The letters ''mv'' are surrounded by the patulous mitral leaflets, open in diastole. The arrowhead points to the left ventricular endocardium. **d**: Pulsed-wave Doppler examination of the mitral valve. The **upper** part of the figure shows a cross-sectional echocardiogram in the apical four-chamber view; the ''x'' marks the sampling space for Doppler interrogation and is located just to the atrial side of the mitral valve. The **lower** part of the figure shows the Doppler tracing, with the arrowhead pointing to turbulent flow away from the sampling space (downward in the figure) in systole, indicative of mitral regurgitation.

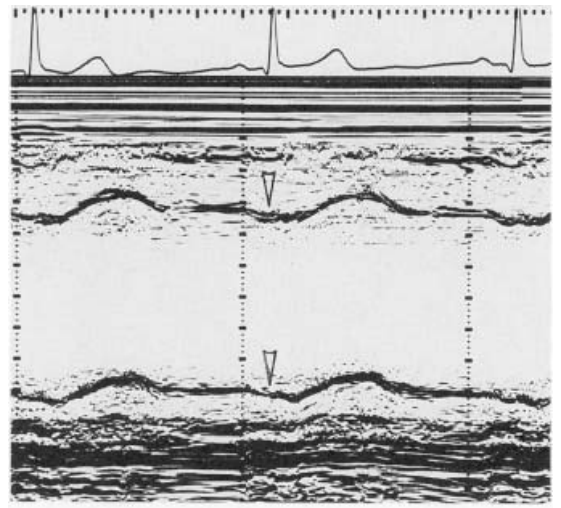
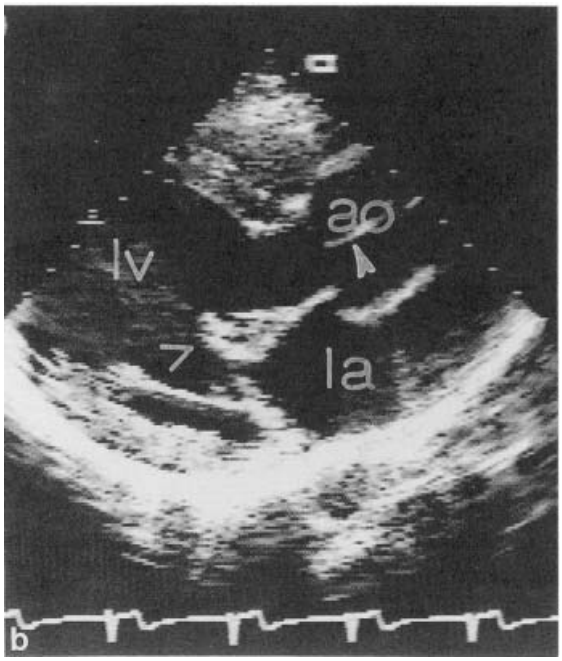


a



b

Figure 4. The aortic root in Marfan syndrome as viewed by echocardiography. **a**: An M-mode view in which the scale is divided into centimeters (between the large dots) and the arrowheads point to the anterior surfaces of the anterior and posterior walls of the aortic root; the diameter at end-diastole (at the Q wave of the EKG) is 58 mm, well above the upper limit of normal for this adult of 37 mm. **b**: A cross-sectional, parasternal long-axis view, labeled as in Figure 3b. The open arrowhead points to a redundant anterior mitral valve leaflet and the closed arrowhead to the aortic valve, here closed in diastole. The aortic root surrounding the aortic valve measures 41 mm (the dots along each edge of the sector are 1 cm apart).

dilatation [62]. Other attempts to define "normal" values, although employing cross-sectionally derived dimensions, are not appropriate because of a limitation to the annular measurement [63]. A useful graph for infants and children relating sinus of Valsalva diameter to body surface area is shown in Figure 5. Adults pose additional problems because body surface area is more often distorted by obesity; hence, correlation coefficients are not as high. This may account, in part, for the looser relationship between aortic size and body surface area for adults over 40 years. We have used the slightly different approach of analyzing the cross-sectionally directed M-mode echocardiographic dimension at the sinuses of Valsalva [64]. By using a regression equation [65],

$$\text{aortic root dimension (mm)} = 24.0\ (\text{BSA})^{1/3} + 0.1\ (\text{age}) - 4.3\ (+/-18\%)$$

(in which BSA, the body surface area, is in m^2 and the age is in years), the expected aortic diameter is calculated and is divided into the patient's measurement to generate an "aortic ratio." Because age and body size are incorporated, a plot of a "normal" aortic ratio against time is a horizontal line of 1.0. This approach can be used to assess dilatation (a ratio of 1.18 is the upper 95% confidence limit of 1.0) and changes with time. Other approaches have been defined [66].

The second issue concerns prognosis. In rough terms, the risk of developing aortic regurgitation is related to aortic diameter. In adults, aortic regurgitation is rarely present when the diameter is less than 40 mm and almost always present when it is above 60 mm [51]. Valve incompetence generally is caused by stretching of the upper attachments of the cusps, and thus the diameter at the supraaortic ridge should be the critical one, although previous studies have employed sinus of Valsalva dimensions [51]. Dissection of the ascending aorta has been reported at aortic dimensions under 50 mm, and some have claimed dissection only occurs in the nondilated state [40]. We and others, however, have documented numerous examples of dissection of the ascending aorta, both with and without rupture, in patients with dilatation greater than 55 mm. Surgical repair of the aorta is recommended when the diameter reaches 50–55 mm, which emphasizes our belief that most well-managed patients can survive until dilatation progresses to that stage [67].

Finally, some have suggested that the shape of the aorta is a marker of clinical prognosis and classification. Devereux and colleagues presented cross-sectional data in which patients with MFS were categorized by whether proximal aortic dilatation was limited to the sinuses of Valsalva or was more fusiform [68]. Diffuse involvement of the proximal aorta was recognized as a risk factor for aortic complications. Unless a dissection is present, the aorta beyond the root rarely dilates in children or adults through middle age [3,69]. Whether older affected adults will be more prone to abdominal aortic aneurysms than the general population is an open question [70,71].

Dissection usually begins in the ascending aorta. Most dissections progress anterogradely to involve the entire aorta, and some extend retrogradely. The latter are particularly life-threatening because of interference with coronary artery blood flow or rupture into the pericardial sac with tamponade. Although most patients experience the classic clinical symptoms associated with the acute dissection [72], some patients are unaware that they have suffered an extensive aortic disruption [73]. Intimal tears, occasionally with circumscribed areas of dissection, are not uncommon in the dilated sinus of Valsalva and are usually recognized at the time of surgery.

Any region of a dissected aorta may dilate over time. Close follow-up is mandatory, and any of the classic clinical signs

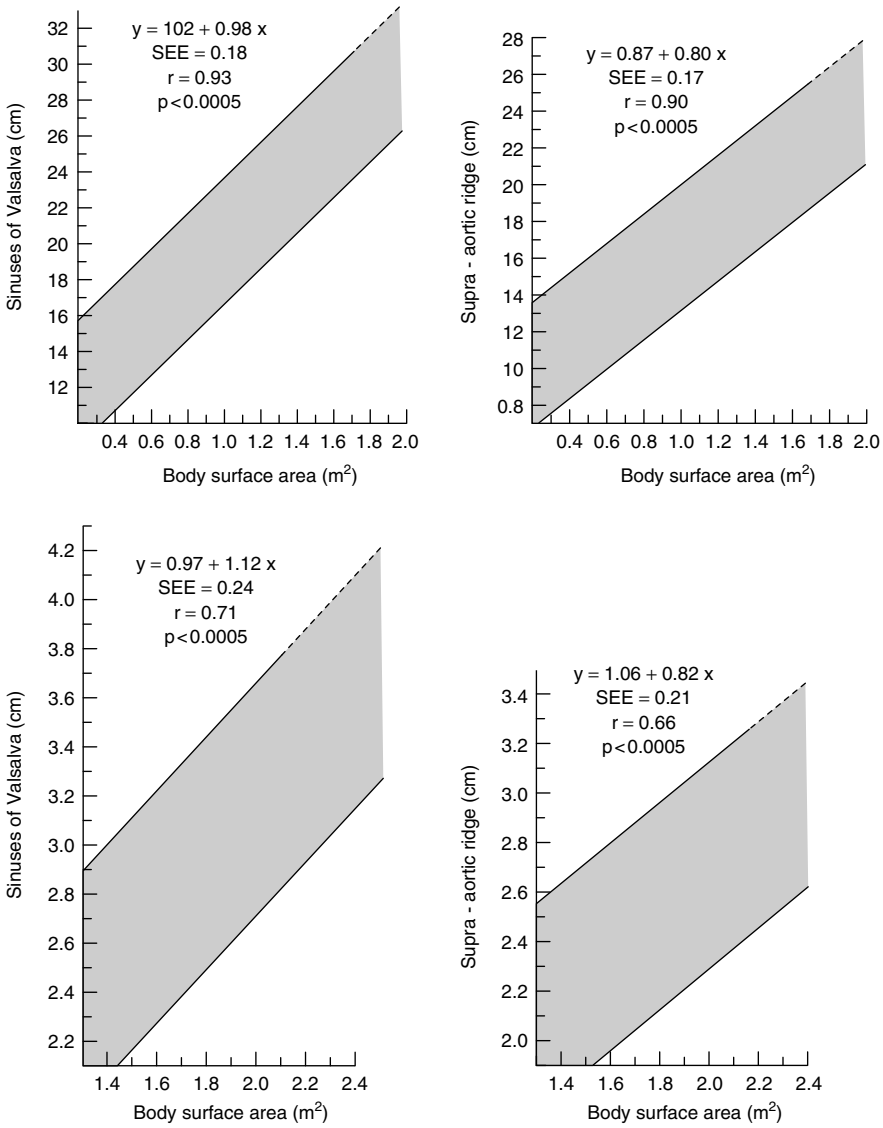


Figure 5. Assessment of the diameter of the aortic root as a function of the body surface area. The **upper** two graphs are for children and adolescents and the **lower** two for adults. The graphs on the **left** are for the aortic diameter at the level of the sinuses of Valsalva and those on the **right** are for the diameter at the supraaortic ridge (sinotubular junction). The shaded areas represent the range of values in which 95% of the population of males and females will fall. Data were from cross-sectional echocardiograms measured at end-diastole using the leading-edge technique. (Courtesy of Dr. Richard Devereux; modified from [62] with permission of the publisher.)

of progression, such as pain, limb or organ ischemia, and hematuria, should be taken quite seriously.

The Respiratory System

Given the predominance of connective tissue in the lung and airways, it is perhaps surprising that the lung is affected clinically so infrequently. The major manifestation is spontaneous pneumothorax, usually due to rupture of an apical bleb [74]. A variety of severe emphysematous changes have been reported in patients, including infants [75–82], but whether MFS predisposes to obstructive lung disease in most patients remains unclear.

Measures of static pulmonary function may be misleading if the patient's values are compared with normative values calculated on the basis of, in part, standing height [83]. Because the legs of the patient are abnormally long, lung volumes are predicted to be greater than warranted, and the patient is reported to have a reduced forced vital capacity and total lung capacity. In fact, when the predicted values are based on sitting height (a more accurate reflection of thoracic size), both are normal in most patients [83]. The exceptions are those with severe pectus excavatum, severe vertebral column deformity, or both, in whom forced vital capacity, total lung capacity, and residual volume are reduced. The pattern is that of restrictive lung disease and may become life-threatening in patients with marked thoracic deformity.

Dynamic pulmonary function has not been assessed rigorously in MFS. There is some suggestion that lung compliance is abnormal [82], but measurements are difficult and abnormalities detected must be partitioned into

intrinsic defects of lung parenchyma and secondary effects of supporting and confining structures. Severe pectus excavatum, for example, markedly alters the mechanics of deep inspiration.

The Integumentary System

In its broadest sense, this system includes not only the skin but fascial coverings of tissues and organs and even intraorgan septae. Given that the primary constituent of this system is connective tissue, it is not surprising to find pleiotropic manifestations of MFS in skin, fascia, and dura.

Skin. In general, skin elasticity is not strikingly unusual, although some patients have more distensible skin than expected, with prompt return to its original tautness; when present, this "hyperelasticity" is typical of the mild forms of the Ehlers-Danlos syndrome (see Chapter 9, this volume) and not of cutis laxa. Some patients complain of easy bruising, and several factors may be at work. First, skin of people with MFS may be thinner than that of age-matched controls, especially the deeper reticular dermis. Second, people with MFS often have decreased subcutaneous fat and hence less protective cushioning for minor contusions. Third, joint laxity, muscular hypoplasia, and poor visual acuity may contribute to a predisposition to contusions in some patients. However, no consistent abnormality of platelet function or coagulation occurs. Healing of both traumatic and surgical disruptions of fascia and skin seems grossly normal, without predisposition to wound dehiscence.

By far, the most common manifestations of MFS in the skin are striae atrophicae [84], which occur in roughly two-thirds of patients. These "stretch marks" occur in areas of flexural stress, such as the lumbar area, buttocks, shoulders, breasts, thighs, and abdomen, in approximate descending order of involvement. Striae may first appear in childhood but are usually first recognized around puberty.

In contrast to the striae common in adolescents who lack a connective tissue disorder, those in MFS persist and are not associated with being overweight. Histologically, striae atrophicae in MFS skin appear no different from stretch marks in the general population; elastic fiber fragmentation is the most striking feature [85]. The striae of pregnancy can be particularly exuberant in the woman with MFS.

Hernia. Inguinal herniae, both congenital and acquired in adolescence or later, are relatively common in MFS. Recurrence after standard surgical therapy is also common, and buttressing with prosthetic meshwork is often required for the second and subsequent repairs. From personal observations, incisional herniae, especially ventral ones, are definitely of increased prevalence and may also require buttressed repair. Herniae of other structures, such as the diaphragm, may be more common in MFS, but a coincidental occurrence is also possible [86].

The Central Nervous System

Intelligence and cortical function. Intelligence, as measured by standard tests of IQ, is unaffected [3,87]. Presence of low intelligence or frank retardation in a person with classic MFS should prompt an intensive search for a cause of the mental deficiency. In the retarded patient with some features suggestive of MFS, homocystinuria, fragile-X syndrome (MIM 309550), Shprintzen-Goldberg syndrome (MIM 182212), and chromosome aberrations should be considered.

In a pilot study of children and adolescents with MFS, Hofman and colleagues [87] found a high prevalence of neurodevelopmental problems. Attention deficit disorder, hyperactivity, and verbal-performance discrepancies are all common in the general population, and ascertainment bias or confounding factors (such as poor visual acuity, muscular incoordination, and β-adrenergic blockade) may have influenced the results of this initial study. However, some young people with MFS clearly have learning problems; whether these represent pleiotropic manifestations of the genetic mutation or epiphenomena remains to be determined.

Several instances of psychosis in people with MFS [88,89] probably represent coincidences.

Dural ectasia. Case reports of marked ectasia of the dural sac in patients with MFS have appeared over the years [90], but the widespread use of CT scanning and MRI has resulted in an appreciation of both the extent and the prevalence of this manifestation [90–94]. In about two-thirds of patients, the dura stretches, presumably under the influence of cerebrospinal fluid pressure, with three prominent effects. In the lumbosacral region, the vertebral canal becomes widened due to pressure-induced remodeling and erosion of vertebral bone (Fig. 6a). If the dura protrudes through the neural foramina, arachnoid cysts and pseudomeningoceles can develop (Fig. 6b). Finally, rare patients develop enlargement of spaces containing cerebrospinal fluid in the head, and the cisterna magnum is especially susceptible; however, no systematic survey of cephalic involvement has been made.

Dural ectasia is usually asymptomatic; the most common clinical presentations are radicular pain from nerve root compression in lumbosacral foramina and pelvic pain from meningoceles. The latter are often misdiagnosed as ovarian cysts.

Other Features

Skeletal muscle. Patients with "classic" MFS often appear "myopathic," with little skeletal muscle bulk, neonatal hypotonia, scoliosis, joint contractures, and a flat, expressionless facies [3]. Joint laxity, cardiovascular problems, or both may limit exercise in childhood and adversely affect development of muscle bulk and strength. Advice to limit exercise out of concern for aortic dilatation may further impair muscle development. Several case reports have suggested that a skeletal muscle myopathy is a pleiotropic manifestation, but adequate controlled studies have not been performed [95–97].

Adipose tissue. Adipose tissue has not been studied in MFS, which is surprising given its obvious deficiency in most children and adolescents. This distribution of adiposity is curious; most young patients lack subcutaneous fat stores throughout their bodies but as adults find that centripetal accumulation is marked, especially around the hips. On the other hand, some patients have considerable bulk, both skeletal muscle and adiposity, from early ages; given tall stature, body weight can be considerable and become an important or even limiting factor in considering cardiopulmonary bypass for cardiac surgery.

Diagnosis

Despite knowledge of the basic genetic defect, the diagnosis of MFS remains firmly rooted in the phenotype. The so-called Ghent criteria [98] are the latest iteration of diagnostic standards and are summarized in Table 1.

Diagnostic Criteria

In 1986, a committee of international consultants first suggested diagnostic criteria (the Berlin nosology) for many common heritable disorders of connective tissue, including MFS [99]. Subsequently, the Ghent criteria were offered by

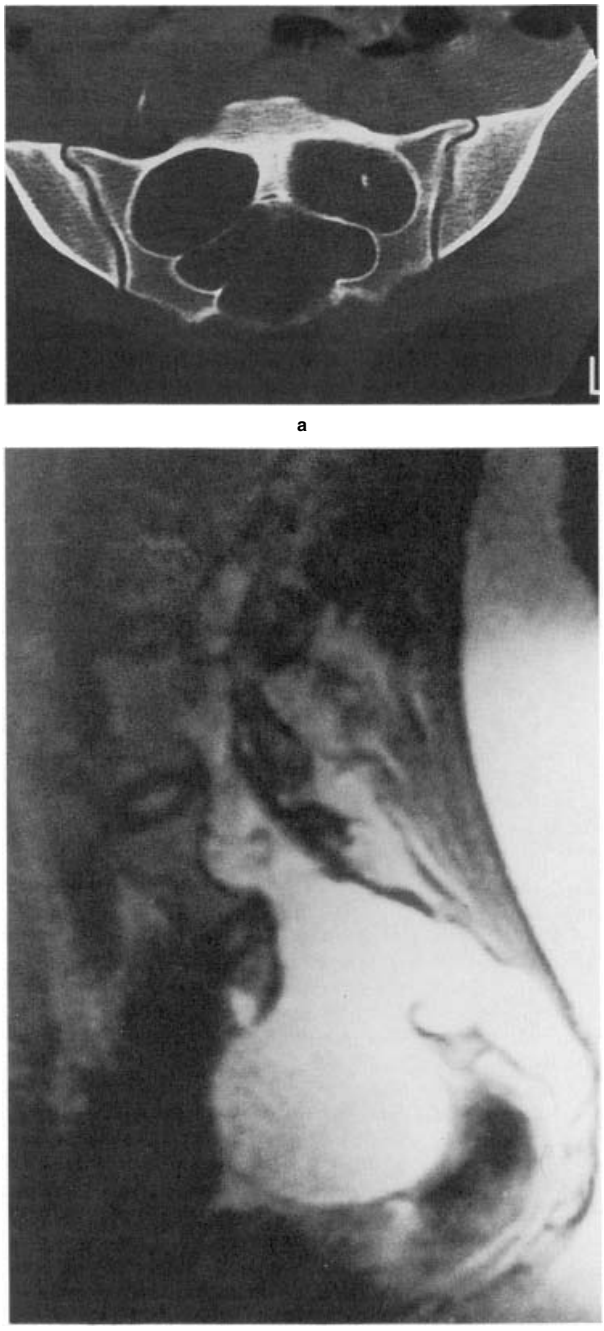

Figure 6. Dural ectasia in Marfan syndrome. a: An axial CT scan of L5, showing marked bony erosion and dilatation of the central spinal canal and the two lateral neural foramina. The scan is oriented with the dorsal surface down. **b**: A myelogram of the lumbar spine showing both dilatation of the spinal canal and a large anterior pseudomeningocele. The radiograph is oriented with the head up and the dorsal surface to the right.

De Paepe and colleagues [98] (Table 1). At one end of a phenotypic continuum resides MFS, and at the opposite end lies the general population. A variety of conditions occupies this continuum.

Diagnosis of MFS is pragmatic, based on what can be done to define the phenotype in any specific case. For example, dural ectasia is a highly specific sign but requires CT or MRI to detect, and such tests are not practical for every patient.

In addition, if a patient has no relative with any suggestion of MFS, or if the patient has been adopted and has no knowledge of relatives, then more phenotypic manifestations are required than when the family history is positive. However, one must be careful in calling the family history positive; many aneurysms, most scoliosis and tall stature, most myopia, and so forth are not due to MFS. In the best circumstance, diagnosis in a relative is based on personal examination or autopsy confirmation.

Clinical diagnosis. When the patient exemplifies the standard medical textbook description of MFS, the diagnosis is rarely in doubt. The clinical challenge comes in the less obvious cases, and here the clinician charged with determining the diagnosis must assemble a full range of objective data. In nearly all instances, the clinician will require the assistance of specialists, particularly the ophthalmologist and the cardiologist.

Thorough reviews of past medical history, current complaints, and family history are essential. The general physical examination focuses on height and body proportions, the shape of the palate and state of dental occlusion, passive joint mobility, shape of the anterior thoracic cage, shape of the vertebral column, and inspection and auscultation of the cardiovascular system.

The ophthalmologist should dilate the pupil to the maximum and inspect for any displacement, including anterior, of the lens. The visual acuity in each eye must be determined. The entire retina should be inspected for tears. Also, the globe in MFS is often elongated and the cornea is usually flattened. Lenticular cataracts often begin to appear in early adulthood. The intraocular pressures should be determined, even in children.

The cardiologist is useful for expert examination and recommending and interpreting diagnostic tests. The transthoracic echocardiogram is an essential diagnostic tool, most useful for detecting redundancy and prolapse of the atrioventricular valves and for measuring aortic diameter and ventricular size and function. Addition of Doppler techniques enhances detection of subtle valvular abnormalities.

Computed tomography (CT) and magnetic resonance imaging (MRI) are useful for defining the mediastinal relationships when severe pectus excavatum is present, the size and shape of the aortic root and entire aorta, whether a dissection is present, and whether protrusio acetabuli or dural ectasia is present.

Molecular diagnosis. Mutations in the locus that encodes fibrillin-1 at 15q21 account for all cases of classic MFS that have been studied. Other loci likely contribute to the panoply of conditions in the phenotypic continuum of MFS. However, because of the extensive intragenic heterogeneity at *FBN1* in MFS, the current technical challenges of mutation detection, and the fact that *FBN1* mutations may cause the same conditions that constitute the differential diagnosis for MFS (see Table 2), molecular diagnosis for the sporadic case has little role [98,100,101].

Two situations occur when molecular diagnosis is practical. First, if the *FBN1* mutation is known for a person with MFS, then that information can be applied to relatives and prenatal diagnosis. Second, sufficient intragenic and tightly linked polymorphisms have been described that

TABLE 2. Differential Diagnosis for Marfan Syndrome

Primarily skeletal features
Homocystinuria (MIM 236200)
Congenital contractural arachnodactyly (MIM 121050)
Klinefelter syndrome
Familial tall stature

Pleiotropic
MASS phenotype (MIM 157700)
Shprintzen-Goldberg syndrome (MIM 182212)

linkage analysis can be performed in families that have several available and willing relatives with MFS [102,103].

Differential Diagnosis

A primary preoccupation of the genetic nosologist is deciding whether to "lump" or "split" similar phenotypes. Evidence of genetic heterogeneity, through analysis of pedigrees, proteins, and genes, is justification for splitting similar phenotypes into distinct clinical disorders. However, not all genetic heterogeneity necessitates splitting; both allelic and locus heterogeneity of the type I procollagen genes produce clinically inseparable osteogenesis imperfecta phenotypes (see Chapter 8, this volume). Differential diagnosis of MFS is hampered by three factors: the range of fibrillin-1 mutations in MFS and related conditions; the considerable prevalence of many phenotypic manifestations in the general population and in other connective tissue disorders; and the existence of a phenotypic continuum, which includes "healthy" people at one extreme and MFS at the other. Often, differential diagnosis in the clinic involves deciding not whether the consultant has MFS or another condition but whether any disease is present at all (Table 2).

Homocystinuria due to deficiency of cystathionine β-synthase (MIM 236200; see Chapter 13, this volume) was for decades lumped with MFS because of common features of tall, dolichostenomelic habitus, scoliosis, anterior chest deformity, and ectopia lentis. However, autosomal recessive inheritance, mental retardation, and vascular thromboses are not manifestations of MFS, and autosomal dominant inheritance, aortic dilatation and dissection, and joint hypermobility are not common in homocystinuria. Nonetheless, sporadic cases in a family, especially when evaluated at a young age, may be difficult to diagnose with certainty. When a person is the first in a family to be evaluated for MFS, a screening test for homocystinuria should be performed.

In some cases, the Stickler syndrome (hereditary arthroophthalmopathy, MIM 108300) shares with MFS autosomal dominant inheritance, tall stature, retrognathia, midfacial hypoplasia, joint problems, retinal detachment, myopia, and mitral valve prolapse. Stickler syndrome (see also Chapter 23, Part II, this volume) can usually be differentiated by the characteristic vitreoretinal degeneration, and by a family history of cleft palate or deafness segregating with the skeletal and ocular problems. Stickler syndrome shows locus heterogeneity, with mutations in the procollagen loci for type II and type XI collagens having been described [104,105]. As methods for detecting mutations in large genes evolve, diagnosis based on direct analysis of the basic defect will become feasible.

Aside from these two well-recognized syndromes that affect multiple organ systems, a host of other Mendelian conditions need to be considered because of the involvement of one of the major systems affected in MFS. The conditions that share skeletal manifestations include: classic and hypermobile Ehlers-Danlos syndrome (MIM 130010 and MIM 130020) (joint hypermobility and scoliosis) (see also Chapter 9, this volume); sickle-cell disease (MIM 141900.0243), multiple endocrine neoplasia type III (MIM 162300), trisomy 8 mosaicism, and Klinefelter syndrome (tall, dolichostenomelic habitus); and congenital contractural arachnodactyly (MIM 121050) (arachnodactyly, joint contractures, and scoliosis, *vide infra*). There is scant evidence that a "Marfanoid hypermobility syndrome" (MIM 154750) exists apart from MFS; rather, patients with marked joint flexibility either have MFS if they have ectopia lentis or aortic dilatation or else a form of Ehlers-Danlos syndrome.

With regard to ocular findings, retinal detachment occurs in Ehlers-Danlos syndrome type VI (MIM 225400), and ectopia lentis is common in Weill-Marchesani syndrome (MIM 277600) and occurs as isolated autosomal dominant (MIM 129600) and recessive traits, the latter with (MIM 225200) and without (MIM 225100) ectopic pupils.

The cardiovascular system poses the most difficult diagnostic dilemmas, not only because of overlapping hereditary and acquired phenotypes but also because inaccuracies can lead to improper counseling and management, with lethal consequences. First, with regard to the atrioventricular valves, a myxomatous valve apparatus is common in the population, is often associated with valvular prolapse and regurgitation, and may be inherited as an autosomal dominant trait (MIM 157700). Moreover, mitral valve prolapse occurs in many genetic conditions, including most of the heritable disorders of connective tissue [38]. The most difficult diagnostic problems arise in individuals with a spectrum of manifestations we have termed the "MASS phenotype" [64], where the M signifies involvement of the mitral valve, the A mild aortic dilatation (without much risk of progression or dissection), and the S's skin (striae atrophicae) and skeletal involvement. We chose the term "phenotype" to signify that there is unlikely to be a unitary cause among individuals with these findings; indeed, some but apparently not all have mild variations of the basic defect underlying MFS. The MASS phenotype accounts for only a small fraction of the ~5% of the general population found to have mitral valve prolapse, but it is important to avoid labeling these people with the Marfan diagnosis because of the prognostic, therapeutic, and psychosocial implications. Certain families are outliers from the MASS phenotype and constitute their own private syndromes, albeit similar to MFS in some respects [106].

Dilatation of the ascending aorta occurs in a number of acquired conditions (tertiary syphilis, ankylosing spondylitis, relapsing polychondritis, Reiter syndrome) that will not be confused with MFS. It occasionally occurs as an isolated problem, even in childhood. Here the causes include a sporadic Mendelian trait, a multifactorial trait, and one part of the triad of bicuspid aortic valve, coarctation of the aorta,

and medial degeneration of the ascending aorta. As with any congenital heart lesion, there is an increased prevalence of skeletal abnormalities in such patients; ascending aortic aneurysm is often accompanied by pectus excavatum, reduction of thoracic vertebral kyphosis ("straight back"), or scoliosis.

Among Mendelian disorders, the vascular type of Ehlers-Danlos syndrome (MIM 130050) causes rupture of large arteries due to defective type III collagen; rarely do aneurysms form, and usually the abdominal portion of the aorta is affected. Erdheim cystic medial necrosis (MIM 132900) is better called "familial aortic dilatation" (*vide infra*) because the histopathology is incorrectly described by "cystic medial necrosis" and there has been a tendency to lump families who primarily have dissection without much dilatation into the Erdheim category along with families in which aneurysms are prominent. At least until the underlying defects are described, the entities should be split. A study of 50 individuals with thoracic and abdominal aortic aneurysms found only one with a defect of type III collagen, and this family likely represented a mild form of vascular EDS [107]. Families in which dissection occurs in the absence of aneurysms pose considerable diagnostic and counseling challenges because of the lack of a clinical marker before tragedy strikes [108].

Prevalence and Demographics

The classic MFS, because of its variability, tends to be underdiagnosed. Current estimates of prevalence, based on the authors' personal experience, suggest a frequency of 1–3 per 10,000. Data from registries produce lower estimates, for example, of 1 per 20,000 for prevalence and 1 per 10,000 for incidence based on a survey of ectopia lentis in Denmark [109]. There does not appear to be any ethnic or geographic preference. Because the condition is a Mendelian dominant and there is a relatively high spontaneous mutation rate, there would be no *a priori* reason to suspect an ethnic predisposition.

Genetics

Weve [9] and Apert [15] were the first to suggest autosomal dominant inheritance of MFS. As the diverse manifestations of MFS were recognized, investigators struggled with the concept of pleiotropy and whether more than one locus was involved [110]. Indirect but convincing evidence of both unimodality of the distribution of intrafamilial phenotypic severity and lack of segregation of manifestations supported the unilocal hypothesis. Penetrance is extremely high, and we have never documented an example of nonpenetrance in hundreds of pedigrees. For example, in the largest pedigree yet described, each of 105 affected individuals had an affected parent [111].

At least one-quarter, and perhaps one-third, of patients have parents who do not have MFS, a revision of the earlier 15% estimate [3]. However, formal studies on this point are lacking and require detailed clinical assessment of the parents. Failure to scrutinize the parents of multiply affected sibs is the most likely explanation for purported autosomal recessive inheritance [112], although genetic heterogeneity of such an extent occurs in other disorders. Both somatic and germ-line mosaicism have been described in MFS [113–115].

Isolated cases are often more severely affected, an observation that reflects ascertainment bias, relatively higher reproductive fitness of patients with less severe phenotypes, and probably other factors. The paternal age at the time of conception of isolated cases is advanced (36 years versus 29 years), consistent with the notion that a new mutation in a spermatagonium is the cause of much sporadic MFS [116].

Several examples of purported "homozygous" MFS have been reported [48,117]. Only one case of compound heterozygosity at the *FBN1* locus has been confirmed at the molecular level, and the affected child had a severe phenotype that led to early demise [118].

Management and Clinical History

The cornerstones of management are prompt diagnosis, prospective assessment, prophylactic intervention, and genetic counseling. Because many patients first come to medical attention through referral to, or diagnosis by, specialists, it is vitally important that the orthopedic surgeon, ophthalmologist, or cardiologist recognizes the importance of multidisciplinary evaluation and follow-up and so advises the patient, parents, and referring physician.

The Skeletal System

Stature. Growth can be modulated by early induction of puberty [119–122]. The indications we have used are moderate scoliosis and markedly tall stature, both in girls. A conjugated estrogen tablet (Premarin), 10 mg daily, and, for 14 consecutive days each month, mederoxyprogesterone acetate (Provera), 10 mg, is one approach. The bone age must be ascertained before therapy and followed every 6 months during it. The endometrium should be biopsied after therapy is well along to ensure that unacceptable hyperplasia has not developed. Timing of therapy is important; beginning too early may reduce adult height unacceptably and may be difficult psychologically, whereas beginning after pubarche will have little impact. This approach has never been subjected to rigorous clinical investigation; however, no short- or long-term adverse effects are known [122]. There is little experience with induction of puberty in boys. The side effects of androgens compared to estrogens are more substantial, and tall stature is generally better tolerated by men.

Anterior chest deformity. Pectus excavatum is an important concern of children, parents, and primary care physicians but rarely causes symptoms or clinical consequences early in life. Repairs performed when substantial rib growth remains carry considerable risk of recurrence. Surgery delayed until midadolescence carries an excellent prognosis, provided a substernal strut is temporarily placed until the costal cartilages regenerate completely [123,124]. We currently recommend that severe pectus excavatum be repaired in all adolescents and adults with MFS. The advantages to respiratory mechanics are considerable, and exposure of the heart and aorta at the time of cardiovascular surgery is greatly facilitated. Combination of pectus repair and cardiovascular surgery is a considerable undertaking, with a risk of major hemorrhage from bone as a consequence of anticoagulation and platelet destruction during the cardiac phase of the procedure. Repair of pectus carinatum is usually performed for cosmetic reasons.

Vertebral column curvature. Abnormal curvature at any level of the vertebral column can develop and progress at any stage of growth (Fig. 7). Some infants have severe deformity and require early bracing or even instrumentation [23]. The hazard, of course, of early surgical manipulation is disruption of vertebral growth plates and reduction in thoracic height. In most patients, abnormal curves develop gradually during childhood and can be followed by both clinical and radiographic examination. Both abnormal kyphosis and

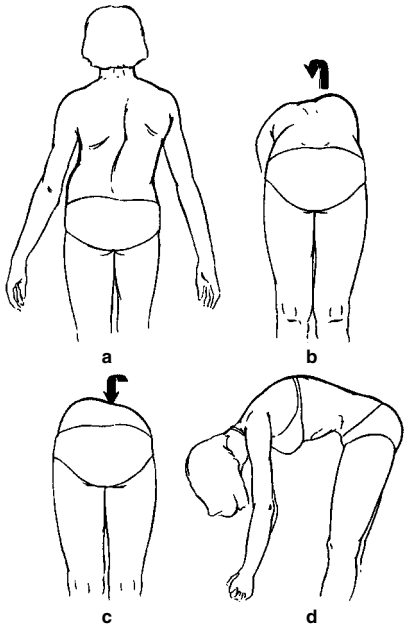

Figure 7. Clinical examination for abnormal vertebral column curvatures. **a**: The patient is first viewed standing upright to detect scoliosis. **b**: Bending forward to about one-half the extent possible will reveal abnormalities of vertebral column rotation of the thoracic spine as well as scoliosis. **c**: Bending forward to the extent possible will reveal abnormal rotation and scoliosis of the lumbar spine. **d**: Positioned as in c, the patient is viewed from the side to detect abnormal lordosis and kyphosis. (Figure courtesy of Paul Sponseller, M.D.)

scoliosis, if not severe, respond to bracing in most cases [21]. Upper thoracic lordosis is a relative contraindication to bracing lower thoracic scoliosis. We recommend bracing for children with scoliotic curves progressing beyond 15–20° and a strong consideration for surgical stabilization as curves increase beyond 40° [22]. Advances in orthopedic surgery obviate the need for prolonged casting or confinement to bed.

Progression of moderate and severe scoliosis in adults is becoming an increasing problem as these patients survive their cardiovascular manifestations. Indications for surgery include pain, neurologic signs, and thoracic curves over 45°, which could progress to cause restrictive lung disease.

The usual criteria for orthopedic management of spondylolisthesis apply [24].

Joints. Surgical stabilization of joints that dislocate repeatedly is occasionally necessary. The patella is the most common problem, followed by the ankle, wrist, and thumb. Every effort should be made at muscle strengthening to substitute for the lax ligaments.

Marked laxity of the ankle and foot produces calcaneoplanovalgus and distorts the normal lines of weight-bearing, which in turn places stress on the hips and knees. This problem is best approached in early childhood by prompt diagnosis and management with orthotics and bracing, followed by osteotomies or arthrodesis if necessary.

Children often have difficulty learning to draw and write because of difficulty holding and stabilizing pencils. The problems are multifaceted and include arachnodactyly, finger laxity or contractures, and wrist laxity. Occupational therapists, through braces, aids, and exercises, can often provide invaluable assistance.

The Ocular System

From the perspective of the primary caregiver, the most important responsibility is referral to an ophthalmologist experienced with MFS as soon as the diagnosis is suspected. Early, accurate detection of ocular problems coupled with aggressive therapy can prevent amblyopia in most patients and optimize development of visual acuity [34]. In practice, infants under 6 months are often easier to examine than toddlers.

The dislocated lens interferes with vision in a minority of people with MFS. In the first place, ectopia lentis is not present in about one-half of patients and in a substantial proportion of the rest is of mild degree. Visual difficulties result primarily from the edge of the lens bisecting the pupillary space. Typically, with a superiorly displaced lens, the patient has phakic vision when gazing upward and aphakic vision when looking downward. Some patients are helped by drugs that keep the pupil constricted (miotics), others by spectacles that incorporate phakic and aphakic correction, and still others by a combination of contact lenses and spectacles. Experience suggests that people with MFS who have serious visual difficulties on account of ectopia lentis respond well to lens extraction and placement of a lens prosthesis [125,126].

Highly myopic patients can generally receive adequate correction. Contact lenses are usually well-tolerated and are welcomed by those patients who must wear thick lenses in spectacles. More than 90% of patients, when treated from childhood, achieve visual acuity of better than or equal to 20/40 in both eyes. Because of the typically flat cornea, various procedures used to correct myopia by reshaping the cornea should be avoided.

There has long been concern about retinal damage, and Maumenee [34] clearly related lens extraction before the newer approaches of the 1990s to an increased risk of detachment. Furthermore, the globe is often elongated and, as in highly myopic patients in general, the retina is under abnormal stretch and more likely to detach. Retrospective evaluation of patients with MFS has found less risk of retinal detachment with exercise than had earlier been feared. Nonetheless, patients should avoid blows to the head (boxing, high-diving) and protect against blows to the globe (racquet sports) with cushioned spectacles.

The Cardiovascular System

As in the other body systems, cardiovascular diagnosis before clinical sequelae is key to the prevention of morbidity and mortality. Once detected, abnormalities must be followed by methods that are both sensitive and practical and interpreted by physicians familiar with both the natural and the clinical histories of the manifestations. Restriction of physical activity, reduction in emotional stress, pharmacologic reduction in hemodynamic stress, and cardiovascular surgery all contribute to improving the long-term function and life expectancy of patients.

Detection of abnormalities. Careful physical examination on a schedule dictated by the severity of the cardiovascular involvement is essential for management. The appearance of aortic regurgitation usually signals substantial aortic root dilatation. Mitral regurgitation may appear at any age as a result of progression of mitral valve prolapse, rupture of chordae tendineae, mitral annular dilatation, endocarditis, or a combination of these factors. Appearance of new systolic

ejection murmurs (especially those radiating to the neck), systolic bruits over the back or abdomen, loss of a peripheral pulse, or blood pressure differences between the arms all may signal aortic dissection. It is crucial to realize that aortic dissection in some patients with MFS is occult.

Transthoracic echocardiography is the mainstay of diagnosis and management of aortic root dilatation. Rarely does the maximum diameter of the undissected ascending aorta occur above the sinotubular ridge, which is the typical limit of visualization. Progression of aortic root dilatation is unpredictable, and a patient's dimensions should be charted regularly; the dimension should be normalized to body surface area for children to account for growth [62,127].

Mitral valve prolapse can also be diagnosed, followed, and defined qualitatively by echocardiography. In about one-quarter of patients with MFS, mitral valve prolapse or mitral regurgitation progress in severity [49]. With mitral regurgitation the most common indication for cardiac surgery in infants and children with MFS [43,47], it is especially important that children with mitral valve prolapse be studied at least annually. Most, but not all, patients with MFS with a prolapsed mitral valve have "floppy" leaflets, defined as thickened, redundant structures by echocardiography. Although not formally studied in MFS, based on studies of mitral valve prolapse in other people, it is likely that redundant valves are more likely associated with progressive mitral valve disease than are valve cusps of normal thickness and length, even if they do prolapse.

Echocardiography is also essential for assessing left ventricular size and function, left atrial size, and tricuspid valve function. Transesophageal echocardiography affords visualization of the distal ascending and the descending aorta and improves assessment of prosthetic valves.

Doppler echocardiography is useful for detecting and grading the severity of aortic regurgitation and mitral regurgitation. For mitral regurgitation in the absence of substantial aortic root dilatation, decisions about the need for surgical correction can be made solely on the clinical examination and the Doppler echocardiogram, and cardiac catheterization can be avoided.

Magnetic resonance imaging (MRI) is the best technique for regular assessment of chronic dissection of any region of the aorta (Fig. 8) and for following the potential for dilatation of any region of the aorta after repair of the root [128]. There is also an emerging role for MRI in the diagnosis of acute dissection when the clinical situation permits the 2 hours required to arrange and perform the scan. Aortography, once a mainstay of diagnosis and presurgical evaluation, is seldom required today (Fig. 9).

Ambulatory monitoring of the electrocardiogram should be performed on any patient with symptomatic palpitations, syncope or near-syncope, or a baseline electrocardiogram that shows major rhythm or conduction disturbance [41].

People with MFS should employ standard indications for routine antibiotic prophylaxis around dental and other procedures that carry a high risk of introducing bacteria into the blood stream [129,130]. Occasional patients may require parenteral antibiotic prophylaxis, but there is no evidence at this time that uncomplicated aortic root surgery alone is an indication.

The chief goal of management is prevention of aortic root dilatation. Acute aortic dissection (Fig. 9) is the major cause of sudden death, which may also be due to myocardial infarction, other organ ischemia, free rupture, pericardial tamponade, or a combination thereof. Because

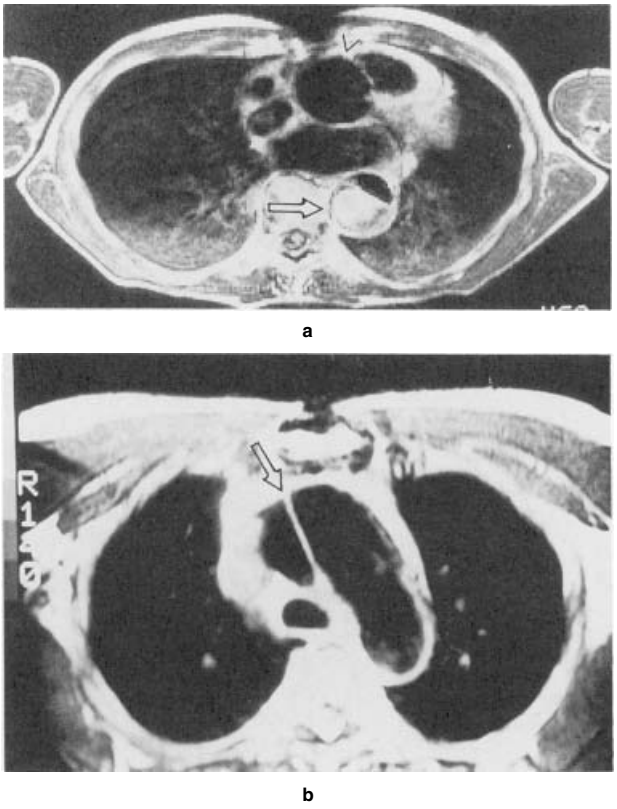

Figure 8. The Marfan aorta as revealed by magnetic resonance imaging. **a**: Axial image of the thorax through the level of the bifurcation of the main pulmonary artery. The aortic root is indicated by the arrowhead; it is moderately dilated. The arrow points to a dissected thoracic aorta that is minimally dilated. The scan is oriented with the dorsal surface down, and the patient's left to the right of the figure. **b**: Axial image of the thorax through the level of the aortic arch. The arrow points to the intimal flap of the dissected aorta. Orientation as in a.

both dissection and aortic regurgitation are associated with marked increase in aortic root diameter, it has long seemed logical that prevention of aortic dilatation would improve longevity [35,36].

Not every aortic dissection occurs during a moment of intense physical or emotional stress, but many do. In competitive athletes who die suddenly, MFS trails hypertrophic cardiomyopathy, congenital anomalies of the coronary arteries, and occlusive coronary disease [131]. Any situation that results in increased catecholamine release will heighten inotropy and, as a result, the rate of change of aortic pressure (dP/dt). Accordingly, we recommend that patients avoid situations of considerable emotional or physical stress. In practical terms, it is almost as difficult to counsel patients about what to avoid as it is for them to alter their lifestyles and personalities. Hence, this effort should not be undertaken lightly, and objective evidence of efficacy would clearly bolster the position and impact of the clinician. Moreover, the counseling should be individualized. A child with an aortic root dimension only slightly dilated is at considerably less risk of dissection than a young adult with an aortic root dimension of 53 mm. The child likely needs no outright restriction, only channeling of interests by parents and

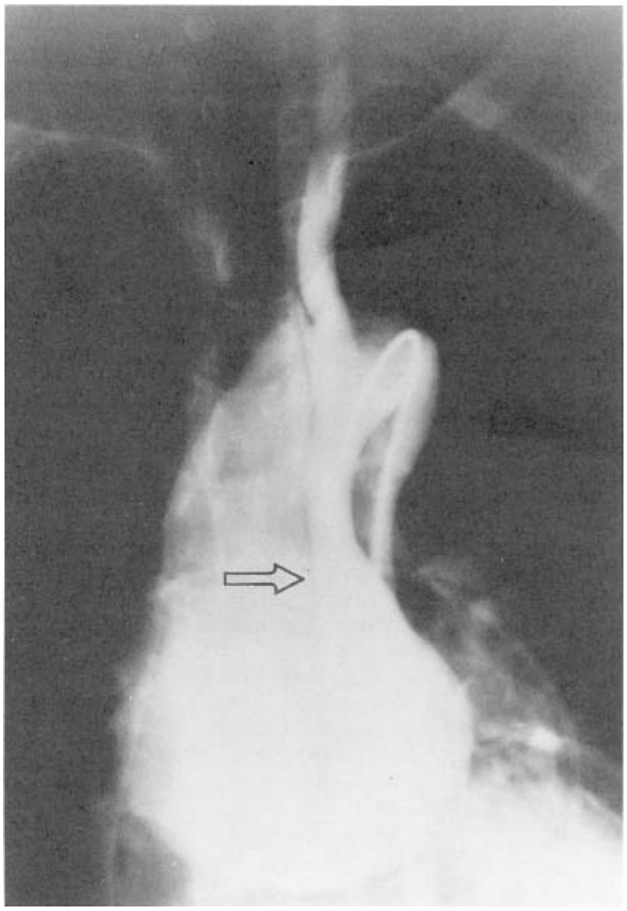

Figure 9. Aortography of a dissected ascending aortic root aneurysm. Anteroposterior radiograph after injection of contrast into the aortic root. The aortic root is markedly dilated, and the arrow points to the intimal flap of the dissection that extends from the valve to the great vessels of the arch. The patient's head is at the top, and the patient's left is to the right of the figure.

teachers away from competitive athletics, whereas the older patient should be told to avoid strenuous exertion of any sort, activities that carry a risk of sudden stops (especially collisions, as occur when playing basketball), or isometric exercises (which increase heart rate and blood pressure more than isokinetic work).

Inotropy of the left ventricle, and dP/dt in the aortic root, are increased by stimulation of myocardial β-adrenergic receptors. The first drug to block these receptors to be approved in the U.S. and to be used worldwide was propranolol. At maximal dosage (which varies widely among individuals), both the increase in heart rate and the more vigorous contraction that occur when isoproterenol is administered are prevented. Propranolol is widely used as an antihypertensive, but in a normotensive person, treatment with β-adrenergic blocking agents has minimal effect on blood pressure in the resting state.

In a randomized clinical trial using propranolol, 76 subjects with MFS were selected to receive either the drug or nothing [132]. The subjects were followed every 6–12 months with serum propranolol levels which averaged 135 ± 80 ng/mL in the treatment group), clinical examination, and echocardiography. Subjects who began the study with immature skeletons were analyzed separately from adults because the aortic diameter was increasing due to growth in the former. Dependent variables were clinical endpoints of the occurrence of aortic dissection or death and the appearance of aortic regurgitation or congestive heart failure, and the aortic root dimension. Follow-up continued for an average of seven years, by which time newer β-adrenergic blocking drugs had become available and a number of subjects in the study had reached a clinical endpoint. In the early years of the study, fewer subjects receiving treatment reached a clinical endpoint than did untreated ones. After nearly a decade, however, the gap between the groups narrowed. The rate of increase in aortic root dimension was significantly slower in both children and adults who took propranolol. In few cases was dilatation actually prevented. Adverse effects of propranolol occurred in one-third of subjects and limited attaining an optimal dose in one [132]. Other studies have confirmed these results [133] while suggesting that some patients may be more responsive than others [134]. The mechanical response of the aorta to acute administration of β-blockade appears variable, with an increase, decrease, or no change in aortic stiffness [134–137]. These differences have not been correlated with clinical outcome.

Because propranolol has unacceptable side effects in some patients, current studies are attempting both to confirm a beneficial effect of β-adrenergic blockade and to study alternative agents [127,136–139].

We currently recommend that all patients with MFS be considered for β-adrenergic blockade. Contraindications include severe diabetes, Raynaud phenomenon, and bronchospasm. The larger the aortic root, the greater the need for treatment. On the other hand, the less the relative dilatation, particularly in young children, the more willing we are to observe the aortic dimension before starting treatment. We start at a low dose and over several months gradually advance until the resting heart rate is in the low 60s and the heart rate after a minute of submaximal exercise does not rise above 100 beats per minute in adults and 110 in children.

Cardiovascular surgery. Techniques for repairing all aspects of cardiovascular disease in MFS have undergone rapid evolution, and today few patients, including children, carry unacceptably high risks of not surviving surgery [67,140]. Three areas of surgery deserve particular mention: the mitral valve, the nondissected aortic root, and the dissected aorta. Most patients with MFS have solid enough connective tissue away from dilatated or dissected areas in which to anchor sutures, and nearly all heal well, with scar tissue of normal substance.

Mitral regurgitation may demand surgical consideration long before the aorta is widely dilated. The surgeon is usually faced with patulous, redundant cusps, a dilated annulus, and occasionally ruptured chordae. Mitral valve repair, rather than replacement, has been developed and shown to be effective over a few years at least [141]. Repair preserves papillary muscle contribution to left ventricular shape and function and obviates the need for chronic anticoagulation (unless atrial fibrillation persists).

The dilated ascending aorta and the leaking aortic valve should be considered as a unit; either or both can be the major indication for repair. The development of the composite graft (Fig. 10), which came into widespread use in the mid-1970s, dramatically improved both operative and long-term survival in MFS [67,73,142,143]. More recently,

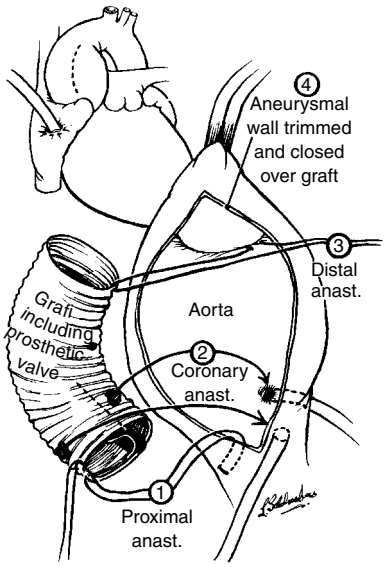

Figure 10. Depiction of the principal steps in composite graft repair of the ascending aorta. In step 1, the proximal end of the graft is sutured into the aortic annulus. In step 2, the coronary ostia are sutured to side holes cut into the graft. In step 3, the distal anastomosis is performed above the upper extent of aortic dilatation. Step 4 refers to a tight closure of the aneurysm wall around the graft, a procedure no longer employed. (Reprinted from [73] by permission of the New England Journal of Medicine.)

David [144,145] has advocated a valve-sparing procedure that has had good success over more than 5 years in some people with MFS [145–149]. This procedure may have limited application when the sinuses are widely dilated and the aortic valve is markedly stretched.

We recommend aortic root surgery when the sinuses dilate to 50–55 mm maximum diameter [150]. If the patient has a family history of sudden cardiovascular death, prophylactic repair should be considered when the diameter reaches 50 mm [151].

The dissected aorta poses the greatest challenge to the surgeon. There is general agreement that acute dissections of the ascending aorta are surgical emergencies; repair with a composite graft is the procedure of choice in MFS [143,146,152,153]. An acute dissection with origin beyond the left subclavian artery should be managed medically (reduction of blood pressure and dP/dt) until the clinical situation stabilizes. Ideally, dissection of the descending aorta will not need surgery but can be followed by MRI at regular intervals. However, progressive dilatation beyond 55 or 60 mm, recurrent pain or signs consistent with fresh dissection, and organ or limb ischemia are all indications for repair [154]. Williams [155] advanced an approach for repairing the chronically dissected abdominal aorta that does not involve a graft. Crawford and colleagues [156] pioneered the staged approach to aortic surgery and performed the first successful replacement of the entire Marfan aorta.

The Respiratory System

To protect against pneumothorax, patients should avoid rapid decompression, such as might occur with rapid ascents in elevators, scuba diving, and flying in unpressurized aircraft. When a clinically important pneumothorax occurs, a chest tube is the appropriate initial therapy; however, in MFS the ruptured bleb may not seal or may rupture again before healing is complete. This clinical history prompted Hall and colleagues [74] to advocate a more aggressive approach and to perform bleb resection and pleurodesis after one recurrence.

Some patients seem predisposed to emphysema, even in the absence of environmental exposures. Because susceptible patients cannot yet be identified, all patients with MFS and their household contacts should abstain from smoking.

The Integument

Striae atrophicae are of cosmetic concern only. An inguinal hernia should be repaired especially carefully because of the risk of recurrence. Similarly, any abdominal incision is at increased risk of ventral herniation. The majority of cases of dural ectasia detected among our clinic population have been asymptomatic [91]. The exceptions have been patients with intrapelvic anterior meningoceles or arachnoid cysts who had radicular pain, parasthesia, and weakness in lumbosacral root distribution. Conservative measures have helped only temporarily. However, attempts to marsupialize the cysts have had mixed success; the cysts may be loculated, and the nerve roots may be stretched across the wall of the cysts and severely limit surgical approaches.

Genetic Counseling

When anyone with MFS reaches reproductive age, he or she should be counseled about the risks of transmitting the mutant allele and of variable expression but not nonpenetrance.

The parents of the first individual diagnosed with MFS in a family should be counseled about the need for a thorough clinical evaluation of themselves to exclude MFS; this evaluation includes an ophthalmologic and an echocardiographic examination. Both somatic and germ-line mosaicism have been described in Marfan syndrome [113–115]. Germinal mosaicism is distinctly uncommon and of minor significance during the counseling of most patients and families.

Pregnancy. The third trimester, labor and delivery, and the first postpartum month carry an increased risk of aortic dissection in all women, especially those with MFS [157]. Most, but not all, cardiovascular complications in the pregnant woman with MFS occur in association with pre-existing problems, such as dilatation of the aortic root, aortic regurgitation, or mitral regurgitation [157–160]. Thus, a woman can be given some estimate of cardiovascular risk before conceiving. Risk of aortic root dissection is quite low when the aortic diameter is 40 mm or less [158] but undoubtedly higher than for women without MFS. However, some women with MFS suffer dissection of the descending thoracic aorta even in the absence of aortic root dilatation. At this time, this risk cannot be quantified but is also clearly greater than for the general population of pregnant women. Whether β-adrenergic blockade is completely harmless to the early fetus is still subject to debate, but such therapy is used routinely by obstetricians for other indications. β-blockade can be used in later stages of pregnancy should dysrhythmia or an increasing aortic root diameter develop.

Delivery should be by whatever method stresses the maternal circulation the least, with due regard to the health of the fetus. Individual assessment of these various risks should be started in advance of term but may not be finalized until early in labor. Epidural and spinal anesthesia should be performed only after consideration of the possibility of dural

ectasia; arachnoid cysts might result in considerable dilution of anesthetic.

Risks to family members. People affected with MFS transmit the condition to one-half of their offspring, on average. In counseling couples with such a risk, variability must be emphasized; an affected child may be more or less severely affected than the parent.

When unaffected parents have a child with MFS, the standard approach to counseling would be to advise of a minuscule risk of recurrence in a subsequent child.

Prenatal testing. Ultrasound is insensitive in the first two trimesters in detecting a fetus with MFS [161]. Prenatal diagnosis based on analysis of DNA obtained from chorionic villi or amniocytes is possible if the mutation is known in the affected parent or if linkage with markers in and around the FBN1 locus can be established [162,163]. Preimplantation diagnosis has been reported [164–166] but, as with all autosomal dominant conditions, is complicated by the potential for selective PCR amplification of the normal allele [167].

Psychosocial Aspects

How patients with MFS cope with the condition and its myriad implications is poorly studied, but in many respects they do not differ from people with other chronic, hereditary conditions. Concerns and emotional responses differ among patients on account of age and prior counseling, among numerous factors [168].

Patients and families often benefit from interacting with peers who have encountered similar problems. Volunteer support groups have been established in more than a dozen countries thus far. Contact details are obtainable from the Web site shown under "Patient Support Groups" at the end of this chapter.

Pathology

Although many reports of autopsies, histopathology, and ultrastructure have been published, no changes are entirely characteristic of MFS.

The gross pathologic alterations follow from the clinical phenotype [3,169–172]. One of the most striking sights in medicine is the massively dilated aortic root, filling the mediastinum of the chest opened by median sternotomy. The wall of the ascending aorta is often so thin as to be translucent, and blood can easily be seen pulsating literally a millimeter from disaster.

Histology of bone, cartilage, and the growth plate is unremarkable. Fascia, ligament, and skeletal muscle (with rare exceptions of possible myopathy [95,97]) appear normal. Skin shows fragmentation of elastic fibers, especially in areas of flexural stress where striae distensae are found; but the striae in MFS are not distinguishable from those occurring in the general population [85]. Immunohistopathology with a monoclonal antibody to fibrillin, a glycoprotein constituent of the microfibrillar component of elastic fibers (*vide infra*), shows considerably reduced binding in skin from patients with MFS [173,174].

The changes in the aortic wall, which are age-dependent, are primarily in the media and include fragmentation and disarray of elastic fibers, a paucity of smooth muscle cells, and the separation of muscle fibers by collagen and glycosaminoglycans [172,175]. The latter pools and resembles cysts, although no walled vesicles occur. Similarly, no necrosis is present, and the term "cystic medial necrosis" should be discarded [40,175] despite its long tradition [176]. These histopathologic changes are not specific for MFS; similar alterations occur in aortas subjected to hemodynamic stresses (e.g., bicuspid aortic valves, hypertension) and as a result of aging [175]. Moreover, the aorta in copper-deficient or lathyritic animals closely resembles that of MFS [177]. Medial degeneration is also present in other elastic arteries, even though dilatation is not common [178,179] except in the main pulmonary artery [180] (Zerhouni and Pyeritz, unpublished). The cardiac valves show myxomatous transformation, with thickening of the spongiosa layer and an increased amount of a cellular, nonfibrous matrix [40].

Studies of the ultrastructure of cells and matrix in the Marfan syndrome have not been particularly revealing. The chief finding is disorganization of constituents of the extracellular matrix [181], especially the elastic fibers [171,182].

Etiology and Pathogenesis

Historical Perspective — Implication of Microfibrils

Many clinical and histopathologic observations in Marfan syndrome suggested a primary defect in the extracellular matrix. Because of autosomal dominant inheritance, mutations in a structural protein that contributes to higher-order macroaggregates seemed likely. Over the years, preliminary evidence implicating most of the major classes of connective tissue components has been presented. One hypothesis held that aortic failure results from deficient tensile strength due to abnormal synthesis, matrix incorporation, and/or tissue homeostasis of fibrillar collagens, particularly type I [183,184]. Supporting evidence included sporadic demonstration of increased urinary excretion of hydroxyproline, increased solubility of dermal collagen, and decreased quantities of collagen cross-links [185–187]. Interest intensified after the reporting of an apparent mutation in the *COL1A2* gene in an affected individual [188]. None of the biochemical abnormalities were consistent findings; however, the putative pathogenic mutation was later shown to be a neutral polymorphism, and all of the genes encoding the major fibrillar procollagens were excluded by linkage analysis [189–194].

Speculation that the basic defect in Marfan syndrome localizes to the ground substance was fueled by the observation of excessive proteoglycans and glycosaminoglycans in affected tissues [171,172,195–197]. This histopathologic finding was later associated with increased hyaluronic acid synthetase activity in patient fibroblast cultures and decreased serum β-glucuronidase activity [198–200]. Others found evidence for decreased mRNA encoding decorin, a chondroitin-dermatan sulfate proteoglycan, in a subset of patients with Marfan syndrome [201–203]. It should be noted, however, that an accumulation of ground substance in the medial layer is a universal finding in aortic aneurysm, irrespective of etiology [204–207]. Moreover, perturbation of proteoglycan or glycosaminoglycan metabolism, including deficient expression of decorin, can be seen in heritable disorders of collagen metabolism and after experimental inhibition of elastin cross-links [208–212]. Thus, it appears that these findings represent nonspecific secondary pathology or compensatory changes that can be elicited by many primary disorders of connective tissue.

As early as 1955, it was suggested that the basic defect in Marfan syndrome localized to the elastic fiber [11]. Initial histopathologic studies demonstrated fragmentation of elastic fibers with a decrease in elastin content in both the skin and medial layer of the aorta [85,169,170,172,213,214]. These findings were later correlated with apparent abnormalities of elastin metabolism in Marfan patients, including decreased

urinary excretion of desmosines, increased elastin solubility, decreased desmosine and isodesmosine content of extracted protein, and increased elastin susceptibility to digestion by pancreatic elastase [213,215–218]. These results suggested a decrease in the density and/or quality of elastin cross-links.

Despite early speculation to the contrary [219], the gene encoding elastin was a poor candidate as the site of primary mutations causing Marfan syndrome. Most importantly, the Marfan phenotype involves tissues that are devoid of elastin, including the ciliary zonules and skeleton [120]. Ultrastructural, biochemical, and immunologic analyses of elastic fibers revealed that the amorphous component was surrounded by rod-like material with a distinct staining pattern and a distinguishable susceptibility to enzymatic digestion [220–223]. These so-called microfibrils have a diameter of 10–14 nm and are constituents of all elastic tissues. Microfibrils are also widely distributed in tissues devoid of amorphous elastin, including the oxytalan fibers intrinsic to the dermal-epidermal junction, tendons, fascia, periosteum, corneal stroma, and the adventitial layer of blood vessels, in numerous basement membranes, and in the mesangium of the renal glomerulus. Of particular interest was the observation that the ciliary zonules that suspend the ocular lens are composed of fibrillar aggregates that demonstrate an ultrastructural appearance and a biochemical profile that is reminiscent of elastin-associated microfibrils [224,225].

It stood to reason that if different tissues, particularly the elastic media of the aorta and the ciliary zonules, shared common mediators of microfibrillar structure, abundance, and/or functional integrity, then the genes encoding such factors would be attractive candidates as the site of primary mutations causing Marfan syndrome. Indeed, Streeten and colleagues [226] first formally proposed an etiologic link between microfibrillar components and the Marfan phenotype after observing that an antibody prepared against sonicated bovine zonules immunolabeled both zonular and elastin-associated microfibrils with an identical periodicity.

The Fundamental Defect — Fibrillin 1

Locus and gene identification. In 1986, Sakai and colleagues [227] first identified fibrillin-1, a 350 kDa glycoprotein component of extracellular microfibrils, and demonstrated that this protein is common to microfibrillar aggregates in all of the tissues altered in the Marfan phenotype, including the skin, vascular wall, hyaline cartilage, perichondrium, ciliary zonules, and alveolar wall. Subsequent immunohistochemical study of Marfan patient tissues showed that the vast majority of patients had diminished amounts of microfibrils in skin, fibroblast culture, or both [173,174]. Study of fibrillin-1 metabolism in cultured skin fibroblasts demonstrated reduced incorporation of fibrillin-1 into the extracellular matrix in about 85% of lines derived from individuals with MFS [228]. In addition, selected patient samples showed defects in protein synthesis or secretion. Subsequently, linkage studies mapped the Marfan locus to anonymous markers on the long arm of chromosome 15, allowing a tentative assignment to 15q15-q21.3 [111,229]. By this time, a portion of the cDNA encoding fibrillin-1 had been characterized [230,231], allowing the gene to be mapped to a position coincident with the Marfan locus at 15q21.1 [12,231,232]. Mutational analysis of fibrillin-1 cDNA from patients with MFS revealed an identical, *de novo* missense mutation in *FBN1*, the gene encoding fibrillin-1, in two unrelated individuals [12]. All linkage evidence suggests the absence of locus heterogeneity for the classic Marfan phenotype with a cumulative lod score in excess of 100 [12,102,111,229,231,233–237]. Although published reports suggest a second locus on chromosome 3p [238], this is based on the analysis of a single kindred that displays both similarities to MFS and differences from it [239]. Thus, it appears that *FBN1* gene mutations account for most, if not all, cases of the classic disorder.

Fibrillin-1 gene and protein. The 8616 bp coding sequence of the *FBN1* gene is contained within 65 exons that span approximately 200 kb of genomic DNA [240–242]. The presence of three alternatively used and in-frame exons upstream of the exon containing the putative initiating methionine in both the human and murine genes initially generated some ambiguity regarding the site of fibrillin-1 translation initiation [240,243]. The first coding exon of the porcine gene contains an in-frame termination codon upstream of the putative initiating methionine [242]. In view of the extreme amino acid conservation of fibrillin-1 among mammals, these data strongly suggest that this ATG methionine codon is the sole start site of translation for fibrillin-1.

Fibrillin-1 is a cysteine-rich 350 kDa glycoprotein with a complex modular organization that is shared within the fibrillin family of proteins [240,241,244,245]. Local differences in amino acid composition or domain content can be highlighted through the designation of five distinct regions of the protein (A–E; Fig. 11) [240,241]. A signal peptide is followed by a short N-terminal sequence encoded by exon 1 that does not show homology with other identified proteins (region A). The C-terminal sequence encoded by exons 64 and 65 (region E) is also unique, but selected features are conserved between fibrillin-1 and fibrillin-2, including a subsequence surrounding two cysteine residues and a high concentration of basic residues [240,241,245]. Both the N- and C-terminal regions contain propeptide cleavage sites that conform to the consensus sequence for furin-like proteases [246–250]. Region C is encoded by exon 10 and is extremely rich in proline residues (38%), in contrast to glycine residues in fibrillin-2 [240,241,245]. Rotary shadowing analysis of monomers reveals a characteristic bend at the corresponding region [227]. It has been postulated that this domain of fibrillin-1 may contribute to the inherent distensibility of microfibrils [240,241]. Further analysis has revealed that region C is sufficient to induce dimer formation of recombinant peptides, suggesting a role in nucleation during microfibrillar assembly [251,252]. This region has also been shown to contain sites susceptible to cleavage by matrix metalloproteinases [253,254]. We have come to appreciate that this domain contains ten perfect tandem repeats of PXXP, where P is proline and X is any residue (commonly also P):

P G R **P** E Y **P** P **P** L G **P** I P **P** V L **P** V P **P** G F **P** P G **P** Q I **P**

This structure is common in Src homology 3 (SH3) domain ligands, but the characteristic positions for interspersed and critical R and L residues are not seen in fibrillin-1 [255]. Rather, it would be predicted that this sequence would form a polyproline II (PPII) helix. PPII helices tend to be found connecting major structural parts of a molecule, where their high conformational mobility confers flexibility [256]. They are frequently located on the surface of proteins, where they can serve as sites of intermolecular interactions, often linking with other PPII helices. PPII helices are conserved in protein families and are found in all serine proteinases including

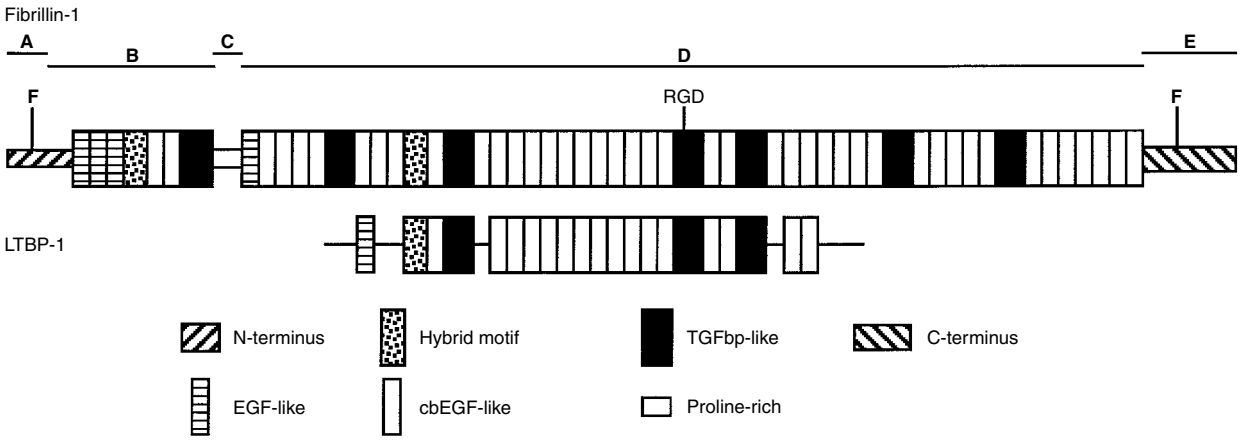

Figure 11. Domain organization of fibrillin-1 and LTBP-1 (latency-inducing transforming growth factor β-binding protein-1). The identity of each domain type is shown at the bottom of the figure. Fibrillin-1 is divided into five regions (A–E) for purposes of discussion (see the text). F, furin-like propeptide cleavage sites. The position of an RGD sequence in fibrillin-1 is indicated. The figure is modified from a previously published version [286].

neutrophil elastase, an enzyme known to cleave fibrillin-1 [256,257].

The bulk of the protein is contained within regions B and D, encoded largely by exons 2–9 and 11–63, respectively [241]. Both regions are characterized by the repetition of cysteine-rich domains, including those that were first identified in epidermal growth factor precursor (EGF-like) and latency-inducing transforming growth factor β-binding proteins (LTBP-like). EGF-like motifs are found in a wide variety of proteins, including many vitamin K-dependent clotting factors and components of the extracellular matrix. One consistent feature is the presence of six predictably spaced cysteine residues that interact via disulfide linkage (1–3,2–4,5–6) to form an antiparallel β-pleated sheet conformation [258] (Fig. 12). A subset of EGF-like domains, including 43 of 47 found in fibrillin-1, satisfy the consensus for calcium binding (cbEGF-like), an event that is required to maintain a rigid, rod-like structure for tandemly repeated motifs and to promote protein-protein interactions [240,259–265]. In brief, calcium binding is dependent on the maintenance of domain structure, as dictated by three intradomain disulfide bonds, and by a number of highly conserved residues that define the consensus sequence

$$(D / N)\ X\ (D / N)(E / Q)\ X_n(D^*/N^*)\ X_m(Y / F)$$

where *n* and *m* are variable and the asterisk indicates potential β-hydroxylation [266,267]. Other conserved residues stabilize the calcium-binding pocket at the N-terminus of an adjacent cbEGF-like domain by mediating interdomain hydrophobic packing interactions [268,269].

LTBP-like domains contain eight conserved cysteine residues that pair via intramolecular disulfide linkage (1–3,2–6,4–7,5–8) [270]. Although this domain contributes to the covalent association between LTBP-1 and TGF-β1 latency-associated propeptide (LAP) through disulfide bond exchange [271,272], the ability of the seven homologous domains in fibrillin-1 to participate in intermolecular interactions remains to be demonstrated. The RGD sequence within the fourth LTBP-like domain of fibrillin-1 has been shown to support cell adhesion through interaction with integrin αVβ3 [273–275]. Little is known regarding the function of other conserved residues in LTBP-like domains. A third cysteine-rich domain, termed the hybrid motif, occurs once in each of the regions B and D and likely manifests fusion between LTBP-like and EGF-like motifs during evolution [241]. The functional characteristics of this novel domain are entirely unexplored.

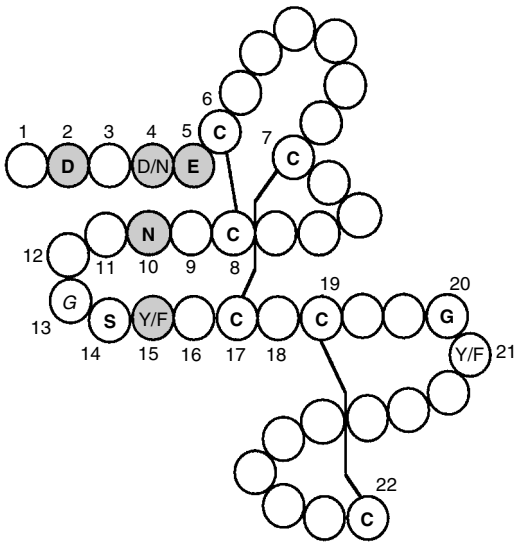

Figure 12. Schematic of a representative cbEGF-like domain from fibrillin-1. Highly conserved residues are indicated using the single-letter amino acid code. Intradomain disulfide linkage between cysteine residues is indicated by lines. Residues important for calcium binding are indicated by shading. Residues shown in italics (positions 13 and 21) are critical for interdomain hydrophobic packing. The figure is modified from a previously published version [290].

***FBN1* mutations imply pathogenetic mechanism.** To date, approximately 150 *FBN1* mutations in patients with MFS or related phenotypes have appeared in the literature or have

been reported to an international database [100,276–279]. More than 90% of mutations are unique to single individuals or families, and the remainder are only present in a handful of apparently unrelated probands. The low rate of recurrent mutations and the high degree of intrafamilial clinical variability has frustrated the development of firm phenotype-to-genotype correlations. The majority of mutations occur within the 47 tandemly repeated EGF-like domains of fibrillin-1, of which 43 satisfy the consensus for calcium binding [266,267]. Many of the mutations substitute one of the six predictably spaced cysteine residues that interact via intradomain disulfide linkage, highly conserved residues within the calcium-binding consensus sequence, or residues important for interdomain hydrophobic packing interactions [100,262,276–279] (Fig. 12). Solving for the solution structure of a pair of cbEGF-like domains demonstrated that calcium binding is required to maintain a rigid rod-like structure for tandemly repeated motifs [262,268]. Moreover, perturbation of domain folding or calcium binding has been shown to result in conformational changes and enhanced proteolytic degradation of single domains, recombinant peptides and intact monomers, and ultrastructural changes in microfibrils [259,263,280–283].

Few clear genotype-to-phenotype correlations have emerged. One exception is the clustering of mutations causing neonatal presentation of severe and rapidly progressive disease in exons 24–27 and 31–32 [284–287]. Interestingly, multiple mutational categories are represented and many mutations within these intervals cause classic or even mild forms of disease [100,276,278,286,288]. As a general rule, mutations causing the in-frame loss or gain of central coding sequence, either through genomic deletions or insertions or splicing errors, are associated with more severe disease [100,289]. In contrast, many mutations that create a premature termination codon and cause rapid degradation of mutant transcripts through the nonsense decay pathway are associated with mild conditions that may fail to meet diagnostic criteria for MFS [286,290–292]. Isolated skeletal abnormalities were observed in individuals harboring a mutation that prevented C-terminal propeptide processing [246]. The mutant gene product was synthesized and secreted but lacked the ability to interact with wild-type protein derived from the normal allele. Taken together, these data suggest a dominant-negative mechanism of disease [100,290]. This model has been validated by immunohistochemical studies and biochemical characterization of cultured patient dermal fibroblasts by pulse-chase analysis. Both methods show that the majority of patient lines exhibit a dramatic paucity of extracellular fibrillin-1, far below the 50% level that might be expected for an autosomal dominant disorder if the relevant mechanism were pure haploinsufficiency [173,228,293–295]. The degree of impairment of extracellular deposition of fibrillin-1 appears to correlate with disease severity and clinical outcome [295].

Although some mutations are associated with a mild phenotype, many that create premature termination codons (PTCs) and transcript instability are associated with the classic Marfan phenotype. As a general rule, the lower the residual mutant mRNA level the less severe the phenotype, but there are clear exceptions [113,296]. It has been hypothesized that N-terminal fragments of fibrillin-1 that are translated from nonsense alleles have dominant-negative activity (i.e., the ability to interfere with the utilization of protein derived from the normal allele through direct interaction). Alternatively, the apparent dominant-negative effect seen with heterozygous nonsense alleles may reflect a decrease in the efficiency of use of protein from the normal allele that is purely dependent on the less-than-normal expression levels [113]. In this scenario, low synthesis, secretion, or stability of mutant protein would all be expected to result in a severe decrease in the level of extracellular microfibrils, below 50% of normal.

The evolutionary conservation of the amino acid sequence of the fibrillins extends beyond the few residues in each EGF-like domain that are known to have functional significance. Indeed, nearly all of the intervening residues in human fibrillin-1 are identical in mouse, pig, and cow [242,243,297]. With few exceptions, missense mutations causing MFS that do not occur in cbEGF-like domains involve cysteine, proline, or glycine residues. The same is true for mutations within cbEGF-like domains that do not replace cysteine or calcium-binding consensus residues. These changes are predicted, or have been proved, to alter protein conformation and stability [262,282,298]. Selected mutations that occur within variable loop regions of EGF-like domains have been associated with very abbreviated forms of disease. Notably, mutation Arg1170His was found in two families with minor skeletal involvement with or without mitral valve prolapse but none of the major manifestations of MFS [113,299]. Such mutations may allow the deposition of stable microfibrils with an as yet undefined but restricted functional deficit.

***FBN1* gene mutations and higher-order pathogenesis of MFS.** The favored model of microfibrillar assembly suggests that fibrillin-1 monomers self-assemble into macroaggregates characterized by parallel arrays of linear extended structures with a head-to-tail orientation [300]. It is easy to imagine how the incorporation of relatively few mutant monomers would be sufficient to cause global perturbation of microfibrillar structure, stability, and function. The tight temporal and spatial link between the formation of microfibrillar aggregates and subsequent deposition of amorphous elastin prompted speculation that microfibrils represent an elastic fiber precursor or regulate elastin deposition during embryonic development [221,222]. In this scenario, the deficiency in elastic fiber abundance and architecture that is observed in mature vascular lesions in MFS predominantly reflects a primary failure of elastogenesis. The absence of organized elastic fibers would cause both a primary structural deficiency and a diminished capacity to modulate hemodynamic stress, perhaps predisposing to secondary damage. Elastic fiber formation is virtually complete after early postnatal life [221,222,301]. Fibrillin-1 and its close family member fibrillin-2 (mutated in congenital contractural arachnodactyly [302]) show divergent temporal and spatial patterns of expression, suggesting that they contribute to structurally and perhaps functionally distinct microfibrillar beds [243,245,303]. Under physiologic conditions, both proteins are no longer expressed after early childhood. Taken together, these data suggest a very limited window of opportunity to modulate the pathogenetic sequence in Marfan syndrome and bode poorly for the development of therapeutic strategies aimed at improving the integrity of elastic tissues including the aortic media. However, this perception may change on the basis of results obtained in studies of the mouse models of Marfan syndrome described below.

The lack of ability to follow the natural history of vascular histologic changes in patients with MFS precluded full appreciation of the pathogenetic sequence leading to aneurysm. New insight has now been provided through

the analysis of mice harboring targeted *Fbn1* alleles. One mutation created an in-frame deletion through the substitution of exons 19–25 with a neomycin resistance cassette (Neo^r) [304]. This so-called mgΔ allele expresses a centrally truncated monomer that was predicted to behave in a dominant-negative manner. However, due to transcriptional interference from Neo^r, very low levels of mutant mRNA and protein are synthesized, with only about 5–10% expression of the mutant allele when compared with its wild-type counterpart. Heterozygous mice were born at the expected frequency and showed only subtle skeletal abnormalities late in life [304]. There were no vascular abnormalities, and life expectancy was normal. Homozygous mgΔ/mgΔ animals were also born at the expected frequency. They died suddenly prior to weaning. Aortic dilatation and dissection were seen, with hemopericardium or hemothorax in all homozygous mutant animals that died naturally [304]. The aortic media showed disruption of elastic laminae and loss of elastin content with the accumulation of amorphous matrix elements, similar to the appearance of mature human lesions [207]. Surprisingly, these abnormalities were extremely focal. At the level of histologic resolution, the bulk of the aorta showed linear, uninterrupted, and parallel elastic fibers. These data demonstrate that minimal microfibrillar function is sufficient to support the deposition of extended elastic structures and highlight the prominent role of fibrillin-1 in elastic fiber homeostasis.

The early death of mgΔ/mgΔ animals prevents a full analysis of pathologic changes leading to aneurysm formation. Important new information, however, has come from the analysis of a second targeted allele (termed mgR) that results from the insertion of Neo^r into intron 18 without rearrangement in the coding sequence [305]. This allele is only expressed at a level approximating 15% of normal. However, protein derived from the mgR allele is normal in structure. Heterozygous mgR/+ animals show no abnormalities. Homozygous mgR/mgR mice show normal intrauterine development but die between 3 and 6 months of age [305]. In addition to vascular disease, these animals show bone overgrowth that is most prominent in the ribs and extremities. Focal calcification of intact elastic laminae is seen in the aortic media as early as six weeks of age. Calcified segments become more numerous and coalesce with advancing age. By 9 weeks of age, intimal hyperplasia with smooth muscle cell proliferation and excessive and disorganized deposition of matrix components is evident. Zones of adventitial inflammation tend to coincide with calcification and intimal thickening. Ultimately, mixed inflammatory cells infiltrate the media with associated expression of matrix metalloproteinases, intense elastolysis, and structural collapse of the vessel wall [305].

A review of autopsy specimens has revealed diffuse calcification and intimal hyperplasia in the aorta and other muscular arteries of young individuals with MFS (own unpublished data). In addition, Takebayashi previously reported the accumulation of an electron-dense and granular material on the surface of, and within, vascular elastic fibers in patients with MFS [171,182]. Although this finding, termed "osmiophilic elastolysis," had been attributed to the accumulation of a peculiar breakdown product of elastin, it is clear in retrospect that the authors were observing diffuse calcification of elastic structures. It is important to note that these findings in patients with MFS do not represent normal age-dependent changes. They were seen in all medium-to-large elastic arteries that were examined and were seen in children without correlation between distribution or severity and the age of the individual (own unpublished data). It is important to note that calcification and intimal hyperplasia occur in vessels that do not dilate or dissect in MFS. This suggests that these changes do not initiate aneurysm formation.

Ultrastructural analysis has defined cellular events that precede and occur coincidentally with destructive changes in the aortic media of fibrillin-1–deficient mice. Normally, elastic laminae connect to adjacent endothelial and smooth muscle cells through junctions composed of microfibrils [306–308], this perhaps being mediated by interaction between the RGD sequence of fibrillin-1 and integrin αVβ3 [273–275]. These connections may contribute to the structural integrity of the vessel wall through cell anchorage and coordination of contractile and elastic tensions [306,307]. Homozygous mgR mice show a striking deficiency of these connections, with direct abutment of smooth muscle cell processes onto elastic lamellae (own unpublished data). Loss of physical interactions, and hence signals that specify context, appears to induce alteration in the morphology and synthetic program of flanking cells that are characteristic of a dedifferentiated state. These cellular changes correlate with the onset of elastolysis (own unpublished data) and the observation of increased immunoreactivity for matrix metalloproteinases at the periphery of mature vascular lesions in patients with MFS [309]. Subsequent disruption of the internal or external elastic laminae in fibrillin-1–deficient mice allows infiltration of inflammatory cells into the media, resulting in accelerated elastolysis and progression to dissection [304,305].

Fibrillin-1–deficient mice and patients with MFS have partial but not complete loss of microfibrillar function due to different pathogenetic mechanisms. Although the *FBN1* genotype is a clear determinant of the degree of functional impairment, hemodynamic stress or other environmental factors may cause progressive loss of residual function. Figure 13 reviews the various molecular mechanisms that have been shown or proposed to result in Marfan syndrome or related phenotypes. Homozygosity for a wild-type allele (+/+) is not associated with abnormalities of the microfibrillar matrix or the development of phenotypic abnormalities. A functional haploinsufficiency state can result when the abnormal product from the mutant allele cannot interact with normal fibrillin-1 derived from the unaltered allele or when the mutant mRNA from heterozygous nonsense alleles is efficiently degraded. Both situations have been observed in association with mild phenotypes in which skeletal manifestations predominate [246,286,290–292]. Near-haploinsufficiency in mgR/+ or mgΔ/+ mice has been correlated with absence or abbreviation, respectively, of the disease phenotype [304,305]. The degree of loss of function that is achieved by the dominant-negative interaction in patients with missense mutations and classic MFS appears to be recapitulated in homozygous mgR mice [305]. Secondary events are required for this deficiency to become clinically manifest. The severe and rapidly progressive phenotype that presents in the neonatal period and is presumed due to alleles with extreme dominant-negative potential [286,289,310] can be recapitulated by homozygosity for an allele that expresses low levels of a centrally deleted monomer in mice (mgΔ/mgΔ) [304]. Even further loss of function is seen on inheritance of two mutant human *FBN1* alleles leading to prenatal fetal loss and absent postnatal viability [118]. An equally severe phenotype is seen

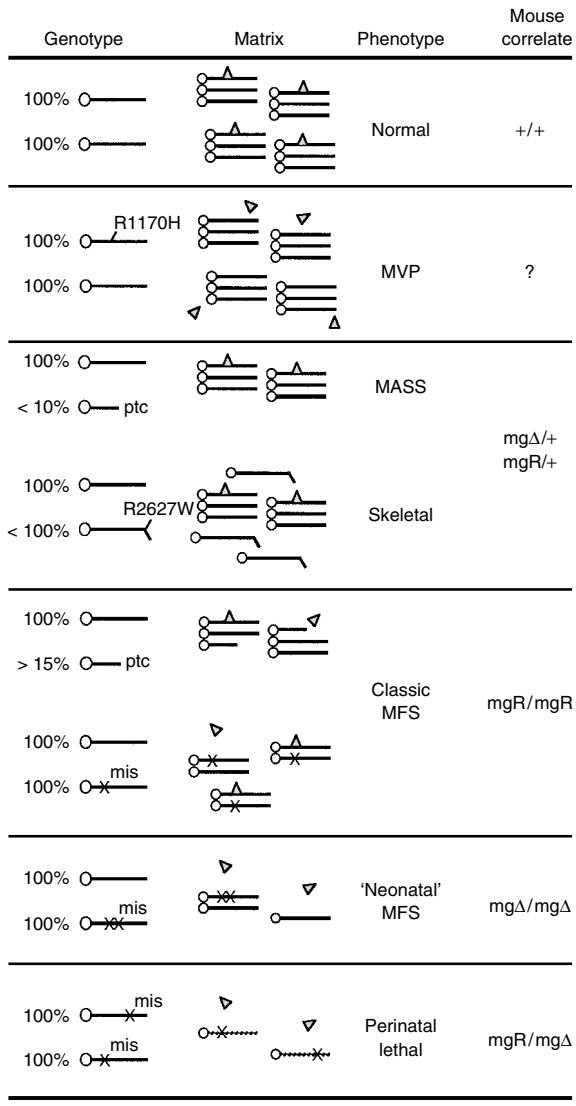

Figure 13. Genotypes and pathogenetic mechanisms in MFS and related disorders. Genotypes: +, wild-type allele; ptc, premature termination codon; X, missense mutation (mis) associated with classic MFS; XX, missense mutation associated with infantile presentation of severe disease (''neonatal MFS''); each horizontal line capped by a circle represents a fibrillin-1 monomer; percentage figure indicates expression level relative to a single + allele. Matrix cartoon indicates the abundance and character of microfibrils. A cluster of three aligned monomers indicates a microfibril; triangle indicates a putative interacting protein. Phenotype: MVP, mitral valve prolapse syndrome; MASS, mitral, aortic, skin, skeletal phenotype; Skeletal; isolated dolichostenomelia. Mouse correlate: genotypes of mice demonstrating a similar phenotype or proposed to manifest a similar pathogenetic mechanism. The figure is modified from a previously published version [390].

when the mgR and mgΔ alleles occur in compound heterozygosity. These data suggest that homopolymers of mutant monomers retain more function than heteropolymers and that the proper alignment of selected domains in adjacent monomers is critical for the assembly or integrity of microfibrils.

The extracellular matrix is an important mediator of many cellular events, including differentiation, proliferation, and migration. The phenotype of smooth muscle cells in developing blood vessels and myofibroblasts in the developing lung may be linked to elastin expression [311–313]. To a large extent, this hypothesis is based on there being an association between alterations in the quantity or quality of extracellular elastin and abnormalities in cellular composition and behavior. Both supravalvular aortic stenosis (SVAS) patients hemizygous for the elastin gene (see also Chapter 10, this volume) and elastin knockout mice show an abnormal proliferative and synthetic smooth muscle cell phenotype, perhaps manifesting a loss of matrix-cellular signaling [313,314]. It is also possible that phenotypic changes simply reflect the loss of a structural constraint to cellular proliferation that is normally imposed by neighboring elastic laminae. The basis for the different vascular phenotypes seen in primary and secondary elastin deficiency in SVAS and MFS, respectively, is not fully understood. Microfibrils may play a structural role in the aorta that is independent of their association with elastin, as seen in the suspensory ligament of the ocular lens. Alternatively, there may be a narrow developmental window for the formation of the obstructive changes characteristic of SVAS. Finally, it is possible that microfibrils have nonstructural functions that are critical in the development and/or homeostasis of the blood vessel wall. For example, it has been proposed that microfibrils may be active in the regulation of the local activity of TGF-β [315]. To an extent, this hypothesis stems from the homology between a repeated 8-cysteine domain in fibrillin-1 and a motif first observed in latency-inducing transforming growth factor β-binding proteins (LTBPs) [271]. TGF-β is secreted in a latent form resulting from its association with its processed propeptide dimer, called the latency-associated peptide (LAP) [316]. This small latent complex binds to LTBPs via a disulfide linkage to form the large latent complex [316,317]. The extracellular matrix regulates TGF-β activity by sequestering the large latent complex from cell-surface–associated activators, including plasmin and integrins αVβ6 and αVβ1 [316,318,319]. There is considerable speculation, and emerging direct evidence, that complexed TGF-β interacts with microfibrils [315,320-323]. In this scenario, a genetically determined deficiency of microfibrils (MFS) would allow excessive processing of the large latent complex, resulting in an increase in TGF-β activity. The effects of TGF-β vary among tissues. In general, this multipotential cytokine inhibits cell proliferation and migration and promotes cellular differentiation and matrix deposition. Interestingly, the embryologic origin of vascular smooth muscle cells determines their response to TGF-β [311,324–327]. Mesoderm-derived vascular smooth muscle cells that populate the descending aorta are inhibited in proliferation and migration and have a neutral response in collagen production. Neural-crest–derived vascular smooth muscle cells that populate the proximal ascending aorta show opposite effects, with the induction of cellular proliferation, migration, and collagen production. Thus, the histologic abnormalities that would be predicted for a pathologic up-regulation of TGF-β activity would occur at the aortic segment that is uniquely predisposed to aneurysm formation in the Marfan syndrome and would closely mimic pathologic findings in fibrillin-1–deficient mice.

Analysis of the tight skin (*Tsk*) mouse provides further evidence for a regulatory role for microfibrils. Homozygosity for this naturally occurring mutation causes early developmental failure. Heterozygosity is associated with a phenotype that

includes progressive tissue fibrosis, obstructive lung changes, and autoimmunity [328,329]. It has now been demonstrated that Tsk mice harbor a large genomic duplication within the *Fbn1* gene, resulting in the tandem repeat of exons 17–40 in the mRNA [330,331]. The fate of the mutant protein is a topic of ongoing investigation [332,333]. Earlier evidence suggested that mutant monomers interact with each other but lack the ability to polymerize with normal fibrillin-1 [332]. More recent results suggest that the abnormal protein is degraded near the cell surface (F. Ramirez, personal communication). It is difficult to reconcile the *Tsk* phenotype with a pure deficiency of the structural functions of microfibrils. It is interesting to note that the duplication within the mutant protein spans the region of fibrillin-1 that shows greatest homology to the LTBPs [330]. There is also preliminary evidence that TGF-β shows increased binding affinity for the *Tsk* gene product in an *in vitro* binding assay [333]. The lack of significant overlap between the *Tsk* and MFS phenotypes suggests that the internally duplicated product may result in excessive fibrosis through a gain-of-function mechanism. In addition, autoantibodies to fibrillin-1 have been identified in *Tsk* mice and patients with scleroderma and other related connective tissue disorders [334,335]. The functional significance of this finding remains to be elucidated.

The study of genetic perturbation of the elastin-microfibrillar array in mice has resulted in an enhanced understanding of multiple disease processes. Although the events and molecules that mediate the clinical expression of a deficiency in this specialized matrix have yet to be fully defined, it is important to note that selected vascular smooth muscle cell and connective tissue abnormalities observed in MFS are also seen in common disease processes, including nonsyndromic aortic aneurysm, hypertension, and atherosclerosis [336–338]. Elastic fiber calcification and degradation and intimal hyperplasia are also a component of the normal aging process. It is therefore possible that an acquired loss of elastic matrix-cell attachments, and consequent destructive changes, are integral to the pathogenesis of disorders resulting from a wide variety of genetic predispositions.

PHENOTYPES THAT OVERLAP WITH MARFAN SYNDROME

Mass Phenotype and Familial Mitral Valve Prolapse Syndrome

Historical Introduction

The clinical signs of mitral valve prolapse (MVP), most typically an apical systolic click, a late-systolic apical murmur, or both, were associated with the angiographic findings of systolic billowing of the mitral leaflets in the early 1960s. Since then, MVP has been associated, whether through chance or true pathophysiology, with a variety of clinical signs and symptoms [339]. It has become clear that in some cases MVP is associated with clear evidence of one or another heritable abnormality in connective tissue other than MFS. In this section, the most common presentations are described. Mitral valve prolapse is also a feature of some forms of the Ehlers-Danlos syndrome (Chapter 9, this volume), pseudoxanthoma elasticum (Chapter 11, this volume), and osteogenesis imperfecta (Chapter 8, this volume).

Phenotype, Natural History, and Prognosis

The skeletal system. Tall, asthenic individuals are more prone to having MVP in the general population, but whether this represents an underlying variation in the extracellular matrix is unknown. Women with MVP in families in which relatives have MVP are more likely to have a relatively long arm span [340]. Deformity of the anterior chest, especially pectus excavatum, scoliosis, and reduced thoracic kyphosis (“straight back”), have been found with relatively high frequency in people with MVP [341]. In our study of probands referred for evaluation of possible MFS, we found a substantial proportion had multisystem involvement but not enough criteria to warrant a diagnosis of MFS. To distinguish these people from those with MFS and from those in the general population with MVP and little else, we coined the term “MASS phenotype” based on the association of mitral valve prolapse, myopia, mild aortic root dilatation, striae, and mild skeletal changes [64]. The word “phenotype” rather than “syndrome” was carefully selected so as not to imply a common pathogenesis in people with MASS. The skeletal features include the mild ones of MFS, namely, tall stature, mild dolichostenomelia, joint hypermobility (but rarely contractures), pectus excavatum, reduced thoracic kyphosis, mild or moderate scoliosis, and pes planus. Occasionally, an individual with MASS will have sufficient skeletal involvement to warrant the skeletal system being a “major criterion” according to the MFS criteria (*vide supra*), but they will not otherwise qualify for MFS.

The ocular system. No specific ocular abnormalities have been described. Myopia may be more common in MASS because it is a diagnostic criterion.

The cardiovascular system. The clinical spectrum of MVP is quite broad, from nonpenetrant (deduced from families in which an autosomal dominant pattern is clear) to causing severe mitral regurgitation in childhood. The occurrence and severity of MVP depend on age and sex; MVP is always more common in women and in both sexes reaches peak prevalence in adolescence and early adulthood [342]. Mitral regurgitation is associated with the severity of the prolapse. When MVP is mild, no regurgitation occurs. As the prolapse increases, leakage first occurs in late systole (hence, the late-systolic murmur), and with severe prolapse, the valve leaks throughout systole. Some factors, such as position, afterload, and medications, affect the tension on the chordae tendineae and the severity of the prolapse and hence the clinical findings. For that reason, failure to detect MVP on an echocardiogram (usually obtained with the subject supine and quiet) does not exclude MVP when the subject is upright and active. Thus, a variety of bedside maneuvers are useful to evoke the click, murmur, or both, even in the face of a negative echocardiogram.

The complications of MVP, in addition to mitral regurgitation, include nonanginal (“atypical”) chest pain, palpitations, bacterial endocarditis, systemic embolization (likely from platelet thrombi that form on the patulous leaflets), and dysrhythmia (including sudden death). Women seem to be predisposed to chest pain and palpitations, whereas men seem more prone to developing mitral regurgitation later in life, which is associated with pronounced thickening and stiffening of the leaflets [339,343]. Complications of MVP have replaced rheumatic disease as the leading cause of surgery on the mitral valve [344].

In one family, MVP was an early sign of severe myxomatous degeneration, with involvement of the aortic and tricuspid valves as well as the mitral. Multiple relatives had required valve replacement. Anatomic inspection showed gross and microscopic calcification of the valves and valve

annuli along with extensive fibrosis and glycosaminoglycan deposition [106].

The tricuspid valve often prolapses if the mitral valve does. Because the right-sided circulation is of lower pressure, the clinical signs and relevance are generally less. The click and murmur of tricuspid valve prolapse are heard at the lower sternal border rather than the apex.

In familial MVP, the aortic root is not dilated. In the MASS phenotype, the aortic root is often at the upper limit of normal, based on body surface area [64]. Although detailed follow-up of subjects has not been performed, the impression is that subjects with MASS do not show progressive dilatation or unusual susceptibility to dissection.

The respiratory system, the integument, and the central nervous system. People who are tall and asthenic are more prone to have MVP and to suffer pneumothorax. People with the MASS phenotype (by definition) are more prone to have striae distensae (atrophicae) at sites of flexural stress. There is no evidence that the CNS is involved in either MVP or MASS.

Diagnosis and Differential Diagnosis

No stringent criteria have yet been established. When multiple individuals in a family have MVP but little in the way of involvement of other systems, the label "familial mitral valve prolapse" seems warranted. When the skeletal, ocular, skin, and cardiovascular systems are involved but no one in the family meets the criteria for MFS, then the label "MASS phenotype" seems reasonable. The entry in MIM 157700, familial mitral valve prolapse, subsumes all of these variants. Marfan syndrome is the major issue in differential diagnosis.

Prevalence, Demographics, and Genetics

All ethnic groups seem to harbor MVP and MASS. Several percent of the population of the U.S. have MVP [345,346].

The familial occurrence of MVP has been noted since the late 1960s [347–349], and the pattern of inheritance is consistent with autosomal dominance with reduced penetrance. The inheritance of the MASS phenotype has not been studied formally, and given that the etiology is undoubtedly heterogeneous, multiple modes of inheritance are possible. In a few families defined both phenotypically and genetically, inheritance was autosomal dominant [100,286].

One family with "familial myxomatous valvular disease" showed autosomal dominant inheritance [106].

Management and Clinical History

The cardiovascular system. People with MVP should be followed by both clinical examination and echocardiography; the frequency of each depends on the severity of the cardiovascular involvement. No therapy has been found to alter the natural history of MVP. Once mitral regurgitation appears, the progression to clinically important leakage can take years, even decades. During this time, the left ventricle gradually dilates and compensates in other ways so that symptoms are a late occurrence. Occasionally, a chorda tendineae ruptures, and the occurrence of acute mitral regurgitation can produce sudden left heart failure, manifested by pulmonary edema, because there has been no time for compensation. In the case of a ruptured chorda, valve repair or replacement is usually necessary. Chronic mitral regurgitation can be managed medically. Complications include left atrial enlargement, supraventricular dysrhythmia, especially atrial fibrillation, left ventricular failure, and embolization [350]. The goal is to protect the circulation, with afterload reduction, while following the size and function of the left ventricle by echocardiography. Mitral valve repair, or, if the valve cannot be repaired, replacement should be performed before irreversible left ventricular enlargement occurs. Chronic or recurrent atrial fibrillation should prompt systemic anticoagulation.

Other systems. Occasional individuals will require repair of pectus excavatum or bracing for scoliosis. The approach to management should follow that described above for MFS. Pneumothorax should be managed as in MFS. Anxiety neurosis and panic disorder have been associated with MVP, but careful studies have cast doubt on any causal link [351,352].

Genetic counseling. People with familial MVP and the MASS phenotype should be counseled about likely autosomal dominant inheritance. To some extent, the complications of MVP tend to recur in a family [347].

Pathology, Etiology, and Pathogenesis

The mitral and tricuspid valve leaflets are often patulous and thickened and, in essence, too large for the opening. The mitral annulus can be dilated, as in MFS, or may be normal. The histology of the valve leaflets shows "myxomatous" degeneration; the excess extracellular matrix is proteoglycan of one sort or another. The gross pathology of the annulus may play a role [353].

In a few patients, the MASS phenotype has been determined to be due to mutations in *FBN1*, the gene coding for fibrillin-1 [286,290–292]. As a general rule, these mutations have created premature termination codons and cause efficient and selective degradation of the mutant transcript. One premature termination codon that was associated with the MASS phenotype occurred in the last exon and therefore did not induce transcript instability [286]. Too few mutations have been described to determine whether the mild character of the disease phenotype is determined by *FBN1* genotype or the influence of modifiers. The fact that the phenotype holds true in extended kindreds is supportive of the former hypothesis. Mutation Arg1170His has been associated with dolichostenomelia with [113] and without [299] MVP. No individual in either family exhibited lens dislocation or aortic enlargement. Finally, an individual who exhibited somatic mosaicism for an *FBN1* mutation showed MVP with subtle skeletal manifestations. The same mutation caused classic and severe MFS when inherited through the germline [113].

It is clear that familial MVP is a genetically heterogeneous disorder. We have excluded linkage to *FBN1* in a number of large pedigrees (unpublished data). Furthermore, a form of familial myxomatous valvular dystrophy has been mapped to Xq28 [354], and a locus for autosomal dominant MVP maps to 16p11.2-p12.1 [355].

Familial Aortic Aneurysm, Dissection, or Both

Relatively little has been written about familial occurrences of aneurysm, dissection, or both, of the ascending aorta. That both can occur in an apparent autosomal dominant mode is certain [108,356–358].

Phenotype, Natural History, and Prognosis

As in the MASS phenotype (*vide supra*), subjects with familial aortic aneurysm have deformity of the thoracic cage at an increased prevalence in relation to the general population. Other subtle signs of connective tissue involvement, such as joint hypermobility and dolichostenomelia, do occur

in some, but overall the diagnostic criteria do not rise to the level of MFS.

In some families, the aortic root dilates in a fashion similar to that of MFS, with the risk of dissection being most dependent on the diameter. In other families, little or no dilatation precedes the dissection. Although these two ends of the spectrum may breed true in some families, others show all gradations [108,357,358]. Mitral valve prolapse occurs with increased frequency in both conditions.

The frequency of myopia may be increased, but if ectopia lentis is present, the person likely has MFS. Striae atrophicae are common.

Diagnosis

No formal criteria have been proposed. Familial aortic aneurysm can be defined as an autosomal dominant condition in which the ascending aorta, beginning in the sinuses of Valsalva, dilates. This condition excludes the ascending aortic aneurysm that is often associated with coarctation of the aorta and/or bicuspid aortic valve [359]; in this association, the aorta may be enlarged when the aortic valve is functionally normal [360]. Familial aortic dissection is an autosomal dominant condition in which the aorta, in the absence of substantial dilatation, dissects, usually first in the ascending segment. This condition excludes the vascular form of Ehlers-Danlos syndrome (see also Chapter 9, this volume).

Prevalence, Demographics, and Genetics

Unsuspected dilatation of the aortic root is the most common cause of isolated aortic regurgitation, having supplanted rheumatic valvular disease [361]. Our suspicion is that many of the cases of "idiopathic" aortic root dilatation represent either familial aortic aneurysm or the developmental defect associated with coarctation and bicuspid aortic valve (all parts of this triad need not be present). Thus, the true prevalences of these two heritable diseases of the aorta, which may be part of the same pathophysiologic spectrum, are unknown. Ascending aortic dissection in the absence of dilatation appears to be exceedingly rare after exclusion of the vascular variant of Ehlers-Danlos syndrome (type IV).

Both familial aortic aneurysm and familial aortic dissection tend to show autosomal dominant segregation, with some families demonstrating high penetrance.

Management and Clinical History

No studies have been conducted on either of these two conditions. For familial aortic aneurysm, affected individuals should be managed in the same way as for the cardiovascular features of MFS (*vide supra*). For familial aortic dissection, the major challenge is identifying those with the predisposition before dissection occurs.

Relatives in families with either of these conditions should undergo transthoracic echocardiography to attempt to document whether disease of the ascending aorta is present. Relatives of an affected individual in a family in which two or more individuals have been affected should be counseled about the risk of autosomal dominant inheritance.

For familial aortic aneurysms, the issues are similar to MFS, and the National Marfan Foundation welcomes such families into full membership. For familial aortic dissection, the anxiety and sense of helplessness in patients can be heightened because of the difficulty in assigning affected status.

Pathology, Etiology, and Pathogenesis

The aortic wall pathology is identical to that of MFS [108]. A few *FBN1* mutations have been reported in families with predominant involvement of the ascending aorta. Mutation Gly1127Ser was found in a large kindred exhibiting late-onset dilatation of the aortic root [362]. Selected individuals in this family showed fragile zonules and/or skeletal manifestations, but no individual satisfied the diagnostic criteria for MFS. This glycine residue is conserved in cbEGF-like domains, but it has not been implicated in calcium binding or hydrophobic packing interactions. NMR analysis revealed defective domain folding [298]. Interestingly, an analogous mutation in a cbEGF-like domain of factor IX is associated with mild hemophilia [363].

Mutations Asp1155Asn and Pro1837Ser were also found in individuals with ascending aortic aneurysms and skeletal involvement that failed to meet diagnostic criteria for MFS [364]. No affected family members were available for analysis. Interestingly, many mutations in cbEGF-like domains at positions analogous to Asp1155Asn have been associated with classic MFS. Also, cells harboring mutations Gly1127Ser and Asp1155Asn showed diminished fibrillin-1 deposition in the extracellular matrix by pulse-chase analysis [362,364]. It is therefore difficult to postulate pathogenetic mechanisms that distinguish MFS from these cases of familial ascending aortic aneurysm.

Many families with familial ascending aortic aneurysm do not show linkage to *FBN1* or the chromosome 3p locus described for a Marfan-like condition [238,357]. The relevant genes have not yet been localized or identified.

Familial Ectopia Lentis

Phenotype, Natural History, and Prognosis

Familial ectopia lentis is another "overlap" phenotype with MFS. The most appropriate MIM number, 129600, isolated ectopia lentis, subsumes autosomal dominant conditions, some with and some seeming to lack involvement of other organ systems. "Isolated" ectopia lentis clearly occurs in an autosomal dominant pattern in some families, although in some the displacement is nonprogressive and the ocular problems relatively benign [365]. In other families, progressive displacement occurs and long-term ophthalmologic management is necessary. Management of the genetic forms of familial ectopia lentis should follow that of MFS.

A mild systemic phenotype (joint stiffness, dolichostenomelia, thoracic cage deformity, and even mild aortic root enlargement) has occurred in a few pedigrees that suggests a generalized connective tissue abnormality [284,366].

Diagnosis

No formal criteria have been established. The major differential diagnosis when inheritance is autosomal dominant is MFS. When only a sibship has affected cases, or in the isolated case, a wide differential diagnosis exists, including autosomal recessive ectopia lentis (MIM 225100) or ectopia lentis with ectopic pupils (MIM 225200), homocystinuria (MIM 236200) (see also Chapter 13, this volume), Weill-Marchesani syndrome (MIM 277600), sulfocysteinuria (sulfite oxidase deficiency) (MIM 272300) (see also Chapter 13, this volume), and hyperlysinemia (MIM 238700).

Prevalence and Genetics

Little formal data exist, but most congenital ectopia lentis is genetic, while that which occurs after adolescence is often traumatic. In a Danish registry, the incidence of congenital

ectopia lentis was 0.83 per 10,000 live births. A cause was evident in about two-thirds, with MFS accounting for two-thirds of those. Ectopia lentis et pupillae was present in 21% of those with a defined cause, and simple dominant ectopia lentis accounted for 8%. Other causes were Weill-Marchesani syndrome, homocystinuria, and sulfite oxidase deficiency in about 1% of those with defined cause [109].

The majority of cases with no or mild systemic manifestations, in the absence of trauma to the head, are autosomal dominant.

Pathology, Etiology, and Pathogenesis

The zonules, which are rich in microfibrils, either stretch or break. The former usually leads to superior displacement; the latter invariably leads to inferior displacement.

The so-called isolated forms of familial ectopia lentis have varied causation. Some forms, including those in families with mild signs of a systemic connective tissue disorder, have shown linkage to *FBN1* [235,367]. To date, however, only a single fibrillin-1 mutation causing dominant ectopia lentis has been identified, and selected members of this family had significant skeletal and skin involvement but none had aortic enlargement. The mutation (Glu2447Lys) resulted in the substitution of lysine for a glutamic acid residue that is highly conserved in cbEGF-like domains and is part of the calcium-binding consensus sequence. Interestingly, mutations at the corresponding residue in other cbEGF-like domains in fibrillin-1 cause typical MFS [100,276,286].

Familial Tall Stature

In one family demonstrating familial tall stature, the proband had mild skeletal features of the MFS (mild dolichostenomelia, pectus carinatum, scoliosis) without involvement of other systems [246]. A mutation in *FBN1* was detected in the proband, and other relatives were examined phenotypically and for the mutation. Those with the mutation were tall without other skeletal manifestations.

No formal criteria have been proposed for diagnosis. Based on this one family, features should be limited to the skeletal system.

The role of mutations in either fibrillin gene in causing "idiopathic" skeletal problems such as scoliosis, anterior chest deformity, congenital joint laxity or contracture, and tall stature is unknown.

Based on the one family and the fact that heterozygosity for mutations in *FBN1* causes other connective tissue conditions, autosomal dominant inheritance should be assumed.

No studies have been done, but the assumption should be that the natural and clinical histories follow those of the skeletal features of the MFS and that their management should be the same.

Mutation Arg2627Trp in fibrillin-1 substitutes a residue that lies immediately adjacent to the consensus site for cleavage by PACE/furin-like proteases [246]. Indeed, this mutation prevents C-terminal processing. The abnormal fibrillin-1 monomer is synthesized and secreted but fails to participate in microfibrillar assembly [246,250]. These data suggest that the initiation of multimerization is negatively regulated by the presence of the C-terminal propeptide. Because the proline-rich domain near the N-terminus can support dimerization [251,252], it is appealing to suggest that this regulation involves intramolecular interactions. This may explain why mutations that truncate or substitute fibrillin-1 beyond the cleavage site can impair microfibrillar assembly and cause MFS.

Shprintzen-Goldberg Syndrome (MIM 182212)

This rare condition was first codified in 1982 [368] on the basis of two unrelated boys with craniosynostosis producing exophthalmos, hypoplasia of the mandible and maxilla, deformed ears, a narrow palate due to hypertrophy of the palatal shelves, anterior chest deformity, arachnodactyly, and camptodactyly. Subsequent cases have broadened the phenotype to include ptosis, hypotonia, developmental delay or moderate mental retardation, osteopenia, and cranial asymmetry [369]. Some have had aortic root dilatation, marked skeletal changes, and a course consistent with MFS [370–372].

The phenotype seems heterogeneous, based on its genetics and diversity of features. Greally and colleagues [373] suggest that in addition to craniosynostosis and other craniofacial features, the presence of dysplasia of the first and second cervical vertebrae, dilatation of the lateral ventricles, and a Chiari I malformation define Shprintzen-Goldberg syndrome. Megarbane and Hokayem suggested that the term Shprintzen-Goldberg syndrome type I be applied to those patients with mental retardation, craniosynostosis, and skeletal changes of MFS, while Shprintzen-Goldberg syndrome type II should include those with normal intelligence and aortic root dilatation [372].

Most cases have been sporadic, occasionally with advanced paternal age. One patient has been shown to be heterozygous for a point mutation in *FBN1*, with neither of the parents having the mutation in somatic tissue [371]. The report of Ades and colleagues described three affected sisters with apparently unaffected parents, suggesting an autosomal recessive variety [374]. Germline mosaicism or nonpenetrance could not be excluded.

All patients suspected of Shprintzen-Goldberg syndrome should have radiologic evaluation of the skull, cervical spine, and brain and echocardiography. Craniosynostosis in an infant and child should be managed by standard techniques to prevent constriction of brain growth and asymmetry of the skull. If aortic root dilatation is present, management should proceed as for MFS.

A fibrillin-1 mutation (Cys1223Tyr) was identified in one patient with Shprintzen-Goldberg syndrome. This mutation involved the substitution of a cysteine residue in a cbEGF-like domain, the most common mutational class causing MFS. This mutation was also identified in a mother and daughter who had been diagnosed with MFS [375]. Despite suggestive data, the diagnosis of Shprintzen-Goldberg syndrome could not be confirmed. Mutation Pro1148Ala was initially identified in a patient with Shprintzen-Goldberg syndrome and in individuals with ascending aortic aneurysm and their family members [371]. This mutation was subsequently also identified in people without apparent connective tissue abnormalities, with an increased population frequency in those of Hispanic or Asian descent [376–378]. In view of the highly variable clinical presentations of individuals diagnosed with Shprintzen-Goldberg syndrome, genetic heterogeneity seems assured.

Congenital Contractural Arachnodactyly

Historical Introduction

Some have argued that Marfan's original patient, Gabrielle P., did not have what we now call MFS but congenital contractural arachnodactyly (CCA) (MIM 121050) [14]. The first cases of CCA were defined in the late 1960s [19]. Beals and Hecht [13] subsequently described two two-generation pedigrees of affected parent and two

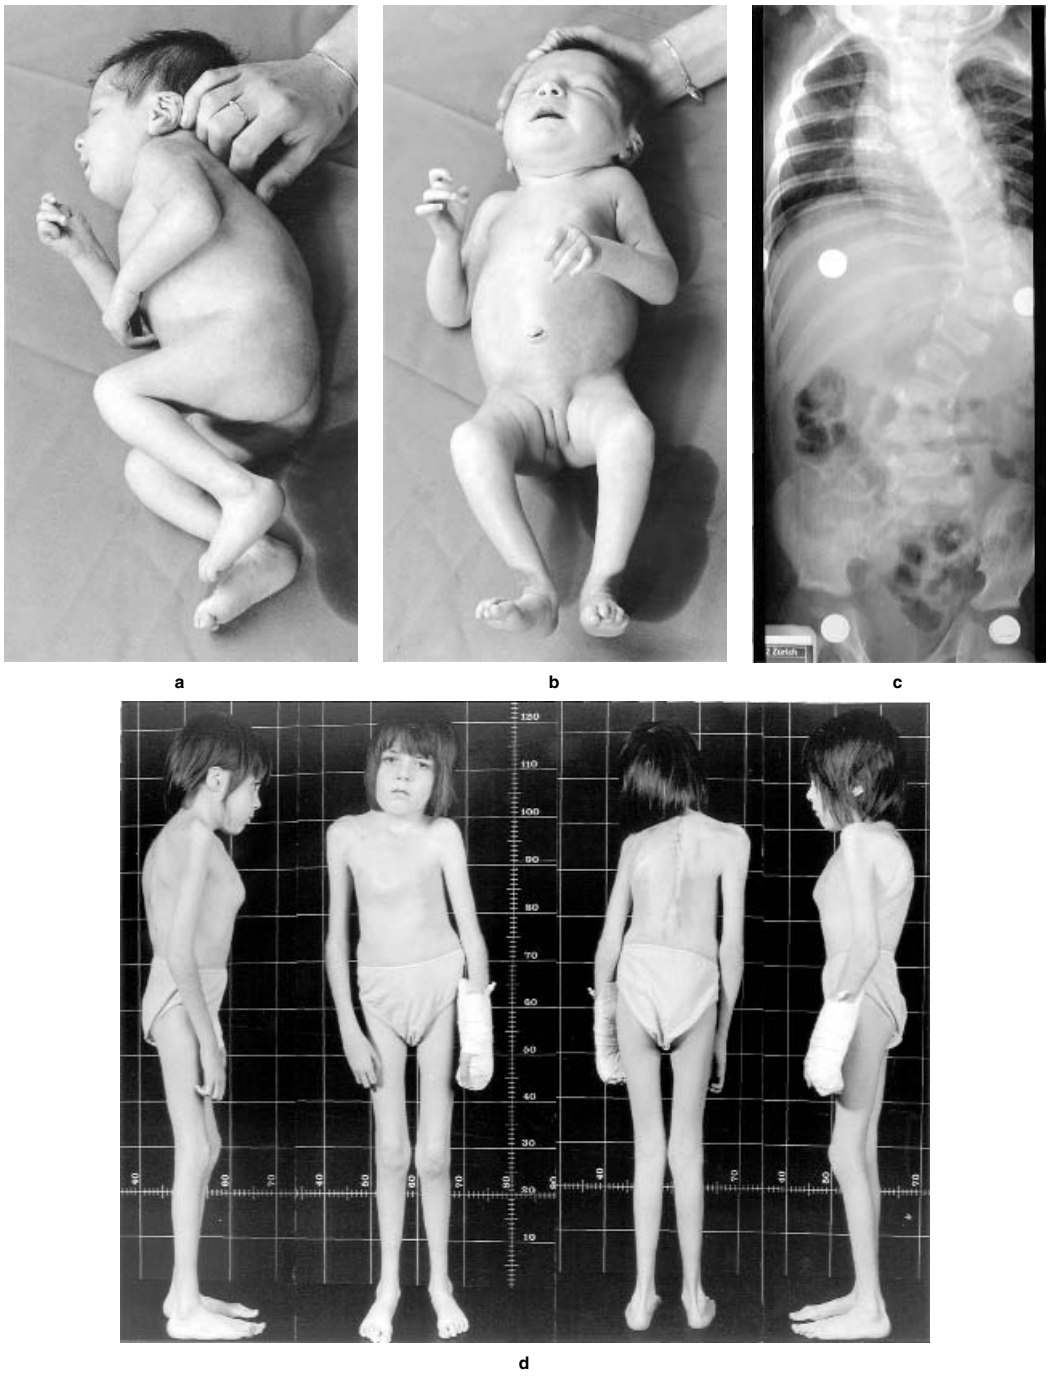

Figure 14. Congenital contractural arachnodactyly. R.R. is the third child of healthy, unrelated parents, born after a normal pregnancy and delivery. Her weight was 3070 g (25th centile), length 55 cm (>95th centile), and head circumference 34 cm (50th centile). Crumpled ears, joint contractures, arachnodactyly, and scoliosis were noted at birth. Numerous procedures had been performed to correct her severe scoliosis, beginning with bracing at 2 months, followed by halo traction and rod insertion at age 2.3 years. This was followed by repeated rod elongation, removal, and replacement. Although her initial growth curve was above the 97th centile, this flattened due to the severity of the scoliosis until it was only at the 3rd centile at age 5 years. Her pulmonary function was restricted. She had a normal 46,XX karyotype. Repeated echocardiographic examinations of her heart were normal, and the results of ophthalmologic examinations were normal. Her defect is due to a *de novo* missense mutation leading to skipping of exon 26. **a** and **b**: R.R. (at age 10 days) presents with contractures of the knees, hips, elbows, and fingers (arachnodactyly), dolichostenomelia, retrognathia, and crumpled ears. **c**: Radiograph at age 4 months shows severe and progressing scoliosis despite bracing. **d**: Severe kyphoscoliosis at age $6\frac{1}{2}$ years despite numerous orthopedic interventions such as bracing at 2 months, halo traction with rodding at 2.3 years, removal of rod at 3.5 years, insertion of rod and partial spondylodesis at 3.7 years, removal of halo at 3.8 years, elongation of broken rod, repair and then removal of broken rod at 4 years, insertions of many rods at 6.3 years, and spondylodesis at 6.5 years. She has severe restrictive pulmonary dysfunction. (Courtesy of Dr. B. Steinmann.)

offspring with arachnodactyly, congenital contractures of peripheral joints that tended to improve with physical therapy, progressive scoliosis, deformed ears ("crumpled" helices), and an apparent absence of cardiovascular and eye manifestations of MFS. Many cases have been reported since, some with clear cardiovascular features consistent with MFS. Given that congenital contractures (especially of the digits and elbows) and some crumpling of the scapha helix are relatively common in MFS, since the mid-1970s there has been much debate whether CCA and MFS are distinct disorders [379–381]. The discovery that CCA is due to mutations in *FBN2*, the gene encoding fibrillin-2, has put to rest the issue of genetic heterogeneity [231,302]. However, given that relatively few subjects of literature reports have been genotyped, the following description of the phenotype may be based on a sample that includes subjects with MFS.

Phenotype, Natural History, and Prognosis

The joints most prone to congenital contractures in CCA are the fingers, elbows, and knees (Fig. 1d). Kyphoscoliosis often appears in childhood and can progress despite orthopedic management (Fig. 14). People with CCA do not have ectopia lentis or any other consistent ocular features. Whether aortic root dilatation occurs in true CCA has not been resolved; this issue will remain uncertain until all patients with congenital contractures and aortic dilatation are shown to have mutations in *FBN1* and not in *FBN2*. Several patients and families with what was called CCA have had MVP [382] and even severe mitral regurgitation due to MVP [383]. Atresia of the gastrointestinal tract (duodenal, esophageal) and intestinal malrotation have been described [384].

Diagnosis

No formal criteria have been established. A minimal set would seem to include congenital contractures, dolichostenomelia including arachnodactyly, crumpled ears, absence of ectopia lentis, and absence of a history of MFS in a close relative.

The principal syndrome overlapping phenotypically is MFS. Congenital contractures are uncommon in the other conditions described in this chapter. Two unrelated Indian females had congenital contractures and a characteristic facies consisting of blepharophimosis, a beaked nose, everted lips, and large ears; the authors suggest that this is a distinct syndrome [384].

Prevalence, Demographics, and Genetics

No ethnic or geographic predilection seems evident. Well over 100 cases have been reported, but the incidence is unknown.

All cases have been sporadic or autosomal dominant. Given that subjects with a defined molecular defect are heterozygous for mutations in *FBN2*, autosomal dominance is secure. In one pedigree, one of the parents of two affected sisters was a somatic mosaic for a mutation in *FBN2* [385].

Management and Clinical History

Aggressive physical therapy, starting in infancy, seems to have a beneficial impact on the congenital contractures and may result in nearly normal joint extension. The spine should be examined regularly, starting in infancy, with aggressive bracing at a relatively early stage, because in some reported examples of CCA, kyphoscoliosis can progress rapidly.

All patients suspected of having CCA should, at several points during growth, have detailed ocular examinations by an ophthalmologist experienced in connective tissue disorders to ensure that ectopia lentis has not appeared. Similarly, a transthoracic echocardiogram should be performed in childhood and early adolescence to ensure that neither MVP nor aortic root dilatation is present. If either is present, management should follow the description in the section on MFS.

Affected subjects should be counseled about autosomal dominant inheritance and variable expression.

Etiology and pathogenesis. All families that have been studied show linkage to the *FBN2* gene on chromosome 5 [231,235]. All of the mutations that have been identified thus far occur in a defined region of fibrillin-2 flanked by exons 24–34. Mutations causing the most severe variant of MFS cluster in the corresponding region of fibrillin-1. The character of mutations seen in *FBN2* closely resembles that of those seen in *FBN1*, including cysteine substitutions in cbEGF-like domains and splicing mutations [302,384–388]. Multiple mutations that have a less obvious functional consequence exactly correspond to *FBN1* mutations causing MFS [387]. In view of the small number of mutations identified to date, it remains unclear whether this clustering of mutations is influenced by any selection bias. It seems likely that mutations outside this region are either phenotypically neutral or result in a milder variant of disease. Interestingly, a fetus with a defined interstitial deletion encompassing the *FBN2* gene showed selected features of CCA [389]. These data suggest that loss of function may be an important pathogenetic mechanism.

Chapter 13

The Homocystinurias

Flemming Skovby and Jan P. Kraus

Department of Clinical Genetics, Rigshospitalet, Copenhagen, Denmark (F.S.) and Department of Pediatrics, University of Colorado School of Medicine, Denver, Colorado 80262 (J.P.K.)

SUMMARY

- **Homocysteine occupies a central position in the transsulfuration pathway. A product of the essential amino acid methionine, homocysteine can either be remethylated to methionine or irreversibly converted to cystathionine. The normal concentration of reduced homocysteine moieties in plasma is 5–15 μmol/L. Several autosomal recessively inherited enzymatic defects cause hyperhomocysteinemia and excretion of homocystine in the urine, called homocystinuria.**
- **Deficiency of cystathionine β-synthase (CBS) is the most common cause of homocystinuria. Major clinical manifestations include dislocated lenses of the eyes, mental retardation, osteoporosis, and thromboembolism. More than 100 mutations have been documented in the *CBS* gene, but the pathophysiological mechanisms are poorly clarified. Increased tissue levels of homocysteine may interfere with disulfide bonding of proteins and cross-linking of collagen. Treatment with a methionine-restricted diet, pyridoxine, and/or betaine will prevent or reduce symptoms, especially if started very early in life.**
- **Deficiency of methylenetetrahydrofolate reductase impairs the remethylation of homocysteine to methionine. Most patients have neurologic dysfunction, failure to thrive, or psychiatric abnormalities, but they have no connective tissue abnormalities. Treatment including betaine may be helpful if started early.**
- **Methylcobalamin is a cofactor of methionine synthase, one of two enzymes responsible for the remethylation of homocysteine, and various genetic defects in the biosynthesis of methylcobalamin may therefore cause hyperhomocysteinemia. Symptoms include neurologic dysfunction, psychiatric abnormalities, and megaloblastic changes in the blood. Some patients respond to betaine and intramuscular hydroxycobalamin, at least biochemically. The long-term prognosis is poor.**
- **Deficiency of sulfite oxidase, due to either defective apoenzyme or deficient biosynthesis of molybdenum-containing cofactor, causes severe neurologic dysfunction and dislocated lenses but no connective tissue abnormalities or homocystinuria. Effective therapy is currently not available, and many affected infants die.**
- **Prenatal diagnosis is feasible for all of the above-mentioned disorders.**

INTRODUCTION

Homocystinuria is an important laboratory finding in several inborn errors of metabolism, some of which have connective tissue manifestations. Disturbances of homocysteine metabolism may also be found in patients with thromboembolic vascular disease. This chapter focuses on the clinical and connective tissue abnormalities in patients with homocystinuria due to deficiency of cystathionine β-synthase and inherited defects of folate and cobalamin metabolism as well as in patients with other disorders of the transsulfuration pathway. Reviews of these disorders with a more comprehensive scope have been published [1–4].

HISTORICAL PERSPECTIVE

Homocystinuria was first discovered by Carson and Neill in 1962 in the course of screening mentally retarded individuals for abnormal urinary amino acids [5,6]. Independently, Gerritsen and colleagues [7,8] found homocystine in the urine of a child with lens abnormalities, mental retardation, and thromboembolism. These and subsequent reports rapidly documented the clinical diversity of "classical "homocystinuria. The biochemical findings of hypermethioninemia, homocyst(e)inemia, and decreased plasma cyst(e)ine enabled Mudd and his co-workers to predict an underlying defect in the transsulfuration pathway. Their hypothesis was soon confirmed by the demonstration of a deficient activity of cystathionine β-synthase (CBS) in liver tissue from a typical patient [9]. The unexpected presence of CBS activity in cultured fibroblasts from normal individuals [10] led to the characterization of a large number of mutant fibroblast lines with respect to catalytic activity. Following the purification of human CBS [11,12] and the cloning of human *CBS* cDNA [13], over 100 mutations have been identified in the *CBS* gene [14].

Applying the lessons learned from phenylketonuria, a low-methionine diet was the first treatment devised for homocystinuria [15]. Shortly thereafter, some patients were found to respond biochemically to oral treatment with pyridoxine (vitamin B_6) by normalizing or improving to varying degrees their plasma and urine levels of sulfur amino acids [16]. An international survey done in 1982–1983

Connective Tissue and Its Heritable Disorders, pages 627–650

of more than 600 patients with CBS deficiency clarified parts of its natural history and demonstrated the efficacy of a low-methionine diet and pyridoxine in preventing or delaying some of the major manifestations of classical homocystinuria [17]. More recent studies have validated the long-term use of betaine in this disorder [18,19].

Before the recognition of homocystinuria as a clinical entity, several patients were "lumped" into the category of Marfan syndrome. Heterogeneity became evident when deficient remethylation of homocysteine was also found to cause homocystinuria. Discoveries of defects in the metabolism of cobalamins have continued the "splitting" of homocystinuria.

METABOLISM OF HOMOCYSTEINE

Homocystinuria due to inborn errors of metabolism is a consequence of elevated levels of homocysteine in the blood, where it circulates as the free thiol, as part of disulfides, and bound to proteins by disulfide bonds.

The pivotal location of homocysteine in the transsulfuration pathway and the methionine-homocysteine cycle is illustrated in Figure 1. The sulfur-containing essential amino acid, methionine, is supplied through catabolism of proteins. The average Western male consumes about 2.4 g methionine per day, or approximately 35 mg/kg [20]. Minimal daily requirements for methionine vary with age and are not well-established; values of 20–40 mg/kg and 10 mg/kg have been suggested for infants and young adults, respectively [21,22].

The vast majority of methionine not used for protein anabolism is converted to S-adenosylmethionine by transfer of the adenosyl moiety of ATP to methionine. The reaction is catalyzed by methionine adenosyltransferase (EC 2.5.1.6). S-adenosylmethionine participates in methylation reactions, polyamine synthesis, and aminobutyryl side-chain donation. It is also an important allosteric enzyme regulator. Transmethylation is the most frequent metabolic fate of S-adenosylmethionine, resulting in S-adenosylhomocysteine and, ultimately, homocysteine.

The rate-limiting enzyme of the transsulfuration pathway, cystathionine β-synthase (CBS, EC 4.2.1.22), condenses homocysteine with serine to form cystathionine in an irreversible reaction requiring pyridoxal 5′-phosphate (reaction 1, Fig. 1). Cystathionine is cleaved to cysteine and α-ketobutyrate by cystathionine γ-lyase (EC 4.4.1.1). The net result of these reactions is the transfer of the sulfur atom of methionine to cysteine, which takes part in several metabolic reactions, such as synthesis of glutathione and proteins. Cysteine may also be converted through intermediates to sulfite, which, after oxidation by sulfite oxidase (EC 1.8.3.1; reaction 2, Fig. 1), is eventually excreted as urinary sulfate.

Instead of being converted to cystathionine, homocysteine can be remethylated to methionine by either of two reactions. One is catalyzed by the vitamin B_{12}-dependent enzyme, methionine synthase (5-methyltetrahydrofolate-homocysteine *S*-methyltransferase; EC 2.1.1.13; reaction 3, Fig. 1), and requires 5-methyltetrahydrofolate, which is produced from 5,10-methylenetetrahydrofolate by methylenetetrahydrofolate reductase ($NADPH_2$) (EC 1.5.1.20; reaction 5, Fig. 1). The other possible remethylation of homocysteine is catalyzed by betaine-homocysteine *S*-methyltransferase (EC 2.1.1.5) and is an obligatory step in the catabolism of choline (reaction 4, Fig. 1).

As an alternative to transsulfuration, methionine may be catabolized by transamination. This pathway has been shown

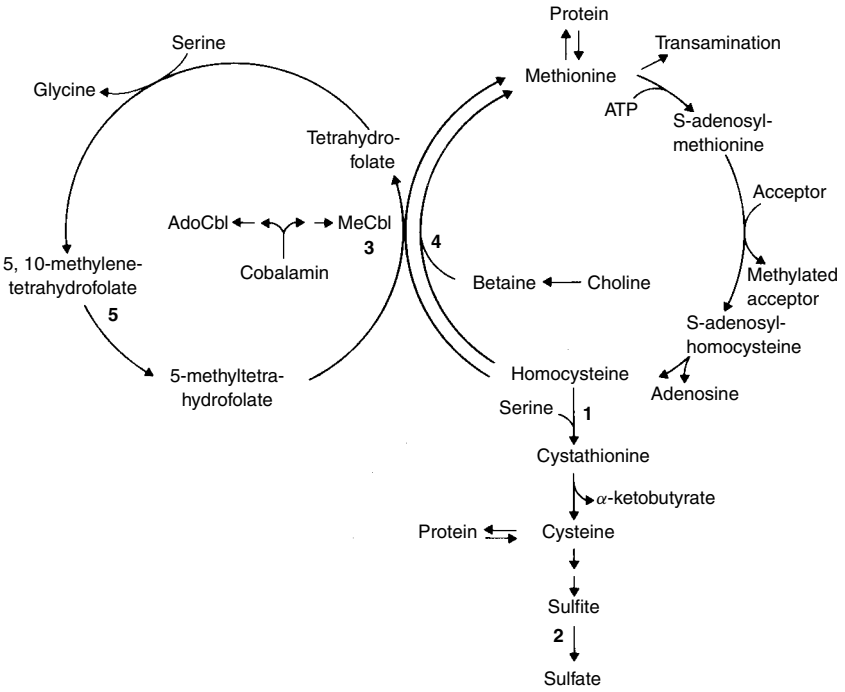

Figure 1. The metabolism of methionine, homocysteine, and tetrahydrofolates. **1**, cystathionine β-synthase, CBS; **2**, sulfite oxidase; **3**, methionine synthase (5-methyltetrahydrofolate-homocysteine *S*-methyltransferase); **4**, betaine-homocysteine *S*-methyltransferase; **5**, methylenetetrahydrofolate reductase. AdoCbl = adenosylcobalamin; MeCbl = methylcobalamin. (Adapted from [2].)

to metabolize at least 20% of the methionine in a patient with very high plasma levels due to deficiency of hepatic methionine adenosyltransferase [23]. In control subjects, however, and even in patients with hypermethioninemia due to deficient CBS, transamination of methionine is of no quantitative significance [24,25].

Molecular Biology and Biochemistry of Cystathionine β-Synthase

CBS catalyzes the replacement of the β-hydroxyl group of serine by homocysteine to form cystathionine in the transsulfuration pathway (reaction 1, Fig. 1). The locus for human *CBS* was mapped to chromosome 21 by study of Chinese hamster-human somatic cell hybrids [26], an assignment corroborated by *in situ* hybridization studies using a cDNA probe for CBS [27]. The gene was subsequently localized more precisely to the subtelomeric region of band 21q22.3 of chromosome 21 [28].

To clone the cDNA for *CBS*, a plasmid library was prepared using rat liver CBS mRNA purified to homogeneity by immunopurification [27]. A partial *CBS* cDNA clone was isolated and used, in turn, to isolate full-length cDNA clones [29,30]. The cDNA with the longest continuous reading frame, type I, was used as a probe to screen a rat genomic library, and genomic inserts were identified that together permitted reconstruction of the organization of the entire rat *CBS* gene. The gene is approximately 25 kbp long, with the coding sequence broken into 18 exons [30,31]. Using the rat *CBS* cDNA as a probe, several human *CBS* cDNAs were isolated from liver and skin fibroblast libraries [13]. The full-length human cDNA is 2,554 nucleotides long and encodes a polypeptide of 551 amino acids. More recently, additional human *CBS* cDNAs have been isolated encoding the most upstream portions of the 5′-untranslated region. The 5′-untranslated region of human CBS mRNA is formed by one of five alternatively used exons, designated −1a to −1e, and one that is invariably present, exon 0, while the 3′-untranslated region is encoded by exons 16 and 17 [32]. Interestingly, intron 16 appears to be retained in the 3′-untranslated region of most of the fibroblast and liver mRNA of every individual [13].

The entire human *CBS* gene was cloned and sequenced in 1998 [33]. In addition to its 23 exons, the 28,046 nucleotides contain approximately 5 kbp of 5′-flanking sequence. The CBS polypeptide is encoded by exons 1–16. Exon 15, the human homolog of rat exon 16, is alternatively spliced and appears to be incorporated in relatively few mature human CBS mRNA molecules. While the exon-intron organization of the human *CBS* gene in the protein-coding region is perfectly conserved with respect to the rat and mouse *CBS* genes, this is not the case for the genomic organization of the untranslated regions [30–33].

There are at least two alternatively used promoters in the human *CBS* gene upstream of exons −1a and −1b. They are GC-rich and contain numerous putative binding sites for proteins known to interact with other promoters such as Sp1, Ap1, Ap2, and c-myb, but they lack the classical TATA box. To evaluate the relative levels of the −1a and −1b promoter activities, reporter constructs were generated by cloning the promoter regions of approximately 400 bp into a luciferase reporter vector. Following transfection of the reporter constructs into COS 7 and HepG cells, analysis of luciferase activity in these cells indicated that both regions contain all of the sequences essential for promoter activity, with the −1b promoter activity being 7–10-fold stronger than that of −1a [33].

An unusually high number of *Alu* repeats may predispose the *CBS* locus to deleterious rearrangements. Additionally, a number of DNA sequence repeats and single base variations that are polymorphic in Caucasians have been reported [13,33]. An insertion of 68 bp in exon 8 (844ins68) was first observed in an allele from a CBS-deficient patient, which also carried the frequent Ile278Thr mutation [34]. The insertion was shown subsequently to be a polymorphism occurring in about 5–10% of Caucasian alleles [35–37]. It duplicates the intron 7 acceptor splice site and may lead to two alternatively spliced transcripts. If the upstream splice site is used, the resulting mRNA will contain the Ile278Thr mutation and a stop codon. If, on the other hand, the downstream site is used, the Ile278Thr mutation and part of the insertion are spliced out, leaving a completely normal *CBS* transcript. Only normal CBS mRNA is detectable in the cytoplasm, whereas both forms are present in the nuclear RNA fraction, suggesting that the abnormal transcript is degraded before it leaves the nucleus [35].

The primary translational product of both the human and the rat *CBS* genes is a polypeptide with a molecular weight of 63 kDa [38]. In fresh liver extracts, the enzyme is found predominantly as a tetramer of this subunit, whereas after a procedure in which the enzyme is first "aged" at 4 °C for 7 days and then purified, CBS is isolated as a dimer of 48 kDa subunits [12,38]. The reduction in size, caused by limited proteolysis, is accompanied by a significant increase in catalytic activity at physiologic concentrations of homocysteine.

CBS has been purified from various vertebrate livers [11,12]. Human *CBS* cDNA has been used in various vector systems to express the human recombinant enzyme in *Escherichia coli* [39], yeast [40], and Chinese hamster ovary cells [13]. Large amounts of recombinant human CBS have been purified from *E. coli* and further characterized [39,41]. Each subunit of CBS binds, in addition to the two substrates, three ligands: pyridoxal 5′-phosphate, S-adenosylmethionine (an allosteric activator), and, surprisingly, heme [41]. It has been suggested that the role of heme in CBS may be catalytic by activating homocysteine [42], similar to the action of zinc in the enzymes involved in remethylation of homocysteine [43,44]. CBS depends fully on the presence of pyridoxal 5′-phosphate for activity [11,45,46], which correlates with the heme saturation. The presence of heme is required for the binding of pyridoxal 5′-phosphate, and the amount of pyridoxal 5′-phosphate bound is limited by the heme content [41]. It has now been demonstrated unequivocally that the residue in CBS forming a Schiff base with pyridoxal 5′-phosphate is Lys 119 [47].

The active core of CBS has been generated by limited digestion with trypsin from the full-length enzyme or, alternatively, by expression of a truncated *CBS* cDNA in *E. coli* [48]. This core, extending from Glu 37 to Arg 413, forms a dimer of 45 kDa subunits. The dimer is about twice as active as the tetramer. It binds both pyridoxal 5′-phosphate and heme cofactors but is no longer activated by S-adenosylmethionine [48]. The 45 kDa active core is the portion of CBS most homologous to the related enzymes isolated from plants, yeast, and bacteria. Similar results were obtained when human *CBS* cDNA containing a premature stop codon at position 409 was expressed in CBS-deficient yeast [49]. The enzyme lacking the carboxyl-terminal 143 amino acids was twice as active as the wild-type enzyme.

Surprisingly, when any one of several human inactivating pathogenic mutations was expressed in yeast in *cis* position with this truncation, CBS activity was restored sufficiently to permit growth of the yeast on medium lacking cysteine. For some mutations, enzyme activities expressed *in vitro* were near wild-type levels.

The displacement of the hydroxyl group of serine by homocysteine proceeds with the retention of configuration [50]. CBS can catalyze alternative β-replacement reactions in which sulfide is a substrate or a product according to the general scheme

$$XCH_2CH(NH_2)COOH + YH \longrightarrow XH + YCH_2CH(NH_2)COOH$$

where X = OH or SH, and Y = SH or S-alkyl [51].

The active core of human CBS shares a high degree of structural similarity (52% if conservative replacements are counted) with the related O-acetylserine sulfhydrases (cysteine synthases) from plants and bacteria [30,52]. These enzymes catalyze the synthesis of cysteine from sulfide and acetylserine. During evolution, the capacity to synthesize cystathionine may have been acquired by broadening the substrate specificity of such enzymes to include homocysteine as well as inorganic sulfide [30].

CYSTATHIONINE β-SYNTHASE DEFICIENCY (MIM 236200)

With more than 700 patients known through an international survey made in 1981–1982 [17], CBS deficiency is by far the most frequent cause of homocystinuria.

Clinical Features and Natural History

The Pyridoxine Response

Based on their biochemical responses in relation to sulfur amino acids in plasma and urine, the majority of patients in the 1981–1982 international survey were classified into two roughly equal groups as being nonresponsive or responsive to pyridoxine [17]. Given our current knowledge, especially about the distribution of homocysteine moieties in plasma, such a classification is an oversimplification. There is a continuum between the two extremes, and the manifestations listed in Table 1 may occur regardless of the extent of the response. In general, so-called pyridoxine-nonresponsive patients present earlier and have more severe phenotypes than patients with a clear response to pyridoxine. The correlation between *CBS* genotype and pyridoxine responsiveness is discussed below.

The Central Nervous System

CBS deficiency often leads to mental retardation. If not detected and treated from early infancy, pyridoxine-responsive and nonresponsive patients have mean intelligence quotients of 79 and 57, respectively [17]. A considerable number of homocystinuric individuals do, however, have normal mental abilities. Epilepsy, most often generalized tonic-clonic seizures, occurs in about 21% of patients, and extrapyramidal symptoms have been noted in several instances [53]. Dystonia, which develops in a high proportion of patients [54], has been mistaken for mental illness [55].

The Eye

Ectopia lentis — that is, subluxation or dislocation of the ocular lens (usually downward, in contrast to Marfan syndrome) due to disruption of its suspensory apparatus — is a highly distinctive feature of CBS deficiency (Fig. 2). It is the clinical sign that most often leads to detection of homocystinuria [17]. Although ectopia lentis has been discovered as early as 4 weeks of age, it is rare in the first two years of life. The risk of ectopia lentis increases with age (Fig. 3). Our current estimate of this risk is probably influenced by ascertainment bias, and the absence of ectopia

lentis at any age should not deter a clinician from screening a patient's urine for abnormal metabolites. Increased curvature of the lens secondary to gradual disintegration of the zonular fibers gives rise to myopia, which usually precedes complete dislocation. On physical examination, ectopia lentis is reflected by iridodonesis, a tremulousness of the iris due to lack of its usual support. Dislocation of the lens into the anterior chamber of the eye may lead to acute angle glaucoma that, if untreated, results in loss of vision of the affected eye. Some of the other ocular abnormalities listed in Table 1 may also be secondary to ectopia lentis.

The Skeleton

Bony abnormalities have been noted in many patients with homocystinuria. Skeletal disproportion due to excessive growth of the long bones is a cardinal feature [56] and one of the causes of confusion with Marfan syndrome. In contrast to the joint laxity of this latter disorder, however, homocystinuric patients often have reduced joint mobility. Other points of differential diagnosis are discussed below. The decreased upper/lower segment ratio of homocystinuric patients may be exaggerated by a scoliosis that is frequently severe enough to require surgical correction (Fig. 4). It is unknown to what extent scoliosis is due to osteoporosis (Fig. 5). In a group of 364 untreated homocystinuric patients all of whom were examined with a lateral radiograph of the spine, the overall risk of having osteoporosis was 50% by age 16 [17] (Fig. 6). The risk is age-dependent and greater in pyridoxine-nonresponsive patients than in

Figure 3. Time-to-event graphs for lens dislocation in untreated patients with cystathionine β-synthase deficiency. Probabilities were calculated from data on the following numbers of patients: all categories, 628; pyridoxine-responsive, 231; pyridoxine-nonresponsive, 231; intermediate response and unclassified, 166. (Reprinted from [17] with permission.)

Figure 4. Kyphoscoliosis and Marfanoid skeletal disproportion in a 15-year-old boy with pyridoxine-nonresponsive cystathionine β-synthase deficiency

responsive patients of the same age. Compared with conventional radiography, determination of bone density by computerized tomography provides a more quantitative measure of the significantly reduced bone mineralization in homocystinuric patients [57]. Osteoporosis may lead to pathological fractures of the long bones and the spine (Fig. 5).

The Skin

The classical description of a patient with homocystinuria includes coarse, wide-pored facial skin with malar flushing, whereas the skin on other body parts is thin, atrophic, or even papyraceous [58–60]. It is not known how frequently these abnormalities occur or how they vary with age. A darkening of the coarse and often fair hair has been observed in some patients during treatment with pyridoxine and betaine [61–63].

The Vascular System

Thromboembolic events in both arterial and venous blood vessels are a major cause of morbidity and mortality in CBS deficiency. The risk of thromboembolism in untreated patients has been estimated from information on 629 individuals with proven or presumed enzyme deficiency out of whom 158 had a total number of 253 events [17]. The predominant locations for thromboemboli were peripheral veins (51%) and cerebral blood vessels (32%); myocardial infarction occurred less often (4%). Vascular events seem to be equally frequent in pyridoxine-responsive and nonresponsive patients, but they generally happen earlier in the latter. The maximal risk of about 0.04 events per year, or one event per 25 years, is attained after age 10. Approximately 50% of all untreated CBS-deficient patients have had a thromboembolic episode by age 25. Endothelial dysfunction and early signs of arterial disease in the absence of ischemic symptoms may be detected by means of ultrasonography [64,65].

Figure 5. Osteoporosis and compression fractures of the lumbar spine. X-ray of 30-year-old woman with pyridoxine-responsive cystathionine β-synthase deficiency

Other Clinical Features

Table 1 lists a variety of other symptoms and signs noted in homocystinuric patients. The frequency with which each of these abnormalities occurs has not been determined, and their individual pathophysiological significance is uncertain.

Laboratory Findings

Patients with CBS deficiency are characterized biochemically by a combination of homocystinuria and hypermethioninemia. Screening for homocystinuria can be done easily by use of a modified cyanide-nitroprusside test [2]. A positive result should be followed by quantitative analysis of amino acids in urine and plasma. Most, but not all, patients with CBS deficiency have plasma concentrations of methionine above the normal range of about 20–40 μmol/L. Hypermethioninemia develops earlier in pyridoxine-nonresponsive patients than in those responsive to pyridoxine. This difference may partly explain the preferential detection of pyridoxine-nonresponsive patients in programs screening neonates for hypermethioninemia [17]. These observations

Figure 6. Time-to-event graphs for radiological spinal osteoporosis in untreated patients with cystathionine β-synthase deficiency. Probabilities were calculated from data on the following numbers of patients: all categories, 364; pyridoxine-responsive, 154; pyridoxine-nonresponsive, 137; intermediate response and unclassified, 73. (Reprinted from [17] with permission.)

and the fact that some patients respond to very small oral doses of pyridoxine make it clear that normal amino acid analyses of blood and urine do not completely rule out deficiency of CBS in a clinically suspect individual. It may be necessary to repeat the studies after a period of no vitamin intake or to measure the catalytic activity of the enzyme directly.

The deficient transsulfuration is responsible for a 10–20-fold increase of free and protein-bound homocysteine as well as for the presence of homocysteine-containing disulfides in plasma. The time- and temperature-dependent protein binding of sulfhydryl moieties complicates measurements of these compounds. If plasma is not deproteinized immediately after sampling, the fraction of protein-bound homocysteine will increase over time and thereby result in lower values of nonprotein-bound (''free'') homocysteine than are found *in vivo* [66]. Total homocyst(e)ine, determined after the release of homocysteine moieties from plasma proteins and disulfides by treatment with reducing reagents, such as 2-mercaptoethanol or dithiothreitol, is a more reliable measure of hyperhomocyst(e)inemia. Untreated CBS-deficient patients may have fasting plasma total homocyst(e)ine levels that are 10–40-fold above the normal adult range of 5–15 μmol/L [67]. Plasma total homocyst(e)ine in healthy individuals is influenced by a number of factors, including age, sex, pre- or post-menopausal status, pregnancy, renal function, lifestyle, and genetic determinants [67].

Cultured skin fibroblasts have been used most often for confirmation of classical homocystinuria, but deficient CBS activity may also be demonstrated in liver tissue, lymphocytes, brain tissue, cultured amniotic fluid cells, and cultured chorionic villi.

Molecular Genetics

CBS Mutations

Work in more than a dozen laboratories around the world has identified 102 different disease-associated mutations in the *CBS* gene among 324 alleles from homocystinuric patients [14]. Most are ''private'' missense mutations. Only four nonsense mutations have been observed; the remainder are various deletions, insertions, and splicing mutations. An up-to-date list of *CBS* mutations is maintained on the CBS Web site at http://www.uchsc.edu/sm/cbs.

Of the 72 missense mutations found in CBS-deficient patients, nearly one-third have been expressed in *E. coli*. All of these had significantly decreased levels of CBS activity. About one-fourth of the missense mutations are found in exon 3 (Fig. 7), which is, evolutionarily, the most conserved part of the *CBS* gene [52,68]. The two most frequent mutations, Ile278Thr and Gly307Ser, are found in exon 8. The Ile278Thr mutation is panethnic and, overall, accounts for almost one-fourth of homocystinuric alleles. In some countries (e.g., the Netherlands), it accounts for more than half of affected alleles [69]. The Gly307Ser mutation is undoubtedly the leading cause of homocystinuria in Ireland (71% of affected alleles) [70]. It has also been detected frequently in U.S. and Australian patients of ''Celtic'' origin, including families with Irish, Scottish, English, French, and Portuguese ancestry. In contrast, the Gly307Ser mutation has not been detected among a large number of alleles in Italy, the Netherlands, Germany, and the Czech Republic. The finding of Gly307Ser in Norway may indicate that it originated in Scandinavia and spread elsewhere [71].

The third most frequent alteration is a splice mutation in intron 11, IVS 11-2 A>C, which results in skipping of the entire exon 12 (Fig. 7). It has been found in Germany in about 20% of affected chromosomes of German and Turkish origin [72]. Surprisingly, it has never been detected in Italy or the Netherlands among nearly 70 alleles studied. Together with the Ile278Thr mutation, IVS 11-2 A>C is the most prevalent mutation in patients of Czech and Slovak origin.

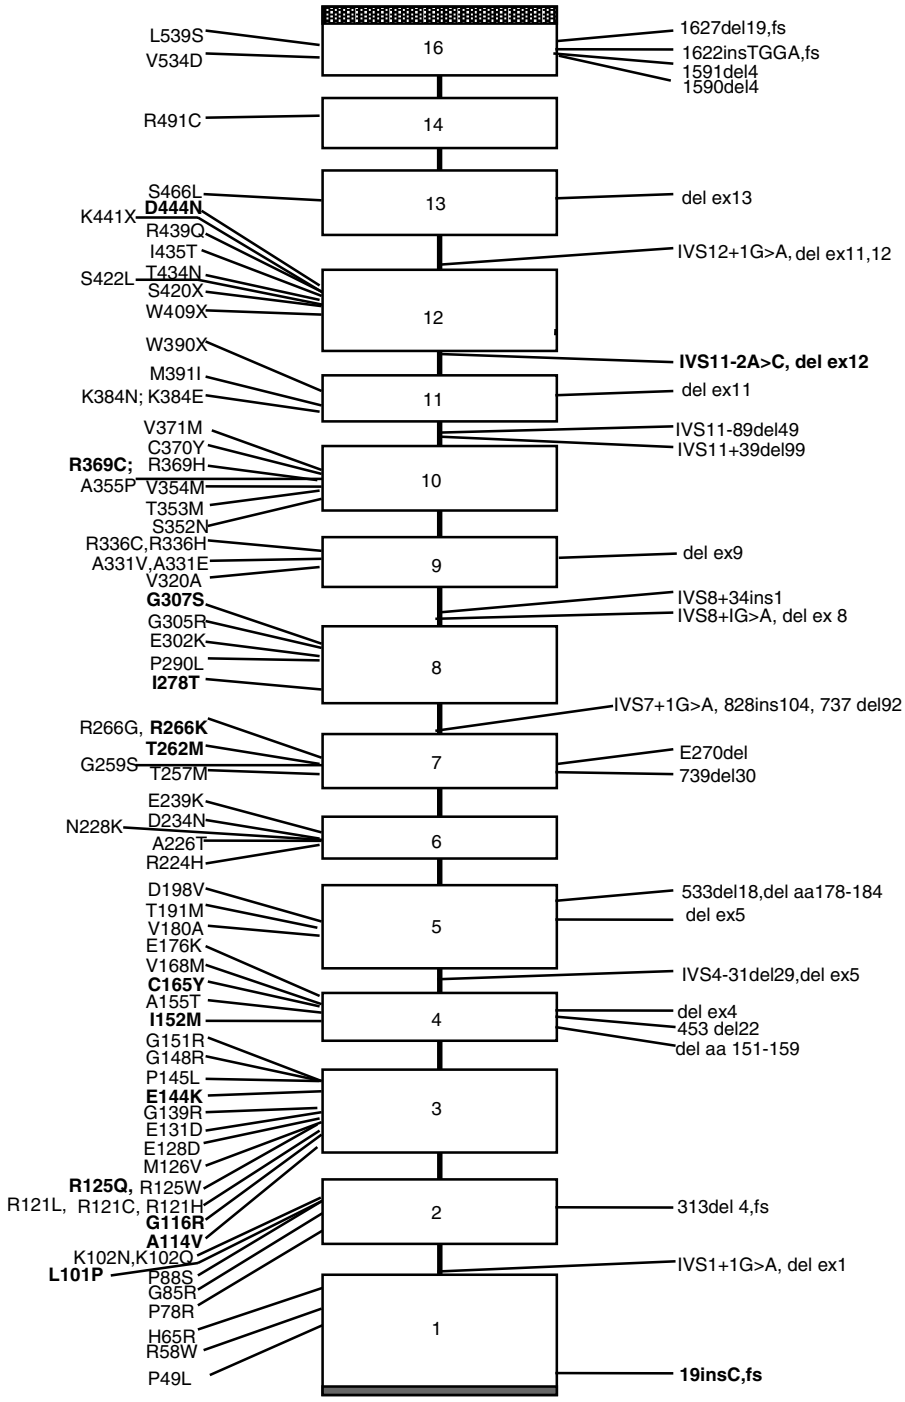

Figure 7. Location of human *CBS* mutations. The exons in the coding region are drawn to scale; the introns are not. The shaded areas are parts of the 5′- and 3′-untranslated regions of CBS mRNA found in exon 1 and exon 16, respectively. The mutations shown on the left are missense and nonsense; the mutations on the right are deletions, insertions, and splicing errors. The mutations shown in bold have been detected in three or more alleles.

Several other, less common splicing mutations as well as insertions and deletions have been found. Some of these mutations result in a frame shift, which, in turn, introduces a premature termination codon.

In nine isolated cases, the mutation has been linked to another mutation on the same allele [14,73]. Most of these mutations have been reproduced separately by *in vitro* mutagenesis, and each has been found to be deleterious to CBS activity. Cystic fibrosis and Gaucher disease (see Chapter 22, this volume) are other examples of diseases with double mutations in *cis* position [74,75]. In Gaucher disease, such alleles are thought to arise from recombination between

the glucocerebrosidase gene and its adjacent pseudogene. The origin of double mutant alleles in the *CBS* gene is not clear because there is no evidence of a *CBS* pseudogene in the human genome. Homologous recombination between the numerous *Alu* sequences or other repetitive elements within the *CBS* gene is an alternative explanation for some of the *CBS* double mutations found in *cis* position [33].

Genotype and Pyridoxine Responsiveness

The majority of homocystinuric patients are compound heterozygotes, with the exception of Ile278Thr/Ile278Thr and Gly307Ser/Gly307Ser homozygotes. The Ile278Thr mutation usually confers pyridoxine responsiveness, whether in the homozygous or the compound heterozygous state (Table 2). With the exception of a group of Dutch patients [69], the clinical phenotype in many of these patients appears to be mild [76]. Although the genotype by itself does not predict the phenotype, several general statements can be drawn from Table 2. In addition to the Ile278Thr mutation, the Ala114Val, Arg266Lys, Ile278Thr, Arg336His, Lys384Glu, and Leu539Ser mutations appear to correlate with pyridoxine responsiveness *in vivo*. On the other hand, the Arg121Leu, Arg125Gln, Cys165Tyr, Glu176Lys, Thr191Met, Thr257Met, Thr262Met, and the frequent Gly307Ser mutation, in one or two copies, appear to be incompatible with pyridoxine responsiveness. Accordingly, patients carrying the Gly307Ser mutation seem to have moderate to severe phenotypes, except for those who have been treated since birth [70]. While pyridoxine responsiveness is constant within sibships, the clinical phenotype often is not [14].

Inheritance and Prevalence

Analysis of pedigrees, enzyme studies of family members, and molecular genetic investigations have firmly documented the autosomal recessive inheritance of CBS deficiency.

The frequency of infants detected by neonatal screening programs varies greatly among different geographic locations, from 1:65,000 in Ireland to 1:900,000 in Japan [77]. The worldwide frequency is 1:344,000 [2]. The reported frequencies may be falsely low due to the failure of amino-acid–based screening programs to detect the majority of pyridoxine-responsive patients. Thus, DNA-based screening of 500 newborns in Denmark showed 1.4% of them to be heterozygous for the Ile278Thr mutation [78]. This corresponds to a homozygote frequency of at least 1:20,500, or 3–4 children per year. Since the authors are not aware of any children diagnosed with classical homocystinuria in Denmark over the past decade, most of these predicted patients have failed so far to reach clinical recognition.

Pathology and Pathophysiology

Despite many studies performed since the 1970s, satisfactory pathophysiological explanations are lacking for most of the clinical manifestations of CBS deficiency. The slow progress in this area of our knowledge has, to a large extent, been due to the absence of a suitable animal model for experimental studies.

Excision of exons 3 and 4 from the mouse *CBS* gene by homologous recombination has generated a CBS knockout mouse [79]. Surprisingly, total CBS deficiency in mice is highly deleterious, with more than 80% of animals dying at a postnatal age of eight weeks. Although the levels of plasma total homocyst(e)ine measured in these mice are comparable to those of human patients, the mice suffer from severe growth retardation and liver damage, characterized by enlarged and multinucleated hepatocytes with lipid droplets and by extramedullary hematopoiesis. Heterozygote mice had liver CBS activity equal to 42% of that of wild-type animals, and plasma total homocyst(e)ine increased twofold above normal for mice. Clinically, the heterozygotes did not have vascular disease or other abnormalities. Further experiments will show the extent to which this animal model

will help to elucidate the pathophysiology of human CBS deficiency.

The Central Nervous System

Ischemic changes due to vascular thromboses or emboli are the only neuropathological abnormalities consistently reported. White matter vacuolar degeneration, hippocampal neuronal loss, and gliosis have been observed in the absence of vascular changes [80,81]. A pathological correlation with dystonic clinical features has suggested a functional disturbance [53]. Indeed, most patients with neurological dysfunction have no focal signs or neuroimaging changes compatible with cerebrovascular disease [82]. Homocysteine, but not methionine or S-adenosylmethionine, induces seizures and epileptiform electroencephalographic activity in rodents after intraperitoneal administration [83]. The neurochemical pathways through which homocysteine or related metabolites cause seizures, extrapyramidal symptoms, and mental retardation are open to speculation. Proposed mechanisms include impairment of brain homeostasis by trapping of adenosine by homocysteine, thereby forming S-adenosylhomocysteine [84], and overproduction of homocysteic acid and homocysteine sulfinic acid, which are excitotoxic (i.e., they cause neuronal damage due to excessive activation of glutamate receptors) [85,86]. CBS is highly expressed in the hippocampus, and CBS deficiency may impair the endogenous production of hydrogen sulfide from L-cysteine and its potential role as a neuromodulator [87]. Dystonia could result from reduced levels of taurine in the basal ganglia or from an effect of folate deficiency on dopaminergic neurotransmission [53].

The Eye

Pathological examination of eyes from CBS-deficient patients with ectopia lentis reveals disrupted zonular fibers attached to either the ciliary body or the lens itself [88,89]. The masses of disrupted fibers contain microfilaments structurally similar to those found in normal zonular fibers but with a degree of disorganization proportional to the age of the patient [90]. The biochemical events behind the disruption are not clear, but several observations of the composition of zonular fibers relate to sulfur amino acid metabolism and connective tissue pathology. Zonular fibers contain the glycoprotein fibrillin, which has a high content of cysteine but lacks the hydroxyproline and hydroxylysine typical of collagen. In this regard, as in their susceptibility to proteases, zonular fibers are like microfibrils of elastin [91–96]. Isolated human zonules are remarkable for their very high cysteine content and no significant amounts of hydroxyproline or hydroxylysine. This implies an important role for intermolecular disulfide bonds in the structure of zonular fibers. Biochemical studies of isolated zonular fibers or fibrillin from homocystinuric individuals, however, have not been reported, and the absence of an appropriate animal model limits the source of material available for laboratory studies. A decreased number of disulfide bonds in zonular proteins of CBS-deficient patients, resulting in impaired functional ability, could be due to interference with the process of disulfide bonding by any of a number of sulfur-containing compounds, including homocysteine, present in increased amounts in homocystinuric individuals. Deficiency of cysteine during formation of the zonular fibers might impair total protein synthesis or diminish glutathione concentrations, thereby altering the redox environment of the cell. The pathophysiological mechanism, yet to be identified, that produces ectopia lentis in CBS deficiency may operate in the same manner in sulfite-oxidase–deficient patients who also have ectopia lentis and an abnormal sulfur amino acid metabolism (but no hyperhomocysteinemia).

The Skeleton

Homocysteic acid, an oxidation product of homocysteine, is found in the urine of homocystinuric patients [97] and in normal human serum [98]. Homocysteic acid was reported to promote growth of hypophysectomized rats, thereby providing an explanation for the excessive length of the long bones in homocystinuria [99]. Intraperitoneal administration of homocysteic acid caused increased tail growth and increased thickness of the epiphyseal cartilage of the tibia, but other workers using larger numbers of animals could not reproduce these observations [100].

In an *in vitro* study using a clonogenic assay, homocysteine, but not homocysteic acid, correlated strongly with the growth-promoting activity of plasma cyclin–dependent kinase [101]. This observation supports earlier theoretical considerations as well as experimental data, which pointed toward a role for homocysteine in the pathophysiology of osteoporosis in homocystinuric patients. McKusick first proposed that excess homocysteine might interfere with the normal synthesis of collagen cross-links [102]. An increased proportion of collagen extractable with 0.5 mol/L acetic acid from skin biopsies was subsequently reported in two of four patients with homocystinuria [103]. Three additional homocystinuric patients with decreased amounts of precursor aldehydes and cross-link compounds in dermal collagen have also been described [104]. Two of these patients, unresponsive to pyridoxine, also had significantly increased solubility of dermal collagen under nondenaturing conditions when compared with controls and one pyridoxine-responsive patient.

Homocysteine may exert its effect on collagen by a mechanism analogous to that of D-penicillamine, which is structurally similar to homocysteine. D-penicillamine has been shown to increase the solubility of collagen, particularly in soft tissues, either by reacting with the lysyl, and to a lesser extent hydroxylysyl, aldehydic groups required for cross-linking [105] or by interfering with polyfunctional cross-link formation from Schiff-base bifunctional cross-links [106]. Support for this idea came from laboratory studies of purified skin collagen in solution in which homocysteine was able to inhibit the synthesis of cross-links [104]. Insoluble collagen fibrils failed to form at high concentrations of homocysteine (10^{-2}–10^{-1} mol/L), and much smaller amounts of cross-link compounds were demonstrated in the presence of homocysteine than in preparations containing similar concentrations of methionine or homocystine.

Lubec et al. [107] have reported measurements in plasma of the terminal propeptides of type I and type III procollagens, which reflect collagen synthesis, and in serum of the carboxyl-terminal telopeptide of collagen I, which reflects collagen cross-linking. Only in the latter measurement was there a significant reduction in the group of nine patients with CBS deficiency compared with the control group. These results support McKusick's hypothesis of deficient collagen cross-linking as an explanation for the osteoporosis in homocystinuria. Alternatively, the effect of homocysteine on connective tissue could be due to direct inhibition of lysyl oxidase. As discussed in Chapter 2 of this volume, this pyrroloquinoline quinone and copper-dependent enzyme catalyzes the cross-linking of collagen

and elastin. *In vitro* studies of lysyl oxidase purified from embryonic chick cartilage showed inhibition of catalytic activity at concentrations of homocysteine greater than 10^{-3} mol/L, whereas little inhibition occurred at concentrations lower than 10^{-4} mol/L or with methionine or homocystine [106,108,109]. In a study of chicks with vitamin B_6 deficiency, which results in reduced lysyl oxidase activity, light microscopy showed abnormalities in the extracellular matrix of the connective tissues, but cross-links and aldehydic content were not significantly lower in cartilage and tendon collagens than in age-matched controls [110]. The activity of lysyl oxidase in cells or tissue from CBS-deficient patients has not been explored.

Homocystinuric patients have abnormally high levels of plasma total copper due to an unexplained increase in ceruloplasmin [111]. Any possible limitation of lysyl oxidase activity is therefore unlikely to be due to shortage of copper. Deficiency of pyridoxine and the use of pyridoxine antagonists have been shown experimentally to decrease cross-linking of collagen, possibly by reducing the activity of lysyl oxidase [112,113], and to decrease cross-linking in lung elastin [114]. However, homocystinuric patients usually show no evidence of pyridoxine deficiency. Asthma has been noted in several patients [60], but neither lung elastin nor the incidence of pulmonary disorders of CBS-deficient patients has been studied in any detail.

The Skin

Because the thin or papyraceous skin of some homocystinuric individuals resembles that of patients after prolonged use of penicillamine, a homocysteine-induced defect of collagen cross-linking, as discussed above, has been proposed to account for the cutaneous pathology in homocystinuria. In addition to the biochemical evidence mentioned previously, a limited number of histological observations point to defects in the connective tissue elements of the skin. Light microscopy of skin from an 8-year-old boy revealed an uneven, granular distribution of collagen fibers in the superficial dermis and too few fibers in the deeper dermis; their ultrastructure was normal [115]. Fragmented and thickened elastic fibers have been observed by both light and electron microscopy of skin from homocystinuric patients [115,116].

Some patients have a hypopigmentation of hair and skin that is reversible after treatment for hyperhomocysteinemia. Experimental evidence has been presented to suggest that homocysteine at concentrations of 110 μmol/L or above inhibits the activity of tyrosinase, the major pigment enzyme [63]. The probable mechanism of this inhibition is an interaction of homocysteine with copper at the active site of tyrosinase.

The Vascular System

Early reports on the clinical manifestations of homocystinuria documented remarkable abnormalities of the arterial walls of patients who had suffered thromboembolic events [117–119]. The gross and microscopic appearance of the blood vessels resembled that of advanced atherosclerosis, which, for the age of the patients, was greatly premature. Following the discovery of vascular pathology in young individuals with homocystinuria due to defects of remethylation, and therefore no elevation of plasma methionine, McCully formulated "the homocysteine theory of arteriosclerosis" [120]. The vascular lesion typical of homocystinuria, irrespective of the responsible enzymatic deficiency, is a fibrous plaque with smooth muscle hyperplasia, deposition of extracellular matrix and collagen, and degeneration and destruction of elastic fibers [121]. Although this description suggests abnormalities of collagen and/or elastin, these changes do not seem to result in vascular complications from weakness of the vascular wall, nor have such changes been shown to cause the observed, widespread endothelial damage. In addition, venous thromboemboli are the most frequent vascular manifestation of homocystinuria [17], yet little pathology of the veins has been reported.

The association of early atherosclerosis and thromboembolism with hyperhomocysteinemia has attracted the interest of many investigators. Detailed reviews of pertinent data can be found elsewhere [1,67,122]. Hypotheses have included endothelial injury [123–127], increased thrombogenesis [128–131], abnormal clotting [132–134], enhanced collagen production [135], decreased availability of nitric oxide [136], and abnormal metabolism of lipoproteins [137,138]. Lipids, however, are notably absent from the vascular plaques seen postmortem in homocystinuric patients [121].

Despite these and other investigations to clarify the pathogenic potential of homocysteine, the exact sequence of pathophysiological events remains obscure. Perhaps other predispositions to cardiovascular disease are required for hyperhomocysteinemia to trigger thrombosis. Thus, in a study of 11 patients with classical homocystinuria, thromboses were observed in only six patients, who also carried the factor V Leiden mutation [139]. Screening for a wide range of cardiovascular risk factors therefore is important in patients with hyperhomocysteinemia.

Mild Hyperhomocysteinemia and Vascular Disease

Wilcken and Wilcken [140] reported in 1976 that seven of 25 patients with coronary heart disease, but only one of 22 control subjects, had elevations of plasma nonprotein-bound homocysteine following a standardized methionine load. Data from about 80 clinical and epidemiological studies, including more than 10,000 patients, have confirmed since that mild hyperhomocysteinemia is a risk factor for vascular disease [67].

Hyperhomocysteinemia without homocystinuria may have several explanations. The degree of homocysteinemia observed in some patients with vascular disease is of the magnitude seen in heterozygotes for CBS deficiency, and such heterozygosity was initially thought to account for about 30% of patients with premature occlusive arterial disease [141]. Subsequent molecular analysis, however, failed to reveal any pathogenic mutations in patients with vascular disease and mild hyperhomocysteinemia [142].

Mild hyperhomocysteinemia is observed also in individuals deficient in cobalamin (vitamin B_{12}) and folate [143–145] as well as in some patients with renal disease, cancer, or psoriasis [66]. Supplements of B vitamins, especially folic acid, can safely reduce plasma total homocyst(e)ine [67]. Deficiencies of cobalamin or folate are not known to be associated with premature atherosclerosis, and there is as yet no evidence that lowering mildly elevated homocysteine with supplements of these vitamins can reduce the risk of vascular disease.

It is conceivable that mild hyperhomocysteinemia is an epiphenomenon of vascular disease. In a study of endothelial dysfunction and acute hyperhomocysteinemia induced by a methionine load, flow-mediated vasodilatation was completely prevented by folic acid supplementation, which did not attenuate the hyperhomocysteinemia [146]. Any explanation of vascular disease due to mild hyperhomocysteinemia will also have to contend with the apparent paucity of vascular episodes in patients with homocystinuria who, despite

dietary and drug therapy, maintain severely elevated plasma total homocyst(e)ine [18,19,147].

Differential Diagnosis

Isolated bilateral ectopia lentis (MIM 129600) may occur as an autosomal dominantly inherited disorder of either congenital or late spontaneous onset. Ectopia lentis and arachnodactyly are frequent findings in Marfan syndrome (MIM 154700) (Chapter 12, this volume), but patients with this dominant disorder have no increased incidence of mental retardation, and their vascular symptoms are usually due to dilatation or dissecting aneurysm of the aorta rather than to thromboembolism. Infants with ectopia lentis should also be examined for deficiency of sulfite oxidase, as discussed at the end of this chapter. Affected children have neurological symptoms and failure to thrive but no manifestations in the skeletal or vascular systems. Furthermore, ectopia lentis is also seen in Weill-Marchesani syndrome (MIM 277600), of which short stature and brachydactyly are additional features, and in occasional patients with Ehlers-Danlos syndrome (Chapter 9, this volume) [148]. The presence of homocystinuria distinguishes deficiency of CBS from all of these disorders.

Homocystinuria, on the other hand, may be caused also by deficient methylenetetrahydrofolate reductase activity or by inherited or acquired states of cobalamin deficiency. These disorders, discussed in more detail below, may be accompanied by mental retardation and thromboembolism but not by ectopia lentis or skeletal abnormalities. Urine should routinely be examined by gas chromatography for the presence of methylmalonic acid due to deficient cobalamin cofactor. Patients with deficient remethylation of homocysteine have low or low-normal concentrations of plasma methionine in contrast to the hypermethioninemia usually seen in CBS deficiency. Definitive diagnosis of the latter can, of course, be established by an absent or significantly reduced enzymatic activity in extracts of cells from a suspected patient.

Management and Prognosis

Treatment of CBS-deficient patients includes methionine restriction to decrease the homocysteine load, cystine supplementation to avoid cysteine deficiency, pyridoxine to increase the residual activity of the enzyme, folate and hydroxycobalamin to correct and prevent respective deficiencies, betaine to increase remethylation of homocysteine to methionine, and antithrombotic agents.

Methionine Restriction

Most homocystinuric individuals diagnosed in early infancy have been managed with methionine restriction. The synthetic formulas with no or low content of methionine that are available for use in children are supplemented with cystine to avoid cysteine deficiency. This is especially important in early life, when cystine may be an essential amino acid [149]. In addition to the formula, the child must receive sufficient methionine from natural proteins to sustain linear growth. The immediate goal of management is to keep blood and urine homocyst(e)ine as low as possible. The long-term results of therapy with methionine restriction have been very encouraging [17,19]. Most children treated since early infancy have normal intelligence, and significantly fewer suffer from ectopia lentis than would have been expected without treatment. In addition, results on pyridoxine-nonresponsive patients diagnosed by neonatal screening in Ireland suggest a significant reduction in the incidence of thromboembolic events [19]. Early treatment of homocystinuria also reduces the incidence of osteoporosis [150].

The unpalatability of a methionine-restricted diet, however, especially in the form of a synthetic formula, makes its use less easily acceptable when introduced after infancy.

Pyridoxine

Identification of an individual with homocystinuria due to deficiency of CBS should prompt a determination of the patient's biochemical responses to oral administration of pyridoxine. Occasional patients improve or normalize their abnormal levels of sulfur amino acids in plasma and urine in response to only a few milligrams of pyridoxine, but most require daily doses of more than 100–200 mg; some patients need 500–1,000 mg daily in order to respond. The classification of many patients as responsive to pyridoxine has probably not taken into account their levels of total plasma homocyst(e)ine, and it is therefore uncertain how many patients have a complete or only a partial biochemical response to these doses of pyridoxine. When exceeding a daily dose of 500 mg, the possibility of pyridoxine-induced neuropathy must be kept in mind [151–153]. Treatment with pyridoxal phosphate at 1,000 mg/day caused hepatic dysfunction in one pyridoxine-nonresponsive patient who subsequently had no untoward reaction to pyridoxine hydrochloride at 1,800 mg/day [154].

Depletion of folate has been reported to obscure the response to pyridoxine in patients otherwise responsive [155]. To optimize the folate-dependent remethylation of homocysteine, most patients therefore have routinely received folate supplements of the order of 5 mg daily, along with pyridoxine. Care should be taken also to ensure that patients are not vitamin B_{12}-deficient.

Determination of time-to-event graphs (e.g., Figs. 3 and 6) for the various major manifestations of untreated CBS deficiency has permitted comparisons with patients treated with pyridoxine (with or without folate supplements) [17]. Because the mainstay of therapy of patients detected as newborns has been methionine restriction, an evaluation of the effect of pyridoxine has been possible only in late-detected pyridoxine-responsive patients, in whom such treatment significantly reduces the rate of occurrence of thromboembolic events.

Betaine

Early interest in the treatment of homocystinuric patients with the methyl donor betaine (trimethylglycine), or its precursor choline, abated due to the high concentration of methionine caused by the treatment [15,156]. As more experience with hypermethioninemic patients has accumulated, and such concern has lessened, several groups have reported the beneficial effects of prolonged treatment with betaine [18,19,62,157,158]. Anhydrous betaine in daily doses of 100 mg/kg is well-tolerated, and treatment of adult patients with 12–15 g/day seems to be without side effects. Even larger doses have been used in children with defects of homocysteine remethylation [159]. Pyridoxine-nonresponsive patients unable to comply with methionine restriction are the prime candidates for betaine treatment. Betaine reduces total homocyst(e)ine in both plasma and cerebrospinal fluid [160]. Reported clinical effects include darkening of new hair growth, improved behavior, and better control of seizures [15,62]. Importantly, among 15 pyridoxine-nonresponsive homocystinurics during 258 patient-years of treatment, betaine contributed to a highly

significant reduction in the number of thromboembolic episodes [18].

Treatment of pyridoxine-responsive patients with pyridoxine and folate does not prevent an abnormal rise of plasma homocyst(e)ine following a methionine load [161,162]. Addition of betaine to the standard regimen of pyridoxine and folate virtually normalizes the homocysteine response in pyridoxine-responsive patients who therefore also may benefit from this form of therapy [158].

Antithrombotic Agents

Aspirin and dipyridamole have been used in many CBS-deficient patients on the assumption that these agents reduce the risk of thrombosis. No studies have evaluated their efficacy, however, in hyperhomocysteinemic patients. Because the pathophysiological mechanisms behind the vascular events are unknown, as discussed above, no recommendations can currently be made as to the use of antithrombotic agents in homocystinuria.

Mortality

Early survivorship data suggested 50% mortality by age 20 [163], but subsequent analysis of more than 600 patients, including many with mild clinical manifestations of homocystinuria, gave evidence of a much better prognosis [17]. The mortality at age 20 was less than 5% among pyridoxine-responsive patients and approximately 20% in those not responsive to pyridoxine. Early dietary intervention and treatment with pyridoxine and betaine seem to further improve these numbers [18,19].

Prenatal Diagnosis

Prenatal diagnosis of CBS deficiency has been performed in both the first and the second trimesters of pregnancies at risk. Fowler and colleagues [164] were first to report the diagnosis of an affected fetus by enzyme assay of an extract of cultured amniotic fluid cells. The range of catalytic activity in cultured cells from heterozygotes overlaps the ranges of both homozygous normal and homozygous abnormal cells. Deficiency of CBS has also been diagnosed, as well as excluded, in the first trimester of several pregnancies by assay of extracts of cells grown from chorionic villi. Chorionic villus biopsies themselves contain insufficient activity for direct assay of CBS.

DNA analysis for first-trimester prenatal diagnosis of CBS deficiency is possible in the few families in which the mutant alleles have been studied previously. The genetic heterogeneity mentioned previously complicates mutation analysis of the majority of probands with CBS deficiency.

DISORDERS OF FOLATE AND COBALAMIN METABOLISM AFFECTING HOMOCYSTEINE REMETHYLATION

A growing number of inborn errors other than CBS deficiency have been found to cause homocystinuria. The common denominator for these metabolic defects is an impaired remethylation of homocysteine to methionine, a reaction catalyzed by methionine synthase (reaction 3, Fig. 1). This enzyme uses 5-methyltetrahydrofolate and methylcobalamin as cosubstrate and cofactor, respectively. Deficient remethylation of homocysteine may therefore result from an inadequate supply of 5-methyltetrahydrofolate due to deficiency of methylenetetrahydrofolate reductase (reaction 5, Fig. 1). It may also be caused by a number of different defects in the biosynthesis of cobalamins. Genetic heterogeneity explains some of the marked clinical variability of these disorders that do not, in general, have connective tissue manifestations. All pedigrees reported so far are compatible with autosomal recessive inheritance.

Methylenetetrahydrofolate Reductase Deficiency (MIM 236250)

Since the original description by Mudd and his colleagues [165], information has been published on approximately 50 patients with severe deficiency of methylenetetrahydrofolate reductase ($NADPH_2$) [3,166–168].

Clinical Features

The age at presentation varies greatly. Table 3 lists some of the clinical abnormalities observed in affected individuals. Most patients present in early childhood or adolescence with neurological dysfunction, psychiatric abnormalities, or failure to thrive. Respiratory difficulties are frequent in the terminal phase of patients with severe neurological damage. Symptoms or signs directly referable to the vascular system have not been observed in living patients. Anemia is unusual, and the lack of megaloblastic anemia is an important point in the differential diagnosis against other inborn errors of homocysteine remethylation.

Biochemical Abnormalities and Molecular Genetics

The homocystinuria and hyperhomocysteinemia of methylenetetrahydrofolate reductase-deficient patients are usually milder than those seen in CBS deficiency. The concentrations of methionine in plasma and cerebrospinal fluid are often low and result in correspondingly low levels of S-adenosylmethionine [169]. The concentrations of folates are reduced in serum and red cells. In addition to low folates, several patients have also had reduced concentrations of neurotransmitter amine metabolites in the cerebrospinal fluid [169–171].

Deficient activity of methylenetetrahydrofolate reductase can be demonstrated in liver, leukocytes, lymphoblasts, and cultured skin fibroblasts from affected patients. The presence of activity in cultured amniotic fluid cells and in chorionic villi allows prenatal diagnosis in the first or second trimester of at-risk pregnancies [172].

Molecular studies have revealed genetic heterogeneity and a good correlation between the genotype, residual enzyme activity, and age at onset and severity of symptoms [166,168]. Five unrelated patients with the lowest levels of enzyme activity (0–3% of control) were each homozygous for one of three mutations. These patients had had onset of symptoms in the first year of life, with a severe form of the disorder and, in some cases, an early demise [166].

Deficiency of methylenetetrahydrofolate reductase due to a thermolabile variant of the enzyme can cause

TABLE 3. Clinical Abnormalities in Homocystinuria Due to Methylenetetrahydrofolate Reductase Deficiency

Lethargy	

mild hyperhomocysteinemia. A single C677T nucleotide exchange resulting in an alanine-to-valine substitution appears to account for most, if not all, such cases [173]. The allele carrying C677T has a frequency of 35–40% in some populations [166,173], and its association with cardiovascular disease in initial reports of homozygosity generated considerable interest. More recent analyses seem to document, however, that although this variant of methylenetetrahydrofolate reductase is associated with hyperhomocysteinemia, it does not increase the risk of vascular disease [174,175].

Pathology and Pathophysiology

Postmortem investigations have been performed in at least 11 children or adolescents with proven or presumed methylenetetrahydrofolate reductase deficiency [171,176,177]. In six of these individuals, vascular occlusions were thought to have contributed significantly to the cause of death. On gross and microscopic examination, the vascular lesions were similar to those observed in CBS deficiency, albeit more severe than one would have expected from the milder aminoacidemia. The accumulated evidence from the two disorders strongly invokes homocysteine as the causative agent of the vascular disease, but the observations made on methylenetetrahydrofolate reductase-deficient patients do not improve our understanding of the vascular pathophysiology of hyperhomocysteinemia.

The neurological manifestations of methylenetetrahydrofolate reductase deficiency can, in contrast to those seen in CBS deficiency, be correlated with consistent neuropathological findings, including cerebral atrophy, gliosis, and demyelination in the brain [177]. Subacute combined degeneration of the spinal cord, a well-known complication of cobalamin deficiency, has been observed in two affected children with fatal courses of progressive demyelination [171,177]. An inadequate supply of methionine or S-adenosylmethionine to the brain, a low concentration of folate in the cerebrospinal fluid, and low levels of amine neurotransmitters could, alone or in combination, play a role in the pathogenesis. There is good evidence for an association between deficient S-adenosylmethionine and demyelination [169,178,179].

There is no animal model that corresponds to the enzyme deficiency in humans. Nitrous oxide (N_2O) inactivates methionine synthase by oxidation of the cobalamin cofactor, and anesthesia with nitrous oxide has been used in monkeys to produce a neuropathy that resembles subacute combined degeneration [180]. The use of nitrous oxide may have precipitated developmental regression and fatal respiratory symptoms in one infant with deficient methylenetetrahydrofolate reductase [171].

Management and Prognosis

Treatment of patients with methylenetetrahydrofolate reductase deficiency has included folic acid, methyltetrahydrofolate, methionine, pyridoxine, cobalamin, carnitine, and betaine [3]. Most patients have received a combination of two or more agents. Administration of folic acid to a 2-year-old girl caused convulsions and acute deterioration of her Parkinsonism [171]. Pyridoxine further aggravated the neurological dysfunction of another patient [181]. Betaine, on the other hand, has had a beneficial effect in all patients in whom it has been used. When started in the neonatal period, therapy including betaine may prevent or improve neurological symptoms. Concentrations of methionine in the cerebrospinal fluid and, probably, of S-adenosylmethionine in the brain appear to be proportional to the daily dose of betaine [169]. Doses of up to 1–1.5 g/kg/day or 20 g/day have been used without side effects [159,168]. Nevertheless, the available data indicate that most patients with methylenetetrahydrofolate reductase deficiency have a poor prognosis. However, ascertainment bias toward the reporting of more severely affected patients, the limited number of patients known, and their genetic heterogeneity should be taken into account.

Inherited Disorders of Cobalamin Metabolism

Only two reactions in mammalian tissues require derivatives of vitamin B_{12}, or cobalamin (Cbl), as cofactors (Fig. 8). One is the conversion of methylmalonyl-CoA to succinyl-CoA by methylmalonyl-CoA mutase (EC 5.4.99.2), which depends on adenosylcobalamin (AdoCbl) for activity. The other is the methylation of homocysteine to methionine by methionine synthase, which requires methylcobalamin (MeCbl). Patients with inborn errors of metabolism causing reduced availability of AdoCbl and/or MeCbl may have methylmalonic aciduria (cbl A and B diseases), homocystinuria (cbl E and G diseases), or both (transcobalamin II deficiency, cbl C, D, and F diseases). Classification into separate genetic entities has been achieved by complementation analysis. Inheritance of all of these disorders is autosomal recessive. Figure 8 shows where the defects are localized in the cobalamin pathway; only those involving homocysteine are mentioned below. Clinically, neurological dysfunction, psychiatric signs, and hematological abnormalities characterize disorders with homocystinuria due to defects of cobalamin biosynthesis; they do not involve connective tissue.

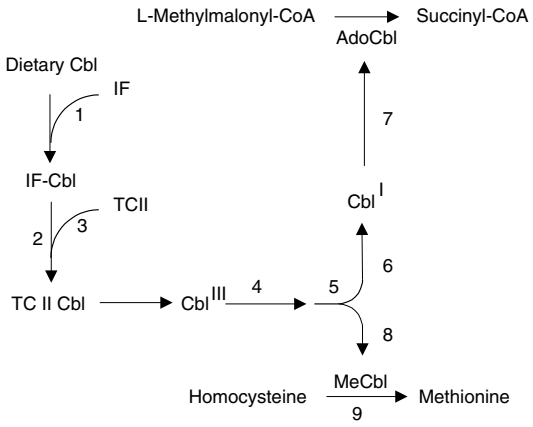
Transcobalamin II Deficiency (MIM 275350)

Transcobalamin II is the major protein carrier of cobalamin in plasma. After recognition by a specific receptor in the cellular membrane, the transcobalamin II-cobalamin complex is endocytosed, transported into lysosomes, and degraded. Cobalamin is then released and used as a cofactor in the cytosol or in mitochondria. Findings in the approximately 40 known infants with genetic deficiency of transcobalamin II include megaloblastic anemia, neurologic abnormalities, immune deficiency, methylmalonic aciduria, and homocystinuria [182]. Deletions in the transcobalamin II gene have been detected in one patient [183]. Patients respond clinically to cobalamin given intramuscularly.

cbl C (MIM 277400), cbl D (MIM 277410), and cbl F (MIM 277380) Diseases

More than 100 patients are known with cbl C disease [182]. Of the 50 patients reported in a survey by Rosenblatt and co-workers, 44 had onset in infancy with feeding difficulties, hypotonia, seizures, ophthalmologic abnormalities, and megaloblastic changes [184]. One-quarter of these children died, and all but one survivor had psychomotor retardation. Onset of cbl C disease later in childhood or adolescence was associated with less severe hematological abnormalities, extrapyramidal signs, dementia, delirium, or psychosis. Some, but not all, of these late-onset patients had mild to moderate neurologic impairment at follow-up [184]. One of the two brothers reported to have cbl D disease was diagnosed at age 14 during admission for acute psychosis; he was mildly retarded and had had a total of four thromboembolic episodes [185]. The pathogenic mechanisms behind cbl C and D diseases are thought to involve the reduction of cobalamin in the cytosol (reaction 5, Fig. 8).

Six patients have been diagnosed with cbl F disease [3,182]. Clinical manifestations include developmental



SITE	MUTANT CLASS	LOCALIZATION OF CONGENITAL DEFECT	MIM NUMBER(S)
1		Intrinsic Factor	193090, 243320, 261000
2		Intestinal Cbl Absorption	261100
3		Transcobalamin II	275350
4	cbl F	Lysosomal Cbl Efflux	277380
5	cbl C, cbl D	Cytosolic Cbl Metabolism	277400, 277410
6	cbl A	Mitochondrial Cbl Reduction	251100
7	cbl B	Mitochondrial Cbl(I) Adenosylation	251110

delay, minor facial anomalies, stomatitis, arthritis, pigmentary skin abnormality, and sudden death in one infant. The defect in cbl F mutant cells appears to reside in the release of cobalamin from the lysosome (reaction 4, Fig. 8), analogous to the defect in nephropathic cystinosis.

Pathological examination of two infants with cbl C disease revealed cerebral lesions typical of those seen in subacute degeneration of the cord in one case [186] and, in the other, vascular abnormalities similar to those of CBS deficiency [187]. Autopsy of a girl with cbl F disease did not explain her sudden death at age 5 months [188]. Focal areas of aortic intimal thickening in this patient were thought to reflect hyperhomocysteinemia; the degree of myelination of the central nervous system was appropriate for age.

Most experience with management has been gained from cbl C patients, in whom partly successful attempts at therapy have included intramuscular doses of hydroxycobalamin, administration of folic acid and betaine, protein restriction, and carnitine supplementation [182,184,189,190]. The poor outcome, with high mortality and residual neurological damage in most survivors, may reflect the duration of the disease prior to diagnosis and treatment, the nature of the disease, or both.

cbl E (MIM 236270) and cbl G (MIM 250940) Diseases

The combination of neurological dysfunction, failure to thrive, megaloblastic anemia, hypomethioninemia, homocystinuria, and low levels of methylcobalamin in cultured cells has been recognized in a group of about 30 patients who fall into one of two complementation groups [2,182,191,192]. Patients with cbl G disease have mutations in the gene for methionine synthase [193–195], while those with cbl E disease have a defect in the regeneration of active methionine synthase, including methionine synthase reductase [196–198]. Most of these individuals have come to medical attention in infancy or early childhood, but delay in onset of neurological symptoms until adult life has been documented in cbl G disease [192,199].

The hematological and biochemical, but not the neurological, abnormalities of patients with cbl E and G diseases fully respond to intramuscular hydroxycobalamin [3,182,192]. The long-term prognosis is unknown. Prenatal diagnosis of cbl E disease has been accomplished by analysis of radiolabeled vitamin B_{12} incorporation by cultured amniotic fluid cells [200].

INHERITED DISORDERS OF SULFITE OXIDASE (MIM 272300) AND MOLYBDENUM METABOLISM (MIM 252150 AND MIM 252160)

Deficiency of sulfite oxidase (reaction 2, Fig. 1) was discovered in 1967 by Mudd and co-workers, who investigated an infant with neurologic symptoms and dislocated lenses but no homocystinuria [201,202]. Sulfite oxidase contains a molybdenum cofactor, and defects in its biosynthesis have subsequently been found to be a more frequent cause of sulfite oxidase deficiency than primary deficiency of the apoenzyme [4]. Regardless of the nature of the basic defect, patients present with devastating neurological dysfunction. They have no connective tissue

manifestations except for dislocated lenses. Effective therapy is currently not available. Inheritance is autosomal recessive, and pathogenic mutations have been identified in patients with isolated sulfite oxidase deficiency [203,204] as well as in those with deficient molybdenum-containing cofactor [205]. First-trimester prenatal diagnosis is feasible by direct assay of sulfite oxidase activity in samples of chorionic villi.

Clinical Features

Neurologic dysfunction and feeding difficulties start shortly after birth. The neonate may have axial hypotonia, increased muscle tone peripherally, and major motor fits that typically are unresponsive to therapy. Some affected infants are claimed to have dysmorphic facial features [206,207]. Survivors have profound mental retardation and dislocated lenses, and neuroimaging shows brain atrophy. A milder course into the third decade with learning disability and moderate hemiplegia has been described [208].

Biochemical Abnormalities and Pathophysiology

Deficiency of sulfite oxidase leads to accumulation of sulfite, and increased levels of sulfite, S-sulfocysteine, thiosulfate, and taurine may be detected in urine. Because sulfite is rapidly oxidized to sulfate by atmospheric oxygen at room temperature, the urine specimen must be fresh to avoid false-negative results [4]. Measurement of the more stable S-sulfocysteine is more reliable for diagnosis. Deficiency of molybdenum cofactor also leads to decreased activity of xanthine dehydrogenase and aldehyde oxidase, which causes a low level of uric acid and xanthinuria but no significant clinical pathology.

The pathophysiology of sulfite oxidase deficiency is unclear. The culprit seems to be excess sulfite, which may disrupt the disulfide bonds of lenticular fibers in the same manner as does excess homocysteine. The steps leading to the severe neuropathology have not been clarified.

RECENT DEVELOPMENTS

Molecular Biology and Biochemistry of Cystathionine β-Synthase

Elucidation of the x-ray crystal structure of the active core of CBS has shown it to share a fold with O-acetylserine sulfhydrylase [209]. More significantly, the location of the heme moiety in the polypeptide chain was revealed, and it was shown to bind in the N-terminal part of the subunit to a region with no secondary structure. This heme binding motif together with a spatially adjacent oxidoreductase active site motif could explain the regulation of CBS enzyme activity by redox changes.

Native western blot analysis of 14 mutant fibroblast lines showed a paucity of CBS antigen, which was detectable only in aggregates [210]. Five mutant polypeptides produced by recombinant expression in *E. coli* predominantly formed aggregates devoid of heme. These findings suggest that abnormal folding, impaired heme binding, and aggregation of mutant polypeptides may be a common pathogenic mechanism in CBS deficiency.

A functional assay in yeast has been used to characterize *CBS* mutations, many of which are functionally suppressed by deletion of the C-terminal 142 amino acids containing a 53 amino acid motif known as the CBS domain [211]. This domain is found in a wide variety of proteins of diverse biological function. When screening for C-terminal missense mutations that can suppress the common Ile278Thr mutation, the assay identified seven suppressor mutations, four of which mapped to the CBS domain. Combined in *cis* position with Val168Met, another pathogenic mutation, six of the seven mutations rescued the yeast phenotype to as much as 64% of wild-type enzymatic activity. These results suggest that subtle changes within the C-terminus can restore mutant CBS activity, and provide a rationale for screening for compounds that can activate mutant CBS alleles.

Purification of two patient-derived C-terminal mutant forms of CBS, Ser466Leu and Ile435Thr, has provided further support for a regulatory function of the CBS domain [212]. The Ile435Thr protein is inducible by S-adenosyl-L-methionine (AdoMet) but the response is 10-fold less than for wild-type CBS. The Ser466Leu form does not respond to AdoMet but is constitutively activated to a level intermediate between that of wild type CBS in the presence and in the absence of AdoMet. Both proteins are able to bind AdoMet, indicating that their impairment is related to their ability to assume the fully activated conformation that AdoMet induces in wild-type CBS. It was possible to activate the Ile325Thr and wild-type CBS by partial thermal denaturation, but neither Ser466Leu CBS nor a truncated form of CBS lacking the C-terminal region could be activated by this treatment. Activation by AdoMet, limited proteolysis, and thermal denaturation share a mechanism involving the displacement of an autoinhibitory domain located in the C-terminus of CBS.

Pathophysiology of Cystathionine β-Synthase Deficiency

Neither the incidence nor the cause of the increased skeletal growth or tall stature of homocystinuric patients is known. One study has demonstrated a direct correlation between plasma free homocyst(e)ine and growth velocity SD scores [213]. Both growth velocity and height SD scores were lower during optimal metabolic control, but growth hormone and growth hormone-related peptides did not deviate significantly from the reference ranges. These findings suggest that overgrowth is directly mediated by homocysteine, and that it may be prevented by optimal metabolic control. The retrospective nature of the study presumably precluded measurements of plasma total homocysteine.

Management of Cystathionine β-Synthase Deficiency

A study involving several large clinical centers has further documented the beneficial effects of long-term treatment on vascular outcome [214]. During 1314 patient-years, 53 vascular events would have been expected without treatment, but only five events were observed with appropriate homocysteine-lowering therapy. The high statistical significance of these data, and of additional data published in abstract form [215], is based on the risk of 0.04 events per year observed in untreated patients [17]. This risk was calculated from data collected in 1981–1982, since which time a greater clinical variability of the disease has been appreciated, especially at the mild end of the spectrum. The likely bias of the 1981–1982 survey should be kept in mind when interpreting recent and future observational studies.

Molybdenum Cofactor Deficiency

Gephyrin is a polypeptide required for the clustering of inhibitory glycine receptors in postsynaptic membranes in the rat central nervous system [216]. It also catalyzes the insertion of molybdenum into molybdopterin, and a

deletion in the gephyrin gene (*GEPH*) has been described in a child with symptoms typical of molybdenum cofactor deficiency [217].

ELECTRONIC DATABASE

Information about *CBS* mutations can be obtained at the following Web site: http://www.uchsc.edu/sm/cbs.

The authors are not aware of any support groups for patients with homocystinuria.

Chapter 14

Menkes Disease and the Occipital Horn Syndrome

Nina Horn and Zeynep Tümer

The John F. Kennedy Institute, 2600 Glostrup, Denmark (N.H.) and Department of Medical Genetics, The Panum Institute, University of Copenhagen, Copenhagen, Denmark (Z.T.)

SUMMARY

- **Menkes disease (MD) is an inborn error of copper metabolism affecting several body systems, including the connective tissues. The clinical manifestations of MD can be quite variable, and both severe and milder forms exist. In the milder forms, the neurological symptoms are less severe, while connective tissue findings remain prominent. This group is likely underdiagnosed.**
- **The classical, severe form of MD comprises 90–95% of all known cases, and its clinical manifestations include progressive neurological degeneration, seizures, growth failure, arterial aneurysms, and skeletal defects, as well as characteristic hair changes (pili torti) and hypopigmentation, and death results in early childhood.**
- **The occipital horn syndrome is the mildest form of MD. Remarkable changes are inguinal herniae, bladder diverticula, skin laxity, and skeletal abnormalities, including a narrow trunk, deformed elbows, and genu valgum. A diagnostically important feature is the occurrence of bony protuberances on the occiput, the so-called occipital horns. Chronic diarrhea and orthostatic hypotension are other characteristic features.**
- **The defect in MD is in the transport of copper into the intracellular sorting station for proteins, the Golgi complex. The affected enzyme is a P-type ATPase, ATP7A, that requires energy for copper transport across the membrane. At basal copper levels, the protein is located in the *trans*-Golgi network, where it transports copper into the lumen for incorporation into secreted and vesicular copper-requiring enzymes. When exposed to excessive copper levels, the protein rapidly moves to the plasma membrane, where it functions in copper efflux. Deficient activity of ATP7A results in intracellular copper accumulation.**
- **The Menkes gene (*ATP7A*) has been cloned, and mutations have been identified in both classical and milder forms of MD. The mutations identified show great variability, but there is as yet no good genotype-phenotype correlation, although more mildly affected patients have been shown to have mutations that are predicted to result in ATP7A with residual enzyme activity.**

Abbreviations: ABP1, amiloride binding protein 1, amine oxidase, copper-containing (MIM 104610); AOC2, amine oxidase, copper-containing (MIM 602268); AOC3, amine oxidase, copper-containing (MIM 603735); ATP, adenosine triphosphate; ATP7A, Cu-transporting ATPase that is deficient in Menkes disease (MIM 300011); *ATP7A*, gene symbol for the Menkes gene; *Atp7a*, the mouse gene homologous to *ATP7A*; *Atp7a*^{Mo}, the mottled mouse locus, previously called *Mo*; ATP7B, Cu-transporting ATPase that is deficient in Wilson disease (see MIM 277900); *ATP7B*, gene symbol for the Wilson gene; Atx1, antioxidant 1, Cu chaperone for Ccc2p, the yeast homolog of HAH1; BAEP, brain stem auditory evoked potential; Ccc2p, yeast homolog of ATP7A/ATP7B; CCS, Cu chaperone for superoxide dismutase 1 (MIM 603864); CP, ceruloplasmin, plasma ferroxidase needed for iron mobilization (MIM 117700); CT, computed tomography; CTR1, Cu transporter 1 that is necessary for cellular uptake of copper, also named COPT1 (MIM 603085); CTR2, Cu transporter 2, possibly involved in cellular copper uptake; also named COPT2 (MIM 603088); COX, cytochrome c oxidase (MTCO1: MIM 516030; MTCO2: MIM 516040); COX17, a mitochondrial copper shuttle or Cu chaperone for delivery to mitochondria and cytochrome c oxidase; DBH, dopamine β-hydroxylase (MIM 223360); ddF, dideoxy fingerprinting; DHPG, dihydroxyphenylglycol; DOPA, dihydroxyphenylalanine; L-DOPS, L-threo-3,4-dihydroxyphenylserine; EDS, Ehlers-Danlos syndrome; EEG, electroencephalogram; ERG, electroretinogram; Fre1, ferrireductase 1 in yeast; Fre2, ferrireductase 2 in yeast; GSH, glutamyl-cysteinyl-glycine, also named glutathione; HAH1, human ATX homolog 1, Cu chaperone for incorporation of copper into ATP7A/ATP7B, also named antioxidant protein 1, ATOX1 (MIM 602270); HEPH, hephaestin, membrane-bound ferroxidase involved in iron absorption; LOX, lysyl oxidase (MIM 153455); LTQ, lysine tyrosylquinone, cofactor of lysyl oxidase; MBD, metal-binding domain; MD, Menkes disease (MIM 309400); MR, magnetic resonance; MTCO1, mitochondrial cytochrome c oxidase subunit 1 (MIM 516030); MTCO2, mitochondrial cytochrome c oxidase subunit 2 (MIM 516040); OHS, occipital horn syndrome (MIM 304150); PAM, peptidyl α-amidating enzyme (MIM 170270); TGN, *trans*-Golgi network; TMD, transmembrane domain; SCO1, *Saccharomyces cerevisiae* COX-deficient homolog 1 (MIM 603644); SOD1, cytoplasmic Cu/Zn superoxide dismutase (MIM 147450); SOD2, mitochondrial Mn superoxide dismutase that is located in the matrix (MIM 147460); SOD3, extracellular Cu/Zn superoxide dismutase (MIM 185490); SSCP, single-strand conformation polymorphism; VEP, visual evoked potential.

Connective Tissue and Its Heritable Disorders, pages 651–685

- **MD shows progressive deterioration. Administration of copper histidine before brain damage may ameliorate the disease progression and result in less severe neurological symptoms. However, connective tissue signs and symptoms remain prominent.**

INTRODUCTION

Copper is a trace element necessary for the normal activity of numerous metalloenzymes. Lack of copper influences vital metabolic processes in the body and causes characteristic disturbances among which connective tissue abnormalities are prominent. Through its role as a cofactor for lysyl oxidase, copper has a profound influence on the formation of the extracellular matrix.

Two hereditary disorders, Menkes disease (MIM 309400) and the occipital horn syndrome (MIM 304150), mimic the effects of copper deficiency. Since the original description of Menkes disease (MD), numerous reports on patients with similar and dissimilar clinical and radiographic features and biochemical findings have been published, the mildest symptoms representing the occipital horn syndrome (OHS). It took a number of years before it was accepted on clinical and biochemical grounds that the spectrum of severity was due not to genetic heterogeneity of similar phenotypes but to allelic variability. It has now been confirmed that these two disorders are caused by mutations in the same gene, *ATP7A*, differing in severity only in relation to the extent to which copper-dependent processes are affected.

ATP7A codes for a copper pump that is responsible for the extrusion of the metal from most types of cells, and cloning of its gene initiated a new interest in copper metabolism. Since then, significant new knowledge about the cellular handling of this metal has been gained, and we therefore start the discussion of the two diseases by reviewing current knowledge about copper homeostasis. In the following, we use Menkes disease as a generic term and only distinguish between the two forms when it is necessary for comparison of, say, the clinical features.

BIOLOGICAL ROLE OF COPPER

Copper Biochemistry

Copper belongs to the transition group of elements and can exist as Cu(I) or Cu(II). Under physiological conditions, the metal is readily convertible between the two oxidation states. This redox property is used in a number of copper-requiring enzymes that are typically involved in electron transfer reactions, and the metal is crucial for the normal activity of these enzymes [1].

However, this same property also makes copper a very toxic element when present at high levels [2]. Consequently, special molecular mechanisms for handling the metal are required. If the copper-specific complexing molecules become saturated, the free ion concentration will increase and copper will bind to other molecules and catalyze unspecific oxidation. Eventually, copper may cause adverse reactions, as has been documented in Wilson disease (MIM 277900), which is caused by a defect in the homologous gene, *ATP7B*. The Wilson gene product is primarily expressed in the liver, and its main function is in excretion of copper via the bile and delivery of copper to ceruloplasmin. Dysfunction of ATP7B leads to hepatic accumulation of copper and subsequent overflow to other organs, especially the brain, kidney, and cornea. Wilson disease is an autosomal recessive disorder that usually presents in late childhood or adolescence with hepatic cirrhosis and neurological or psychiatric problems and the typical Kayser-Fleischer rings in the cornea [3].

Copper Homeostasis

Whole Body Transport

In the body, the balance between requirement and toxicity of copper is tightly controlled [3–7]. Homeostatic regulation of copper levels in the whole body and individual cells appears to be achieved primarily via an efficient export mechanism combined with detoxification of surplus of the metal.

Total body stores of copper are dependent on a balance between intestinal absorption, distribution to organs and tissues, and biliary excretion. Absorption occurs primarily in the upper small intestine, and gut transfer contains an energy-dependent step (probably the release from the enterocytes by ATP7A). Once in the bloodstream, copper is bound to albumin and amino acids and is then rapidly taken up by tissues, mainly the liver, where it is either stored or secreted. Hepatic release occurs by two different routes, namely secretion to the circulation bound to ceruloplasmin or excretion via bile. Biliary excretion is the principal route for elimination of excess copper, and ATP7B is involved in export from the hepatocytes. Thereby, the liver plays a central role in the regulation of whole-body copper homeostasis. Urinary loss is negligible due to an efficient reabsorption of copper filtered in the glomeruli, but there is minimal enterohepatic recirculation of biliary excreted metal. Copper transport into the brain is also a regulated process but is not yet fully understood [3].

Copper ions remain tightly bound to specific carrier molecules, from absorption in the gut to export via the bile, and are carefully transferred from one carrier to another in blood and extracellular fluid, across cell membranes, and even within cells.

Ceruloplasmin. Ceruloplasmin is a quantitatively important copper-binding protein in the circulation. It binds about 90% of serum copper and has long been regarded as a tissue copper donor. Its role in copper transport has been disputed, and it is no longer regarded as a specific transport protein for copper [8]. However, the role of ceruloplasmin as a transport vehicle has been discussed thoroughly [7], and it still remains plausible that ceruloplasmin participates in whole-body copper homeostasis.

Ceruloplasmin appears primarily to be important for iron mobilization through its role as a ferroxidase (see below). Individuals with an inherited deficiency of ceruloplasmin, aceruloplasminemia (MIM 604290), suffer from specific disturbances of iron metabolism with accumulation of the metal in certain tissues, primarily the brain, whereas copper metabolism appears to be normal [8,9].

Albumin. Another important copper carrier in blood is albumin, which possesses a copper-specific binding site in its amino-terminal portion [10]. It is also a carrier for several other molecules, such as steroids, fatty acids, and thyroid hormone. Only about 5% of the total serum copper content is complexed with albumin, but this form is still thought to constitute the major transport form in blood. Albumin appears, however, not to be a prerequisite for delivery of the metal to tissues and organs because individuals with analbuminemia (MIM 103600) due to a genetic defect do not show symptoms of copper deficiency [11].

Copper bound to albumin is in dynamic equilibrium with copper bound to amino acids, especially histidine. This dissociable pool is in rapid equilibrium with copper

in the tissues and may be regarded as a buffer securing the availability of sufficient copper for various organs and cells and also protecting the organism against copper toxicity. Dogs lack the terminal copper-binding imidazole group of albumin, and this species appears to be highly susceptible to copper toxicosis.

Cellular Transport

Also at the cellular level, uptake, export, and intracellular compartmentalization, as well as the buffering of copper ions, appears to be strictly regulated [6,12–13]. Several of the components participating in copper transport have now been identified, and significant advances have been made toward understanding cellular copper homeostasis. Cells have developed specific mechanisms to ensure a unidirectional flow of copper ions from when they are taken up by the cell until they are pumped out again. In individual cells, copper is taken up across the plasma membrane by specific carriers, and once inside the cell, the metal is distributed to various enzymes and compartments bound to other carriers. Surplus of copper is either neutralized by a specific storage protein or pumped out of the cell (Fig. 1).

Knowledge of how copper is handled at the cellular level has broadened dramatically since the identification of the export mechanism, ATP7A. This protein belongs to a unique family of energy-requiring metal pumps and possesses metal-binding sites that are highly homologous to sites in a yeast protein with a similar function, Ccc2p. The discovery of a strong evolutionary conservation of protein sites used for metal coordination led to the rapid identification of several other specific copper carriers, isolated by functional complementation of yeast strains deficient in specific known transport mechanisms.

Uptake. Uptake of copper across the plasma membrane seems to occur via facilitated transfer using an energy-independent membrane carrier, CTR1 (Fig. 1). CTR1 was identified by functional complementation of a yeast mutant (ctr1) defective in high-affinity copper uptake [14], and a second, homologous membrane protein, CTR2, was identified by database searching. Both proteins contain three potential membrane-spanning regions. In addition, CTR1 contains repeated metal-binding sequences rich in methionine and histidine. CTR2 has a lower abundance of these residues and lacks obvious metal-binding motifs, and it has therefore been proposed to be a low-affinity uptake carrier, but this needs to be demonstrated. Both proteins were expressed in all tissues examined, suggesting a ubiquitous role for the proteins in copper transport in humans [14].

By analogy with yeast, the metal is most likely taken up as Cu(I) and therefore needs to be reduced from the Cu(II) state prior to uptake. Two plasma membrane proteins (Fre1p, Fre2p) with iron and copper reductase activity have been identified in yeast [15]. In human liver, a similar reductase activity has been identified, but the gene remains to be isolated [16]. Copper reductases are probably operating in other cell types as well.

Buffering. On entering the cell, copper is immediately bound to intracellular ligands. The cytoplasm constitutes a reducing environment, and glutathione, a tripeptide thiol (glutamyl-cysteinyl-glycine; GSH) that is found ubiquitously in all living cells, is effective in stabilizing copper ions in the Cu(I) state [17]. Free ionic copper is thereby maintained at very low concentrations, and if the buffering capacity of this system is exceeded, the metal will induce synthesis of metallothionein, to which copper is bound efficiently

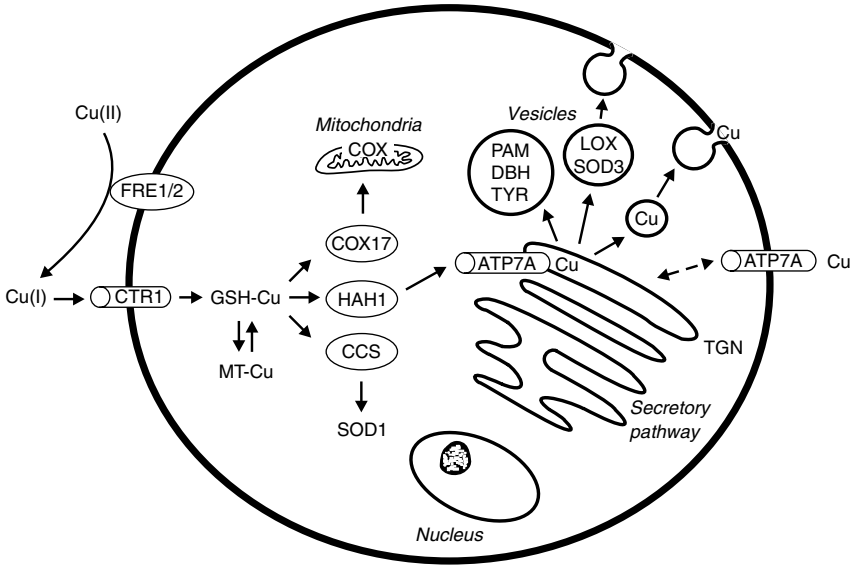

Figure 1. Schematic illustration of cellular copper transport. Analogously to the liver in respect of the whole body, the Golgi network is the organelle controlling cellular copper metabolism. Copper is taken up across the plasma membrane by the copper uptake transporter (CTR1) after it has been reduced from cupric ions to cuprous ions by ferrireductase 1 and 2 (FRE1/2). Within the cell, copper is first attached to glutathione (GSH), and surplus is scavenged by metallothionein (MT). Specific chaperones deliver copper to enzymes and compartments: COX17 is the copper chaperone for cytochrome c oxidase (COX), CCS is the copper chaperone for the cytoplasmic superoxide dismutase (SOD1), and HAH1 is the copper chaperone for ATP7A that delivers copper to peptidyl α-amidating enzyme (PAM), dopamine β-hydroxylase (DBH), tyrosinase (TYR), lysyl oxidase (LOX), and extracellular superoxide dismutase (SOD3). ATP7A is also responsible for copper export from cells. At low copper concentrations, the localization of the protein is at the *trans*-Golgi network (TGN), but at high copper concentrations it is relocated to the plasma membrane.

in a strong thiolate complex and thereby neutralized. Metallothionein therefore scavenges the cell, protecting against toxic accumulations of copper [18]. Metallothionein has also been proposed as a physiological storage protein for copper, but the mechanism by which copper is mobilized from metallothionein is not fully understood. Evidence indicates that glutathione interacts with the thiolate ligands to release the metal [19].

Chaperoning. Because copper cannot exist in its free form, metal delivery to various compartments for incorporation into enzymes also needs to be carrier-mediated. ''Chaperoning'' is now the accepted term for this process, whereby a copper ion is directed and donated to a specific acceptor molecule by a small soluble carrier molecule that binds and escorts the metal to its destination (Fig. 1). Copper-requiring enzymes are thereby loaded without other cellular components being damaged.

To date, three genes coding for cytosolic copper chaperones have been identified by functional complementation cloning, and each protein delivers copper to a specific target molecule. The first cytoplasmic copper carrier to be identified was HAH1 (human ATX homolog; also named ATOX1), which delivers copper ions to the Golgi complex. By analogy with yeast, it was suggested that HAH1 binds and donates cytosolic copper to ATP7A and ATP7B in the *trans*-Golgi network [20–23]. Another protein that delivers copper intracellularly is CCS, the copper chaperone for superoxide dismutase (SOD1) [24]. Direct chaperoning of copper from CCS to its target enzyme, SOD1 (cytoplasmic superoxide dismutase), has been demonstrated [25]. A third chaperone, COX17, delivers copper to the periplasmic space of the mitochondrion (Fig. 1) [26–28]. Before the copper can be incorporated into the two copper-containing subunits of cytochrome c oxidase, a second mitochondrial-specific factor SCO1 (*Saccharomyces cerevisiae* COX-deficient homolog 1) seems to be required for the transfer of copper across the inner mitochondrial membrane into the matrix [29,30]. SCO1 contains a mitochondrial leader peptide, a putative transmembrane domain, and a copper-containing domain.

These chaperones are small cytosolic proteins containing one metal-binding site. The chaperones CCS and HAH1 share a copper-binding site (MTCXXC), that is very similar to those found in ATP7A and ATP7B and probably has a similar affinity for copper. The motif of COX17 is slightly different (CCXC) but also implies a strong metal-binding capacity [31]. Studies on the homologous yeast proteins indicate that copper binds as Cu(I) to these chaperones [26,31].

Besides the copper-binding motif, other unique sequences secure an efficient metal delivery from the chaperone to the target enzyme. Thus, copper-mediated protein-protein interactions have been demonstrated for Atx1 (antioxidant 1), the yeast homolog of HAH1 (human ATX homolog 1) [21]. Sequence similarities between CCS and SOD1 have been demonstrated [32], suggesting that copper exchange occurs through specific interaction between the donor and acceptor molecules. These features ensure a unidirectional flow of copper from one protein to another, from weaker to stronger binding, until the metal is pumped out of the cell. Copper is pumped out as Cu(I), but before the metal is bound as histidine or albumin complexes for return to the liver, it needs to be oxidized to Cu(II). Nothing is known about enzymes or proteins involved in this step.

It is conceivable that additional copper-specific chaperones exist in the cell. Chaperone-like mechanisms are responsible for activation of the copper uptake and export genes in *Enterococcus hirae*. This regulation occurs through a copper-sensitive gene repressor, and direct chaperoning of copper to the repressor has been demonstrated [33].

Export. In the individual cell, copper homeostasis is controlled by excretion of the metal, and ATP7A plays a key role in cellular copper metabolism by controlling the export of copper from nonhepatic tissues. In the liver, this function is taken over by the homologous ATP7B, which is defective in Wilson disease.

ATP7A pumps copper from the cytoplasm into the secretory pathway for incorporation into secreted enzymes or export. Several lines of evidence suggest that it is located in the *trans*-Golgi network [34–36], the same compartment in which sorting between secretory and constitutive proteins takes place. It is conceivable that ATP7A is responsible for the copper loading of most, if not all, secreted copper enzymes.

When the cell is exposed to high copper levels, ATP7A is reversibly translocated to the plasma membrane, indicating that it also plays a role in the exocytosis of copper. This occurs either by the metal being pumped into secretory vesicles, which are subsequently sorted to the plasma membrane for release of their contents, or by direct extrusion by ATP7A located at the plasma membrane. ATP7A cycles between the *trans*-Golgi network and the plasma membrane, depending on the concentration of copper within the cell [34,37]. This copper-dependent shuttling between the plasma membrane and the Golgi complex seems to be a physiologically important mechanism for the cellular extrusion of surplus copper. The gene sequences necessary for localization to the Golgi complex and for recycling between the two membranes are beginning to be defined [12,38–42]. Gene regulation of the export of excess copper is, however, not well-understood. Although copper regulates its efflux, this does not occur at the transcriptional level since ATP7A mRNA is not responsive to copper [43]. In yeast, the expression of the homologous gene (Ccc2p) is controlled by iron and not copper [44].

Apparently, the membranes of other cellular organelles also use energy-dependent transport mechanisms for translocating heavy metals. Thus, copper translocation across the inner mitochondrial membrane and incorporation into the metallocenter of COX (cytochrome c oxidase) also seems to require a specific membrane carrier [29]. Used copper also needs to be exported again from this organelle, and the homologous protein ATP7B may be implicated in this step [45]. In the lysosomal membrane, an energy-dependent transporter that binds the heavy metals silver, copper, and cadmium has been characterized [46]. This protein was proposed to be a P-type ATPase, but the gene remains to be isolated. It is probable that other organelles such as peroxisomes may also possess a specific copper pump.

THE CLINICAL SPECTRUM OF MENKES DISEASE AND THE OCCIPITAL HORN SYNDROME

Menkes disease (MD) is a multisystemic disorder resulting from a disturbed copper metabolism. The phenotype of Menkes disease includes a wide range of symptoms in many body systems, all of which can be explained by the disturbed copper metabolism, but there is considerable variability in the severity of clinical expression. In the most common, classic, severe form, symptoms may appear during the neonatal period, but milder forms, which first present with symptoms much later, have also been described. Today, it is clear that the different phenotypes form a clinical continuum from

severe to mild disease with variable somatic and mental problems. In this chapter, we discuss the clinical features of the disease under four categories: classical Menkes disease, the occipital horn syndrome as the mildest form, intermediate phenotypes, and treated patients who show a considerable divergence from the classical severe form.

Classical Menkes Disease

Clinical Characteristics

In 1962, Menkes and his co-workers reported on five male members of a family who were similarly affected with developmental regression starting from the age of four months. Clinical symptoms comprised peculiar facial features and unusual hair, and there were cerebral and cerebellar degenerative symptoms, including hypotonia, spasticity, and convulsions, that eventually led to death by ages between 7 months and 3 years. The children were related through female members in the family, suggesting an X-linked recessive inheritance [47]. This initial description has been followed by numerous additional observations, which, over the past more than 35 years, have defined the clinical phenotype of MD [5,48–52].

The early clinical features of classical MD are quite uniform, whereas the long-term course seems to be more variable. The evidence indicates that there is a remarkable clinical phenotypic spectrum from a severe, early lethal form to milder forms of MD, the mildest form being classified separately as the occipital horn syndrome [5,48,49,53].

During pregnancy, there are no predictive symptoms, and the results of current procedures for maternal health care, including maternal serum studies for α-fetoprotein, and repeated routine fetal ultrasound examinations are normal. There may be premature labor and delivery, but most male patients are born at term with appropriate birth measurements. Postnatal cephalohematomas and spontaneous fractures have occasionally been observed. In the early neonatal period, patients may present with hypothermia, hypoglycemia, and prolonged jaundice, and feeding problems, pectus excavatum, and umbilical and inguinal hernias have been reported [50]. However, the first sign may be unusual sparse and lusterless scalp hair that becomes tangled on the top of the head at 1–2 months of age. Initial psychomotor development is usually unremarkable, with normal babbling and smiling up to about 2–4 months of age, whereafter hypotonia, failure to thrive, poor eating, vomiting, diarrhea, and gradual loss of psychomotor milestones become evident. Most patients will also develop seizures that are difficult to control. These problems combined with characteristic physical findings, such as pudgy cheeks, lack of facial expressions, and lax skin, usually bring the child to pediatric attention early (Figs. 2 and 3). Hair and eyebrows become steely, hypopigmented, and breakable, causing a stubble on the occipital and temporal areas (Fig. 4). Weight gain, growth in length and head circumference, and psychomotor development gradually come to a complete halt. There is a marked truncal hypotonia, inability to lift the head, and spasticity of the extremities, and gradual loss of reactivity. Recurrent urinary tract infections are associated with bladder diverticula, which occasionally may cause spontaneous bladder ruptures, ureteropelvic obstruction, and hydronephrosis [54,55]. The occasional intracranial hemorrhage and massive bleeding in other sites are associated with evolving intimal thickening and aneurysms of the arteries. Optic atrophy, abnormal ERG (electroretinogram), and loss of VEP (visual evoked potential) and BAEP (brain stem auditory evoked potential) have been observed, suggesting progressive deterioration of vision and hearing [56,57]. Initially, microscopic examination of hair may be normal, but later typical changes and loss of pigmentation become evident (Fig. 4). The diagnosis of MD is usually suspected by the age of 3 to 6 months and can be confirmed by laboratory investigations. In the classical form, the clinical course of MD is a gradual neurodegenerative deterioration with subdural hematomas, and affected children usually die of neurological and respiratory failure by the age of 3 years. However, careful medical care and possibly copper therapy may extend life up to 13 years or even more [58–60].

Radiographic Observations

Radiographs at the time of suggestive clinical signs and symptoms show a number of specific changes that are reminiscent of acquired copper deficiency and scurvy. These abnormalities include a generalized osteoporosis, metaphyseal flaring and spurs in the tubular bones (Fig. 5), multiple rib fractures, and Wormian bones in the skull [61,62]. Cystourethrography and ultrasound may demonstrate bladder diverticula and, occasionally, ureter diverticula. By arteriography there may be widespread elongation, tortuosity, and variation in caliber of the abdominal and cerebral arteries (Fig. 6). Head CT (computed tomography) and MR (magnetic resonance) imaging reveal progressive patchy areas of white matter abnormalities, suggesting disordered myelinization and diffuse cerebral

atrophy with dilatations of the ventricles. Cerebellar inferior vermian hypoplasia has also been described [57].

Occipital Horn Syndrome

Clinical Characteristics

The phenotypic manifestations of the occipital horn syndrome (OHS) [5,49,63,64] were first described by Lazoff et al. [65] in an 11-year-old boy and his two maternal uncles. The child presented with diarrhea, recurrent urinary tract infections, bladder diverticula, inguinal hernia, and peculiar occipital horns. All three had educational problems but were not mentally retarded. One year later, a new form of X-linked cutis laxa with bladder diverticula and skeletal abnormalities was reported [66]. The phenotype was associated with a deficiency of lysyl oxidase that was later inferred to result from disordered copper metabolism [67]. The condition was later renamed Ehlers-Danlos (EDS) type IX [63], but because of the skin laxity it was withdrawn from the EDS nosology [53] and the accepted term is now the occipital horn syndrome. The proper term should be mild Menkes disease with occipital horns.

Since the first description, more than 20 OHS case reports have been published with the essential observation of the radiographic occipital horns [49,64]. The diagnostic criteria differentiating classical MD, mild MD, variant MD, and OHS are artificial. The principal clinical features in the mild end of the spectrum, OHS, are related to the connective tissues and the skeleton and the extended prognosis for life.

Figure 5. Characteristic bone changes in classical Menkes disease. Generalized osteopenia with metaphyseal irregularities at both distal femoral and proximal tibial metaphyses and a corner spur on the medial aspect of the right femur (arrow). (Courtesy of D. C. Davidson, Alder Hey Children's Hospital, Liverpool L12 2AP, England.)

Pregnancy and delivery of an OHS child are usually normal. The skin may appear wrinkled and lax at birth, and the child may have umbilical and inguinal herniae. Within days, hypothermia, jaundice, hypotonia, and feeding problems may transiently ensue. Over the years, the clinical problems gradually become obvious, and the first signs that bring the child to medical attention may be intractable diarrhea and recurrent urinary tract infections. Cystography usually reveals an atonic bladder with diverticula suggesting obstructive urethropathy (Fig. 7). Motor development is delayed due to muscular hypotonia and is associated with unusual clumsiness. Prepubertal growth in height is usually normal, while mild disproportion with a long trunk and the development of flat feet, knock-knees, thoracolumbar kyphosis or scoliosis, and pectus deformity with narrow chest and shoulders are common (Fig. 8). The joints are hypermobile, and operations may be required to stabilize the ankle joints. Gradually, flexion and supination-pronation limitations at the elbows ensue due to hyperostosis of the proximal ulna and radius. There is also a tendency toward dislocation of the elbows (Figs. 9b and 9c). The face becomes narrow, often with a high forehead, downslanting palpebral fissures, a hooked nose and long philtrum, and dental alveolar hyperplasia. Skin laxity is variable and may increase with age, resulting in droopy wrinkles around the trunk (Fig. 8a). However, there is no particular bruisability or fragility of the skin, and surgical incisions either heal normally or may form atrophic scars. Hair is not usually reported as abnormal. However, some patients may have lusterless and unusually coarse hair. Recurrence of the inguinal hernia is common. Vascular anomalies, such as varicose and tortuous veins, are common, and arterial aneurysms have also been described [68]. Gradually, full extension of the head becomes limited. A particular problem is syncopic orthostatic episodes resembling convulsions. Intellectual development is normal or mildly retarded. Pubertal development is normal.

Despite the many clinical problems, the diagnosis of OHS is usually arrived at only around 5 to 10 years of age. The clinical course is characterized by chronic diarrhea, recurrent urinary tract infections with bladder diverticula and occasional spontaneous bladder ruptures, orthostatic syncopes, and joint instabilities in the inferior extremities and limitations at the elbows. Severe progressive thoracolumbar kyphosis, spontaneous retinal ablation, and mitral valve insufficiency, all requiring operative procedures, have also been encountered (I. Kaitila, personal communication). Based on family histories of case descriptions, life expectancy in OHS is variable. There are adult patients aged up to 50 years who have maternal male relatives dying in early childhood, usually of infections. One Finnish patient died at 32 years of age of fulminant peritonitis caused by rupture of an intestinal diverticulum [69], and his brother later died at 26 years of age from subdural hemorrhage (I. Kaitila, personal communication).

Radiographic Findings

There is little information on skeletal radiographic abnormalities in infancy and early childhood. In the skull, there may be Wormian bones, which disappear within a few years. An atonic, often diverticulous bladder is observed in investigations into recurrent urinary tract infections in early childhood by cystography. In the skeleton, osteoporosis is found in later childhood. There are coxa valga and horizontal, flattened acetabula. Chest radiographs show a narrow thorax, somewhat thickened ribs, and short, thick clavicles with hammer-shaped distal ends (Fig. 9a). There is characteristic progressive deforming hyperostosis at the proximal ends of the bones in the forearm. This results in the appearance of dislocation of the proximal radial head. Kyphoscoliosis is common, but there is no consensus as to whether vertebrae are normal or abnormal. The most peculiar and characteristic radiographic finding is the symmetric parasagittal bony projections extending down the extensor musculature of the neck (i.e., occipital horns) (Fig. 10). The mastoid processes similarly extend along the sternocleidomastoid musculature. The horns may be found around 1–2 years of age if looked for [70], but are usually detected only around 5–10 years of age and continue to grow up to early adulthood.

Intermediate Phenotypes

Clinical Characteristics

In several case reports, the description of the symptoms and signs indicates a later onset and milder problems than in typical classical Menkes patients, and such an

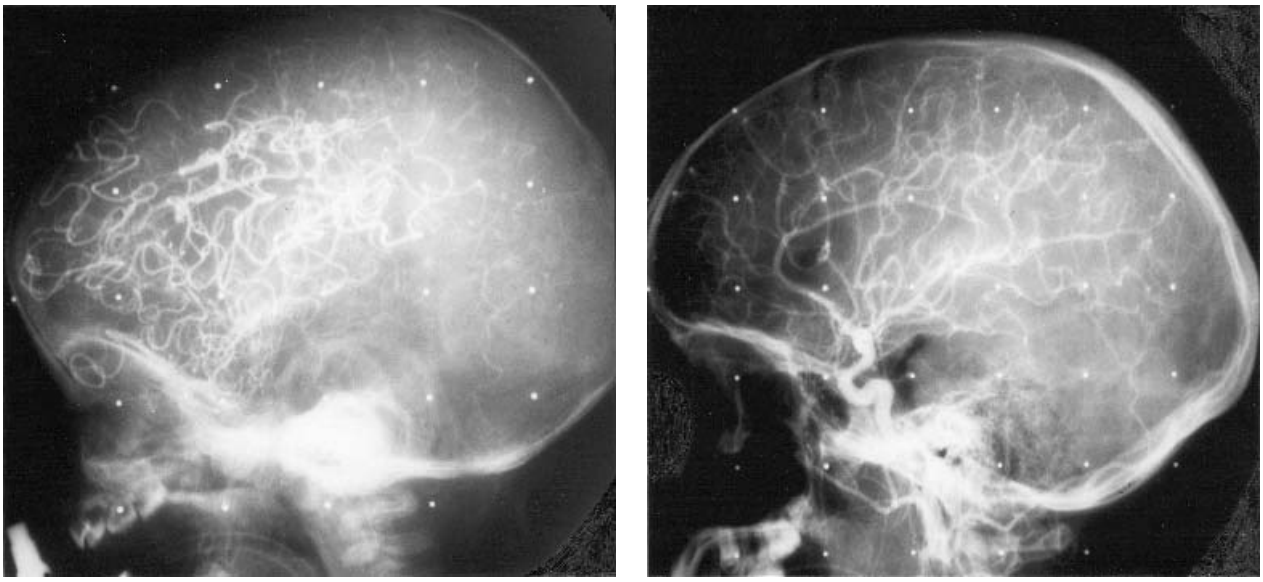

Figure 6. Vascular abnormalities in Menkes disease **a:** Carotid angiography in a classical MD patient showing hairpin bends of the artery in the neck and elongated, twisted, and numerous intracranial branches. **b:** Normal carotid arterial system in a normal child, shown for comparison. occurrence may result in delayed diagnosis of the condition. In several of these cases, typical hair changes led to the suspicion of a clinical variant of MD [49,71–76], and occipital horns have also been the diagnostic pointer in some cases [74,77]. Initial symptoms may include ataxia, mild mental retardation [49,71,72], and extrapyramidal movement disorder [78,79]. Intellectual capacity varies from severe retardation, although less striking than that in classical MD [74–76,78], to only mild mental deficit [49,73]. One of the mildly affected patients later developed occipital horns and has therefore been reclassified as having OHS [80].

In addition, a number of long-surviving though severely affected Menkes patients have also been reported [58–60]. There seems to be a consensus that modern clinical patient care *per se* might alleviate the clinical problems and extend life span, independent of medical treatment (i.e., copper therapy).

Because OHS and classical MD share many clinical features, reduced concentration of copper, and low lysyl oxidase activity, allelism of the two conditions was suggested quite early [81]. Mutation analysis of *ATP7A* in patients with classical MD, OHS, and intermediate phenotypes has definitively proven this to be the case, thus confirming the phenotypic diversity in the clinical spectrum of Menkes disease.

Radiographic Findings

There are limited detailed follow-up descriptions of radiographic findings in the variants of Menkes disease. Bone x-rays were reported to be unremarkable at 10 years of age in the mild MD patient reported by David Danks [49]. The American patient originally classified as mildly affected was later reported to have developed changes specific for the occipital horn syndrome [80]. One family with a variant form of MD showed a number of radiographic features very similar to those described in the occipital horn syndrome, and the findings have been thoroughly documented [74].

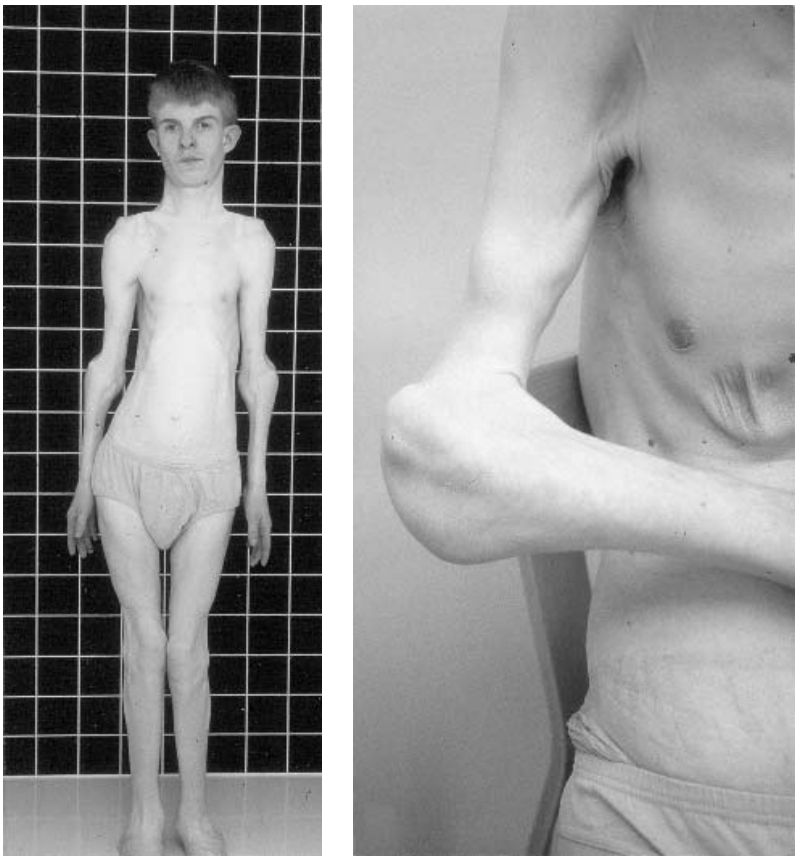

Figure 8. Patient with the occipital horn syndrome. Clinical appearance at age 23 years. He has a narrow chest and knock-knee as well as deformity of the elbow (**a**). Close-up of the elbow and the chest demonstrates loose skin and an atrophic scar on the trunk (**b**). (Courtesy of I. Kaitila, Helsinki University Hospital, SF-00290 Helsinki, Finland.)

Treated Patients

Copper therapy initiated after the development of brain abnormalities will not change the clinical course significantly, although survival may be prolonged [60]. If initiated early, copper therapy may, however, modify disease progression substantially. Four classical MD patients have received long-term parenteral treatment with complexed copper, and it is now possible to predict the phenotypic expression after successful copper therapy. All four treated patients have exhibited a clearly milder clinical course [82]. They have limited brain involvement with near-normal intellectual development, no seizures, and mild to moderate ataxia. Some problems related to autonomic failure, such as postural hypotension and chronic diarrhea, are, however, of concern in these well-treated patients. They have all developed skeletal dysplasias similar to the OHS patients. Poor wound healing with atrophic, stretched scars has also been described [83].

PATHOLOGY

The pathological changes observed in Menkes disease (MD) are diverse, reflecting the multisystemic involvement, and connective tissue and central nervous system (CNS) disturbances are the most prominent. In classical MD, due to the severe neurological involvement, the main interest has been in pathological changes in the brain. In OHS, the neurological involvement is milder, making the connective tissue manifestations more conspicuous and the main focus of investigation, while CNS changes have received limited attention. Below we describe the connective tissue changes in detail and summarize CNS changes, referring to reviews of this issue.

Connective Tissue

All patients exhibit connective tissue symptoms to varying degrees as a metabolic consequence of the restricted availability of copper for synthesis of the extracellular matrix. The fiber-forming proteins, elastin and collagen, are secreted as soluble monomers, which are organized into polymers and stabilized by intermolecular cross-linking. The cross-linking process requires the copper-dependent enzyme lysyl oxidase (see below and also Chapter 2, this volume). Consequently, a compromised copper metabolism will interfere with normal collagen and elastin fibrillogenesis and affect the stability of these two proteins. In humans, elastogenesis seems to be particularly sensitive to disturbance [84], and marked changes in the elastic fibers are evident in Menkes disease. Collagen synthesis seems to be affected to a lesser extent, although collagen fibril diameter can be variable, and collagen fibrils are often more prominent, which probably represents a repair response. Microfibrillar structures remain unaffected because their biosynthesis is not copper-dependent. In the light of this

Figure 9. Radiograph of the upper chest at age nine years (same patient as in Fig. 8) showing the thick and short clavicles with hammer-shaped ends. The humerus and the scapula also appear dysmorphic (**a**). Radiographs of the elbow show abnormal-shaped joints, dislocation of the head of the radius, and metaphyseal spurring (**b**,**c**). (Courtesy of I. Kaitila, Helsinki University Hospital, SF-00290 Helsinki, Finland.)

knowledge, it is obvious that blood vessels, skin, bones, and lungs will display profound pathological changes, which are discussed below.

Blood Vessels

In classical MD, profound changes have been documented in the elastic-walled arteries, both systemically and within the brain [49]. Major arteries are elongated and dilated, leading to rupture and hemorrhage and subintimal thickening with partial occlusion. The arteries are tortuous, with an irregular lumen and a frayed and split intimal lining. The aorta and larger arteries may be grossly tortuous, with multiple areas of localized narrowing, while smaller vessels that contain more smooth muscle in their walls may display this feature to a lesser extent [51]. Histological cross sections of the arteries show intimal thickening and fragmentation and reduplication of the internal elastic lamina (Fig. 11). In severely affected arteries, fragmentation of elastic tissue is seen throughout the media, extending into a ''heaped-up'' intima that can completely occlude the lumen. Major arteries may show intimal fibromuscular proliferation [85].

Ultrastructural studies show that the elastin that is present is electron-dense and surrounded by a prominent sheath of microfibrils. Collagen is much less disturbed and shows a proliferation, apparently as a healing response. The cells present in the arterial wall show accumulations of metachromatic material thought to be proteoglycans [49,86] that play a role in the assembly of the fibrous matrix proteins. Arterial disease is less severe in OHS but can be observed. Degeneration of elastic fibers of the vessel walls has also been described in a moderately affected case [77].

Skin

The skin also shows specific alterations of elastic tissue [87]. The elastin fibers may be granular and fragmented in the lower dermis, while a normal microfibrillar structure is preserved. The diminished formation of insoluble elastin may give an empty impression that has been described as a ''moth-eaten'' appearance of the fibers. An overactive proteolytic degradation of the improperly organized elastic fibers may explain the histological appearance of the elastic tissues. Collagen fibers are less affected. They may be widely spaced and usually have an irregular thickness and contour. Histological changes in the skin, with a decreased number of elastic fibers in addition to degeneration and splitting of elastic fibers in the dermis,

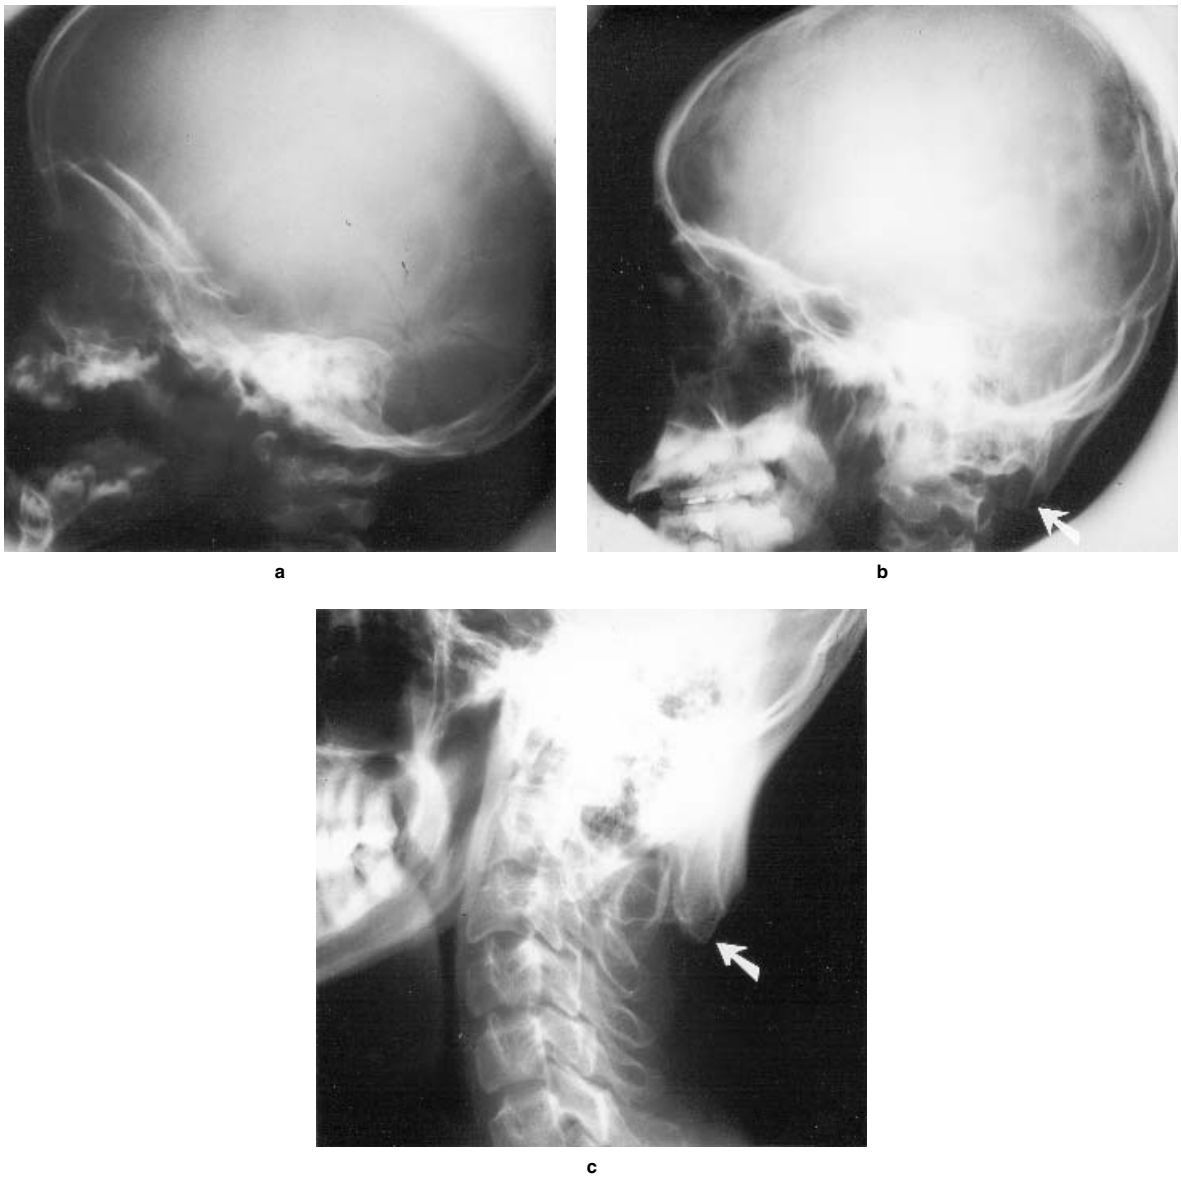

Figure 10. Lateral skull radiographs of the same patient as in Figure 8, demonstrating occipital horns. The skull at age one year and four months shows no signs of occipital exostoses (**a**). The skull at nine years of age demonstrates typical occipital exostoses (arrow) (**b**). At age 23 years, the occipital exostoses become more prominent (arrow) (**c**). (Courtesy of I. Kaitila, Helsinki University Hospital, SF-00290 Helsinki, Finland.)

have also been demonstrated in a more mildly affected case [77]. In OHS, hypertrophic collagen fibers with dense fiber bundles and excessive diffuse matrix have been observed [67]. The cross-sectional appearance of the fibers has been described as "collagen flowers" because of their irregular contours [88]. In contrast, elastin fibers appear normal.

Lung

In MD, elastin in the pulmonary alveoli may also be affected, leading to emphysema [89]. The lung contains abundant elastin in the walls of alveoli, alveolar ducts, bronchioles, and bronchi, as well as in lung vessels. It is thus reasonable to expect that any quantitative or qualitative abnormality of elastin would result in emphysema.

Bones

Skeletal changes are prevalent and may be observed in both severe and milder cases. Normal cross-linking of collagen seems to play an important role in the proper mineralization of bone tissue [90], and poor cross-linking may explain the numerous skeletal changes, including the occurrence of osteoporosis. Polarized light microscopy of bone showed a "woven" pattern rather than the normal lamellar rib pattern [51]. Focal hyperostosis observed at sites of tendinous and ligamentous insertions into bones in milder Menkes cases may represent traction phenomena secondary to abnormal bone collagen [91]. This is manifested as occipital horns in OHS patients, which may also be observed in classical MD patients who have received long-term copper treatment.

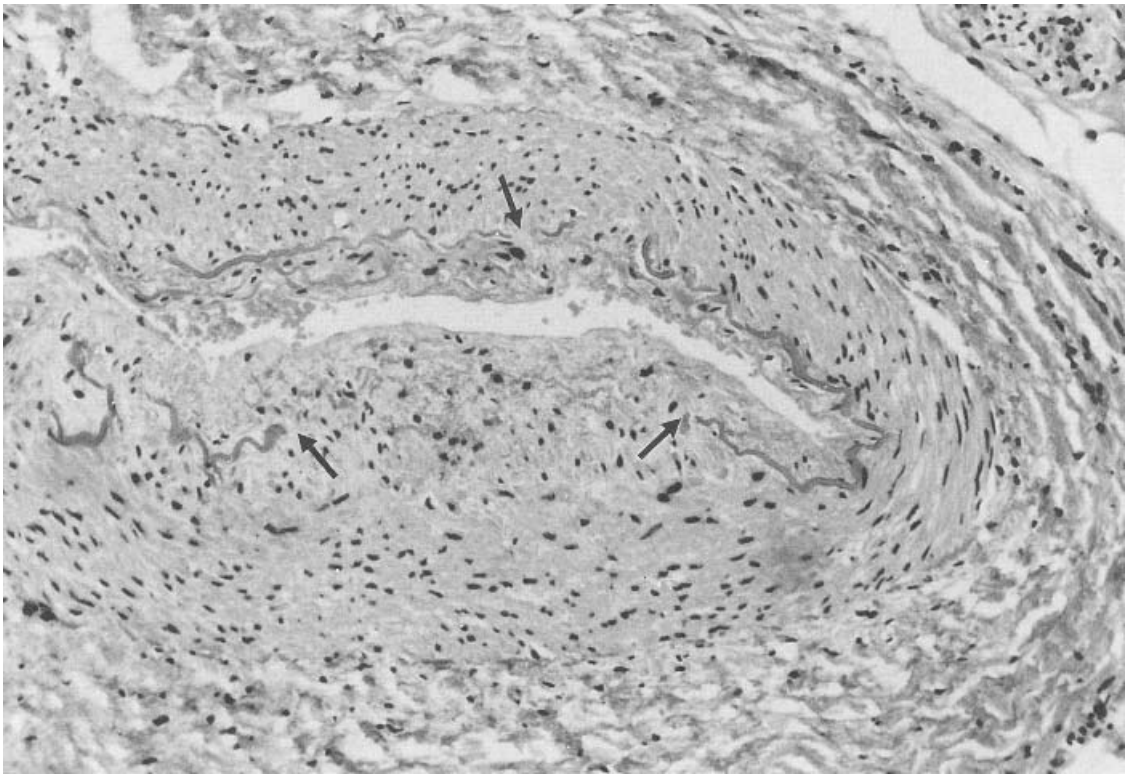

Figure 11. Disruption of internal elastic lamina of a large artery (arrowed), with proliferation of bundles of poorly organized elastic fibers and intimal thickening. (Courtesy of D. Danks, Royal Children's Hospital, Melbourne, Victoria 3052, Australia.)

Hair

Pathognomonic hair changes are observed in classical MD. The hair is typically hypopigmented, and its color may be almost white or grayish [92]. A decreased melanin content of hypopigmented hair has been demonstrated [93]. Light microscopy shows individual hairs that are twisted about their own axes (pili torti), which may show fraying and splitting at the ends (trichorrhexis nodosa) and show varying diameters of the shafts (monilethrix). There seems to be a gross reduction in number of disulfide bonds and an increase in free sulfhydryl groups in the hair [94]. Some more mildly affected cases may also show hair changes, but they are usually less pronounced and the color is darker.

Central Nervous System

Central nervous system pathology observed in classical MD has been reviewed extensively in the medical literature [48,49] and is only summarized in this chapter. Pathological alterations within the CNS are mainly confined to the cerebral hemispheres and the cerebellum. The brain shows evidence of a progressive and extensive degeneration of gray matter with resultant neuronal loss, gliosis, and secondary white-matter degeneration. A generalized atrophy and secondary subdural fluid collections accompany the neuronal loss. Areas of infarction secondary to vascular ischemia are also common. At the microscopic level, severe neuronal loss is evident, with replacement by proliferating astrocytic glial cells and macrophages. The white matter is usually markedly demyelinated and shows evidence of a glial reaction. Severe demyelination in the cerebellum, midbrain, pons, and medulla is frequently observed. Cerebellar sections show a substantially reduced number of Purkinje cells, which are irregularly distributed, some of them deep in the granular layer. Their shape is highly pathological, with abnormal dendritic arborization (weeping willow) and perisomatic processes (somal sprouts), and focal axonal swellings (torpedoes) are also observed.

More mildly affected cases may suffer from ataxia, which is likely caused by cerebellar dysfunction, because this feature persisted in a well-treated MD patient despite administration of L-DOPS (L-threo-3,4-dihydroxyphenylserine) to circumvent the metabolic block in noradrenaline biosynthesis [82]. This may be due to poor development of the adrenergic innervation secondary to low transmitter levels. Investigation of Purkinje cells in milder forms of the disease will therefore be of great interest.

Mitochondrial disorganization and accumulation of glycogen has been observed in brain tissue and retina, as well as in skeletal muscle [95]. Subsarcolemmal clustering of mitochondria (''ragged-red'' fibers), which is a specific sign of mitochondrial dysfunction, has also been reported [96].

Tissue Copper

Abnormal cellular sequestration of copper leading to organ-specific accumulation and depletion is a characteristic feature of classical MD, and maldistribution is already evident at the fetal stage. High placental levels indicate a compromised maternal-fetal transfer of copper, but the supply is sufficient to allow the accumulation of abnormally high levels in most nonhepatic tissues. Copper storage in the placentae of affected males is of diagnostic value. In contrast to the situation in postnatal life, fetal brain copper

levels are not significantly reduced, indicating that poor brain function is primarily the result of copper deprivation after birth. However, the fetal hepatic stores fail to build up, indicating a disturbance in copper availability already before birth [1,48].

In affected children, accumulation of copper in nonhepatic tissues, except the brain, is well-documented, and the levels are especially high in the intestine, kidneys, muscles, and pancreas. This accumulation is augmented further by copper therapy, but brain levels still remain subnormal. Hepatic copper stores are low in untreated patients, but copper injections can restore the levels to normal [1].

Tissue copper stores also appear to be elevated in the milder forms of the disorder, but tissue levels have been reported for only one OHS patient [69]. When compared with age-matched controls, the overall picture is very similar to that in classical MD patients. Increased storage of copper is documented in most tissues, except for the liver and brain, where low levels are found. The spleen level appears to be normal.

As a result of the basic disturbance in extrusion of copper from cells, nearly all tissues except liver and brain will accumulate copper to abnormal levels. The transport disturbance also affects the intestinal mucosa, leading to copper malabsorption. Nevertheless, the absorption of copper is sufficient to build up large copper stores in the bodies of affected males. At the whole-body level, the problem associated with dysfunction of ATP7A is a maldistribution of copper between organs combined with abnormal compartmentalization within cells. This makes the surplus copper unavailable for incorporation into several enzymes, resulting in a functional copper deficiency rather than a gross deficiency in the body. The low brain levels indicate a disturbance in copper uptake into the central nervous system that will probably aggravate the severity of the functional copper deficiency in this organ. In the liver, the role of ATP7A is taken over by the Wilson disease homolog, ATP7B, and no intracellular copper disturbance is present, but sequestration of copper elsewhere results in depletion of the metal in this organ. The low ceruloplasmin activity in plasma underscores that MD babies are indeed copper-deficient despite the increased stores in extrahepatic tissues.

PHYSIOPATHOLOGY

General Cellular Physiopathology

On entering the cell by the normal uptake mechanisms, copper is attached to the cytoplasmic chaperones, COX17, CCS, and HAH1, which deliver copper to cellular enzymes and compartments (Fig. 1). In Menkes disease, the defect in ATP7A results in an increase in intracellular free copper ion levels. This, in turn, induces metallothionein synthesis in an attempt to detoxify surplus metal. Metallothionein has been known and well-studied for decades, whereas little is known about the more recently identified chaperones. HAH1, the chaperone for ATP7A, is likely to be saturated as the next step in the pathway is blocked. On the other hand, COX17 and CCS are not expected to be deficient in copper, and the delivery of copper to COX and SOD1 should, in theory, not be diminished. However, because a mitochondrial disturbance is evident in MD, this suggests that COX may not receive sufficient copper even in organs with surplus copper [96]. SOD1 is deficient in the copper-deprived brain, while normal levels have been found in red blood cells.

ATP7A is necessary for the delivery of copper to the secretory pathway; hence, all secreted and vesicular copper-requiring enzymes may not receive sufficient metal for their normal function. The secretory pathway consists of stacks of disk-shaped membranous sacs (cisternae), the Golgi apparatus, through which proteins migrate during their biosynthesis. Nascent proteins are synthesized in the endoplasmic reticulum and transported in vesicles to the *cis*-Golgi cisternae (entry face) and gradually moved to the *trans*-Golgi cisternae (exit face) while the enzyme is post-translationally modified and the metallic cofactor is incorporated. Several of the copper-requiring enzymes can only incorporate copper during their passage through the Golgi apparatus. Information about the copper loading of various secreted enzymes is included in the general descriptions of the copper-requiring enzymes below.

Copper Enzymes

Copper enzymes are widely distributed in the body and are found both intracellularly and extracellularly. The intracellular enzymes are located in various cellular compartments, and biosynthesis of the active enzymes as well as their site of function is reviewed in the following.

Copper enzymes are involved in a number of reactions, and according to their main functions they can roughly be categorized as being involved in (1) energy formation, (2) protection against free radicals, (3) communication between cells and organs, and (4) formation of extracellular structure (Table 1).

Energy Formation

A prerequisite for life is the existence of mechanisms that can capture and store energy, and the respiratory chain

TABLE 1. Mammalian Copper Enzymes

Function	Enzyme	Biological Activity
Energy Capture	Cytochrome c oxidase	Cellular respiration
Protection	Superoxide dismutase	Free radical scavenging
	Ceruloplasmin	Ferroxidase
	Tyrosinase	Pigment formation
Communication	Dopamine β-hydroxylase	Catecholamine production
	Peptidyl α-amidating enzyme	Activation of peptide hormones
	Amine oxidases	Mono-, di- and poly-amine catabolism
Structural	Lysyl oxidase	Collagen and elastin cross-linking
	Sulfhydryl oxidase	Cross-linking of keratin

constitutes such a mechanism. In the respiratory chain, electrons are passed from one respiratory complex to another with the concomitant formation of energy-rich phosphate molecules (ATP), and the terminal oxidase reacting with molecular oxygen, cytochrome c oxidase, is a copper-dependent enzyme. Thus, copper plays an important role in cellular respiration. ATP is used as the energy source in numerous reactions in the body, and copper deficiency is therefore likely to result in widespread effects. Especially tissues with a high-energy requirement, such as muscles and brain, will likely be affected [97].

Cytochrome c oxidase. Cytochrome c oxidase (COX) [EC 1.9.3.1] is a large enzyme complex located in the inner mitochondrial membrane. It consists of 13 polypeptides, and the two copper-containing subunits (MTCO1 and MTCO2), which form the catalytic center of the enzyme, are encoded by the mitochondrial genome [31]. Hence, copper needs to be translocated across the mitochondrial membranes for incorporation into COX. Two genes involved in this translocation have been identified, namely the chaperone COX17, which transports copper to the periplasmic space [26–28], and SCO1, which is involved in incorporation of the metal into the metallocenter of the COX complex [29].

Protection Against Free Radicals

In several metabolic processes, highly reactive superoxide anions (O_2^-), also described as free radicals, are produced by partial reduction of molecular oxygen [98]. Because of their very toxic nature, free radicals need to be eliminated immediately, and numerous systems to protect the body against oxidative stress have been developed. An important class of protective enzymes is the superoxide dismutases, but other copper enzymes, such as ceruloplasmin and tyrosinase, also serve a scavenging role. Free radicals will attack and oxidize various molecular structures, such as lipids in the brain, and are believed to be involved in aging [99] and the development of Alzheimer disease [100].

Superoxide dismutase. Superoxide dismutase (SOD) [EC 1.15.1.1] converts superoxide anions into oxygen and hydrogen peroxide and thereby prevents the accumulation of toxic intermediates. Superoxide dismutase exists as three forms, encoded by three different genes. Two of these forms, SOD1 and SOD3, contain copper and zinc. SOD1 is the best-studied of the two enzymes. It is localized mainly in the cytoplasm, but evidence suggests that it is also located in peroxisomes and the nucleus [101]. SOD3 is secreted from the cell and has often been referred to as extracellular SOD (EC-SOD). SOD3 is found attached to the vascular wall and is the major superoxide dismutase in such extracellular fluids as plasma, lymph, and synovial fluid. Because it is secreted, the enzyme is most likely copper-loaded in the secretory pathway [102].

On the other hand, SOD2 (Mn-SOD) is manganese-dependent and is found in the matrix of mitochondria. There seems to be some interaction between SOD1 and SOD2 in their protective function. If one is low, perhaps due to a low body content of the catalytic metal, the amount of the other will increase [103]. However, the cytoplasmic SOD1 is present in greater quantities and may therefore be the physiologically most important form.

Ceruloplasmin. Besides SOD, ceruloplasmin (CP) [EC 1.16.3.1] is also involved in free radical scavenging. CP has ferroxidase activity and catalyzes the oxidation of highly reactive ferrous ions, Fe(II), to less toxic ferric ions, Fe(III), which, in turn, are bound to transferrin. During this oxidation process, ferrous ions can react with molecular oxygen and form superoxide radicals [98]. Rapid removal of free ferrous ions is therefore necessary. Findings in patients with aceruloplasminemia (MIM 604290) indicate that the main function of CP is indeed in iron metabolism. Thus, CP may play an important function in providing protection against superoxide radicals. Deficient iron mobilization will also affect heme biosynthesis and may cause anemia if the CP concentration is below 5% [104].

Circulating CP is synthesized primarily in the liver, and copper ions are incorporated during its synthesis by means of ATP7B. Copper does not influence the rate of synthesis or secretion of apoceruloplasmin, but a failure to incorporate copper during biosynthesis results in the secretion of an apoprotein that is devoid of oxidase activity and is easily degradable [105].

Hephaestin. Hephaestin (HEPH) is a protein identified in the late 1990s that plays an important role in intestinal iron absorption [106]. It is homologous to CP and contains similar copper-binding sites. In addition, it contains a transmembrane domain, indicating that the CP-like domain is located extracellularly. Based on its homology to CP, it has been proposed that HEPH is a ferroxidase necessary for iron release from intestinal epithelial cells. It has been suggested that ATP7A is involved in the copper loading of HEPH (C.D. Vulpe, personal communication). Deficiency of HEPH may also be speculated to result in hypochromic anemia. Thus, both CP and HEPH represent links between copper and iron metabolism and may explain iron-deficiency anemia associated with copper deficiency.

Tyrosinase. The production of free radicals may also be induced by photons, and the harmful effect of the sun is neutralized by the presence of melanin pigment in the skin. One of the enzymes involved in the production of melanin is the copper-requiring tyrosinase [EC 1.10.3.1; EC 1.14.18.1] that catalyzes several steps in the biosynthesis of melanin pigment. Dysfunction of the enzyme will consequently lead to hypopigmentation of the skin and hair. Tyrosinase is stored in pigment granules and thus is probably copper-loaded during its passage through the endoplasmic reticulum or Golgi apparatus.

Communication Between Cells and Organs

In any multicellular organism, communication between cells and organs is necessary. Copper participates in a number of reactions that have evolved to ensure the production and removal of various neurohormones and transmitters, and copper is necessary for the normal function of important enzymes such as dopamine β-hydroxylase, peptidyl α-amidating monooxygenase, and amine oxidases.

Dopamine β-hydroxylase. Dopamine β-hydroxylase (DBH) [EC 1.14.17.1] participates in the formation of adrenaline and noradrenaline from dopamine, and deficient activity of DBH will likely lead to autonomic failure. Besides copper, the enzyme requires ascorbate as a cofactor [107]. DBH is stored in secretory vesicles in nerve terminals and the adrenal medulla. Because of its vesicular location, the enzyme has to pass through the secretory pathway of the cells, and it is likely that copper is added at this stage. Low brain levels of copper will reduce the activity of DBH [108], but addition of copper after the enzyme has been synthesized can restore enzymatic activity [109].

Peptidyl α-amidating monooxygenase. Peptidyl α-amidating monooxygenase (PAM) [EC 1.14.17.3] is structurally similar to DBH, and it also requires copper

and ascorbic acid as cofactors [107]. PAM catalyzes the post-translational amidation of a number of essential peptide hormones involved in hypothalamic-pituitary regulation, as well as intestinal function, and such modification is required for full biological activity. The functional significance of PAM is not well-understood, but its deficiency will most probably result in widespread effects. Like DBH, PAM is found in both secreted and membrane-associated forms, and the biosynthesis of the enzyme is likely to be similar to that of DBH, with copper loading occurring in the secretory pathway. By analogy with DBH, the enzymatic activity of copper-deficient PAM can probably be restored after its biosynthesis by addition of the metal.

Amine oxidases. The copper-containing amine oxidases (AOCs) [EC 1.4.3.6] comprise a heterogeneous group of enzymes that are found in various tissues, including vascular smooth muscle, lung, eye, adipose tissue, placenta, and, in particular, intestine and plasma [110,111]. AOCs catabolize a variety of substrates, including monoamines, diamines, and polyamines, and thus regulate the intracellular concentrations of putrescine, spermine, and spermidine [112]. These polyamines exhibit a wide variety of functions and have been recognized to be vitally important in numerous fundamental cellular processes, including wound healing, tissue differentiation, cellular proliferation, and possibly apoptosis [110]. Modulation of ion channels has also been implicated [113]. One of the AOCs, histaminase, has long been recognized to play a role in inflammation, allergy, and ischemia. However, the exact physiological functions of AOCs are still unresolved, and because of the diversity of the substrates, it is difficult to delineate the precise clinical importance of this enzyme group.

Human genes for kidney (ABP1), retina (AOC2), and placenta (AOC3) specific oxidases have been identified [114–116], and the structural determinants of the proteins are beginning to be defined. A novel quinone cofactor has been identified in several amine oxidases, and these enzymes are now called quinoenzymes. The cofactor is formed by a copper-dependent post-translational modification of a tyrosine residue in the backbone of the enzyme [117]. Lysyl oxidase, which is discussed below, is also a quinoenzyme. Studies on a copper-free form of histaminase indicate that its enzymatic activity can be restored by the addition of copper after the protein has been synthesized and excreted [117], although this is not the case for lysyl oxidase.

Formation of Extracellular Matrix

Multicellular organisms obviously also have a need for intercellular stability, and copper enzymes play a major role in this function. Copper plays a key role in the biosynthesis of the extracellular matrix proteins, collagen and elastin, through its function as a cofactor for the enzyme lysyl oxidase.

Lysyl oxidase. Lysyl oxidase (LOX) [EC 1.4.3.13] is a secreted enzyme, which catalyzes the initial cross-linking of collagen and elastin and is found extracellularly attached to its substrates. Inhibition of LOX has profound effects on the strength of bone and elastic tissues. Collagen type I comprises 90% of the organic matrix of bone, and a decrease in the number of cross-links is accompanied by reduced mechanical strength of the bone, which may lead to spontaneous fractures [90]. Dysfunction of LOX will also affect other types of collagen, resulting in several connective tissue defects. When cross-linking is inhibited, the tensile strength of the collagen fibrils is reduced and they become fragile. Together with low elasticity due to defective cross-linking of elastin, this affects structures such as blood vessels, which become friable and may eventually rupture. Elastic tissues in skin become less stretchable and will not restore shape after extension, leading to premature wrinkling. Copper deficiency may therefore mimic heritable disorders of collagen and elastin (see also Chapter 9, this volume).

As mentioned above, lysyl oxidase is a quinoenzyme using a quinone cofactor named lysine tyrosylquinone (LTQ) as a transient electron carrier in the enzymatic reaction cycle [118–120]. After LOX has been synthesized, the enzyme is copper-loaded and the quinone cofactor is formed as part of the Golgi or *trans*-Golgi processing. In contrast to other quinoenzymes, a copper-catalyzed intrachain cross-linking of two amino acids in the LOX molecule is a prerequisite for a functional cofactor.

The LTQ cofactor is an integral part of the enzyme molecule and is formed by a copper-catalyzed cross-linking of the ε-amino group of a peptidyl lysine with the modified side chain of a tyrosyl residue before the enzyme is secreted. The formation of the quinone cofactor of LOX is clearly distinct from that of other quinoenzymes in the requirement of copper first for modification of the tyrosine residue and subsequently for the cross-linking of this modified residue to the lysine residue. This knowledge is important for the understanding of why LOX in particular is susceptible to copper deficiency.

Copper deficiency will affect the formation of the cofactor and hence the function of LOX, but it does not appear to affect the biosynthesis of the apoenzyme [121]. Copper added after secretion of the enzyme is unable to catalyze the intramolecular cross-linking and restore the enzymatic activity of LOX, in contrast to other quinoenzymes for which only a copper-dependent modification of a tyrosine residue is required. Thus, LOX activity in the body is solely dependent on the amount of copper available during the biosynthesis of the enzyme.

Keratinization. The skin constitutes a mechanical protective barrier to the body. Keratinization is also a copper-dependent process, although the precise enzymatic reaction has not yet been characterized. Lack of copper results in deficient cross-linking of keratin in hair and skin by an as yet unidentified mechanism [94]. Copper therapy may, however, ameliorate the structural defects seen in Menkes disease patients.

Clotting factors V and VIII. The blood-clotting factors V and VIII both contain copper, and failure of incorporation of the metal might impair the synthesis or function of the proteins. The copper-binding site is structurally related to that of ceruloplasmin, and this suggests a role for copper in these coagulation factors, the specific nature of which is not yet known. It has been suggested that copper may play a role in the correct folding of the proteins [122]. Lack of copper could be speculated to result in a bleeding tendency, and hematomas are frequently observed in MD.

Whole Body Physiopathology

The clinical and pathological features of MD are the result of a complex interplay of several copper-dependent processes. Certain features can be clearly related to dysfunction of specific copper-requiring enzymes, but for other symptoms it can be difficult to identify the role of each enzyme in the overall picture (Table 2). Biochemical defects in one

TABLE 2. Relationship Between Symptoms and Copper Enzymes in Menkes Disease and the Occipital Horn Syndrome

Symptom	Enzyme Involved
Premature rupture of fetal membranes Cephalohematoma Abnormal facies High-arched palate Emphysema Hernias Bladder diverticula Arterial aneurysms Loose skin and joints Osteoporosis	Lysyl oxidase
Petechial hemorrhage	Lysyl oxidase, clotting factors V+VIII
Poor wound healing	Lysyl oxidase, amine oxidase?
Abnormal hair Dry skin	Sulfhydryl oxidase
Hypopigmentation	Tyrosinase
CNS degeneration	Superoxide dismutase, cytochrome c oxidase, lysyl oxidase
Ataxia	Dopamine β-hydroxylase, cytochrome c oxidase
Muscle weakness	Cytochrome c oxidase
Hypothermia Hypotension Diarrhea	Dopamine β-hydroxylase
Anemia	Ceruloplasmin, hephaestin

metabolic pathway can be influenced by the concurrent failure of other copper-dependent systems. These processes may act synergistically and aggravate disease progression.

Changes in enzymes necessary for the formation of body structures such as the connective tissues and skin and hair will cause profound visible effects. Defects in other enzyme systems may add to these changes or primarily affect the way in which the body reacts to stress of different types. In the following, we discuss the defects at a structural and functional level, still knowing that these categories overlap.

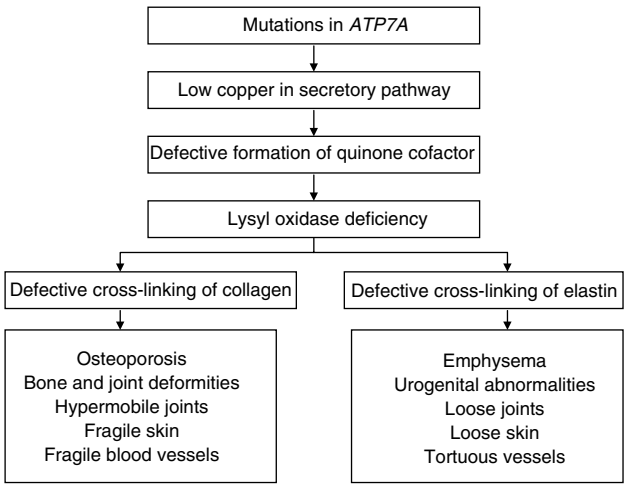

Figure 12. Physiopathological mechanisms of the connective tissue disturbances in Menkes disease.

Structural Defects

Copper is involved in the formation of collagen and elastin, and in MD connective tissues, and hence organs rich in this type of tissue, are severely affected (Fig. 12). Collagen and elastic fiber pathology is the result of deficient LOX activity secondary to a defect in the cellular copper pump, ATP7A, resulting in the faulty delivery of copper for activation of LOX. A defect in ATP7A will result in a reduced availability of copper and affect the formation of the quinocofactor in LOX and hence the activity of the enzyme. After secretion, this activity cannot be restored by copper supplementation, pointing to a direct link between the availability of copper in the Golgi complex and LOX activity [120,121]. This is also reflected by the inefficiency of copper-histidine treatment in correcting the connective tissue manifestations (see "Treatment" below).

The cross-linking defect may affect a number of types of collagen. Thus, changes that are specific to collagen defects of type I (bone fractures as in osteogenesis imperfecta — Chapter 8, this volume), type II (bone and joint deformities as in chondrodysplasia — Chapter 23, part II, this volume), and type III (fragile skin and blood vessels as in Ehlers-Danlos syndrome type IV — Chapter 9, this volume) can be seen in MD. Classical MD patients exhibit a wide range of connective tissue defects ranging from lax skin and joints to osteoporosis. In severe cases, bone fractures and vascular rupture may even raise the suspicion of child abuse. Milder forms of MD manifest progressive connective tissue defects as a result of long-term effects of poor connective tissue cross-linking.

Deficient LOX activity also interferes with the cross-linking of elastin, affecting connective tissues with a high content of elastic fibers, including ligaments, arterial walls,

and elastic cartilage. Humans appear to be extremely sensitive to reduced elastin levels and may develop profound symptoms, as can be seen in various inherited disorders such as supravalvular aortic stenosis (MIM 185500), Williams syndrome (MIM 194050), and certain forms of cutis laxa (MIM 123700) [123,124] (see also Chapter 10, this volume).

The elastic fiber is responsible for restoring shape after stretch in a variety of tissues, and symptoms related to improper function of elastic tissues are prominent in both severe and milder cases of MD. These symptoms comprise inguinal and umbilical hernias, diverticula of the bowel and bladder, gastric polyps [125], skin laxity, hyperextensible joints, and, later, joint contractures and lordosis, or kyphosis.

The striking hair changes seen in MD are probably the result of defective keratin cross-linking. This process appears to be copper-dependent because copper deficiency in sheep leads to the formation of abnormal wool with defective cross-linking of disulfide bonds. This led Danks and his co-workers in 1972 to detect the abnormal copper metabolism [51]. They recognized the similarity of patients' hair to wool from sheep grazing on copper-deficient pastures and subsequently demonstrated copper deficiency in the brain, liver, and blood of MD patients. In MD patients, the content of free sulfhydryl groups in hair is increased, and the diminished cross-linking of the hair results in an abnormal structure with easily recognizable changes. In fact, the hair changes are one of the key symptoms in identifying patients with classical Menkes disease. Patients with a milder clinical course have less severe hair changes, and it also appears that the hair tends to normalize with increasing age and with copper therapy. Defective keratinization can also explain the high prevalence of seborrheic dermatitis in Menkes patients. The hypopigmentation of skin and hair is most likely due to decreased activity of tyrosinase, which is involved in melanogenesis.

Functional Defects

When functional defects in MD are discussed, the body tissues and organs can be viewed in three categories: liver, brain, and other tissues. In liver, ATP7A is not expressed, underscoring the fact that its role is taken over by ATP7B. Liver copper levels are low in Menkes disease, but this can be corrected by copper supplementation, indicating that it is a secondary effect. Brain is unique in that it is the only organ deprived of copper due to the blood-brain barrier, whereas for the other organs and tissues copper deficiency is functional. Therefore, the pathological mechanisms are likely to be different in the peripheral and central nervous systems.

Although LOX is the enzyme responsible for most of the connective tissue disturbances, the other main group of symptoms, the neurological abnormalities, is probably the consequence of a combined deficiency of several copper-dependent enzymes. Low amounts of COX will result in deficient energy production, affecting nerve conduction. Defects in the respiratory chain will also lead to the production of free radicals and, in combination with deficient activity of superoxide dismutase, this will lead to further accumulation of superoxide anions. This in turn, will result in peroxidation of unsaturated lipids and cause irreversible damage to myelin sheaths and result in neuronal degeneration. Reduced activity of DBH will affect the production of neurotransmitters, resulting in increased levels of dopamine and low levels of catecholamines and noradrenaline. Low levels of neurotransmitters in early life will lead to deficient brain development, and this cannot be corrected later by restoration of transmitter function. PAM is involved in the maturation of neuropeptide hormones, and low levels of this enzyme may therefore also contribute to the neurological defects. Vascular abnormalities as a result of defective LOX will cause intracranial bleeding and further aggravate the neurological dysfunction.

Another way of discussing the relative contributions of the copper enzymes to the neurological symptoms is to consider the possible effect of each individual enzyme, such as COX, SOD, and DBH. Cytochrome c oxidase is one of the enzymes in the respiratory chain, deficiency of any of which will affect energy production and hence all energy-requiring (ATP-dependent) processes in the body, including nerve transmission. MD may therefore mimic a mitochondrial disorder in which multiorgan involvement may also be present and complicate the clinical picture. Low activity of COX could result in hypotonia besides being partly responsible for the complex neurological picture seen in MD patients. Patients with mitochondrial myopathy due to a specific COX deficiency often suffer from neurological disturbances, with mental retardation and seizures, and cardiac and skeletal muscle weakness [97], but deficient thermoregulation is not a common feature. The claimed effect of COX on thermoregulation [49] is therefore disputable.

Superoxide dismutase may be affected differently in the peripheral and central nervous systems. In the brain, there is a well-documented lack of copper and the activity of SOD1 is decreased as expected, but there appears to be overexpression of the manganese form of superoxide dismutase (SOD2) [103]. This form of the enzyme is localized in the mitochondria, and the production of superoxide radicals in the respiratory chain may hence be partly neutralized. The full contribution of superoxide dismutase deficiency to the neurodegenerative processes in MD is therefore difficult to determine. In the peripheral nervous system, the cellular free-copper pool is increased and there may therefore be no lack of copper for incorporation into SOD1. The activity of SOD1 in red blood cells has been reported to be normal in several patients [1].

DBH is important for the biosynthesis of catecholamines, and deficient production in MD is documented by an abnormal pattern of catecholamine metabolites. Several clinical features seen in MD and OHS can be explained by an autonomic dysfunction, and orthostatic hypotension is a common problem in OHS and well-treated MD patients, which can be corrected by ingestion of L-DOPS [82]. The sympathetic nervous system is also important for thermoregulation, and hypothermia is a recurrent problem in MD patients. Mice deficient in DBH due to a targeted gene disruption show poor thermogenesis, leading to low body temperature when exposed to cold [126]. Like MD babies, neonates with congenital DBH deficiency suffer from episodic hypothermia [127]. Chronic diarrhea also seems to be caused by autonomic dysfunction because the administration of L-DOPS can control this problem [82]. Ataxia is yet another symptom that can be aggravated by lack of DBH. Mice deficient in DBH have fewer noradrenergic terminals in cerebellum compared with controls [128], and this region of the brain appears particularly resistant to the restoration of noradrenaline by administration of L-DOPS. This could explain the persistent occurrence of ataxia in a well-treated MD patient receiving supplementary treatment with this drug [82].

PAM is required for the activation of numerous peptide hormones (e.g., corticotrophin-releasing factor, thyrotropin-releasing hormone, growth hormone–releasing hormone, gastrin, vasopressin, calcitonin, and cholecystokinin) involved in hypothalamic-pituitary regulation as

well as in gut function. Low activity of PAM might be expected to cause a wide range of effects, although the precise consequences are difficult to predict. Both central nervous system effects and systemic problems are likely. The activity of this enzyme has been investigated in serum samples from moderately affected MD patients and found not to be diminished [129]. However, when copper was added to the serum samples, the enzyme activity increased. This might indicate the presence of extra apoenzyme released as a compensatory secretion secondary to copper deficiency at the site of loading of the PAM molecule.

Low tyrosinase activity can easily explain the hypopigmentation of skin and hair [1], but it may also affect visual function. A hypopigmented fundus has been described in MD patients [130], and it is well-known that albinism (MIM 203100) due to a genetic defect of tyrosinase is accompanied by visual problems.

Low levels of ceruloplasmin are well-documented in classical MD patients, but on the whole the ferroxidase activity appears to be sufficient for iron mobilization. However, some MD patients may show moderate hypochromic anemia. The newly discovered iron transporter, hephaestin, may also be speculated to play a role in the development of anemia. The low availability of hepatic copper could also be speculated to affect clotting factors V and VIII, interfering with the normal function of the coagulation cascade. This could add to the bleeding tendency that is caused by the fragile blood vessels secondary to LOX deficiency.

MOLECULAR PATHOLOGY

Structure of the Protein (ATP7A)

ATP7A is a member of the copper ATPase protein family, which is a subgroup of a large family of P-type ATPases that are energy-using membrane proteins functioning as cation pumps. They are called "P-type" ATPases because they form a phosphorylated intermediate during the transport of cations across a membrane.

ATP7A has functional domains with highly conserved motifs that are common to all P-type ATPases (Fig. 13). The so-called phosphorylation domain contains an invariant cytoplasmic DKTGT motif within which the aspartate

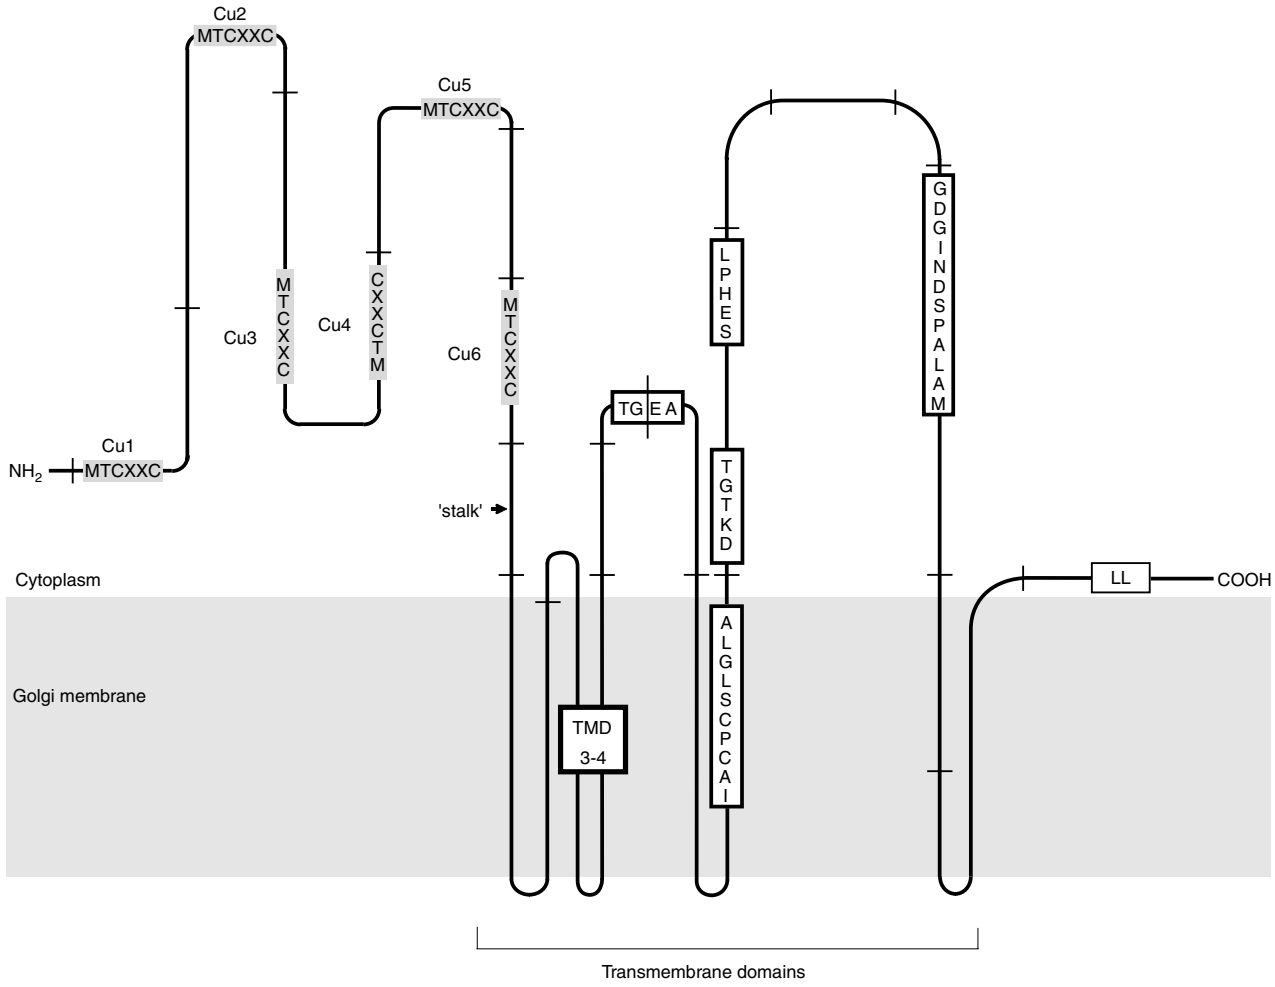

Figure 13. Protein structure of ATP7A. Cross lines indicate the positions of exon/intron boundaries. The copper-binding motifs (MTCXXC) are numbered Cu1–6; transmembrane domains 3 and 4 (TMD 3-4) contain a Golgi localization signal; phosphatase domain (TGEA); transduction domain (IACPCSLGLA); phosphorylation domain (DKTGT); loop motif (SEHPL); ATP-binding domain (GDGINDSPALAM); recycling signal (LL). "Stalk" indicates the region between the last metal-binding domain and the ATPase core.

residue is phosphorylated by the terminal phosphate of ATP in the transport cycle. The ATP-binding domain with a conserved GDGXNDXP motif is responsible for the binding of ATP. The phosphatase domain contains the consensus TGEA/S sequence, which removes the phosphate from the phosphorylated aspartic acid during cation transport. These proteins also possess hydrophobic transmembrane domains (TMD), but their numbers differ among the ATPases. ATP7A, like the other Cu-ATPases, has eight TMDs that anchor the protein into the Golgi membrane [131].

Besides having features common to all P-type ATPases, ATP7A and other copper ATPases also contain some motifs specific for this subgroup [131,132]. Interestingly, these motifs are also conserved in P-type ATPases transporting other heavy metals, such as mercury or cadmium. A remarkable feature of Cu-ATPases is a characteristic intramembranous motif, CPC, unique to this subgroup. This motif is likely to constitute the cation channel involved in transduction of the metal through the Golgi membrane. A highly conserved HP motif (SEHPL/I) situated in the second cytoplasmic loop C-terminal to the phosphorylation domain is present in all known copper-transporting ATPases characterized so far. This motif is likely to have a regulatory role in copper translocation because its position is analogous to that of the regions that modulate the affinity of ion binding in calcium-transporting P-type ATPases [131].

At the amino terminus, ATP7A has six domains of approximately 100 amino acids, each containing a consensus GMXCXXC motif, where the two cysteine residues play an important role in copper binding. Studies suggest that this region is directly involved in the selective binding of heavy metals, the highest affinity being toward copper, followed by zinc, nickel, and cobalt [133–135]. The whole region binds six copper atoms, one atom per metal-binding repeat [136,137]. NMR studies on the fourth metal-binding domain of ATP7A demonstrated that Ag(I) could bind to the two cysteine residues of the conserved GMXCXXC motif [138]. Different site-directed mutagenesis studies suggest that not all of the metal-binding domains are equally important for the normal function of the protein, but a consensus has not yet been reached on which is most essential [139,140]. The functional significance of the repetition of these metal-binding sites is not yet clearly understood either. Both a regulatory role and direct involvement in transfer of the metal have been suggested [132]. Analysis of the whole copper-binding region indicates an allosteric control of metal binding [137,141]. It has also been suggested that binding of copper to the repeated motifs is the signal required for the reallocation of the protein from the Golgi apparatus to the plasma membrane [41,42,141].

Structure of the Gene (*ATP7A*)

The 8.5 kb *ATP7A* mRNA consists of 23 exons and spans approximately 150 kb of genomic DNA [142,143]. The 5′-untranslated region of the gene is rich in GC sequences, which is a feature of housekeeping genes required by all or most tissues. This is in line with the multisystemic character of Menkes disease (MD). An interesting feature of the promoter region of *ATP7A* is the presence of three 98 bp tandem repeats. The function of these sequences is still unknown, but deletion of one of these repeats has been observed in one OHS patient (see below) [144]. The 134 bp first exon of *ATP7A* contains only untranslated sequences, and the first base pair of this exon has been suggested as the transcription start site [142]. Levinson et al. [144] have also identified other possible transcription start sites. The ATG translation start codon is within the 141 bp second exon, which also contains part of the 5′-untranslated region and the first metal-binding domain. The last exon is 4,120 bp in length and contains a 274 bp translated sequence, a TAA translation termination site, a large 3′-untranslated region, and a polyadenylation site. Apart from the 23 exons mentioned, the large first intron of *ATP7A* includes a 192 bp exon (exon 1b), which is alternatively spliced and expressed in low amounts in several tissues examined (T. W. Glover, personal communication).

In *ATP7A*, the exons seem to correspond to the predicted functional/structural domains of the protein product, and this may be of importance in the case of in-frame mutations [142]. The predicted metal-binding domains (Cu1–6) and the transmembrane domains (TMD) are encoded by separate uninterrupted exons, with some exceptions: Cu3 and Cu4 are together encoded by a single exon, and the exons coding for TMD2 and TMD7 are interrupted by introns. The phosphorylation and ATP-binding domains are also encoded by a single exon, while the exon coding for the phosphatase domain is interrupted by an intron.

Several exons in *ATP7A* are alternatively spliced [143]. One of these is exon 10, encoding TMD3 and TMD4. Exon 14 coding for TMD5 and/or exon 15 coding for TMD6 and the putative cation channel with the highly conserved CPC motif are also alternatively spliced. Exon 1b identified within intron 1 is another alternatively spliced exon (T. W. Glover, personal communication).

Mutation Spectrum of *ATP7A*

To date, a total of 191 mutations affecting *ATP7A* have been identified in unrelated MD patients with the classical severe form or with one of the atypical phenotypes [145].

Chromosomal abnormalities affecting *ATP7A* have been detected in seven patients. One of these patients was a male with a unique abnormality whereby the segment Xq13.3-q21.1 was inserted into the short arm of the X chromosome [146]. One female patient was mosaic for the Turner karyotype [147] and the remainder had X;autosome translocations [148–150] (D. Wattana and S. Mohammed, personal communication).

Of the remaining 184 gene mutations identified, 35 have been partial gene deletions of different sizes and locations. The largest defect observed has been the deletion of the whole gene except for the first two exons, and the smallest one detectable by Southern blot hybridization has been a deletion of the first exon.

The total number of point mutations identified within *ATP7A* is 149, comprising 78% of all the mutations. Eighteen of these mutations have been reported by other groups [80,144,151–155,159] and 44 by ours [156–158], while 87 mutations have not yet been published. Of the 149 point mutations, 132 were novel. A common mutation observed is a missense mutation within exon 10 [151], which has been detected in nine unrelated families.

The four types of point mutation in *ATP7A* (deletions/insertions, missense and nonsense mutations, and splice site mutations) are represented in almost equal proportions (Fig. 14). About half of the point mutations are frame-shift or nonsense mutations (22% and 14% of all *ATP7A* mutations, respectively), which are predicted to result in a nonfunctional truncated protein. These truncating mutations are distributed almost equally throughout the gene, although none has been observed in exons 1, 2, 5, or 23. A clustering of mutations

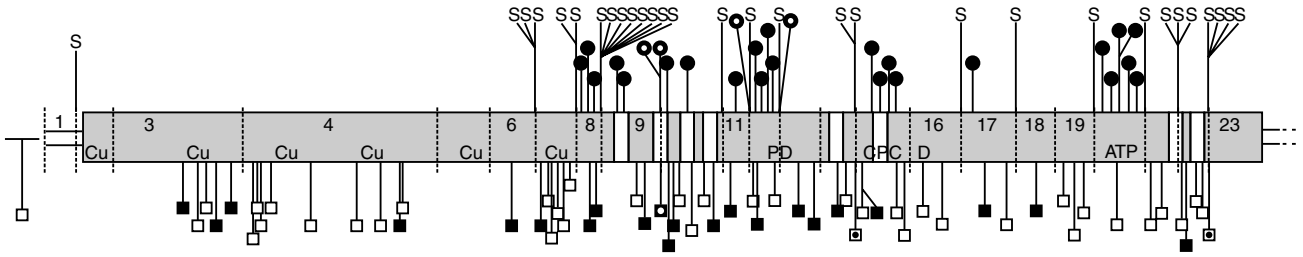

Figure 14. Mutation spectrum of Menkes disease. Localization of 118 different point mutations identified in *ATP7A*. The copper-binding domains are indicated by Cu and the transmembrane domains by vertical white bars. PD: the phosphatase domain; CPC: the cation channel; D: phosphorylation domain; ATP: ATP-binding domain. The coding region of *ATP7A* is shown as a gray horizontal box. The vertical dotted lines indicate the positions of the introns, and the exons are numbered from 1 up to 23. The 3′- and 5′-untranslated regions are shown as horizontal empty boxes, and a horizontal line indicates the flanking genomic sequence of the 5′ untranslated region. Empty squares: insertion/deletion mutations; filled squares: nonsense mutations; filled circles: missense mutations; S: splice site mutations. Mutations at the coding sequences that are predicted to affect normal splicing are marked with a small dot.

can be observed in those exons that represent the functionally important and highly conserved regions of the protein; these are 12, 15, and 20, coding for the phosphatase, transduction, and ATP-binding domains of the protein, respectively. An exception to this is exon 8, in which a total of 15 point mutations (including acceptor and donor site mutations) have been identified [151,155,158]. Exon 8 encodes a region between the last metal-binding domain and the first transmembrane domain of ATP7A. Although a specific function has not yet been ascribed to this region, it may play an important role in the folding of the protein and serve as a "stalk" joining the metal-binding domains and the ATPase core.

No missense mutations have been observed in the copper-binding domains of ATP7A encoded by exons 2–7. This lack is in line with the amino acid diversity allowed between species. In contrast, missense mutations are frequent in exons 8 to 23, encoding the ATPase core, especially in the conserved motifs, underscoring the importance of these domains for the normal function of the protein.

Relationship Between Type of *ATP7A* Mutation and Severity of Menkes Disease

Naturally occurring mutations are invaluable in assessing the importance of the functional domains of a protein, and the nearly 200 mutations of the *ATP7A* gene identified in MD patients give important clues. However, spontaneous mutations are limited, and site-directed mutation analysis using a yeast system has been applied to *ATP7A* (and *ATP7B*). These studies may, at the same time, give a better understanding of the mechanisms that may lead to differences in the severity of symptoms among MD patients. We will therefore discuss the mutations found in OHS patients in more detail in this part. In general, MD patients with milder phenotypes seem to have a higher proportion of mutations that would result in a protein with residual activity.

To date, seven point mutations have been reported in patients diagnosed with OHS [80,144,152,155,159]. In all of these, except for that described by Levinson et al. [144], the DNA mutation has led to RNA splicing defects. In general, splice mutations comprise approximately 30% of the point mutations and 20% of all mutations found in MD patients.

In five OHS patients [80,152,159], the mutations have been at the consensus splice site sequences affecting normal RNA splicing. In three of these patients [80,152], in addition to the abnormal size transcripts, a normal transcript was always present in low amounts. The milder phenotype of the patients could thus be explained by the presence of the normal transcript, albeit in low amounts.

In one patient, the mutation was a single base-pair substitution within the splice site sequence of exon 11 (Ser833Gly). In addition to two abnormal size transcripts, a normal size transcript was present, but this transcript included the mutation [80]. This missense mutation was not within a region coding for a conserved motif, and its effect on the function of the protein probably was not severe.

In the patient described by Ronce et al. [155], the RNA-splicing defect was due to a missense mutation in exon 8. In this patient, both a normal size transcript bearing the mutation and abnormal size transcripts were detected. A possible explanation for the mild phenotype is the presence of an at least partially functional protein coded by the normal size transcript bearing the missense mutation. Previously, a missense mutation within exon 8 was detected in a patient with the classical phenotype, but this mutation has not yet been analyzed at the transcriptional level [158].

In the OHS patient described by Qi and Byers [159], a normal size transcript was not present. The abnormal transcript lacked exon 10 which is alternatively spliced out in normal individuals [143]. The protein product missing transmembrane domains 3 and 4 encoded by exon 10 was localized to the endoplasmic reticulum [159] instead of the Golgi complex, where normal ATP7A resides [34–36]. Part of the amino acid sequence encoded by exon 10 was suggested to be responsible for the Golgi localization of ATP7A [40]. The milder phenotype of the OHS patient suggests that at least some of the enzymes, other than LOX and DBH, could receive copper, even though ATP7A was mislocalized.

The only mutation not to affect RNA splicing in an OHS patient was described by Levinson et al. [144]. One of the three repeated elements in the regulatory region of *ATP7A* was deleted [144], but the level of transcription was normal. In this patient, other *ATP7A* mutations could not be detected, and the relationship of this deletion to OHS remains to be investigated.

ANIMAL MODEL

The mottled mouse has long been considered an animal model of MD on the basis of phenotypic and biochemical evidence, but its status as a true animal model was only proven in the late 1990s by the demonstration of mutations in the homologous murine gene, *Atp7a*, in several mottled alleles [160].

The first mutant, the mottled mouse, arose spontaneously in 1953 [161]. Mutations at the X-linked mottled locus (*Atp7a*^{Mo}) lead to a characteristic variegated coat color in female heterozygotes. In 1974, a defect in copper metabolism was demonstrated in mice bearing the mottled brindled allele [162]. Since then, several similarities between the biochemical pathology and phenotypic features of the mottled mouse and Menkes disease (MD) have been delineated [160,163,164]. Another indication of homology between MD and the mottled phenotype is that both loci belong to a region of genes on the X-chromosome that are highly conserved in both man and mouse.

Following the isolation of *ATP7A*, the mouse gene (*Atp7a*) was cloned using the human sequences [165,166]. The predicted protein product shows great sequence homology to ATP7A, and the tissue expression profile is also similar [167,168]. The genomic structure of the mouse gene is highly homologous to that of the human gene. The 8.0 kb transcript sequence consists of 23 exons spanning about 120 kb, and all the introns interrupt the aligned coding regions at the same positions [169].

There are about 30 independent mottled mutants, which show considerable variability of neurological and connective tissue abnormalities ranging in severity from allowing viable and fertile males with coat hypopigmentation to causing death *in utero* of affected male pups [170] (Boyd, personal communication). Today, *Atp7a* mutations have been identified in nine of the mottled alleles [152,166,171–177] (Cunliffe et al., personal communication).

Two of the most well-characterized mottled mutants, the mottled brindled and mottled macular, present with severe neurological impairment and death about day 14 and are suggested as murine models for the classical form of MD [160,162,163,177]. Mottled brindled has a 6 bp deletion in the cytoplasmic loop containing the phosphatase domain of *Atp7a*, and mottled macular has a missense mutation in the eighth transmembrane domain (TMD). On the other hand, the mottled blotchy phenotype resembles OHS by showing predominantly connective tissue manifestations [178]. Mottled blotchy has a splice site mutation affecting normal RNA splicing, similar to that observed in several OHS patients [80,152,159]. Interestingly, Kaler and co-workers have described an OHS patient with a mutation occurring at the same splice site (IVS, DS 11) as in mottled blotchy [80]. The mottled viable brindled phenotype is similar to that of mild MD [160], and this allele has a missense mutation in a conserved domain of *Atp7a* [174]. A missense mutation in the seventh TMD has now been identified in a patient with mild MD [179].

In general, the mutations in *Atp7a* are rather similar to those in *ATP7A* [160]. Small insertions or nonsense mutations have not been identified in mottled mice, but the presently elucidated nine mutations are not sufficient to define the mutation spectrum of *Atp7a*.

DIAGNOSIS

The initial diagnosis of Menkes disease (MD) and its milder variants is based on the clinical symptoms. In classical cases, the typical hair changes are a valuable diagnostic pointer. Low serum copper and ceruloplasmin levels will support the clinical suspicion, but biochemical confirmation in tissue culture is needed, especially in milder cases (Table 3). The ultimate diagnostic proof is the demonstration of a molecular defect in *ATP7A*.

Clinical Diagnosis

All MD patients exhibit connective tissue symptoms to varying degrees. Classical MD patients also have severe neurodegeneration, whereas the neurological symptoms of OHS are mild, leading to a clinical picture characterized

TABLE 3. Postnatal Diagnostic Markers for Menkes Disease and the Occipital Horn Syndrome

	Menkes	OHS	Comments
Pathognomonic features	Pili torti	Occipital horns	Clinical continuum
Blood markers			
Copper	Severely decreased	Moderately decreased	Not diagnostic in neonates
Ceruloplasmin	Severely decreased	Moderately decreased	Not diagnostic in neonates
DOPA/DHPG[1]	Significantly increased	Significantly increased	Diagnostic in neonates
Tissue copper			
Placenta[2]	Significantly increased	Probably increased	Diagnostic in neonates, noninvasive
Liver	Significantly decreased	Decreased	Invasive, not routine
Cultured fibroblasts			
Lysyl oxidase	Decreased	Decreased	Great interlaboratory variation, not routine
Radiolabeled Cu/Ag[2]	Increased uptake and retention[2]	Increased uptake and retention[2]	Not discriminatory between severe and mild forms
Mutation[2]			
DNA	Broad spectrum of mutations; all types represented	Splice mutations prevalent	Large gene (23 exons); clustering of mutations in central portion of the gene
RNA/protein	80% leading to translation stops	Residual protein activity likely	

[1] DOPA: dihydroxyphenylalanine; DHPG: dihydroxyphenylglycol.

[2] Definitive diagnosis.

mainly by connective tissue manifestations. Intermediate variants show less pronounced CNS involvement, although usually marked connective tissue symptoms.

Physical Examination

Clinical diagnosis of classical MD is often fairly easy once a few cases have been seen, but the diagnosis of milder cases may still pose a problem and they are probably underdiagnosed. The cloning of the gene has increased interest in the variant phenotypes, including OHS. The X-linked inheritance may help to direct attention to the correct diagnosis in familial cases.

In classical MD, the most striking and diagnostically important symptom is the abnormal hair structure. The hair appears colorless and friable. There may be a good reason for keeping the eponymic name, Menkes steely (kinky) hair disease, to direct attention to this important diagnostic feature. There is marked hypotonia, poor head control, and the facies is often characteristic, with frontal bossing and an expressionless appearance due to facial hypotonia. The skin is pale and loose, and the joints are hypermobile. Umbilical and inguinal hernias are frequent. Other manifestations are hypothermia, poor feeding, impaired weight gain, delayed developmental milestones, and the occurrence of intractable seizures.

Physical findings in OHS comprise craniofacial abnormalities, with a long face and neck, a high forehead and a hooked nose, and skeletal dysplasia with a narrow chest and shoulders, deformed elbows, genu valgum, and pes planus, as well as other connective tissue abnormalities that are reminiscent of Ehlers-Danlos syndrome (EDS) (see Chapter 9, this volume). Chronic diarrhea with malabsorption and orthostatic hypotension are two other common problems associated with OHS. Seizures may be observed, but intellectual development is usually borderline normal. There may also be muscular atrophy with muscle weakness. Demonstration of the bony protuberances on the occiput will clinch the diagnosis, and these can be palpated in some patients, usually around puberty.

Clinical Diagnostic Tests

Clinical tests are often distinctive and of diagnostic value. Electroencephalograms (EEGs) are usually moderately to severely abnormal in classical MD patients, with multifocal spike and wave discharges, but may be normal in young MD babies [180,181]. Unspecific EEG changes have also been reported in a few OHS patients [182]. Electrocardiography may be helpful in detecting cardiac murmur [64,68].

Magnetic resonance (MR) angiography and computed tomography (CT) are helpful for imaging the brain and thorax [183,184]. Brain (MR) imaging [185] readily detects diagnostically significant features such as white matter abnormalities due to impaired myelination, diffuse atrophy with ventriculomegaly, cerebral blood vessels with a corkscrew-like appearance, and subdural collections and hematomas. MR angiography is a noninvasive method for the study of the vasculature. Ultrasonography with color-flow Doppler imaging is another powerful tool for screening for aneurysms [68], while invasive diagnostic techniques such as arteriography should preferably be avoided. Urogenital abnormalities [50] can be detected by pelvic ultrasonography (with or without color-flow Doppler imaging) or cystography.

Radiographs are distinctive in both classical MD and milder forms. In classical MD, they often disclose mild diffuse osteoporosis and abnormalities of bone formation in the posterior region of the skull (Wormian bones), long bones (metaphyseal spurring), and ribs (anterior flaring and multiple fractures). The bone abnormalities may mimic changes observed in scurvy and nonaccidental injury but are symmetrical. Bilateral calcified projections from the occipital calvarium (occipital horns) and short, broad clavicles with hammer-shaped distal ends are pathognomonic skeletal findings in OHS. Additional findings are dislocation of the radial head, an undulating cortical configuration of the long bones, and hyperostosis at sites of ligamentous insertions.

Differential Diagnosis

Because of the pronounced involvement of the connective tissues, MD and occipital horn syndrome patients share phenotypic traits with a number of other connective tissue disturbances (see "Physiopathology" above). Some of these are important to keep in mind when evaluating a patient with an as yet undiagnosed condition.

Ehlers-Danlos Syndrome

Several clinical features are shared with those of the Ehlers-Danlos syndrome (EDS), which is described in detail in Chapter 9 of this volume. These include joint laxity, easy bruisability, and atrophic scarring. Vascular abnormalities such as varicose veins, tortuous peripheral veins, and aneurysms are also features that may be shared with several types of EDS [68]. The presence of occipital horns, narrow shoulders and chest, and deformed elbows may help to differentiate OHS from EDS.

The term Ehlers-Danlos syndrome type V (MIM 305200) has been used to describe an apparently X-linked recessive trait. Skin hyperextensibility, joint mobility, bruising, and intramuscular hemorrhage characterize the disease. Deficient lysyl oxidase activity has been reported in one family [186], but this could not be confirmed in later investigations [49,187]. The molecular etiology of EDS V remains unknown and indeed the existence of EDS V as a separate entity is questionable (Chapter 9, this volume).

Marfan Syndrome

Marfan syndrome (MIM 154700) (Chapter 12, this volume) is an autosomal dominant disease caused by a defect in a structural protein, fibrillin. Fibrillin is necessary for the proper organization of matrix proteins including elastin, and defects in fibrillin may therefore produce some of the features seen in OHS [188]. A significant proportion of Marfan cases are sporadic and, like OHS patients, they exhibit a marked variability in skeletal features, including a highly arched palate, pectus deformities (excavatum and carinatum), inguinal hernias, joint hypermobility, and scoliosis.

Cutis Laxa

A number of MD patients present with unusually lax skin [189,190] that may lead to a diagnosis of cutis laxa. In one of the first reports of OHS, the condition was named X-linked cutis laxa, and this eponym is still widely used although no longer officially promulgated [53].

Cutis laxa due to a defect in the elastin gene [123,124] (see also Chapter 10, this volume) may lead to symptoms similar to those seen in classical Menkes disease and OHS. Thus, angiographic abnormalities of the aorta and great vessels, lax inelastic skin, hernias, and genital prolapse are common features.

Osteogenesis Imperfecta

A significant proportion of patients are born with fractures of the skull and long bones, and a suspicion of osteogenesis imperfecta (Chapter 8, this volume) was raised in a number of cases before the correct diagnosis was reached [189,190].

Child Abuse

Because of the metaphyseal spurs, periosteal reaction, and cerebrovascular abnormalities, MD can also be confused with child abuse. The symmetrical involvement should, however, alert the physician, and other clinical manifestations such as mental retardation, seizures, and abnormal hair should direct attention to a specific metabolic disorder. In one case, a family was brought into court for child abuse before the correct diagnosis was established [191].

Mitochondrial Disorders

Most classical MD patients are hypotonic and floppy, and milder cases may show a myopathy that may lead to the suspicion of a mitochondrial disturbance. The finding of high lactate levels in blood and cerebrospinal fluid due to a deficiency of COX may further strengthen this suspicion. Measurement of respiratory enzymes in a muscle biopsy may show low activities, and "ragged-red" fibers, symptomatic of mitochondrial abnormalities, have also been reported in an MD patient [96].

Biochemical Diagnosis

Body Fluids

Serum copper and ceruloplasmin levels are decreased in both classical MD and OHS. Although levels in OHS may be only moderately reduced, this cannot be used in the differential diagnosis of these two forms. Furthermore, these markers are unreliable during the first months of life due to low levels in all newborn babies [192].

Deficiency of dopamine β-hydroxylase (DBH) in MD patients is reflected by an abnormal pattern of catecholamine metabolites in blood and cerebrospinal fluid. Kaler and his colleagues have demonstrated that the ratio of the catecholamine precursor, DOPA (dihydroxyphenylalanine), to the metabolite DHPG (dihydroxyphenylglycol) is a good indicator of intraneuronal DBH deficiency [50,193]. This ratio also has a diagnostic value in MD, especially in the newborn period, where low copper and ceruloplasmin levels are not reliable.

Tissue Culture

The abnormal accumulation of copper by cells is reflected in tissue culture (fibroblasts), and this can be used as a very reliable marker for confirmation of a clinical suspicion. In contrast to the use of serum copper levels, both MD and OHS can be safely diagnosed this way, but the test cannot distinguish between classical cases and milder forms [49,60].

The test is based on two parameters, increased accumulation and retention of copper in cultured cells, both of which are consequences of impaired efflux [194]. Accumulation is usually measured in cultured fibroblasts after a 20 hour pulse using radioactive copper, followed by a 24 hour chase period. Evaluation of the results needs expertise, and tissue culture diagnosis has therefore been confined to a few specialized centers worldwide. The short half-lives and low specific activities of the copper isotopes available (^{64}Cu: $T_{1/2}$ 12.8 hours; ^{67}Cu: $T_{1/2}$ 61.8 hours) have further limited the use of these diagnostic methods.

An additional test has been developed based on the uptake and retention of silver. The tissue culture phenotype observed using silver is very similar to that obtained with copper [195]. Silver is also a heavy metal with many biological properties similar to those of copper, but its radioisotope has a much longer half-life ($^{110\ m}$Ag: $T_{1/2}$ 255 days). It is, however, more radiotoxic than the short-lived copper isotopes and requires high biological containment as a safety precaution, which limits its widespread use.

Molecular Diagnosis

Molecular diagnosis of MD is established by identifying the disease-causing mutation in the *ATP7A* gene. The extreme heterogeneity observed among *ATP7A* mutations and the length of the *ATP7A* mRNA may, however, diminish the immediate prospects of developing a rapid genetic test for MD. Therefore, in a family in which the mutation is unknown, the coding sequences and the splice sites of noncoding sequences are screened by a mutation screening technique, such as SSCP (single-strand conformation polymorphism) or ddF (dideoxy fingerprinting), followed by direct sequencing of the regions showing an abnormal band pattern. Because a large proportion of the known mutations have been found in exons 7–15, it is appropriate to start screening from these exons and subsequently to expand the analyses to other exons and untranslated regions. When the mutation within a family is known, this mutation is directly analyzed on the referred specimen (skin fibroblasts, leukocytes, chorionic villi, or amniotic fluid cells). Genetic testing is currently only performed in a few laboratories worldwide.

PRENATAL AND CARRIER DIAGNOSIS

Both severe and mild forms of Menkes disease (MD) are devastating diseases without effective treatment, and their occurrence may impose a severe psychosocial stress on the family. Prenatal diagnosis and carrier detection therefore become an important preventive aspect (Table 4).

Prenatal Diagnosis

Because only limited success has been achieved with copper therapy, prenatal detection is of importance in at-risk families, and both biochemical and molecular studies can be applied to prevent the birth of another affected child. Only male fetuses need to be evaluated, and rapid sexing can be achieved using Y-chromosome-specific DNA sequences.

Prenatal diagnosis using biochemical methods has been an option for many years [196]. Like most other cell types, amniotic fluid cells and chorionic villi sequester large amounts of copper, making both first-trimester and second-trimester diagnosis a possibility [197–199].

In the first trimester, the total copper content in chorionic villus samples can be measured directly by neutron activation analysis. However, due to the limited amount of tissue used (about 20 mg), a significant risk of false-positive results through contamination with exogenous copper exists. Copper may originate from the utensils used to handle the tissue specimen as well as from the solutions used. Handling of chorionic villus samples therefore requires special caution to prevent contamination [199].

The method for second-trimester prenatal diagnosis is similar to that described for diagnosis using cultured fibroblasts (see "Tissue Culture"). However, the incorporation of copper into cultured amniotic fluid cells is less pronounced than in fibroblasts, and this problem tends to get worse with increasing gestational age. Early amniocentesis is therefore recommended.

TABLE 4. Carrier Diagnosis and Prenatal Diagnosis

	Prenatal	Carrier	Comments
Copper accumulation			
Tissue copper	Chorionic villi	Not used	CAUTION! Risk of false-positive results*
Radiolabeled Cu/Ag	Amniocytes	Not discriminatory	Carrier diagnosis complicated by X-inactivation
DNA analysis for known mutations			
Point mutation	Applicable	Applicable	
Partial gene deletion	Applicable	Not applicable**	Contamination with maternal tissue deleterious in PD
Linkage analysis in familial cases			
Val767Leu polymorphism	Applicable	Applicable	Only in a core family***
Intragenic CA repeats	Not applicable	Applicable	Too many ''shadow'' bands for safe reading in PD

*Contamination by exogenous copper in chorionic villi.

**Occasionally carriers can be detected (Southern blot; deletion spanning).

***High gene frequency in the normal population.

PD: prenatal diagnosis.

With the isolation of *ATP7A* and the determination of its exon/intron structure, the use of routine DNA-based methods has now become possible [194]. Due to the size of *ATP7A* and the diversity of mutations observed, the family-specific mutation must be identified before prenatal testing. In first-trimester diagnosis, incomplete separation of maternal deciduum can be a significant source of error. Due to the sensitivity of PCR-based methods, contamination of fetal DNA by maternal DNA may be deleterious. Genotyping with several autosomal markers may minimize this risk.

Carrier Diagnosis

Reliable determination of carrier status in a female is important for clarification of the true risk of having an affected child. Heterozygous females may show phenotypic signs such as hypopigmented areas of the skin [200] and mild hair changes [201], but generally female carriers show no obvious clinical manifestations and, as expected, serum copper and ceruloplasmin levels are normal.

Some female carriers show abnormal handling of copper in tissue culture, indicating carriership. The absence of a mutant cellular phenotype in a woman at risk will, however, not exclude heterozygosity. Due to random X-inactivation, a significant proportion of female carriers will go undetected when applying a method dependent on gene expression.

The situation has changed dramatically with the cloning of the gene, and the availability of direct testing for mutations in *ATP7A* constitutes a major advance in carrier diagnosis. It is now possible, in most cases, to define a woman's carrier status unequivocally. It will even allow carrier detection in families with only a single affected male.

In families where the mutation has not been detected, indirect testing for carrier status by linkage analysis is possible. However, carrier detection of this type is limited to familial cases and cannot be used in families with single affected males in whom the disorder may be the result of a new mutation. In addition, successful linkage analysis is dependent on the availability of informative family members for study [202].

Polymorphic markers within the gene constitute the optimal basis for a reliable linkage analysis, and *ATP7A* contains a common amino acid polymorphism, Val767Leu [151] in exon 10, that can be used for linkage analysis in a core family. Due to a high frequency in the normal population, this marker cannot safely be applied for carrier diagnosis in more distant female relatives. Two highly polymorphic intragenic ''microsatellite'' markers comprising dinucleotide (CA) repeats are present in introns 2 and 5, respectively [203], and can be applied for carrier diagnosis in families with a positive family history.

As with any lethal X-linked disease, two-thirds of new cases of MD can be predicted to have inherited the disorder from their carrier mother, while one-third represent sporadic cases [204]. In the one-third of cases for which the mother cannot be shown to be a carrier, gonadal mosaicism may result in the birth of another affected child [205]. Prenatal monitoring may therefore still be indicated in these mothers.

TREATMENT

The treatment of Menkes disease (MD) is mainly symptomatic. Clinical reports suggest that care is an important factor in elongating survival. Copper treatment has been useful in correcting the neurological symptoms in a few cases, when given at a very early stage, but it cannot yet be accepted as a definitive cure.

Symptomatic Treatment

Seizures are usually resistant to antiepileptic drugs but can be controlled in some cases. Chronic diarrhea is a lifelong problem that is difficult to control. Evidence indicates that it may be secondary to dopaminergic imbalance and treatable by administration of L-DOPS (see below) [82]. The urogenital abnormalities with incomplete bladder emptying may cause frequent urinary tract infections that may need prophylactic antibiotic treatment [64,206]. In some cases, surgical correction is necessary. Hernias are also correctable by surgery. There are a limited number of reports describing adverse events in MD patients following surgery, but the high prevalence of seizure disorders, gastroesophageal reflux with the risk of aspiration, and airway complications related to poor pharyngeal muscle control are of anesthetic concern [206]. Postoperative complications include the risk of respiratory failure and precipitation of neurological problems. In addition, stretchable scars, poor wound healing,

a poor immune response, and a bleeding tendency may cause complications [83].

Specific Treatment

Copper Therapy

With the level of current knowledge about the widespread and fundamental disturbance of cellular copper transport in MD, it is not surprising that administration of various copper compounds has been disappointingly ineffective in most cases. However, encouraging long-term clinical outcomes with four early-treated MD patients have been reviewed [82], showing that in some cases copper treatment can moderate the progression of the neurological disease substantially.

A therapeutic trial with copper necessitates consideration of some fundamental issues. First and most importantly, the treatment must be started very early. Once brain damage has developed, copper therapy will not alter the course of the disease significantly. Secondly, the copper compound should be chosen carefully to allow the metal to reach the target sites for incorporation into metalloenzymes. Crossing of the blood-brain barrier is very important, and the intestinal block must also be bypassed by applying copper parenterally. Furthermore, the success of any copper therapy may depend partly on the gene mutation, but this issue requires further research. Finally, treatment should still be regarded as experimental and not as a serious alternative to prevention through prenatal diagnosis.

Several copper compounds have been tried over the years, but copper-histidine has proven most successful, and there are good reasons for choosing it. Copper-histidine is one of the forms in which copper is found in plasma and is possibly of physiological importance. Histidine facilitates copper uptake into liver and brain, suggesting that this may be the form recognized by specific membrane carriers in tissues [49,207].

If started early, parenteral copper-histidine administration can prevent the severe neurodegenerative problems, but the patients may still develop substantial residual abnormalities. The four patients mentioned above who received parenteral copper histidine from an early age have had significantly milder clinical courses with less severe neurological symptoms. All of them have, however, developed connective tissue symptoms to varying degrees, emphasizing that LOX is particularly sensitive to lack of copper.

Parenteral copper-histidine therapy can restore plasma copper and ceruloplasmin levels to normal. Copper therapy will not, however, restore normal copper brain levels [1,208]. Nevertheless, significant cerebral uptake of the metal could be demonstrated at the functional level [208]. Thus, catecholamine metabolism can be modified, although even in well-treated patients symptoms of autonomic failure persist, such as ataxia, orthostatic hypotension, and chronic diarrhea [82].

The efficacy of the copper dose needs to be monitored, mainly by serum copper and ceruloplasmin measurements. Monitoring of liver stores has rarely been used because it involves an invasive procedure. The catecholamine pattern in cerebrospinal fluid may also be a useful indicator for monitoring the effect of copper supplementation [193].

Copper therapy carries the risk of systemic overload. D-penicillamine is a potent copper chelator that is successfully used in Wilson disease [3] and has also been applied in MD to control the body stores [208,209].

Metabolite Substitution

The frequent observation of orthostatic hypotension in MD patients successfully treated with copper-histidine [82] suggests that dopamine β-hydroxylase (DBH) may not be receiving sufficient copper to allow restoration of normal activity. In one such patient, hypotension could be corrected by the administration of L-DOPS (L-threo-3,4-dihydroxyphenylserine), which has been used successfully in patients with autonomic failure due to DBH deficiency [210]. Moreover, this compound could also control chronic diarrhea. L-DOPS is a synthetic amino acid that is converted to noradrenaline by aromatic L-amino acid decarboxylase, which is present in all adrenergic cells. In this way, the requirement for DBH can be bypassed. L-DOPS is efficiently absorbed in the small intestine and readily crosses the blood-brain barrier. Oral administration may therefore be used to restore normal central and peripheral noradrenaline levels.

Cerebellar ataxia may also be partly due to deficient DBH activity, but the administration of L-DOPS may not be very beneficial. The cerebellum of DBH knockout mice has fewer noradrenergic terminals [128], and this region appears to be very resistant to the restoration of normal noradrenaline levels using the L-DOPS precursor. The persistent occurrence of ataxia in a well-treated MD patient receiving L-DOPS [82] is in line with this observation.

Antioxidant Supplementation

Protection against oxidative stress is defective in MD due to the malfunctioning of several enzymes involved in free radical detoxification. The administration of antioxidants such as oral vitamin C and vitamin E may constitute important adjunctive therapy, although this has attracted little attention. Vitamin C has, however, been given with variable results to a few classical cases because of the similarity between the skeletal changes observed in MD and scurvy [211,212].

RECENT DEVELOPMENTS

Several reviews have recently been published on copper metabolism [213–217].

Copper Pathway

CTR1 (Cu transporter 1) has been demonstrated to promote copper uptake into human fibroblasts [218] and mouse cells [219], and targeted gene disruption in the mouse has shown it to have an essential role in early embryogenesis [219, 220] and to affect copper accumulation in certain tissues in heterozygous animals. Defective embryogenesis in these animals is probably due to the cumulative lack of several copper-dependent enzymes. Deficient development of the mesoderm and mesoderm-derived structures, and the severe basement membrane defects observed in CTR1 knockout mice [220], may thus be the result of deficient lysyl oxidase activity.

In mice, disruption of *Atox1* (*Hah1* in the earlier nosology) leads to a phenotype similar to that of the mottled mouse, although less severe than observed in some of the allelic variants [221]. This indicates that it may still be possible to deliver copper to ATP7A by means other than ATOX1, perhaps as a Cu-GSH complex. The intra-peritoneal administration of copper leads to improved survival of affected mice, and the normalization of pigmentation that occurs supports this hypothesis. Cultured cells from *Atox1* knockout mice show increased copper retention similar to that observed in Menkes fibroblasts. The phenotype of the

Atox1 knockout mouse can thus be attributed to deficiency of copper-dependent enzymes by analogy with Menkes disease. In support of this presumption, decreased activities of tyrosinase, in skin, and cytochrome c oxidase, in brain, are demonstrable. The mice also suffer from severe hemorrhage, which may be explained by defective delivery of copper to factors V and VIII in the liver. These results emphasize that ATOX1 is the chaperone for copper delivery to both ATP7A and ATP7B.

The crystal structure of copper-containing ATOX1 has been established, and provides structural support for direct metal ion exchange between the conserved copper-binding motif of the chaperone and its target protein [222]. The interaction between two such molecules requires copper [223–225]. This is in line with the metal transfer mechanism proposed for the exchange of copper between ATOX1 and ATP7A (or ATP7B) [226], which is also potentially applicable to intramolecular copper transfer between individual metal-binding repeats in ATP7A. The vectorial delivery of copper is not based on a higher affinity of the target molecule, but rather on rapid metal transfer to the recipient partner. Thus, chaperones possess a catalytic function similar to that of enzymes [227].

The repetitive metal-binding domains in ATP7A seem to act as sensors of low concentrations of copper and to activate the protein, but seem not to be essential for overall ATPase catalytic activity at basal copper levels [228–230]. Mutation of the six metal-binding motifs resulted in a mutant transport molecule with a lower affinity for copper than the wild-type protein, indicating that these motifs may be internal regulators of the pump function [229]. Binding of copper to these high affinity copper sensors facilitates catalysis, probably by altering the conformation of the molecule and thereby initiating phosphorylation and transport through the channel, as well as trafficking of the protein [230,231]. The six metal-binding repeats thus possess a dual role, regulating both the catalytic activity and the intracellular localization of the protein by controlling its phosphorylation. Cycling between the plasma membrane and the *trans*-Golgi network occurs at both basal and elevated copper levels [232].

Copper Pathway in Mitochondria

Mutations in *SCO1* and *SCO2* have been shown to result in two distinct disease phenotypes, early onset hepatic failure with encephalomyopathy [233] and fatal hypertrophic cardiomyopathy with encephalopathy (MIM 604377) [234,235], respectively.

Copper Activation of Enzymes

Direct evidence for the activation of tyrosinase by ATP7A has been obtained by transfection studies [236]. In Menkes fibroblast cell lines, tyrosinase is inactive, whereas in normal fibroblasts its activity is substantial. The co-expression of ATP7A and tyrosinase in Menkes fibroblasts was shown to lead to the activation of tyrosinase and subsequent melanogenesis.

Sulfhydryl oxidases contribute to disulfide bridge formation by catalyzing the oxidation of sulfhydryl groups in disulfides. The role of copper in activation of a subset of this group of enzymes has mainly been deduced indirectly, and we have recently reviewed the current state of knowledge [237]. Sulfhydryl oxidases have been purified from a number of mammalian sources, but a possible copper-dependent form has only been described in skin [238].

The *LOX* Gene Family

Besides its well-known role in extracellular matrix formation, several new biological functions have been attributed to LOX, ranging from developmental regulation to tumor suppression and cell growth control [239]. Apart from *LOX*, four distinct genes belonging to the expanding LOX gene family have been isolated: lysyl oxidase-like genes 1,2 and 3 (*LOXL1*, *LOXL2*, and *LOXL3*, respectively) [240–244] and lysyl oxidase-related gene, *LOR* [245]. The products of these new members may contribute to the diverse functions attributed to LOX. The predicted amino acid sequences of the products of all members of this gene family contain a copper-binding site and the two conserved amino acids (Lys and Tyr) that are known to participate in the formation of the intramolecular quinone cofactor (LQT). All these enzymes, except for LOXL2, which lacks a hydrophobic export signal sequence necessary for extracellular transport, are likely or known to act extracellularly. LOXL1 apparently cross-links type III collagen [246], and it has been suggested that LOR might be involved in cell adhesion and senescence [245]. High expression levels of LOXL2 in reproductive tissues suggest a role in the reproductive system. LOXL3 is expressed in several tissues, but no specific function has yet been attributed to it [243,244]. Lysyl oxidase (and hence also each other member of this gene family) is particularly sensitive to impaired delivery of copper, because the metal has an essential role in biogenesis of the cofactor [247]. Although the mechanisms by which copper is delivered to lysyl oxidase are still not well studied, it is likely that ATP7A is involved in this process, as LOX secretion and copper efflux use the same pathway. This hypothesis is supported by studies in rat which showed that the relative levels of LOX and ATP7A mRNA transcripts were quantitatively similar throughout embryonic and early fetal life [248].

Mutation Update

Thirty six additional mutations in *ATP7A* have been reported. These include mutations in three OHS patients, one mildly affected patient, and one early-treated patient [249–256]. Two of the OHS patients had the same splicing mutation, but showed some difference in its phenotypic expression [250,252]. The milder case had normal serum copper and ceruloplasmin levels, and about 19% normally spliced mRNA transcript [252]. The more severe case, however, had only 2–5% correctly spliced *ATP7A* and also showed decreased serum copper and ceruloplasmin levels [250]. This suggests that minute amounts of ATP7A are sufficient to prevent the development of a severe phenotype and will lead to milder symptoms

The third OHS patient had a small deletion in the last exon of the gene, leading to a truncated protein lacking the di-leucine motif that is important for retrieval of the protein from the plasma membrane [254]. When ATP7A is located principally at the plasma membrane, lysyl oxidase will receive insufficient copper for normal activity, explaining the development of connective tissue symptoms, whereas other secreted enzymes, such as peptidyl α-amidating enzyme and dopamine β-hydroxylase, may still receive sufficient copper for near normal function.

The mildly affected patient previously described clinically [71,72] was found to have an amino acid substitution in the highly conserved seventh transmembrane domain (TM7) of ATP7A [249]. Its Golgi localization was preserved, suggesting that the defective protein may deliver sufficient copper

to lysyl oxidase to prevent the development of severe connective tissue symptoms.

The early-treated case (GV) [82] was found to have an insertion of a single base in exon 22 leading to a truncated protein lacking the last two transmembrane domains [249]. This suggests that when excess copper is provided as Cu-histidine, the truncated protein can still translocate copper across the membrane, as reflected by the patient's mild symptoms [249].

A study showing partial gene deletions in *Atp7a* has expanded the mutation spectrum of mottled alleles [257]. In mottled mice, three distinct groups of phenotypic severity can be delineated, partial gene deletions occurring in the most severely affected group with embryonic lethality [257]. In contrast, Menkes patients with similar gene deletions survive beyond infancy, and caution should therefore be applied when extrapolating from mottled mice to the human disease [257].

Early Symptoms in Menkes Disease

Congenital skull fractures acquired during or around the time of delivery represent a rare perinatal complication of Menkes disease, and their occurrence should raise the suspicion of this severe disorder in newborns [258]. Small occipital horns have led to the biochemically confirmed diagnosis of the mildest form of Menkes disease in a 2-year-old boy [259].

Follow-up on Treated Patients

Two patients treated early with copper histidine [82] have died suddenly. MF died at age 20, but autopsy that could have established the cause of death was not performed (J. Clarke, personal communication, 2000). RH died at 10 years of age [260]. He suffered from recurrent, and ultimately fatal, peritonitis secondary to a ruptured bladder diverticulum. At autopsy, occipital horns not present at eight years of age were observed. The third patient described by Christodoulou et al. [82], (GV), had developed occipital horns at eight years of age and suffered from marked connective tissue abnormalities, but was otherwise reported to be doing well at 11 years of age [249].

Chapter 15

Epidermolysis Bullosa

Leena Bruckner-Tuderman

Department of Dermatology, University Hospital Muenster, 48149 Muenster, Germany

SUMMARY

- **Epidermolysis bullosa (EB) is a clinically and genetically heterogeneous group of inherited disorders that are characterized by blistering of the skin and certain other tissues. In all subtypes, the blisters result from minor trauma, although the severity of expression ranges from mild occasional blistering to severe bulla formation, erosions, scarring, and mutilation. The group contains many distinct disorders and, to date, defects in ten different genes are known to lead to the clinical abnormalities.**
- **Classification of this heterogeneous group is problematic because of the multitude of clinical presentations and the number of genetic and molecular abnormalities. The currently used practical classification is based on categorization according to the precise level of blister formation in the dermal-epidermal junction (DEJ) zone and subsequent clinical presentation. Three major categories are defined.**
- **EB simplex (EBS) exhibits trauma-induced skin blistering as a consequence of cytolysis of basal keratinocytes. Keratin intermediate filament scaffolding, which sustains the three-dimensional structure of the cells, is weakened due to defects of the keratins or their linker proteins and collapses as a result of external shearing forces. The blistering is intraepidermal, and healing takes place without scarring. In general, the prognosis is favorable, and blistering activity diminishes with age. Defects in the genes for keratins 5 and 14 and plectin have been shown to underlie several of the subtypes.**
- **Junctional EB (JEB) is a heterogeneous group with extreme clinical variation and defects in at least six distinct genes. In the most severe subtype, JEB Herlitz, the course is usually lethal within two years after birth. In contrast, JEB progressiva only manifests at school age and progresses slowly. Healing takes place without scarring. Nail and dental problems as well as alopecia are often associated with this category. The hemidesmosome-anchoring filament complex is weakened by genetic defects of one of the structural proteins, resulting in epidermal detachment. Mutations in the genes for laminin 5, α6β4 integrin, and collagen XVII cause different JEB subtypes.**
- **Dystrophic EB (DEB) is characterized by dermal blistering below the basement membrane and subsequent scarring. Within this category, the clinical presentation varies from localized mild acral involvement to generalized blistering, scarring, and disabling mutilation of hands and feet. Mucous membranes are often involved, nails shed, or dystrophic and dental problems common. Abnormalities of the anchoring fibrils and mutations in *COL7A1*, the gene encoding collagen VII, the major anchoring fibril protein, underlie all subtypes. Traditionally, DEB contained two dominantly and four recessively inherited subtypes, but molecular genetic studies have shown that dominant and recessive mutation combinations also exist.**
- **Extracutaneous abnormalities can be associated with EB because the basement membrane zones of the eye, the mucous membranes of the orifices, the gastrointestinal, respiratory, and urogenital tracts, and even of muscles are similar to that in the skin.**
- **For the diagnosis of EB, a combination of the family history, clinical examination of the index patient and family members, a skin biopsy for antigen mapping and eventually for electron microscopy and cell cultures, and blood samples for mutation analysis are required.**
- **At present, the management of EB is mainly supportive and therapy symptomatic because no specific cure exists. A high standard of personal hygiene and daily skin care, protection from trauma, and avoidance of infection are fundamental for optimal management. In some cases, surgical release of contractures and skin grafting have been successful, and secondary growth retardation and anemia in some affected children have been reversed using additional feeding via a gastrostomy tube. For the future treatment of EB, the development of successful gene therapy approaches is required. Although the application of gene therapy for EB may still be years away, the rapid development of new technologies holds**

[1] *Abbreviations used are*: EB, epidermolysis bullosa; EBS, EB simplex; EBS-L, EB simplex localisata; EBS-MD, EB simplex with muscular dystrophy; JEB, junctional EB; JEB-PA, junctional EB with pyloric atresia; DEB, dystrophic EB; GABEB, generalized atrophic benign EB; DEJ, dermal-epidermal junction; PTC, premature termination codon; CSGE, conformation sensitive gel electrophoresis; PGD, preimplantation genetic diagnosis; TBDN, transient bullous dermolysis of the newborn.

Connective Tissue and Its Heritable Disorders, pages 687–725

promise for individually designed and biologically valid curative treatments for different EB subtypes.

INTRODUCTION

Definition

The term epidermolysis bullosa (EB)[1] refers to a clinically, genetically, and biologically heterogeneous group of inherited disorders that are characterized by blistering of the skin and certain other tissues with stratified epithelia. The blisters usually result from minor trauma but may appear spontaneously. This characteristic is common to the whole group, although the severity of expression ranges from mild occasional blistering to severe extensive bulla formation, erosions, scarring, and mutilation [1,2]. The group contains many distinct disorders and, to date, defects in ten different genes are known to lead to the clinical abnormalities [3].

Enormous progress has been made since the mid-1990s in understanding the molecular basis of EB, and some of the old concepts about this disease have had to be modified. Classification of this heterogeneous group is problematic because of the multitude of clinical presentations and the number of genetic, biological, biochemical, and morphological abnormalities continually being detected. The currently used practical classification was suggested by Gedde-Dahl Jr. [2] and is based on categorization according to the precise level of blister formation in the dermal-epidermal junction (DEJ) zone and subsequent clinical presentation. Three major categories are defined: in EB simplex (EBS), the separation occurs within the basal keratinocytes, as a consequence of cytolysis of the cells; in junctional EB (JEB), the cleavage occurs along the lamina lucida; and in dystrophic EB (DEB), the cleavage occurs below the basement membrane, within the uppermost dermis. Predictably, abnormality of any molecular component of the dermal-epidermal junction zone can lead to diminished adhesion of the skin layers and blistering. The multitude of pathologic alterations is alluded to by the extensive clinical heterogeneity of EB, and more than 20 genetic and clinical subtypes are known [3–5]. In Table 1, the clinical subtypes of EB and their underlying molecular defects are summarized. The present classification may have to be modified after more complete data on the abnormal molecules and the genes coding for them become available.

Investigations into EB by ultrastructural analysis, determination of candidate genes, and isolation and characterization of target proteins have also had a major impact on our understanding of the normal biology of the dermal-epidermal junction, of epithelial-mesenchymal interactions, and of epithelial cell adhesion in general. Data on the molecular basis of blistering diseases have already disclosed ample new information about the physiological functions of many of the molecular components of the dermal-epidermal junction, and a rapid expansion of knowledge in the field can be anticipated when genotype-phenotype correlations of more patients are discerned. Further, these new data have allowed the characterization of autoantigens in acquired autoimmune blistering skin diseases, making better diagnostic procedures and the design of novel therapeutic strategies possible.

History

First descriptions of EB appeared in the medical literature more than 100 years ago [6,7]. The name epidermolysis bullosa refers to the mechanically induced detachment of the epidermis from the dermis, into the blister roof, and was coined for these conditions by Köbner [6]. Despite modern knowledge about the genetic and biological heterogeneity of the disease group, the name has stayed.

EB subtypes that have long been characterized have been assigned numbers in McKusick's *Mendelian Inheritance in Man* [8], the on-line version of which, OMIM, can be found under http://www.ncbi.nlm.nih.gov/Omim. The MIM numbers do not exactly correspond to the present clinical classification, and some confusion results, for example from the fact that two separate dominant disorders, the localized EBS and the localized DEB, have received the same number (MIM 131800).

Other Names and Synonyms

Many of the EB subtypes have been called by the name of their first describer. In this chapter, in the subheadings, following the names of the EB subgroups, synonyms used to denote the disorder and the abbreviations commonly used, as well as the MIM numbers, are written in parentheses. The first letters of each abbreviation describe the mode of inheritance (i.e., AD for autosomal dominant, AR for autosomal recessive, and XL for X-linked).

GENERAL ASPECTS OF EPIDERMOLYSIS BULLOSA

Dermatological Features

Since the first description of EB, the group of clinical entities has grown to contain three major categories and more than 20 clinically and genetically defined subtypes (Table 1). The clinical symptoms in the major categories were first believed to be constant and pathognomonic. However, in recent years, many such clinical concepts have had to be modified. Based on reports of mutations and examination of a growing number of patients, it has become clear that phenotypic variability is more extensive than thought before. Traditional characteristic signs, such as milia, scarring, and albulopapuloid lesions, have been described as secondary changes in "nontypical" EB subgroups, and children with different EB subtypes can have indistinguishable cutaneous features during the neonatal period. Thus, clinical diagnosis alone is no longer sufficient, and immunopathological, and eventually ultrastructural, investigations are necessary for classification. Mutation analysis is required for ultimate confirmation of a diagnosis. In the following, the typical clinical signs of the different EB categories are commented on.

Blistering

Blisters usually result from minor trauma but may appear spontaneously. This characteristic is common to the whole group, although the severity of expression ranges from mild occasional blistering to the formation of severe extensive bullae in the skin and mucous membranes. The blisters are filled with a clear serous liquid but can occasionally be hemorrhagic. If a fresh blister is left unopened, it has a tendency to enlarge centrifugally. It is not possible to differentiate clinically by naked eye between blisters within the epidermis, in the basement membrane, or below it (i.e., between the different EB categories).

Scarring and Milia

Scars and milia are typical secondary phenomena in DEB but occur in other subtypes as well, often as a result of secondary traumatization and chronic inflammation. Any wound that reaches into the dermis, below the basement membrane, heals with scarring. Most EB children, regardless of subtype, have temporary milia at trauma-prone sites. In the most severe forms of recessive dystrophic EB, DEB

TABLE 1. Subtypes of Epidermolysis Bullosa

Subtype	Gene	Chromosomal Locus	Inheritance	Predilection Sites	Remarks, Synonyms
EB Simplex (EBS)					
EBS generalisata	*KRT5*	12q11–q13	AD (AR)*	generalized	Koebner disease
	KRT14	17q12–q21			
EBS localisata	*KRT5*	12q11–q13	AD (AR)	acral	Most common EB subtype, often very mild, Weber-Cockayne disease
	KRT14	17q12–q21			
EBS herpetiformis	*KRT5*	12q11–q13	AD	generalized	Dowling-Meara subtype
	KRT14	17q12–q21			
EBS with ''mottled pigmentation''	*KRT5*	12q11–q13	AD	generalized	Pigment anomalies
EBS with muscular dystrophy	*PLEC1*	8q24	AR	generalized	Late-onset muscular dystrophy
EBS Ogna	*PLEC1*	8q24	AD	acral	Bruising, common in Norway
EBS herpetiformis with ''mottled pigmentation''	Not known		AD	generalized	Pigment anomalies
EBS Kallin	Not known		AR	acral	Anodontia, hair and nail anomalies
EBS Mendes da Costa	Not known		XL	acral	Alopecia, hyperpigmentation
Junctional EB (JEB)					
JEB Herlitz	*LAMA3*	18q11.2	AR	generalized	Lethal within 1–2 years, JEB gravis
	LAMB3	1q32			
	LAMC2	1q25–31			
Generalized atrophic benign EB	*COL17A1*	10q24	AR	generalized	GABEB, JEB atrophicans mitis, alopecia
	LAMB3	1q32			
JEB localisata	*COL17A1*	10q24	AR	acral	No alopecia, nail dystrophy
JEB with pyloric atresia	*ITGA6*	17q25	AR	generalized	Pyloric atresia at birth
	ITGB4	2q24–q31		acral	
JEB inversa	Not known		AR	major flexures	
JEB progressiva	Not known		AR	acral	Late onset
JEB cicatricans	Not known		AR	generalized	Unusual scarring
Dystrophic EB (DEB)					
DEB generalisata	*COL7A1*	3p21.1	AD	generalized	Pasini disease, albulopapuloid papules
DEB localisata	*COL7A1*	3p21.1	AD	acral	Cockayne-Touraine disease
DEB generalisata mutilans	*COL7A1*	3p21.1	AR	generalized	Hallopeau-Siemens subtype, mutilation
DEB generalisata nonmutilans	*COL7A1*	3p21.1	AR	generalized	No synechia
DEB localisata	*COL7A1*	3p21.1	AR	acral	
DEB inversa	*COL7A1*	3p21.1	AR	major flexures	
Transient bullous dermolysis of the newborn	*COL7A1*	3p21.1	AR/AD	generalized at birth	TBDN, self-limiting course

*AD: autosomal dominant; AR: autosomal recessive; XL: X-linked.

generalisata mutilans and DEB generalisata nonmutilans, significant scarring is a constant feature of the disease, often also causing joint contractures. In the mutilans subtype, the fingers and toes are fused together and covered with an atrophic, scarred, and nailless skin, a phenomenon for which the term "mitten hands" has been coined. In certain generalized JEB subtypes, such as generalized atrophic benign EB, a moderate generalized atrophy of the skin develops in the course of the disease.

Nail Changes

Nail changes in EB are characteristic and sometimes highly suggestive, but not pathognomonic [9]. They result from abnormalities of the nail matrix and nail bed due to the genetic defects underlying EB. In addition, secondary traumatization in areas of epidermal-dermal separation and chronic inflammation of the nail matrix contribute to the development of nail dystrophy in nonscarring forms of EB also. This sometimes creates unexpected and confusing phenotypes. In EBS, the nails usually remain normal. Regrowth and regeneration follow nail loss after blistering. Onychodystrophy may represent pathologic signs induced by injury to the nail matrix or scarring of the nail bed. The fact that big toe nails are often affected supports this hypothesis. In the most severe JEB subtype, JEB Herlitz, nail involvement typically begins early as paronychia-like periungual lesions. These are followed by loss of nails due to extensive blistering and the development of large plaques of granulation tissue that cover most of the dorsal finger tip. Most JEB subtypes are associated with generalized nail dystrophy. The nails are often lost after subungual blistering and regrow normally at the beginning, but they become thickened, dome-shaped, or sometimes onychogryphotic in the course of the disease. The rare JEB progressiva can show dystrophy and loss of nails as first symptoms in the teens without any other signs of skin disease, and acral blistering may follow years later. In the most severe forms of recessive DEB, loss of all nails is a constant feature. Repeated, extensive blistering and scarring lead to permanent loss of the germinative nail matrix. In other DEB subtypes, dystrophy and loss of some nails due to scarring, atrophy, and hyperkeratosis of the germinative matrix and the nail bed are also common. In individuals with localized DEB with mild expression, some or all nails may remain normal or, on the contrary, nail dystrophy may be the only symptom of DEB.

Hair Anomalies

The most dramatic hair anomalies are seen in the JEB subtype called generalized atrophic benign EB, GABEB. A nonscarring, diffuse, or parietal alopecia develops at school age, often leading to total alopecia by the teenage years or early adulthood. Here again, clinical heterogeneity is evident, with not all patients showing a similar degree of alopecia. The reason for the loss of hair is not known. Mild to moderate scarring alopecia is typical in DEB.

Dental Anomalies

Dental anomalies are common in EB (e.g., enamel defects and dystrophy of the teeth). Because the tooth anlage during development contains an epithelial-mesenchymal interface and a basement membrane very similar to that of the skin, anomalies of the structural components lead to abnormal development of the teeth, with enamel hypoplasia as the most common symptom [3,4,10,11]. In addition, gingival erosions, bleeding, and pain impede dental hygiene, with insufficient dental care and extensive caries as consequences [11]. More recent studies on heterozygous carriers suggest that enamel defects may represent a minimal symptom of mutations in the genes coding for structural proteins of the DEJ.

Pigment Anomalies

Hyperpigmented maculae can be associated with several EB subtypes. EBS with mottled hyperpigmentation and EBS herpetiformis with mottled hyperpigmentation present with light brown, ephelis-like spots with bizarre configurations on the trunk. The hyperpigmentation seems to be associated with the blistering, but its biological basis remains elusive. In GABEB, dark brown pigmented maculae or nevi are sometimes seen. Early reports on this condition described hyperpigmentation as an obligatory sign of the subtype [12], but observations of more patients have shown that many lack such maculae. As an unspecific sign, reversible diffuse, postlesional hyperpigmentation can be associated with many EB subtypes.

Hyperkeratosis

In EBS, hyperkeratosis of the palms and soles is a typical sign and a common problem. Pressure-induced hyperkeratosis is often a consequence of repeated blistering and can be very painful. In contrast to normal skin, which reacts to strong mechanical stimulus such as walking or manual labor with hyperkeratosis, EBS-associated hyperkeratosis is induced by minimal mechanical trauma.

Skin Cancer

Statistical analysis has revealed a high incidence of squamous cell carcinoma in patients with generalized DEB in early adulthood [13]. Repeated blistering and scarring contributes to malignant transformation of the epithelial cells, and even today many patients develop metastasizing carcinomas before the 40th year of life. DEB patients seem to be most at risk, although one report describes multiple squamous cell carcinomas also in two patients with GABEB [14].

Extracutaneous Features

General Aspects

Because the basement membrane zone at the dermal-epidermal junction is similar to that of the eye, the mucous membranes of the orifices, the gastrointestinal, respiratory, and urogenital tracts, and even muscles to some extent, abnormalities of these organs can be associated with EB. Extracutaneous involvement of all types of epithelia has been observed in EB despite the fact that this disorder is commonly considered to affect only the stratified squamous epithelia of the skin and related mucous membranes [15]. It is possible that deeper epithelia are more extensively involved than is currently recognized, thus leading to the different extracutaneous symptoms of EB [3–5,15–18].

Gastrointestinal Complications

In both JEB and DEB, affection of at least some parts of the gastrointestinal tract is common. Blistering of the oral or laryngopharyngeal mucosa causes hoarseness and pain and disturbs feeding. Scarring of the oral mucosa and the lingual band restricts opening of the mouth and movement of the tongue and may lead to speech difficulties. Esophageal involvement, in particular in DEB in the form of strictures, and occasionally in JEB, causes difficulties in swallowing. Anal blisters, fissures, and strictures lead to painful and difficult defecation. If these symptoms are strong, they result in intake of liquid, low-fiber foods with insufficient nutritional content. Dietary problems, together with protein

loss through the blisters and erosions, can lead to anemia and growth retardation, typically seen in DEB generalisata mutilans and nonmutilans.

In a rare JEB form, pyloric atresia (PA) is associated with skin blistering [19]. In severe cases of this subtype, JEB-PA, the association is evident and the diagnosis clear. In milder phenotypes, only pyloric atresia, and not skin blistering, is present at birth. The skin phenotype may develop later, during the first months or even years of life [20].

Neuromuscular Features

A distinct EBS variant, EBS with muscular dystrophy (EBS-MD), manifests relatively mild blistering at birth and late-onset muscular dystrophy, which is progressive and leads eventually to patients being wheelchair-bound [21]. This phenotypic constellation was initially puzzling, and it was suggested that the occurrence of these two relatively rare clinical conditions, EB and muscular dystrophy, may be coincidental because no clear explanation was apparent [21]. However, it is now known that mutations in the gene for plectin, which is expressed in both skin and muscle, underlie this variant of EB [22].

Ophthalmological Aspects

Blistering of the corneal and conjunctival epithelium manifests with strong pain. Patients typically cannot open the eyes, and they keep them closed for a day or two until reepithelialization has taken place. The ophthalmologist observes erosions, occasionally a blister, and a conjunctival redness. The erosions usually heal well, without affecting visual acuity [16].

Abnormalities of the Urogenital Tract

In different JEB subtypes, erosions and/or subepithelial cleavage may be present in the urinary tract. Dysuria and secondary urinary tract obstruction caused by meatal or other stenosis, as well as dilatation of the proximal urogenital tract, are sometimes seen. Certain facultative features are unique to JEB with pyloric atresia (e.g., obstruction of the ureterovesical junction) [23].

The Dermal-Epidermal Junction

Before discussion of ultrastructural, immunopathological, and molecular abnormalities in EB, a short review of the normal dermal-epidermal junction (DEJ) [24–26] is useful. This zone is the site of attachment of the epithelium to the dermis and is pathologically altered in EB. Figure 1 summarizes in a schematic way the microanatomy of the zone, as it appears in the electron microscope, and the location of some of its structural macromolecules. The basal epithelial cells are attached to a bilaminar basement membrane consisting of the 25–50 nm in wide, optically translucent lamina lucida and, below this, the optically dense

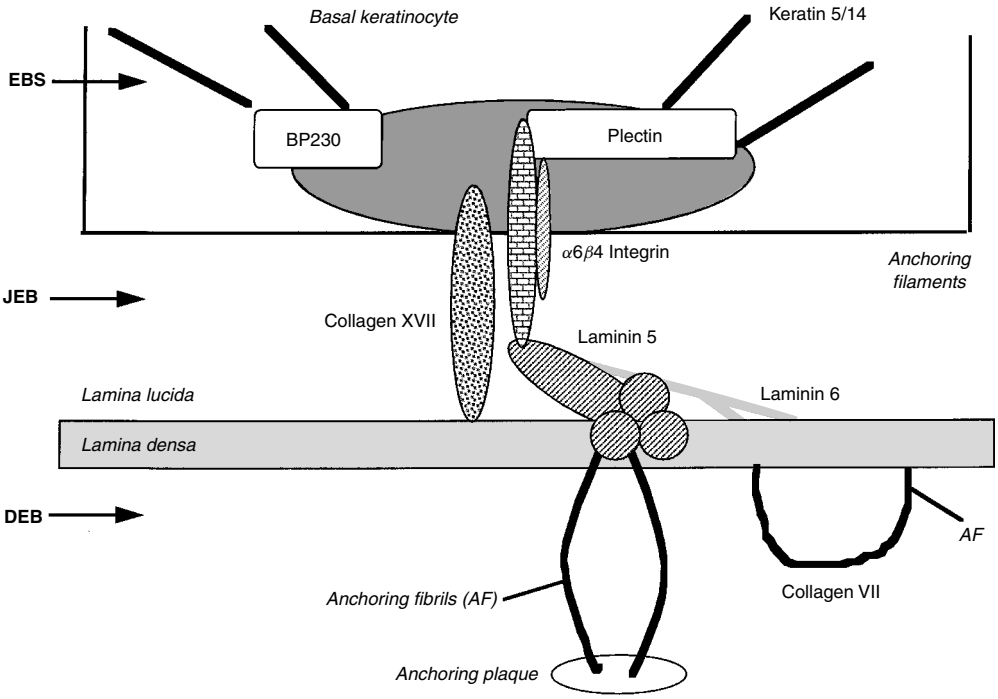

Figure 1. A schematic representation of the anchoring complex at the dermal-epidermal junction. The anchoring complex is an ultrastructurally recognizable unit, comprising hemidesmosomes, anchoring filaments, and anchoring fibrils. Hemidesmosomes (gray oval) at the basal surfaces of the basal keratinocytes connect the intracellular cytoskeleton to anchoring filaments that traverse the lamina lucida and connect with the anchoring fibrils (AF), which originate in the lamina densa and either end in anchoring plaques (morphologically defined electron-dense, plaque-like structures in the papillary dermis) or loop back to the lamina densa. Keratins 5 and 14 are the major components of the intermediate filaments in basal keratinocytes. Plectin and BP230 (bullous pemphigoid antigen-1, BPAG-1) are structural proteins of the hemidesmosomal plaque together with the intracellular domains of collagen XVII (BP180, bullous pemphigoid antigen-2, BPAG-2) and α6β4 integrin. The extracellular domains of these two transmembrane proteins, together with laminins 5 and 6, form the anchoring filaments. Collagen VII is the major structural component of the anchoring fibrils, which often enmesh dermal collagen fibrils, thus ensuring the connection between the anchoring complex and the dermal extracellular matrix. Integrin α3β1, also a component of the basal keratinocyte surface, is located outside the anchoring complex and is not shown in this figure.

lamina densa, 20–50 nm in width. The attachment of the basal keratinocytes to the basement membrane is mediated by the so-called anchoring complex, which consists of the hemidesmosome and the underlying anchoring filaments that traverse the lamina lucida and insert into the lamina densa. The basement membrane is joined to the dermal connective tissue by a three-dimensional network of anchoring fibrils, which is intersected by interstitial collagen fibers and other microfibrillar structures. The anchoring fibrils are fibrous aggregates, 20–75 nm in diameter, with a nonperiodic cross-striated banding pattern and frayed ends [27]. The upper ends insert into the lamina densa and, at their lower ends, the fibrils either insert into so-called anchoring plaques or loop back to the lamina densa [28–30]. The distinct ultrastructural units of the DEJ result from highly specific protein interactions of the structural macromolecules of the zone.

Many of the molecular components of the DEJ (Table 2) have been characterized at the protein and cDNA levels (for reviews, see [5,24–26,28,30]). Important hemidesmosomal proteins are the intracellular bullous pemphigoid antigen-1, or BP230, and plectin, and the transmembrane components α6β4 integrin and BP180/collagen XVII, which together form the intracellular hemidesmosomal plaque. Together with laminins 5 and 6, the extracellular domains of collagen XVII and α6β4 integrin are likely to participate in the formation of the anchoring filaments. α3β1 integrin is located in the plasma membrane between the hemidesmosomes. The lamina densa contains a number of macromolecules [26]. Collagen IV is the major structural protein in all basement membranes and provides a basic three-dimensional scaffold through the association of the individual molecules through their globular N- and C-terminal domains. Within the mesh of the network, perlecan, nidogen/entactin, and in the skin also the N-terminal globular domain of collagen VII may be intertwined. The main structural component of the anchoring fibrils, collagen VII, has an extended triple helix and amino- and carboxyl-terminal globular domains. It forms antiparallel dimers with the N-termini pointing outward, and several dimers aggregate laterally to form the anchoring fibrils [30] (see also Chapter 2, this volume). A functionally important affinity between collagen VII and laminin 5 has been described [31,32]. The papillary dermal connective tissue contains a variety of collagens: types I, III, V, VI, XII, XIV, and XVI are built into interstitial collagen fibrils or other fibrillar-filamentous structures. Together with elastin, fibrillins, fibulins, vitronectin, proteoglycans, and other macromolecules, they form the stroma of the dermis [33].

All DEJ molecules have a modular structure, with typical domains of adhesive extracellular matrix components, and are strongly interactive, with multiple binding sites through which they contribute to dermal-epidermal cohesion by chemical and physical interactions. Experimental evidence exists for the following interactions: β4 integrin-plectin [34,35], α6β4 integrin-laminin 5 [36], α6 integrin-collagen XVII [37], β4 integrin-collagen XVII [34], laminin 5-laminin 6 [38], laminin 6-nidogen, nidogen-collagen IV and nidogen-perlecan [26,39], laminin 5-collagen VII, and collagen IV-collagen VII [31,32].

Both keratinocytes and fibroblasts contribute to the synthesis of the DEJ. Ample evidence points to active epithelial-mesenchymal crosstalk in the regulation of DEJ

TABLE 2. Molecular Components of the Dermal-Epidermal Junction

Molecule	Synthezised by	Special Features	Ligands
Intermediate filament components			
Keratin 5	K	Dimer → intermediate filaments	Plectin, BP230
Keratin 14	K	Dimer → intermediate filaments	Plectin, BP230
Hemidesmosomal plaque components			
BP230	K	Cytoskeleton linker, isoforms	Keratins 5 and 14
Plectin	K	Cytoskeleton linker, isoforms	Keratins 5 and 14, β4 integrin
Transmembrane components			
α6β4 Integrin	K	Heterodimer	Plectin, collagen XVII, laminin 5
Collagen XVII	K	Homotrimer, ectodomain proteolytically shed	α6β4 integrin, laminin 5?
α3β1 Integrin	K	Plasma membrane between hemidesmosomes	Laminin 5
Lamina lucida components			
Laminin 5	K	Heterotrimer, major anchoring protein	α6β4 integrin, collagen VII
Laminin 6	K	Heterotrimer, linked to laminin 5	Laminin 5
Lamina densa components			
Collagen IV	K/F	Heterotrimer, forms basic basement membrane scaffold	Nidogen, perlecan
Nidogen	F	Forms a network	Collagen IV, perlecan, laminin 6
BM-40/SPARC	K/F	Calcium binding	
Perlecan	F	Heparan sulfate proteoglycan	Collagen IV, nidogen
Anchoring fibril components			
Collagen VII	K	Proteolytically processed, dimer → fibril	Laminin 5, collagen IV

formation, the biosynthesis of molecules in one cell type being modulated by soluble signals from neighboring cells or from the extracellular matrix. *In vitro*, depending on experimental conditions, one or another cell type plays a more active role in the production of certain molecules [40–42]. Epithelial cells manufacture collagen VII and most laminin chains, whereas mesenchymal cells synthesize collagen IV, nidogen, perlecan, and the laminin α2 chain [43]. In skin equivalent cultures [42] and developing mouse organs [44], fibroblasts are the only source of nidogen at the epithelial-mesenchymal interface.

An interesting additional regulatory step in the supramolecular assembly of the DEJ is provided by the post-translational proteolytic processing of some components. Such trimming is thought to contribute to the correct association and folding of the polypeptide subunits, because propeptides can recognize binding sites for the accurate alignment of subunits or prevent premature aggregation of the molecules. Two important components of the anchoring complex are subject to such processing, laminin 5 and collagen VII. The 200 kDa α3 chain of laminin 5 is processed to a 145 kDa mature chain by cleavage in the C-terminal G domain, and the 155 kDa γ2 chain is cleaved within the N-terminal short arm to yield a 105 kDa polypeptide [40]. The carboxyl-terminal NC-2 domain of procollagen VII is removed before stabilization of the anchoring fibrils [45]. BMP-1 (bone morphogenetic protein 1), also known as procollagen C-proteinase [46], processes the γ2 chain of laminin 5 [47], and possibly procollagen VII, in the extracellular space. Interestingly, BMP-1 is synthesized mainly by fibroblasts, whereas both laminin 5 and collagen VII are epithelial products, suggesting that epithelial-mesenchymal interactions play an important regulatory role at this step. The significance of proteolytic processing in assembly of the DEJ was demonstrated in BMP-1 knockout mice, which showed a disorganized basement membrane structure [48]. This is further corroborated by the finding that a deletion of the BMP-1 consensus sequence in human procollagen VII is associated with DEB [49].

Yet another form of regulation may be proteolytic cleavage of the extracellular domains of integral transmembrane proteins in type 1 or type 2 orientation. The ectodomains of collagen XVII and syndecans are shed from the keratinocyte surface by selective proteolysis [50–52]. The process is catalyzed by a group of enzymes collectively referred to as secretases, or sheddases, which have been only partially characterized but of which many can be grouped as metalloproteinases and/or serine proteinases [53]. At least in some instances, such as in the processing of the collagen XVII ectodomain, proprotein convertases of the furin/PACE family are involved. Furin-mediated proteolysis is also required to yield a heavy and a light chain of the α6 integrin polypeptide, a necessary step for activation of the integrin [54]. The proteolytic cleavage of the ectodomains of keratinocyte surface proteins may provide a means of regulating cell adhesion, differentiation, and migration at the DEJ; however, the details of these events still remain unclear.

Current evidence indicates that the DEJ contains additional physiologically and pathologically relevant components. For example, syndecans, collagen XIII, and β-dystroglycan are transmembrane proteins in basal keratinocytes, laminins 2 and 10 [25,43] are localized in the lamina lucida of the DEJ, and several distinct proteins colocalized with the anchoring fibrils, such as the GDA-J/F3 antigen [55] and collagen XVIII [56], are known to exist. Future research must show whether these molecules and their genes are involved in the pathogenesis of EB.

Classification of EB

On Clinical Grounds

The clinical classification of EB only becomes reliable when the full clinical picture has developed. Apart from certain obvious associations, such as skin blistering and pyloric atresia, a purely clinical diagnosis is not possible at birth. The differential diagnosis of EB and other bullous affections in the newborn is listed in Table 3. Corresponding microbiological, histological, ultrastructural, serological, and other laboratory tests help discern these conditions. Within the first months and years of life, the secondary signs of EB begin to develop, allowing clinical determination of the major EB categories. In EBS, intraepidermal blisters heal without atrophy or scarring. The prognosis is mostly good, and the blistering activity decreases with age. In JEB, blistering occurs at the basement membrane through the

TABLE 3. Differential Diagnosis of Epidermolysis Bullosa and Neonatal Vesicobullous Disorders

Condition	Characteristic Features
Genetic	
Bullous ichthyosiform erythroderma (MIM 113800)	Red, scaly skin; flaccid bullae at trauma-exposed sites; hyperkeratosis, AD*
Incontinentia pigmenti (MIM 308300)	Streaky blistering, resulting in swirly pigmentation, mainly on trunk, XL
Aplasia cutis congenita (MIM 107600,207700)	Focal absence of skin on scalp, rarely elsewhere, AD or AR
Kindler's disease (MIM 173650)	Poikiloderma, acral blistering, cutaneous atrophy
Infectious	
Congenital herpes simplex	Herpetiform blisters and erosions, generalized
Staphylococcal scalded skin syndrome	Generalized erythema, fever, and necrotic peeling of the epidermis
Candidiasis	Erythematous vesicular or pustular eruption in diaper area or generalized
Impetigo neonatorum	Vesicles, bullae, or pustules on erythematous base, crusts
Autoimmune	
Bullous autoimmune dermatoses	Maternal disease? Immune deposits in skin
Mechanical	
Suction blisters	Noninflammatory blisters on thumb or radial aspects of the hand

*AD: autosomal dominant; AR: autosomal recessive; XL: X-linked.

lamina lucida. Healing takes place without scarring, but minor skin atrophy follows repeated blister formation. This category is clinically heterogeneous, ranging from the very severe lethal subtype to mild disease with late onset. DEB is characterized by dermal blistering below the basement membrane and subsequent scarring and milia formation. Clinical expression varies from a localized acral blistering to a severe mutilating disease with extensive extracutaneous involvement and poor prognosis. Traditionally, DEB has been believed to comprise two dominant and four recessive subtypes; however, molecular genetic analyses have revealed combinations of dominant and recessive mutations in several cases. Consequently, it is not possible to distinguish the DEB subtypes on clinical grounds except maybe for the severe DEB generalisata mutilans with typical early formation of synechia. DEB may be the first EB category to undergo reclassification on molecular and genetic grounds.

On Biochemical and Molecular Grounds

The classification of EB on biochemical and molecular grounds is based on the knowledge of the ultrastructural location of the molecular components of the DEJ. Specific monoclonal and polyclonal antibodies are useful for antigen mapping (Fig. 2), a technique employing marker antibodies with restricted, well-characterized binding sites at the dermal-epidermal junction for immunofluorescence staining [57]. When spontaneously blistered skin is stained, the level of dermal-epidermal separation can be deduced from the disposition of fluorescent markers on the blister roof or base. This fast technique has become a routine supplement and an alternative to electron microscopy in defining the precise splitting level in EB skin (Fig. 2) and with it the major EB category. Another important diagnostic sign is the lack of an indicator molecule in certain EB subtypes: plectin in EBS with muscular dystrophy, laminin 5 in JEB Herlitz, α6 or β4 integrin in JEB with pyloric atresia, collagen XVII in generalized atrophic benign EB (Fig. 2C), and collagen VII in DEB mutilans [22,58–62]. Correspondingly, mutations in the genes encoding these proteins cause these and related EB subtypes, and mutation analysis finally confirms the diagnosis.

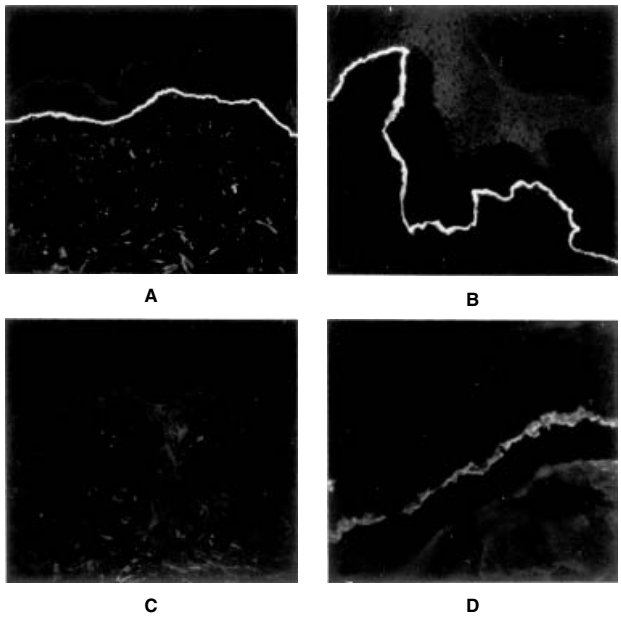

Figure 2. Antigen mapping. Indirect immunofluorescence staining of components of the dermal-epidermal junction in spontaneously separated EB skin. **A**: Laminin 5 shows a linear fluorescence in normal dermal-epidermal junction. **B**: Laminin 5 on the floor of a junctional blister. **C**: Lack of collagen XVII in generalized atrophic benign EB skin. **D**: Reduced collagen VII staining in blister roof in DEB.

Some EB subtypes are very rare, being represented in only single families, and some subtypes have not yet been investigated with molecular markers. Careful clinical, genetic, and biochemical characterization of as many cases as possible will show whether all of these subtypes stand out as distinct defects or whether they represent the same disorders with variable phenotypic expression.

The classification is further complicated by the fact that studies on JEB have indicated that mutations in different genes can lead to a similar clinical presentation [63,64] and that different defects in the same gene can lead to very different clinical phenotypes [65]. An additional problem in the classification of EB is the combination of dominant and recessive gene mutations. It has come as a surprise that a significant number of EB patients are compound heterozygotes for two different mutations and that in several DEB families the combination has been shown to consist of a recessive and a dominant mutation [49,66–68]. Discovery of the extensive variability of combinations of mutations has consequences not only for classification but also for genetic counseling of affected families. Detection of one or two mutations in the index patient does not always allow as unambiguous a determination of the diagnosis, inheritance pattern, and prognosis as previously assumed.

Approach to the Patient

For the careful evaluation of an EB patient, a combination of the family history, clinical examination of the index patient and family members, and a skin biopsy for antigen mapping, and eventually for electron microscopy and keratinocyte and fibroblast cultures, as well as blood samples for mutation analysis, are required (Fig. 3). In the postnatal period, the clinical presentation can be unspecific and, as discussed above, it is not possible to differentiate among the subtypes on clinical grounds. Often, the major EB category can easily be determined by antigen mapping of a skin biopsy of a newborn; however, for many patients the exact clinical subtype cannot be determined until the course of the disease has been observed. Therefore, regular follow-up visits are required.

Relative Frequencies of the Different Types

Relative frequencies of the EB subtypes have not been determined, and only fragmentary data exist in the literature [3]. Generally, EBS is the most common EB category and EBS localisata the most common subtype. DEB is clearly more common than JEB. The striking difference in the incidence of JEB Herlitz between two neighboring countries, Sweden (very high) and Finland (very low), argues against recurrent mutations in hotspot regions. Only one gene is likely to have a "hotspot" mutation, namely the *LAMB3* (laminin β3) mutation R635X, which is found in 40% of JEB Herlitz cases [69]. Gedde-Dahl has calculated that because all DEB mutations have been found at a single locus, *COL7A1*, the pooled frequency of recessively acting alleles is 0.0024 in Norway, implying that 0.5% of the population are heterozygous carriers of *COL7A1* mutations [3].

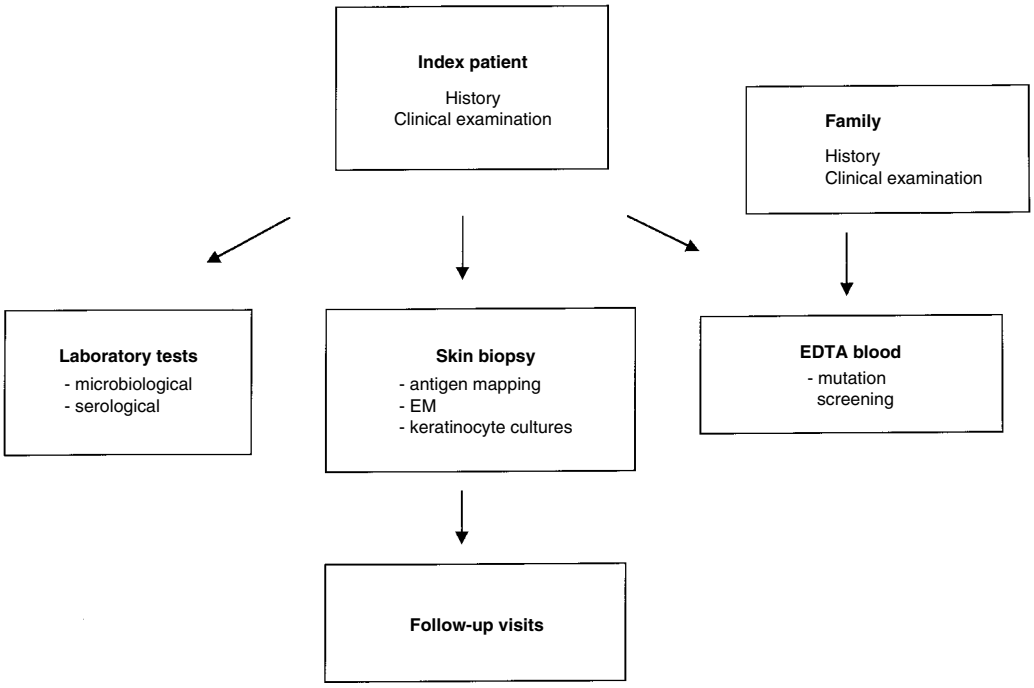

Figure 3. Flow sheet for EB diagnosis.

Prevalence and Epidemiology

It has not been possible to establish reliably the overall prevalence of EB. However, several rather similar estimates of prevalence and incidence have been published from different countries: Gedde-Dahl reports a prevalence in Norway of 42×10^{-6} for EBS (23×10^{-6} if EBS Ogna, which is very common in Norway, is excluded), 2×10^{-6} for JEB, and 10×10^{-6} for DEB [3]. In his study of EB in Finland, Kero [70] reports a prevalence of 27×10^{-6} for all EB subtypes. A similar figure, a morbidity of 25×10^{-6}, was found in Denmark in the 1950s [71]. The incidence of EB in the U.S. and in Europe has been estimated to be about 1:20,000 to 1:50,000, or 20×10^{-6} births [72].

EPIDERMOLYSIS BULLOSA SIMPLEX

Common Aspects

This EB category exhibits trauma-induced skin blistering as a consequence of cytolysis of basal keratinocytes. Keratin intermediate filament scaffolding, which sustains the three-dimensional structure of the cells, is weakened due to defects of the keratins or the linker proteins that attach the intermediate filaments to the hemidesmosomes and collapses as a result of external shearing stress. The blistering is intraepidermal, and healing takes place without scarring. In general, the prognosis is favorable, and blistering activity diminishes with advancing age. Defects in the keratin and plectin genes have been shown to underlie several of the subtypes despite clinical heterogeneity.

Clinical Features

EBS Generalisata (MIM 131900, Koebner Disease, AD-EBS-G)

Blistering occurs from birth, or the first few weeks of life, on the whole integument (Fig. 4) but preferentially involves the skin of the hands and feet, especially the palms and soles [3,4]. The frequency of blistering usually increases at high temperatures or after trivial trauma such as walking. The severity of involvement varies greatly between sibships. Healing usually takes place without scars, although secondary traumatization or infection may lead to scarring and milia formation. Diffuse palmar-plantar hyperkeratosis is common, as is hyperhidrosis of the feet. Nails and teeth are normal, and oral mucous membranes are rarely involved. The primary complication seems to be secondary infection of the blistered skin. The disease may be severe at birth, but although the widespread blistering may be debilitating, the condition is not threatening and patients can have a normal life span. Many experience improvement after reaching maturity.

EBS Localisata (MIM 131800, Weber-Cockayne Disease, AD-EBS-L; MIM 601001, AR-EDS-L)

AD-EBS-L is the most common EBS variant [3,4,70–72]. A few families with identical clinical presentation but with recessive inheritance have been described [73,74]. Blisters are clinically indistinguishable from those in EBS generalisata but are limited primarily to hands and feet. Blistering recurs particularly in the warm seasons. The blisters can be painful and even disabling. Onset is usually by toddler age but can be delayed to the twenties. Nails are uninvolved (Fig. 4), and blistering of the oral mucous membranes is rare. Hyperhidrosis of the feet and palmar-plantar hyperkeratosis are often present. Differentiation between a mild phenotypic variant of EBS generalisata and EBS localisata is arbitrary.

EBS Herpetiformis (MIM 131760, Dowling-Meara Disease, AD-EBS-H)

Generalized blisters and erosions are often present congenitally or develop shortly after birth [3,4]. The symptoms may be severe in the infantile period [75]. Large

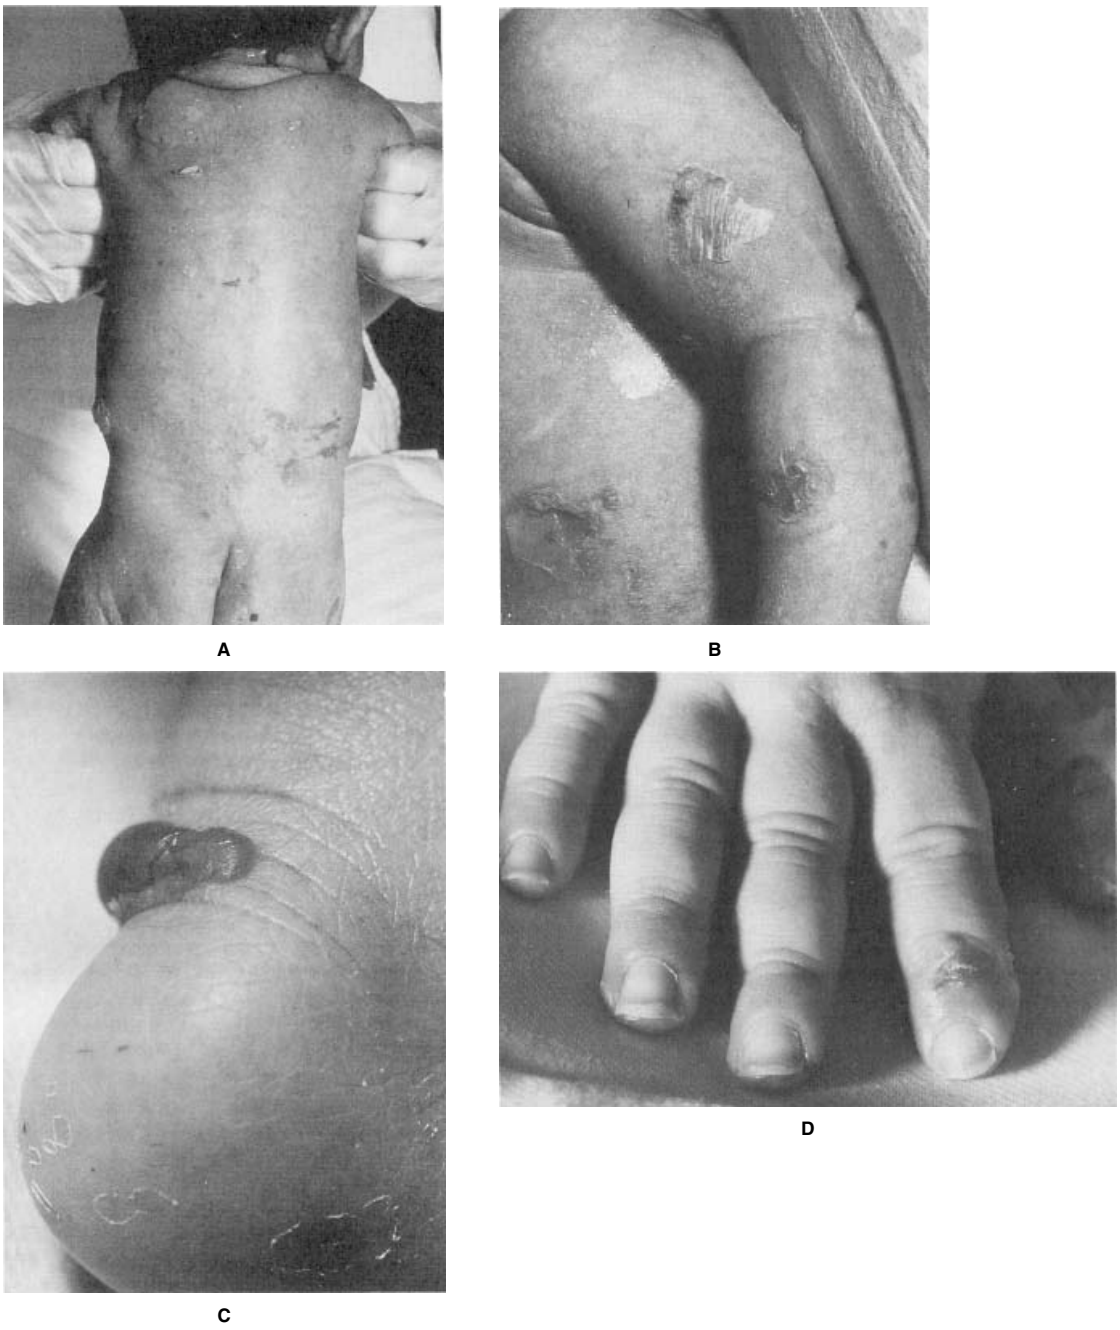

Figure 4. Clinical features of EB simplex. **A**: Generalized blistering in an infant with EBS generalisata. **B**: Superficial flaccid bullae and erosions. **C**: The blisters are occasionally hemorrhagic. Healing takes place without scarring. **D**: Localized blistering of the hand in EBS localisata. The nails are normal.

blisters on the hands and feet, including the palms and soles, and smaller blisters in herpetiform arrangement on the proximal extremities and trunk are typical. Small vesicles can appear on the face. The blisters may spread in a centrifugal manner and heal rapidly, leaving no scars but postlesional hyperpigmentation. Nails may be lost due to subungual blistering but regrow normally. In childhood, hyperkeratotic palms and soles are typical. Oral blistering can occur in early phases. Oddly, the skin clears during high fever, and no typical summertime aggravation is observed. Around school age, the skin improves rapidly, and in adulthood friction blisters rarely occur. At adult age, plantar hyperkeratosis is the main problem. Oral blistering, dental abnormalities, and corneal erosions may accompany this entity.

EBS with Mottled Pigmentation (MIM 131960)

An irregular mottled hyperpigmentation and hypopigmentation (Fig. 9G) of the proximal extremities and trunk accompanying blistering of trauma-exposed sites has been

described in a few European families [3,76,77]. Blisters are present at birth, but the pigment maculae appear during the first years of life. Blistering intensity decreases with age, but the pigmentation tends to persist. The blisters heal without scars, but slight skin atrophy imitating premature skin aging is typical. Most patients have plantar hyperkeratosis and onychodystrophy. Caries and mucosal fragility also occur.

EBS Associated with Muscular Dystrophy (MIM 226670, AR-EBS-MD)

A recessively inherited form of EBS associated with late-onset progressive muscular dystrophy has been described in many families worldwide [5,20,21]. The patients have congenital generalized blistering and healing without scarring but with the development of atrophic skin changes and nail abnormalities. Mild palmo-plantar hyperkeratosis, dental anomalies, and corneal involvement, as well as extensive mucosal erosions and urethral strictures, have been described in some probands. The onset and extent of the muscle symptoms vary greatly among kindreds. Some develop severe progressive muscular dystrophy during early infancy but others not until the third decade of life. In most cases described, the muscular weakness led eventually to the patients being wheelchair-bound.

EBS Ogna (MIM 131950, AD-EBS-O)

This variant has been described only in one large Norwegian kindred with a dominant inheritance pattern [3]. It has its onset in infancy, and patients exhibit a generalized tendency for skin bruising and often onychogryphotic nail changes in addition to seasonal acral blistering. The disease generally follows a mild clinical course.

EBS Herpetiformis with Mottled Pigmentation (AD-EBS-HMP)

This entity has been described in two families [78,79]. Generalized serous and hemorrhagic blisters in herpetiform arrangement were present from birth. The blisters healed rapidly without scarring but left a postbullous pigmentation. The skin rapidly normalized during episodes of high fever, and the blistering showed a marked improvement at school age. A mottled macular pigmentation developed on the neck and trunk in childhood, and the intensity of the staining increased with age. Palmo-plantar hyperkeratosis had an onset at school age and showed increasing severity with age. Subungual blistering in the toes was frequent. Mucous membranes were rarely involved.

EBS Associated with Anodontia and Hair and Nail Disorders (Kallin Syndrome)

A localized EBS associated with anodontia and hair and nail disorders was described in two Swedish families, one clearly demonstrating recessive inheritance [3]. The onset of nonscarring, seasonally aggravated blistering was within the first year of life. Onychogryphosis and transient nonscarring alopecia were observed. Abnormal mineralization led to the underdevelopment of teeth.

EBS Mendes da Costa (MIM 302000)

Trauma-induced blistering with a predilection for the extremities during the first 2–3 years of life is part of a syndrome including alopecia, reticulated hyperpigmentation, and skin atrophy of the face and extremities. Microcephaly is a noncutaneous-associated symptom. This X-linked condition has been described in a Dutch kindred [3].

Other Potential EBS Subtypes

A novel type of EBS with acantholytic blistering within the epidermis was described in one family [80]. The inheritance was dominant, and the blistering was acral and aggravated during summer months. Future research and description of more probands must show whether this represents a distinct EBS subtype or belongs to another disease group.

Genetics

EBS was the first EB category in which causative mutations were identified. First, transgenic mice with a truncated keratin 14 were found to exhibit a blistering skin phenotype on mild mechanical trauma, very similar to human EBS [81]. Parallel independent studies showed linkage of EBS to the type II keratin gene locus on chromosome 12q13, and soon after a number of mutations in the genes for keratin 5 at this locus and keratin 14 on the long arm of chromosome 17 were identified in EBS families [82–85]. Interestingly, mutations in these two genes seem to cause several clinical subtypes, and therefore the EBS subtypes generalisata, localisata, herpetiformis, and EBS with mottled pigmentation are allelic [86–88]. Most keratin mutations in EBS are inherited in a dominant manner. However, rare recessive keratin 14 null mutations have been reported; these seem to result in a somewhat milder phenotype than the dominant mutations [73,74].

Recessively inherited mutations in the gene encoding the hemidesmosomal plaque protein plectin, *PLEC1*, underlie EBS with muscular dystrophy. To date, about a dozen *PLEC1* mutations have been reported [89–94]. Some years ago, a genetic linkage to glutamine-pyruvate transferase (*GPT*; EC 2.6.1.15) at chromosomal locus 8q24.2–q24.3 was demonstrated for EBS Ogna [3]. Because the plectin gene is also located at this same locus, it is possible that dominant plectin mutation are associated with EBS Ogna. Indeed, Koss-Harness and co-workers have evidence for abnormal plectin expression in two EBS Ogna families [95].

Keratins 5 and 14

Keratins belong to the intermediate filament superfamily, which has more than 50 members differentially expressed in nearly all cells of the body (see Chapter 6, this volume). The intermediate filament cytoskeletons seem to be tailored to suit the specific functional needs of each cell type, but despite their functional diversity, the members of the intermediate filament superfamily share a common structure, a dimer composed of two α-helical polypeptide chains oriented in parallel and intertwined in the form of a coiled-coil rod. The highly conserved ends of the intermediate filament rod associate in a head-to-tail fashion and copolymerize to form the supramolecular intermediate filament aggregates. The major keratins expressed in the basal cells of the epidermis are keratins 5 and 14, the former a type II and the latter a type I keratin that, as a pair, form the coiled-coil rod [96]. After the identification of numerous mutations in the genes for keratins 5 and 14 in EBS families, it has become evident that mutations in the highly conserved ends of the rod have more deleterious consequences for filament assembly than mutations in other portions of the rod. Consequently, different mutations in the same gene(s) have been shown to cause a variety of clinical phenotypes [82–88].

Plectin

Abnormalities of plectin, a cytoskeleton-associated protein widely distributed in squamous epithelia and muscle [97], are associated with autosomal recessive EBS with muscular dystrophy [21,22,89–94]. Consistently, plectin has both an intermediate filament and an actin-binding domain. In the skin, it is a hemidesmosomal plaque protein that mediates the attachment of keratin intermediate filaments

to the hemidesmosomes. Consistent with this, experimental evidence exists for ligand interactions between plectin and another component of the hemidesmosomal plaque, β4 integrin [34,35]. Lack or functional deficiency of plectin in keratinocytes leads to defective anchorage of the cytoskeleton to the plasma membrane and to cell fragility as a result of shearing forces in the skin. In muscle cells, plectin bridges intermediate filaments and actin filaments, and its abnormalities cause disorganization of the structural filament networks in the cells and diminished mechanical resistance of the muscle cells, thus leading to muscle wasting in EBS with muscular dystrophy.

Bullous Pemphigoid Antigen-1

Another intracellular hemidesmosome protein with the capacity to bind intermediate filaments, bullous pemphigoid antigen-1, or BPAG1 or BP230, was targeted in mice [98]. In the absence of BP230, the intermediate filaments were severed from the hemidesmosomes, generating intracellular fragility and resulting in skin blistering. Disruption of the locus also resulted in degeneration of the sensory nervous system [98]. This puzzling finding was later explained by the discovery of a neural isoform of bullous pemphigoid antigen-1, BPAG1-n, which was also ablated by the gene-targeting construct [99]. Despite the establishment of the *BPAG1* gene, which encodes bullous pemphigoid antigen-1, as a candidate gene for EBS by these experiments, no mutations in humans have yet been reported.

Physical Properties and Morphology of Keratin Intermediate Filaments and Pathogenesis of the Disorder

In epidermal keratinocytes, the keratin filaments provide a cellular framework that reaches from the nucleus to the specialized cell-cell junctions, the desmosomes, and cell-matrix junctions, the hemidesmosomes. Ultrastructural studies on EBS skin reveal, in addition to intracellular splitting, clumping of the keratin intermediate filament bundles in basal keratinocytes [3]. Genotype-phenotype correlation analysis using filament assembly assays with mutant keratins isolated from patients' cells pointed to a tendency of mutations in the highly conserved ends of the intermediate filament rods to cause severe disruption of the filament network and the more severe phenotypes, whereas mutations in the less conserved domains had less deleterious effects on the filament network and seem to be associated with milder clinical phenotypes [96]. When the network is disrupted as a consequence of dominant missense mutations, insoluble keratin aggregates exacerbate the situation, making the cells sensitive to external mechanical stress and resulting in cell degeneration and skin blistering. Surprisingly, when the network is missing in recessive null mutants, cells become fragile but require greater mechanical stress before rupturing than cells containing mutant keratins [96].

JUNCTIONAL EPIDERMOLYSIS BULLOSA

Common Aspects

Junctional EB (JEB) is a heterogeneous group of disorders with extreme clinical variation and defects in at least six distinct genes underlying the different clinical subtypes [3,5]. In the most severe subtype, JEB Herlitz, the course is usually lethal within two years after birth. In contrast, JEB progressiva only manifests at school age and progresses slowly, and observations indicate that heterozygous carriers may exhibit only minimal associated symptoms, such as enamel hypoplasia, and no skin blistering at all [100,101]. The hemidesmosome-anchoring filament complex is weakened by genetic defects in one of the structural molecules, resulting in epidermal dysadhesion. Healing takes place without scarring; however, a light skin atrophy, nail and dental problems, and alopecia are often associated with this EB category. Because a number of genes are involved, the determination of the candidate gene for each patient necessitates a careful clinical assessment and antigen-mapping analysis of a skin biopsy.

Clinical Features

JEB Herlitz (MIM 226700, JEB Gravis)

This is the most severe subtype of the EB family and has also been called EB letalis because it usually leads to death within the first two years of life [3]. The disorder is characterized by the onset at birth of severe generalized blistering and congenital ulcerations and erosions on the extremities. Blisters on the hands and feet occur soon after birth, but later these locations may be spared. Scalp lesions are common. The blisters heal without scars, but a mild atrophy at the sites of recurrent lesions can be seen. Milia are rarely present. Paronychia-like lesions lead to early loss of the nails. Tooth enamel is defective, but dental growth is normal. At some stage, the healing stops, leaving large excoriations and chronic plaques of granulation tissue, which are characteristically found in the perioral region and at the fingertips. Oral blistering can be moderate to severe, and hoarseness resulting from laryngeal mucosal blistering is a characteristic sign of this disease. Severe blistering of the skin and mucous membranes leads to protein and fluid loss and exposes the organism to secondary infections, thereby resulting in extensive systemic disease, including cardiac and pulmonary problems.

Generalized Atrophic Benign EB (MIM 226650, GABEB, JEB Atrophicans Mitis)

This form has had many names. The first description [102] called it JEB atrophicans mitis, or JEB Disentis, after the village in Switzerland where the affected family resided. Subsequently, the subtype has become commonly known as generalized atrophic benign EB, or GABEB [12]. The name stresses the benign course of the disease and the atrophic changes that develop during the course of the blistering. Generalized blistering begins at birth and continues with at most a moderate improvement to at least middle adult life. The extremities, hands, and feet are predominantly involved. However, the trunk, scalp, and face are usually also affected (Fig. 5). Large serosanguineous blisters heal with local erythema, atrophy, and fragility and sometimes hyperpigmentation. Milia are absent. Nail involvement is common, resulting in dystrophy or loss of nails, and mild palmo-plantar hyperkeratosis may be present. Some degree of alopecia is seen in most patients, and some develop an extensive or total alopecia early in life [65]. Oral blistering is mild and often temporary. Enamel defects may lead to dystrophic dentition and so-called enamel pitting.

JEB Localisata

Blisters indistinguishable from those seen in the generalized JEB are limited to hands, feet, and shins. Onset of the blistering can be from birth to school age. Nail involvement leading to nail dystrophy or loss and oral blistering are sometimes observed. Enamel hypoplasia can be associated with the disease and is sometimes the only symptom in heterozygous carriers [65,100,101].

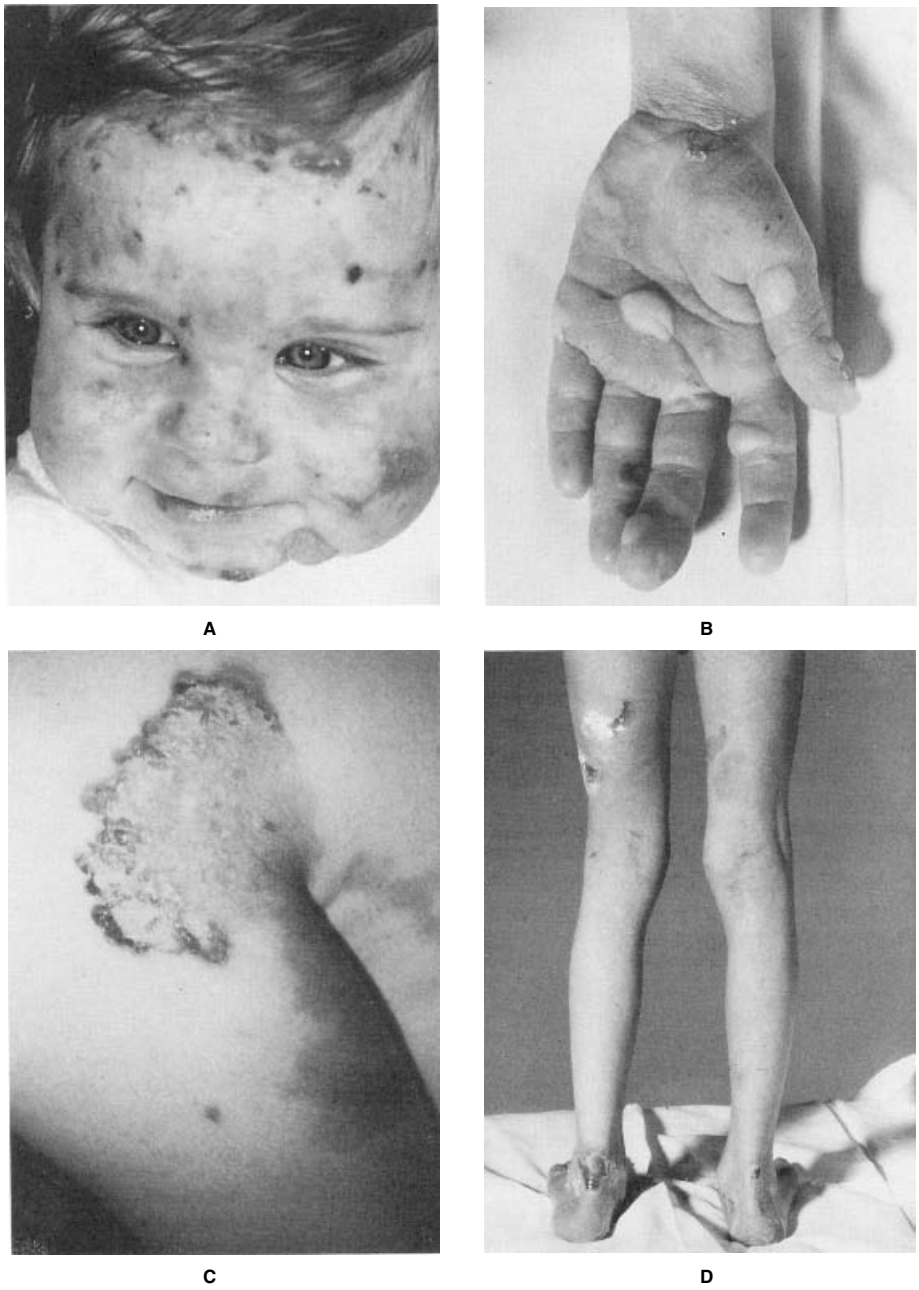

Figure 5. Clinical features of junctional EB. Disseminated blistering in generalized atrophic benign EB (GABEB) typically involves the face, **A**, and palms, **B**. **C**: Polycyclic lesion with blisters, crusts, and postlesional hyperpigmentation in the axillary fold in JEB inversa. **D**: A teenager with generalized atrophic benign EB shows disseminated but not severe blistering.

JEB Inversa

Neonatal blistering may present as pyoderma-like erosions in a generalized distribution. Often, the blistering disappears within a few months only to recur later. Then, bulla formation is concentrated in the inguinal, perigenital, and axillary folds (Fig. 5) and later also in the submammary regions [3]. Blistering of the hands and feet continues. Healing may be slow, leaving erosions, atrophy, and postlesional hyperpigmentation. Nails are sometimes dystrophic, and most patients develop, presumably due to scratching, small, white, atrophic maculae and streaks on the trunk and proximal extremities. Mild to moderate mucosal blistering has been observed. Curiously, the female sex hormones have a positive effect; the course of the disease is better between menarche and menopause, and some patients experience improvement during pregnancy [3].

JEB Progressiva (MIM 226500)

Earlier, this disorder was called EB dystrophica neurotrophica [3]. The discovery of the junctional nature of the blisters and of its progressive course led to the present name.

In this subgroup, dystrophy and loss of nails is usually the first symptom to appear, with late onset between ages 5 and 15 years. Serosanguineous acral blistering, which can also involve palms and soles, follows even after years. Healing leads to gradual mild atrophy with loss of fingerprints. Oral blisters occur, and lingual papillae may disappear similarly to the fingerprints. In the Norwegian families described first, hypoacusis was found as an associated symptom. However, other reports from elsewhere have found individuals with JEB progressiva with normal hearing capacity [103].

JEB Cicatricans

In this subtype, a discrepancy exists between the clinical appearance and the ultrastructural findings. Despite junctional splitting with rudimentary hemidesmosomes visible in the electron microscope, the blisters heal with scarring, and partial syndactylies may occur. Blistering starts at or soon after birth with a generalized distribution but with a predilection for the distal extremities. Blisters heal with scarring and occasionally with milia. The scarring can lead to syndactyly and flexion contractures with apparent shortening of the digits, but a true mitten-like deformity as seen in mutilating recessive dystrophic EB does not develop. Another major feature is the presence of nasal blisters from infancy, which eventually may result in complete closure of the anterior nares. Oral blisters and erosions are moderate and frequently accompanied by dental caries. Nails are completely lost from birth or within the first year of life [104].

JEB with Pyloric Atresia (MIM 226730, AR-JEB-PA)

JEB with pyloric atresia is a rare subtype with skin blistering associated with pyloric atresia at birth. Previously, it was not clear whether JEB-PA represented a distinct subtype or just a coincidence of JEB Herlitz and pyloric atresia. Only after mutations in the genes for α6 and β4 integrin subunits were found in patients with JEB-PA was its identity as a distinct EB form ascertained [3,5,19]. In severe cases, the condition is lethal during the postnatal period and, similarly to JEB Herlitz, affected children die of systemic complications despite surgical correction of the intestinal abnormalities. Mild, nonlethal JEB-PA cases have been recognized. The probands have minimal skin involvement, occasionally noted after surgery to correct the pyloric atresia but sometimes not until the early years of life [20,105]. Acral blistering may be induced by trauma, and dystrophy of some nails may develop. Enamel hypoplasia can be associated with the disease. The prognosis in mild cases is very good after the pyloric atresia is surgically corrected.

Acquired Autoimmune Diseases with Junctional Blistering

The term "acquired JEB" is not used, but certain inflammatory bullous skin disorders could be thought of as acquired forms of JEB. In some autoimmune dermatoses with subepidermal blistering, namely the pemphigoid group, circulating and tissue-bound autoantibodies target hemidesmosomal and anchoring filament proteins. In bullous, cicatricial, and gestational pemphigoid skin disorders, collagen XVII has been identified as a major autoantigen, but reports of autoantibody reactivity with laminin 5 also exist [24,51,52,124,133,134]. In linear IgA dermatosis, IgA autoantibodies, in contrast to mainly IgGs in pemphigoids, target collagen XVII and its soluble ectodomain. Most patients with autoimmune dermatoses are adults, but sometimes children are affected. In such cases, the distinction from a hereditary JEB with late onset may not be trivial, and molecular and immunological diagnostic tests are required to distinguish the two forms.

Genetics

All JEB subtypes are inherited in a recessive manner. Mutations in at least six different genes are involved, including the *LAMA3*, *LAMB3*, and *LAMC2* genes encoding laminin 5 [106–109], the *COL17A1* gene for collagen XVII [110–114], the *ITGA6* gene for integrin α6 [115,116], and the *ITGB4* gene for integrin β4 [19,20,105]. A significant number of patients show compound heterozygosity for two different mutations [5]. Homozygosity or compound heterozygosity for nonsense mutations in these genes is usually associated with severe phenotypes and missense mutations or missense/nonsense combinations with milder clinical presentation. Nonsense mutations in the laminin 5 genes generally lead to JEB Herlitz and missense mutations to a GABEB phenotype [117,118]. Nonsense mutations in the collagen XVII gene are associated with an extensive GABEB subtype and missense mutations with JEB localisata [65,113]. Lethal JEB-PA results from nonsense mutations in the *ITGA6* and *ITGB4* genes, whereas mild JEB-PA phenotypes have been observed in children with missense mutations in *ITGB4* [20,105]. In all these genes, most defects seem to be private mutations and spread over the entire gene, which makes mutational screening tedious, expensive, and time-consuming. Only in the case of the JEB Herlitz subtype does a different situation prevail. *LAMB3* mutations account for 80% of all laminin 5 gene defects in JEB [5]. In 50% of these cases, one of the two common mutations, R42X or R635X, is seen [69]. R635X in combination with missense mutations has been found associated with milder, nonlethal JEB subtypes (Fig. 6). The molecular genetics of JEB may turn out to be more complex than previously anticipated. We have identified a JEB child with digenic mutations in both *COL17A1* and *LAMB3* genes [101] who was mixed heterozygous for *COL17A1* nonsense mutations and carried the *LAMB3* mutation R635X in addition.

Basic Defects

Detachment of basal keratinocytes from the lamina densa and rudimentary or absent hemidesmosomes and anchoring filaments are ultrastructural hallmarks of JEB [119]. Indeed, absence or functional deficiency of the molecular components of the hemidesmosome-anchoring filament complex, laminin 5, α6β4 integrin, and collagen XVII, cause the clinically diverse JEB subtypes [3,5].

Laminin 5

Laminin 5, a heterotrimer of α3, β3, and γ2 chains, is the primary link between the hemidesmosomal α6β4 integrin and the anchoring fibril component, collagen VII. Because laminin 5 is a small laminin isoform with truncated short arms and hence reduced capacity to form self-assemblies, it is cross-linked to the laminin 6 network in the basement membrane, which in turn is connected to the other basement membrane networks [24–26]. Lack of laminin 5 results in extreme cutaneous and mucosal fragility in JEB Herlitz. Homozygous or compound heterozygous null mutations in the *LAMA3*, *LAMB3*, and *LAMC2* genes encoding the α3, β3, and γ2 chains of laminin 5 often lead to nonsense-mediated mRNA decay [120] and lack of synthesis of the corresponding polypeptide chain. Remarkably, absence of any one of the three subunit polypeptides prevents assembly and secretion of the entire heterotrimeric laminin 5 molecule [59]. Further, in the case of *LAMA3* nonsense mutations, laminin 6, with the chain composition α3β1γ1, is also absent from the DEJ. In view of the well-known severe phenotypes caused by lack of laminin 5, the observation of patients between 5 and

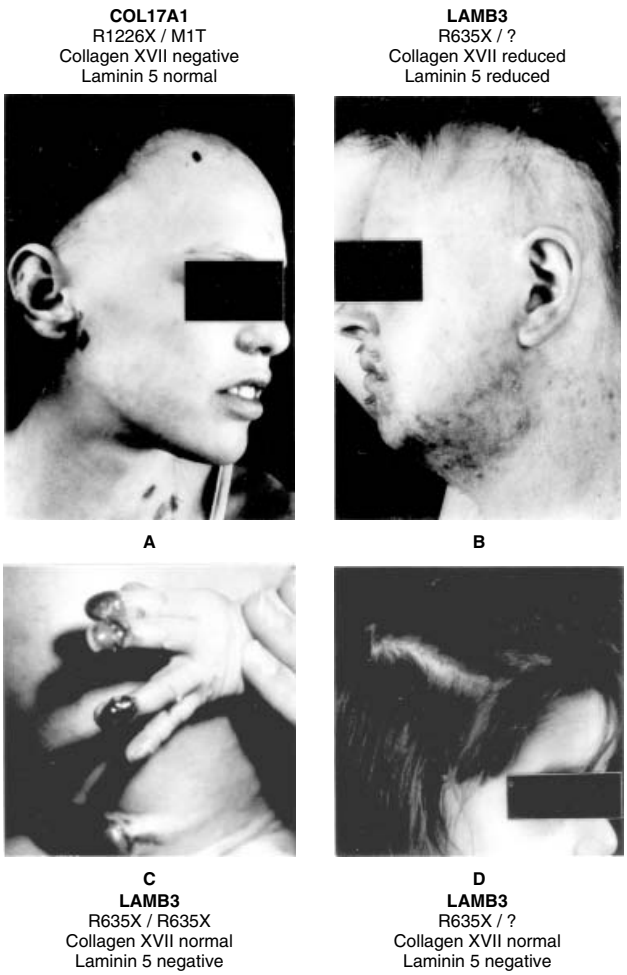

Figure 6. Genotype-phenotype correlations demonstrate unexpected JEB phenotypes. The characteristic phenotype of generalized atrophic benign EB (GABEB) with blistering, slight skin atrophy and temporal alopecia can be caused by mutations in *COL17A1* (**A**) or *LAMB3* (**B**). The common *LAMB3* mutation R635X is associated with 40% of all JEB Herlitz cases (**C**) but has been found in probands with very different, nonlethal phenotypes as well (**B**, **D**). Unanticipated is the clinical presentation of the child in the **lower right** panel; she shows a biological phenotype indicative of JEB Herlitz (i.e., a lack of laminin 5 protein in the skin and heterozygosity for R635X). However, she exhibits only mild acral blistering at the age of 7 years and shows no typical clinical features of either GABEB or JEB Herlitz.

25 years of age who have JEB of mild to moderate severity and who lack laminin 5 in the skin has been very puzzling (Fig. 6). We have shown that two schoolchildren with mild skin blistering practically lack laminin 5 at the DEJ and are heterozygous carriers of the *LAMB3* hotspot mutation R635X (L. Bruckner-Tuderman, unpublished observations). In each case, the second mutation has remained elusive so far. In concert with our observations, a mutation report described compound heterozygosity for *LAMB3* nonsense mutations in an adult with generalized JEB [121]. At present, there is no plausible explanation for the differing phenotypes, and further research on the biology of the laminins and their ligands must clarify this point. The presence of mutant, functionally abnormal laminin 5 at the DEJ has been observed in other nonlethal JEB subtypes, including generalized atrophic benign EB, but essentially nothing is known about the genotype-phenotype correlations in these cases.

α6β4 Integrin

Deficiency of α6β4 integrin is associated with abnormal hemidesmosomes, blistering of the skin, and pyloric atresia [19,20,61,105,115,116]. This JEB subtype often has a lethal outcome due to extensive skin fragility. Because the integrin binds to other hemidesmosome components (i.e., plectin, collagen XVII, and laminin 5), the disruption of ligand interactions is likely to lead to diminished epidermal adhesion. Several components of the anchoring complex have been shown to be expressed in the gastrointestinal epithelia [122,123]. This may explain the association of pyloric atresia with mutations in the genes for α6 and β4 integrin subunits. Nonsense mutations in the *ITGA6* and *ITGB4* genes lead to a complete lack of the integrin in the skin and to severe phenotypes, and missense mutations are found in association with milder phenotypes [105], but very little is known about how the gene defects modify the structure and ligand-binding activities of the integrin.

Collagen XVII

Collagen XVII (see also Chapter 2, this volume) is an unusual transmembrane collagen in type II orientation with an intracellular amino terminus and extracellular carboxyl terminus. It exists in two molecular forms, as a full-length transmembrane protein and as a shed soluble ectodomain [51,52]. The full-length collagen is a homotrimer of three 180 kDa α1(XVII) chains; the globular intracellular domain is disulfide-linked, and the N-glycosylated extracellular domain is triple-helical [52,124]. The soluble form is a triple-helical molecule comprising three 120 kDa polypeptides. The details of shedding are not yet understood, but current data strongly suggest that the soluble ectodomain is generated through furin-mediated proteolytic processing [52]. Thus, collagen XVII is not only an unusual transmembrane collagen but the first collagen with a specifically shed soluble triple-helical ectodomain.

Abnormalities of collagen XVII underlie most cases of GABEB [60,63–65,100,101,110–114]. Many patients are compound heterozygous for two different mutations. Most of the two dozen or so mutations known to date lead to a premature termination codon, nonsense-mediated mRNA decay, and an absence of collagen XVII from the skin (Fig. 7). Only a few missense mutations or missense/nonsense mutation combinations have been described. These allow the synthesis of structurally abnormal collagen XVII and cause milder JEB subtypes, including the JEB localisata subtype with mostly acral blistering, but not with alopecia [65,113]. The genotype-phenotype correlations of collagen XVII abnormalities are only just beginning to emerge. It will be interesting to observe how gene mutations alter the structure-function relationships of this unusual transmembrane collagen and its shedding.

Physical Properties and Morphology of Hemidesmosomes and Anchoring Filaments and Pathogenesis of the Disorder

The ultrastructure of the hemidesmosomes and the anchoring filaments is well-known, but we are only beginning to understand the assembly of these structures. Investigations using the expression of recombinant hemidesmosomal proteins in COS cells have indicated that α6β4 integrin,

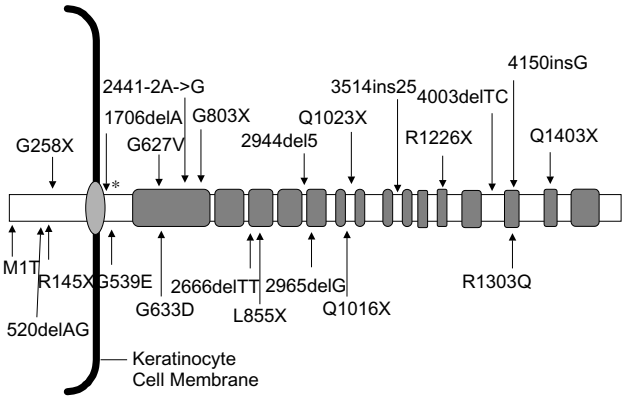

Figure 7. A schematic representation of the collagen XVII molecule and its mutations. Collagen XVII is an unusual transmembrane collagen in type II orientation, with a shorter intracellular amino terminus and a long extracellular carboxyl-terminal domain, which contains 15 collagenous subdomains with Gly–X–Y repeat sequences (gray bars). The oval, light gray symbol indicates the transmembrane domain. Most known mutations in the *COL17A1* gene lead to a premature termination codon and are associated with the generalized atrophic benign EB phenotype. The amino acid substitution mutations G633D and R1303Q have been reported in patients with localized JEB. The asterisk denotes the putative site for shedding of the soluble ectodomain.

collagen XVII, and plectin are essential for the formation of the hemidesmosomal plaque [34]. Ultrastructural studies on JEB skin have shown that the hemidesmosomes can have a rudimentary structure with a hypoplastic inner plaque and outer dense plate or be lacking completely. The most extensive hemidesmosome abnormalities are found in JEB Herlitz and severe JEB with pyloric atresia, suggesting that laminin 5 and the $\alpha 6\beta 4$ integrin are essential for normal hemidesmosome morphology. In JEB Herlitz, the anchoring filaments are also missing, indicating that laminin 5 is an important structural component of the filaments. In milder JEB subtypes, various degrees of lesser ultrastructural abnormalities of the hemidesmosomes are observed. In concert with the assumption that many protein-protein ligand interactions are required for the formation of a functional hemidesmosome-anchoring filament complex, lack of one component sometimes leads to the absence of other components as well, as observed with antigen mapping of JEB skin. For example, in generalized atrophic benign EB, antibodies to both laminin 5 and collagen XVII may show a negative reaction in the immunofluorescence staining of the skin, suggesting that the two proteins represent physiological ligands and that one of them is rendered unstable in the absence of the other.

DYSTROPHIC EPIDERMOLYSIS BULLOSA

Common Aspects

Dystrophic EB (DEB) is characterized by dermal blistering below the basement membrane and subsequent scarring (Fig. 8). Great progress has been made in defining the molecular basis of DEB, and new data have altered some of the concepts about this EB category. In the late 1980s–early 1990s, transmission electron microscopy had revealed abnormalities in anchoring fibrils [3,125–127], and immunohistochemistry of the skin in patients with the most severe DEB forms revealed entirely negative staining for collagen VII epitopes [62,127]. On the basis of these observations, the collagen VII gene was proposed to be at fault in DEB, and as of this writing over 150 mutations have been identified in this gene [5,30]. Traditionally, DEB contained two dominantly and four recessively inherited subtypes, but molecular genetic studies have shown that dominant and recessive mutation combinations and a new subtype also exist. Therefore, DEB may be the first EB category to be reclassified on molecular grounds.

Clinical Features and Complications

Dominant DEB Generalisata (MIM 131750, Pasini Disease, AD-DEB-G)

The blistering is usually seen at birth or in the first week of life and is generalized, involving also the face and ears [3,4]. Later in life, there is a predilection for the extremities, but occasionally blistering of the buttocks and even generalization is seen. Healing occurs with scars (Fig. 9B) and milia formation (Fig. 9E) often leading to large red atrophic areas on the extremities (Fig. 8D). Dystrophic or absent nails are common. Oral blistering is infrequent. Usually around adolescence, but sometimes before, characteristic albulopapuloid, white, scar-like lesions appear spontaneously on the trunk (Fig. 9D). The genesis and significance of these lesions are not yet known. The teeth are not affected.

Dominant DEB Localisata (MIM 131800, Cockayne-Touraine Disease, AD-DEB-L; MIM 131850, Pretibial DEB)

Serosanguineous blistering has its onset in infancy or early childhood, up to the fifth year of life [3,4]. The blisters are strictly localized to the extremities, with a preference for trauma-exposed sites over bony protuberances (Fig. 9A). Healing takes place, occasionally with hypertrophic scars and milia. Joint contractures may follow scarring (Fig. 9F). Some nails may be dystrophic or absent, but others may remain normal. Oral blistering is rare and teeth are normal. In extreme cases, nail changes are the only manifestation. Pretibial DEB cannot clearly be separated from DEB localisata, and since both are caused by mutations in the same gene, these subtypes should be considered the same [128].

Recessive DEB Generalisata Mutilans (MIM 226600, AR-DEB-GM)

This form belongs among the most severe subtypes of the EB family and leads to invalidity, with a poor prognosis owing to extracutaneous complications [3,4]. Severe, generalized blistering is present at birth, extends progressively, and leads to remarkable scarring. Recurrent blistering leads to erosions, which heal slowly with scarring and milia formation. Already in childhood, syndactylies lead to the characteristic mitten-like hands and feet (Fig. 8A,B). Nails become dystrophic and are lost early in life. Scarring causes joint contractures. Mucosal involvement of the oral cavity, pharynx, larynx, and esophagus makes eating difficult. Anal blistering and erosions cause difficulty in defecation and constipation. Impaired nutritional intake and protein loss through chronic erosions lead to anemia and growth retardation. Corneal and conjunctival blistering and erosions are present in some patients.

Recessive DEB Generalisata Nonmutilans (AR-DEB-G)

Generalized blistering is present at birth, with a predilection for the hands and feet. Later, generalized

Figure 8. Clinical features of dystrophic EB. **A**: Severe blistering and nail loss in a 4-week-old child with DEB generalisata mutilans. **B**: Mutilation of the feet in a 32-year-old with DEB generalisata mutilans. **C**: Localized blistering, scarring, and nail dystrophy of the feet in recessive DEB localisata. **D**: Blisters, erosions, scarring, and red atrophic areas of the lower extremities in dominant DEB generalisata.

traumatic blisters on the trunk occur as well. Mucosal blistering is extensive, and dystrophy of teeth is evident. Loss of nails is almost always present. Notably, there are no mutilations or syndactylies [3,4].

Recessive DEB Inversa (MIM 226450, AR-DEB-I)

Neonatal blistering and congenital ulcerations are followed by blistering concentrated on the trunk in childhood and later in the axillary, inguinogenital, and perianal folds and belt-like blistering over the sacrum and the neck [3,4]. Some acral involvement continues. The lesions heal with red atrophic scars and only rarely with milia. Early oral blistering leads to scarring and the characteristic shortening of the lingual frenulum. Perianal fissures or blisters may occur. The teeth are normal.

Recessive DEB Localisata (AR-DEB-L)

Acral blistering appears from birth. Atrophic cigarette paper-like scars develop distally from the elbows (Fig. 9B) and the knees [3,4]. Nail and tooth dystrophies are common (Fig. 8C). This subgroup may be clinically indistinguishable from the dominant EBD localisata. A patient with recessive

Figure 9. Some characteristic accompanying lesions in EB. **A**: Scarring at trauma-exposed sites. **B**: Atrophic scar. **C**: Nail dystrophy. **D**: Albulopapuloid lesion. **E**: Milia. **F**: Contractures due to scarring. **G**: Irregular pigmentation in EBS with mottled pigmentation. **H**: Alopecia.

pretibial DEB has been described [129], but, as noted above, pretibial DEB cannot clearly be distinguished from DEB localisata, and because both are caused by mutations in the same gene [128], these subtypes should be considered the same.

Transient Bullous Dermolysis of the Newborn (TBDN)

An unusual self-limiting postnatal blistering disease, TBDN is allelic to DEB (Fig. 10). It is characterized by highly fragile skin and blister formation at birth and by rapid amelioration within the first two years of life [3,4,130]. The skin blisters and erosions heal with mild atrophy and scarring, but other secondary signs such as hyperpigmentation, hyperkeratosis, nail dystrophy, and dental anomalies are usually absent. Disappearance of apparent clinical disease during the first years of life is typical, even though mild and variable skin fragility persists in some cases [4,131]. TBDN was previously distinguished from DEB by its benign, limited course and by distinctive pathomorphogenetic changes, such as, retention of collagen VII within the epidermis (Fig. 10), but the discovery of mutations in the collagen VII gene has now established TBDN as a DEB subtype [66,67].

EB Acquisita (EBA)

EBA is an acquired, inflammatory autoimmune blistering disorder that clinically resembles DEB, with blistering at trauma-exposed sites and subsequent scarring and milia formation. Autoantibodies to collagen VII bind to anchoring fibrils and are associated with dermal-epidermal separation below the lamina densa with subsequent scarring of variable degree. The antibodies are believed to perturb functions of the anchoring fibrils and thereby to contribute to blister formation [132–134]. In most cases, the immunodominant epitopes have been shown to reside within the globular NC1 domain of collagen VII [135]. However, a novel EBA subgroup with a milder clinical presentation has been defined in children with tissue-bound and circulating autoantibodies targeting only the triple-helical central domain of collagen VII and not the NC1 domain [136]. The diagnosis of EBA is established by direct immunofluorescence staining of the patient's skin for the demonstration of immunoglobulin deposits at the DEJ and the demonstration of circulating anticollagen VII antibodies in serum. Therapeutic strategies include immunosuppressive regimens with systemic steroids, azathioprine, cyclosporin A, and other agents [132]. Apart from EBA, antibodies to collagen VII have been described in association with bullous systemic lupus erythematosus [137] and some forms of inflammatory bowel disease [138].

Genetics

As far as is known today, all DEB subtypes are caused by mutations in the collagen VII gene, *COL7A1*,

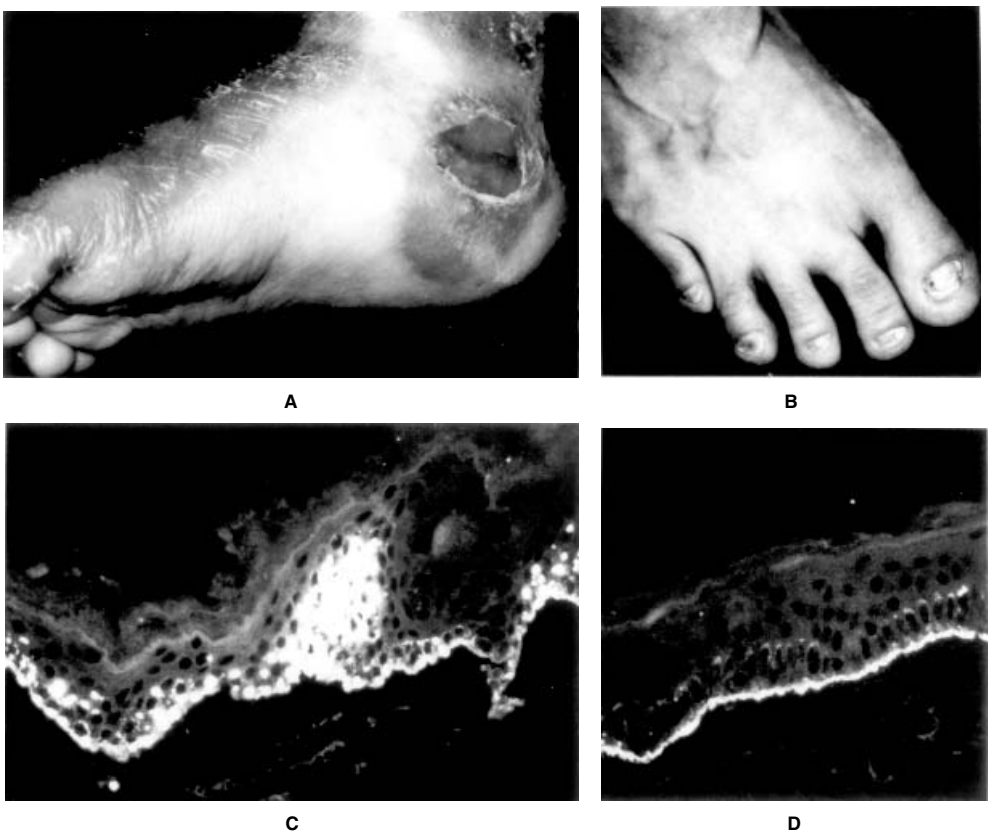

Figure 10. Transient bullous dermolysis of the newborn (TBDN): minimal phenotypes of heterozygous *COL7A1* mutations may be modulated by a second mutation. **A**: A proband with TBDN and massive blistering at birth was compound heterozygous for two different glycine substitution mutations in *COL7A1*, G2251E, and G1519D. **B**: The maternal mutation G2251E caused toenail dystrophy but no skin blistering. The paternal mutation G1519D was silent in the heterozygous state, and the father was clinically unaffected. **C**: In the skin of the newborn, the mutations caused abnormal folding, slow secretion, and intraepidermal accumulation of collagen VII. **D**: After 14 months, in parallel with clinical amelioration, collagen VII was found deposited at the dermal-epidermal junction, with minimal accumulation in the epidermis.

on chromosome 3p21, and are therefore allelic. More than 150 mutations have been reported to date and, remarkably, most patients with recessive DEB are compound heterozygous for two different mutations. Most of the mutations in recessive DEB are nonsense mutations or small insertions or deletions, which lead to frame shift and premature termination codons (PTCs) for translation [5,30]. In general, PTCs are associated with strongly reduced levels of the corresponding mRNA transcripts due to nonsense-mediated mRNA decay [120] and lack of synthesis of the corresponding polypeptide. The PTC mutations are silent in the heterozygous state but when homozygous or combined with another PTC mutation in the other allele, they lead to severe skin fragility, as illustrated by DEB generalisata mutilans.

A large number of missense mutations have also been identified and shown to be associated with an unusually broad spectrum of DEB phenotypes. Particularly interesting are mutations causing the substitution of a glycine residue within the triple-helical domain of collagen VII by another amino acid. In the case of other collagen genes, glycine substitution mutations characteristically cause dominantly inherited disease through dominant negative interference [139] (see also Chapters 8 and 9, this volume). *COL7A1* is, however, an exception among the collagen genes in that not all glycine substitution mutations are dominant, and in several cases remain silent when combined with a normal allele, although they lead to clinical manifestations when combined with another aberration in the other allele [140]. *COL7A1* is also unique among the collagen genes in that a single class of mutations — such as glycine substitutions or deletions — can cause either dominantly or recessively inherited DEB [5].

Most *COL7A1* gene defects are private mutations and spread over the entire gene, with the exception of exon 73. One study implicated this exon as a highly mutable region; over 10% of all *COL7A1* mutations reported to date have been found in exon 73 (Fig. 11). In a series of 53 European DEB families with dominant or recessive inheritance, 28% of the families had a mutation in exon 73 [141].

Basic Defects

Collagen VII

In DEB, the tissue separation occurs at the level of the anchoring fibrils. Abnormalities of collagen VII (see Chapter 2, this volume), the major structural protein of the fibrils, are known to be associated with DEB, and the most recent studies on the consequences of collagen VII mutations in DEB have revealed novel aspects of the biology of this collagen and the anchoring fibrils. Procollagen VII is a homotrimer of three proα1(VII) chains of 2,944 amino acids, each polypeptide consisting of a large 145 kDa central triple-helical collagenous domain flanked by an amino-terminal 145 kDa NC1 and carboxyl-terminal 30 kDa NC2 noncollagenous domain [28,30,142]. The collagenous domain contains repeating Gly–X–Y sequences that fold into a triple helix. The helix is interrupted 19 times by short noncollagenous sequences varying from 1 to 39 amino acid residues, which are thought to provide conformational flexibility to the molecule, a feature that may be of utmost importance for the functions of collagen VII fibrils as anchoring structures of the epidermis. Consistently, the positions of the noncollagenous interruptions within the Gly–X–Y repeat sequences are evolutionarily highly conserved [143]. The longest interruption of 39 amino acid residues lies in the middle of the helical domain. Rotary shadowing electron microscopic studies have shown that the molecule contains at this site a major flexible region [144], a fact that has lent the name "hinge region" to this 39 amino acid stretch. This site is also more sensitive to limited pepsin or trypsin digestion, and the triple helix can be cleaved into the carboxyl-terminal P1 and amino-terminal P2 fragments, each representing approximately one-half of the triple-helical domain [28,30]. During fibrillogenesis, procollagen VII monomers form antiparallel tail-to-tail dimers with a central carboxyl-terminal overlap and with the amino termini pointing outward. The dimers aggregate laterally in a nonstaggered manner into the anchoring fibrils, and before or during this process a C-terminal propeptide is proteolytically removed [45,145]. *In situ*, anchoring fibrils appear also to be transamidated, and both the triple-helical

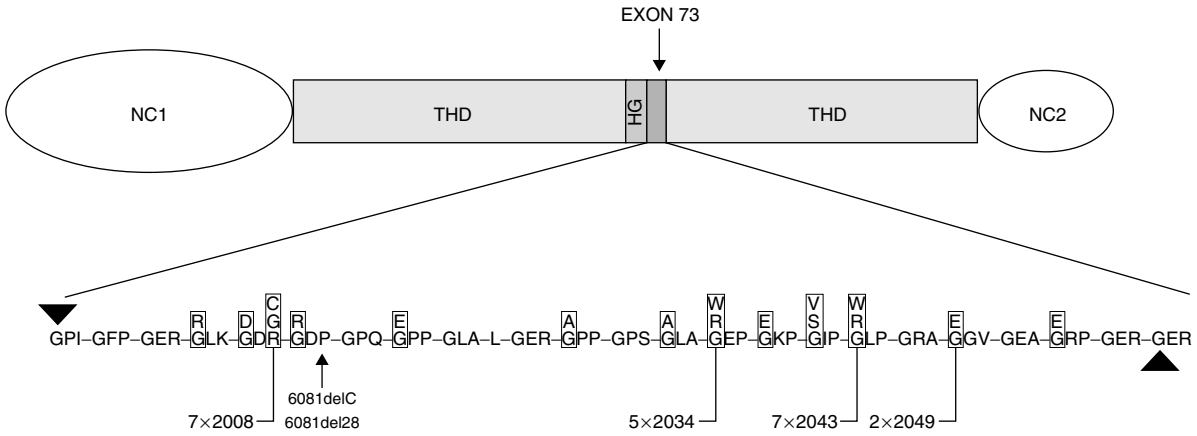

Figure 11. Clustering of *COL7A1* mutations in exon 73. Schematic representation of the collagen VII molecule and the location of the segment encoded by exon 73 (arrowheads). It is part of a 23 Gly–X–Y triplet stretch which is flanked N-terminally by the noncollagenous hinge region (HG) of 39 amino acids; NC1 = noncollagenous domain-1; THD = triple-helical domain; NC2 = noncollagenous domain-2. Amino acid substitutions in positions 2008 and 2043 have been reported in seven families, in position 2034 in five, and in position 2049 in two. In addition to the missense mutations indicated in this figure, two deletion mutations [141] have been reported in exon 73 (arrow).

and the carboxyl-terminal NC2 domains of collagen VII serve as substrates for tissue transglutaminase-2 *in vitro* [146]. These findings suggest that after anchoring fibrils have polymerized, transglutaminase cross-links are formed to stabilize the mature fibrils.

Several lines of evidence suggest that anchoring fibrils contain, in addition to collagen VII, other proteins that may be candidate proteins/genes for DEB [30]. For example, the monoclonal antibodies AF1 and AF2 decorate anchoring fibrils in immunoelectron microscopy but do not react with collagen VII. Another monoclonal antibody, GDA-J/F3, has been used to identify a novel anchoring fibril-associated epitope. The antibody recognizes a 50 kDa noncollagenous protein at the DEJ that by immunoelectron microscopy was localized to the insertion points of the anchoring fibrils into the lamina densa. Its integration into the histoarchitecture of the DEJ is dependent on the presence of collagen VII and the anchoring fibrils because the GDA-J/F3 epitope was missing in several DEB patients with absent or mutated collagen VII [55].

Extensive Molecular Heterogeneity of Collagen VII Mutations

COL7A1 mutations have a broad spectrum of biological consequences and lead to heterogeneous collagen VII abnormalities. From a protein chemical point of view, many of the pathogenetic mechanisms seem predictable; others, however, were completely unanticipated. Predictably, many mutations in severe recessive DEB lead to a premature termination codon (PTC) and a lack of protein synthesis. When the PTC mutations are homozygous or compound heterozygous with another PTC mutation, they cause severe phenotypes, as illustrated by DEB generalisata mutilans. Heterozygous carriers do not express truncated polypeptides but only the normal allelic product. The normal gene product does not appear to be compensatorily up-regulated, because keratinocytes from heterozygous carriers of *COL7A1* nonsense mutations have been shown to synthesize reduced amounts of collagen VII *in vitro* [147]. Therefore, one-half of the amount of collagen VII present in normal skin seems sufficient for adequate dermal-epidermal cohesion.

It has come as a surprise that the triple-helical collagen VII molecule can tolerate a number of structural aberrations without exhibiting any obvious functional defect. For example, glycine substitutions or other mutations causing rather significant changes in the primary structure of the proα1(VII) polypeptide can result in extremely mild clinical phenotypes or no disease phenotype at all. In contrast to other collagens, where glycine substitutions are common and interfere with triple-helical folding causing severe phenotypes [139] (see also Chapters 8 and 9, this volume), only a minority of *COL7A1* mutations cause glycine substitutions [49,66,140,141,148–150]. Furthermore, the mutations cause very variable phenotypes. Some glycine substitutions are associated with a classic dominant DEB

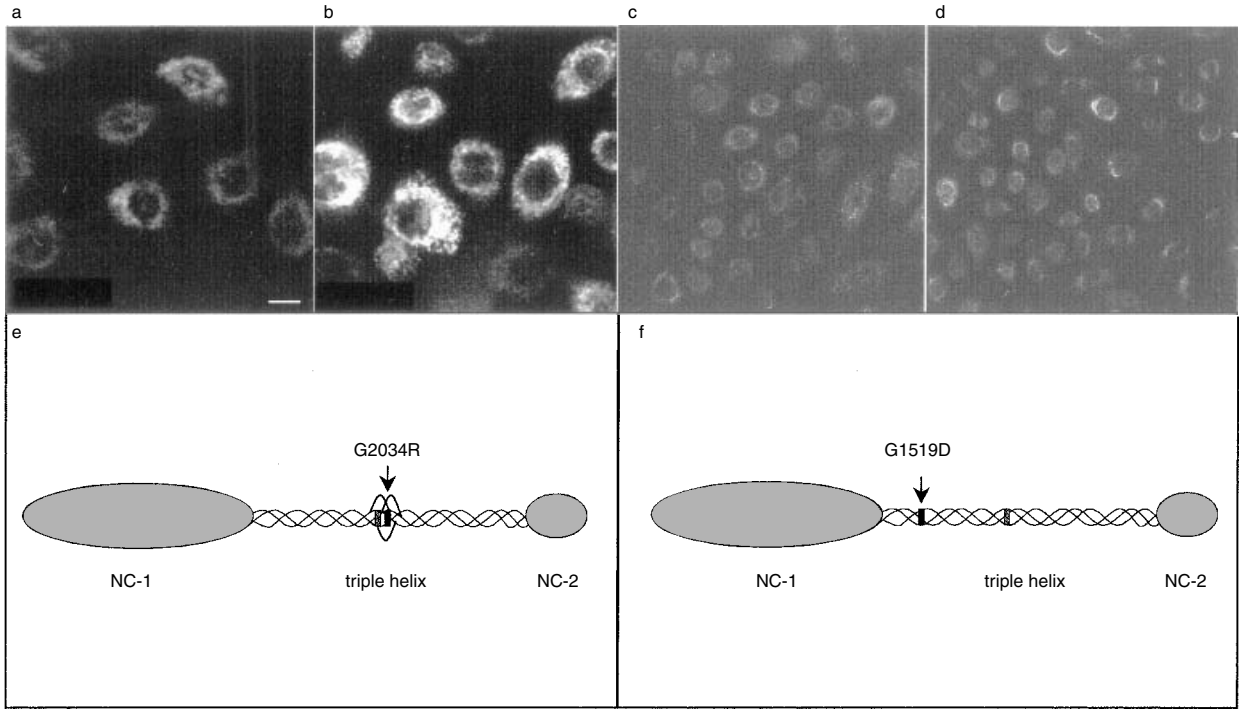

Figure 12. Some but not all glycine substitutions in collagen VII cause dominant negative effects. Immunofluorescence (IF) staining for collagen VII produces a moderate signal in normal control keratinocytes (**a**), whereas keratinocytes with a heterozygous *COL7A1* mutation causing G2034R substitution (**b**) exhibit a clearly stronger IF staining, indicating the intracellular accumulation of procollagen VII. In contrast, IF staining of mutant keratinocytes with the heterozygous glycine substitution G1519D (**c**) show an intracellular IF signal comparable to controls (**d**). The glycine substitution G2034R close to the central noncollagenous hinge region (**e**) interferes more strongly with triple-helical folding than glycine substitution G1519D situated within a long uninterrupted Gly–X–Y sequence close to the amino-terminal end of the triple helix (**f**). Consequently, the extent of the intracellular accumulation of procollagen VII is reflected in the degree of severity of the effects of the mutation. For details, see [140].

phenotype (Fig. 8), such as the mutations G2006D, G2015E, G2034R, and G2043W (Fig. 12) [140,141]. In contrast, the dominant mutations G2251E (Fig. 10) and G2287R merely cause nail dystrophy but no skin blistering, and the mutations G1347R, G1519D, and G2316R result in no disease phenotype at all (Fig. 12) [66,67,140,150].

Another study showed that, surprisingly, mild dominant negative interference resulted from large deletions in collagen VII [151]. Heterozygous intraexonic deletions altered splicing and led to the elimination of ten Gly–X–Y triplets from the center of the triple-helical domain of collagen VII in one DEB patient and to the omission of eight Gly–X–Y triplets from the carboxyl-terminal half of the triple helix in another DEB proband. DEB keratinocytes synthesized equal amounts of normal and shortened collagen VII polypeptides *in vitro* and showed intracellular accumulation of procollagen VII, but some mutant molecules were also secreted. This resulted in a reduced number and abnormal morphology of anchoring fibrils in the skin. These collagen VII abnormalities are analogous to the single-exon deletions in *COL1A2*, *COL3A1*, and *COL11A2* genes reported in, for example, osteogenesis imperfecta type I, Ehlers-Danlos syndrome type IV, and dominant Stickler syndrome, respectively [152–154] (see also Chapters 8, 9, and 23, this volume). However, in comparison with these other collagen disorders, the very mild phenotype and cessation of blistering by adulthood were striking in the case of the DEB patients.

The normal or mild DEB phenotypes associated with heterozygous mutations can, however, be severely modified if combined with another aberration. This is well-illustrated by three unrelated DEB families all of whom had a genomic deletion (8523del14) causing in-frame skipping of exon 115 [45,49]. The deletion alone did not cause a pathologic phenotype, as shown by the unaffected heterozygous carriers (Fig. 13). In the first family, the deletion was combined with a splice site mutation 425A-to-G, which led to abnormal splicing of exon 3 and the generation of several transcripts all of which contained a PTC. Therefore, the proband was hemizygous for the deletion mutation and exhibited a severe phenotype with generalized blistering. Both parents, heterozygous carriers of the mutations, were normal. In the second family, the combination of the same deletion with the glycine substitution mutation G2009R [45] caused a mild phenotype with acral blistering. Again, the mother, who was a carrier of the deletion, was healthy. In a third family, the deletion was combined with a dominant glycine substitution mutation G2043R [49]. This combination resulted in a severe phenotype, whereas the dominant mutation alone caused only mild skin blistering. These examples demonstrate that even significant deletions in collagen VII protein, such as skipping of the 29 amino acids encoded by exon 115, do not necessarily cause a pathologic phenotype. However, combination of the clinically silent deletion with another gene defect can result in drastic modulation of the phenotype (Fig. 13).

Transient bullous dermolysis of the newborn (TBDN) presents another example of modulation of the phenotype by a second mutation. Compound heterozygosity for dominant and recessive glycine substitution mutations in *COL7A1* was found in two unrelated probands [66,67]. In both families, the dominant glycine substitution mutation caused a minimal phenotype of toenail dystrophy but not skin blistering, whereas the recessive glycine substitution mutations remained silent when in the heterozygous state.

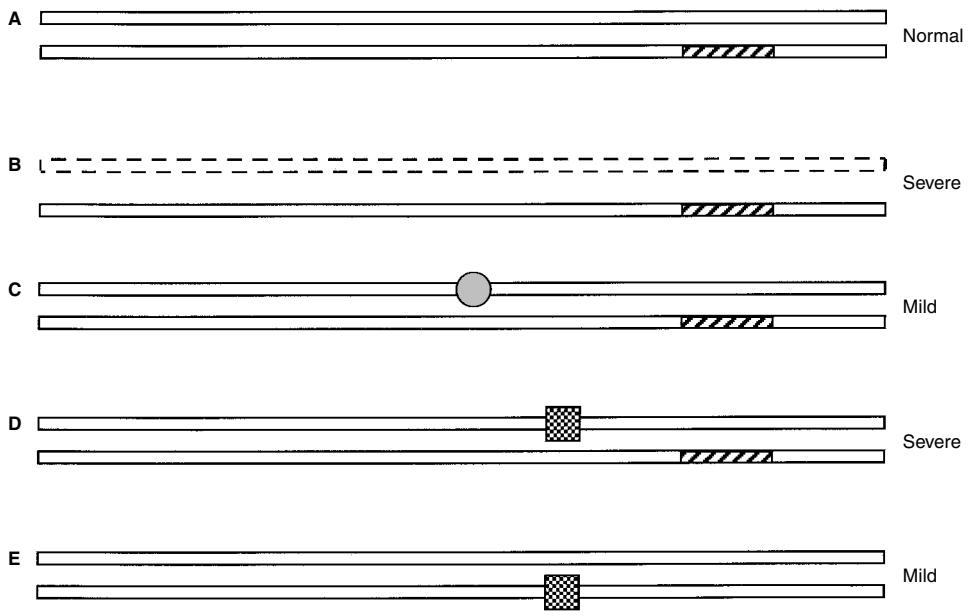

Figure 13. Modulation of the DEB phenotype by a second mutation. The *COL7A1* deletion mutation 8523del14 (striped bar) has been found in several unrelated DEB families from different European countries. Depending on the mutation constellation, the phenotypes differed significantly. (**A**) In combination with a normal allele, *COL7A1* 8523del14 did not cause a pathological phenotype in any of the families. (**B**) In the hemizygous state, when combined with a null allele (interrupted line), a severe phenotype resulted. (**C**) Compound heterozygosity for the deletion and the glycine substitution mutation G2009R (shaded circle) resulted in a mild phenotype. (**D**) In contrast, in combination with the dominant glycine substitution G2043R (shaded square), the deletion led to a severe affection. (**E**) The dominant G2043R mutation alone caused a mild DEB phenotype [49].

Only a combination of the two mutations led to a severe blistering phenotype at birth (Fig. 10). These are the first observations of compound heterozygosity for glycine substitutions in any collagen, and the dramatic intracellular accumulation of the mutant protein in the epidermis may result from "doubly" dominant negative interference in collagen VII folding by two different glycine substitutions. Because the TBDN cells do not synthesize any normal α1(VII) chains, collagen triple helices containing only mutant polypeptides are likely to be retained intracellularly or secreted slowly [66]. Highly active collagen biosynthesis during the postnatal period may be a contributing factor, and a high rate of synthesis of mutant, slowly secreted collagen VII molecules may manifest as intraepidermal accumulation of collagen VII (Fig. 10) and subsequent lack of anchoring fibrils at the DEJ.

Based on the examples above and other similar observations, it seems likely that the specific location of a mutation within a particular submodule of collagen VII, some of them more critical than others for the supramolecular assembly and function of this protein, is important in determining its impact on the overall stability, ligand binding, and other functions. One should keep in mind that the mutant polypeptides fold together with normal polypeptides into collagen triple helices and that the structurally aberrant trimeric molecules are incorporated into fibrils. The effects of the initially rather small structural abnormality are thereby accentuated, or perhaps attenuated, by the supramolecular assembly, and the resulting collagen fibrils are rendered inadequate in different ways. The biological and clinical phenotype is therefore determined by the uniqueness of each particular function and by the extent to which it is lost through the mutation.

Physical Properties and Morphology of Anchoring Fibrils and Pathogenesis of the Disorder

Ultrastructurally, in contrast to normal skin with its well-defined slender and centrosymmetrically cross-banded anchoring fibrils [27], DEB skin displays broad, blunt, whispy fibrils without cross-banding or no fibrils at all [3,125,126]. Complete lack of anchoring fibrils and collagen VII are characteristic signs of the most severe subtype, DEB generalisata mutilans [127]. In milder DEB forms, mutant collagen VII polypeptides are synthesized and incorporated into the fibrils, resulting in variably abnormal morphology and functions of the fibrils. As discussed above, despite the large number of known mutations in *COL7A1* in different DEB subtypes [5,30], correlations between the individual mutations and their suprastructural consequences are only now beginning to emerge. Future studies using mutant collagen VII molecules isolated from DEB skin or keratinocyte cultures, or normal and mutated recombinant collagen VII fragments, must address the effects of a genetic defect on the assembly and fibrillogenesis of collagen VII.

TBDN skin demonstrates very different ultrastructural features at birth. No normal anchoring fibrils can be discerned at the DEJ. Instead, highly dilated rough endoplasmic reticulum in basal and suprabasal keratinocytes of the epidermis is characteristically filled with filamentous material, electron-dense granules and rods [130], which were identified as consisting of collagen VII by immunofluorescence [131]. Curiously, at the age of about 12 months, the morphology normalizes, the intraepidermal accumulation of collagen VII disappears, and anchoring fibrils begin to appear at the DEJ.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS OF EPIDERMOLYSIS BULLOSA SUBTYPES

Family History

In families with dominant EB, the pedigree is useful in determining the likelihood of recurrence. However, most EB patients do not have an obvious family history. Nevertheless, a careful history should be taken and all family members be examined for minimal signs of the disease, such as nail dystrophy or enamel hypoplasia, because these minor symptoms may indicate heterozygous mutations. Compound heterozygosity for mutations in a large number of EB patients with different subtypes, and the fact that several families have mixed dominant/recessive mutations [66–68], call for careful (re)consideration of inheritance patterns and the recognition of rare genetic constellations, which seem to be more common in EB than in other genetic disorders.

Clinical Evaluation

At birth, the clinical presentation of EB is unspecific, and it is not possible to differentiate between the main categories and the subtypes on clinical grounds. The secondary signs, such as scarring, milia, hyperkeratosis, alopecia, nail dystrophy, and hyperpigmentation, that are helpful in determination of the EB category only develop within months or years. Therefore, the major category should be defined by antigen mapping as early as possible. The clinical subtype within the major category often becomes obvious when lesions at the predilection sites and the secondary signs have developed. Consequently, regular follow-up visits are required for observation of the course of the disease.

Morphological and Molecular Analysis

A skin biopsy is essential for the diagnosis and classification of EB. The major category can often be determined by antigen mapping of a skin sample from a newborn because a fresh blister shows the typical cleavage plane at the DEJ. The sample should be obtained from clinically uninvolved skin at a distance of 5–10 mm from a blister. Conventional light microscopy is not indicated because in all subtypes blisters form within a narrow zone at the DEJ. The resolution of the light microscope does not suffice for differentiation between intrabasal cell, intralamina lucida, and sublamina densa blistering. Electron-microscopic studies have substantially aided the diagnosis and classification of EB in the past but have been largely replaced by antigen mapping (Fig. 2). However, electron microscopy may still be useful for the study of structural abnormalities of the anchoring complex.

Differential Diagnosis

Table 3 summarizes conditions that may cause difficulty in the differential diagnosis of hereditary EB in the neonate. Genetic disorders, such as bullous ichthyosiform erythroderma, incontinentia pigmenti, congenital poikiloderma with subepidermal blistering, or congenital aplasia cutis, may present with blisters or erosions at birth. However, all of them exhibit characteristic ultrastructural features that can be recognized by electron-microscopic examination [3]. Congenital herpes simplex, staphylococcal scalded skin syndrome, and neonatal candidiasis and impetigo can be differentiated from EB by microbiological means. Neonatal pemphigoid gestationes, pemphigus vulgaris, and, at a later age, other acquired blistering diseases, such as EB acquisita, bullous pemphigoid, and dermatitis herpetiformis, can be diagnosed by direct immunofluorescence on frozen sections to reveal the characteristic immune deposit patterns in the skin. On

rare occasions, suction blisters on the thumb or the radial aspect of the hand in newborns have been observed. These bullae are presumably the self-inflicted results of sucking *in utero* [155].

Mutation Detection Strategies for Epidermolysis Bullosa

As indicated in Table 1, mutations in ten distinct genes have been identified in different EB subtypes thus far. In most cases, the genes were identified as candidate genes and proteins on the basis of ultrastructural and/or immunohistochemical observations. Initial studies identifying mutations in different forms of EB used RT-PCR and direct sequencing of the cDNAs. It soon became evident, however, that many of the mRNA transcripts were relatively large, and the corresponding gene structures were found to be complex, thus rendering mutation search by direct sequencing of the genes time-consuming and expensive. Therefore, mutation detection strategies based on amplification of the exons directly from genomic DNA have been developed [156].

Heteroduplex Scanning Strategy

Mutation screening strategies developed for the identification of mutations in the genes for collagen VII, collagen XVII, laminin 5, α6 and β4 integrins, and plectin [5,93,110,156] have been adopted by many laboratories. For this purpose, primers placed on flanking intronic sequences are used. These primers reliably amplify all coding sequences from the genes in PCR products varying from about 200 to 600 bp in size. The PCR products are then subjected to heteroduplex scanning by conformation-sensitive gel electrophoresis (CSGE) [157], which, in the case of heterozygous sequence variants, displays heteroduplex bands. This is followed by direct automated sequencing of the PCR products displaying heteroduplexes. If the sequence variants are potentially pathogenic mutations, their inheritance will be examined in the family by restriction enzyme digestion or allele-specific oligonucleotide hybridization. Pulkkinen and Uitto [5] have estimated that this methodology is able to detect approximately 80% of all single base-pair substitutions and small insertions or deletions in the genes. However, the strategy may miss large deletions or major rearrangements in the gene. It should also be noted that in the case of recessively inherited homozygous mutations, a proband's PCR products have to be mixed with control PCR products to detect heteroduplexes by CSGE. Alternatively, DNA from the obligate heterozygote parents can be examined.

Mutation screening of JEB and DEB is facilitated by the occurrence of common mutations in two genes. In *LAMB3*, two hotspot mutations, R42X and R635X, have been shown to account for 50% of all mutations associated with JEB Herlitz [69]. Therefore, these two mutations are tested with priority when JEB is suspected. The test is fast because both mutations can be verified by restriction enzyme digestion of DNA amplified by PCR. Evidence suggests that *COL7A1* mutations may cluster in exon 73 [141]. So far, 17 different mutations in this 200 bp exon have been observed, and in our series of 53 DEB families, 28% of families had a mutation in this exon (Fig. 11). Recurrent mutations causing amino acid substitutions in positions 2008, 2034, and 2043 can be verified by restriction enzyme analysis. Therefore, exon 73 is now being screened with priority in our laboratory before initiating the analysis of the 117 other exons of the *COL7A1* gene.

MANAGEMENT OF EPIDERMOLYSIS BULLOSA

No specific cure exists for EB. Although a number of pharmacological regimens have been reported, none has been uniformly successful. The reason for the variable response is not clear, but it may be due to genetic and molecular heterogeneity within the major clinical categories. At present, the management of EB is mainly supportive, and the therapy is symptomatic. A high standard of personal hygiene, careful nursing and daily skin care, protection from trauma, and avoidance of infection are fundamental for optimal management.

Conventional Therapies

General Care

To avoid friction and heat, soft, well-ventilated clothing and footwear should be chosen. Additional reduction of sweating of the feet by administration of aluminum salts or formaldehyde may be beneficial for some patients. Blisters should be burst with a sterile needle or lancet, and erosive skin areas should be soaked with mild cleansing solutions, disinfected, and treated with soft creams or lotions. The dressing materials should not cause friction, and tape should not be applied directly to the skin. Physical therapy is important to prevent joint contractures after scarring. Nutritional advice concerning sufficient calorie, protein, fiber, vitamin, and mineral intake is essential. Patients with laryngeal or esophageal involvement may have to take liquidized food. Good prophylactic dental care and advice are necessary because gingival blisters and erosions may make normal dental hygiene painful or impossible. Detailed instructions about the nursing and care of EB skin can be found in excellent booklets available from DEBRA (Dystrophic Epidermolysis Bullosa Research Association; addresses at the end of this chapter).

Topical Medication

Simple blistering without secondary traumatization or infection usually heals well with everyday skin care and disinfection. Antibiotics are recommended only for secondary infections. Fucidic acid, tetracycline, erythromycin, and clindamycin ointments have proven to be successful regimens. Creams supporting reepithelialization are also useful.

Systemic Therapy

Several therapeutic modalities have been tested in the past, such as phenytoin, retinoids, and tetracyclines [3,4]. Initially, a favorable response to phenytoin was observed in a number of patients with different DEB or JEB subtypes. However, in a multicenter study, no statistically significant effect of phenytoin could be observed [158]. Positive effects of tetracycline and a negative response to retinoids have been reported in individual patients. Systemic corticosteroids have been applied in very severe cases of JEB Herlitz and EBS herpetiformis. Some suppression of blistering activity and inflammation was achieved, but high dosage was required and the side effects were massive. No large studies document the usefulness of these hormones in EB. Systemic antibiotics are indicated when secondary infections occur. Some of these drugs may exhibit an additional beneficial effect on blistering activity, but they should not, for obvious reasons, be used in the absence of infection. Vitamin E has previously been widely used in the therapy of all EB subtypes. Its antioxidant effect was believed to suppress blistering, but the experience of most investigators with this therapy is not encouraging. Dapsone inhibited blistering in an infant with JEB Herlitz, although in other cases the response was not

remarkable. Because nutritional zinc deficiency may occur in some probands, zinc substitution has been used to support wound healing in EB. Oral contraceptives may benefit female patients suffering from JEB inversa whose condition worsens after the menopause.

Surgical Treatment

Surgical degloving of fused hands and feet of patients with AR-DEB generalisata mutilans is routinely and successfully performed in several centers [159,160]. However, repetition of the procedure, often at frequent intervals, may become necessary. Esophageal dilatation, with either a balloon or an instrument, is often required by patients with DEB generalisata mutilans and DEB inversa to release strictures [3,161]. Skin grafting and cultured epidermal autografts have been partially successful in covering denuded areas in DEB [162]. Healing of both the donor and recipient sites has, perhaps surprisingly, been unproblematic. Reepithelialization of chronically denuded areas has been achieved after repeated grafting; however, the autograft contains the same genetic defect as all cells of the patient and thus remains fragile.

Gastrostomy Feeding

Nutrition is a problem in patients who suffer from subtypes of EB involving the oropharynx and esophagus. The use of feeding tube gastrostomy, mostly with button devices, has proven to be a valuable method to complement the oral intake of foods and enhance nutrition in JEB and DEB. Regular overnight feeding via gastrostomy tube resulted in remarkable growth of affected children and the augmentation of blood cell counts and hemoglobin concentrations [163].

Gene Therapy Approaches

For the future treatment of EB, the development of successful gene therapy approaches is required. This could involve the *ex vivo* manipulation of cultured cells in such a manner that a mutation is corrected, followed by grafting of the cells onto eroded areas of skin. Alternatively, direct application of DNA into skin could be used in an attempt to elicit genetic reversal of the underlying mutation [164,165]. Despite the fact that skin, because of its accessibility, seems an optimal target organ for gene therapy, concerns regarding the efficiency of gene therapy approaches have been raised in relation to methods of delivery, targeting of epidermal stem cells, duration of expression of transgenes, and long-term safety. Although the successful application of gene therapy for the treatment of EB may still be several years away, the rapid development of new technologies, such as the use of ribozymes or the application of chimeric RNA/DNA nucleotides for the correction of a mutation by homologous recombination, hold promise for gene therapy for different EB subtypes.

Several *in vitro* studies have already described the correction of deficient gene expression in EB keratinocytes. In one study, epidermal keratinocytes from a JEB Herlitz patient with a homozygous *LAMB3* mutation were immortalized using SV40 virions [166]. The cells were unable to synthesize laminin 5, to assemble hemidesmosomes, or to adhere. Transduction of the β3-null keratinocytes with a retroviral construct expressing a human β3 cDNA rendered the cells able to synthesize and secrete mature heterotrimeric laminin 5. The gene correction fully restored the keratinocyte adhesion machinery, including the capacity for proper hemidesmosomal assembly [167]. In another investigation, collagen XVII-deficient keratinocytes derived from a patient with generalized atrophic benign EB were immortalized and transfected with cDNAs for wild-type collagen XVII. This resulted in the expression of recombinant collagen XVII protein that was correctly polarized at the basal cell surface together with α6β4 integrin [168]. Seitz et al. [169] used a retroviral expression vector for human BP180/collagen XVII to transfect primary JEB keratinocytes and construct skin grafts on immune-deficient mice and showed that the gene-transduced grafts expressed collagen XVII and deposited it at the DEJ *in vivo*. Because cultured keratinocytes are used routinely to make autologous grafts for patients suffering from large skin or mucosal defects, the full phenotypic reversion of primary human epidermal cells defective for a structural protein opens perspectives in the long-term treatment of genodermatoses.

Genetic Counseling of Epidermolysis Bullosa Families

Genetic counseling is an essential part of the management of EB, and all persons involved should be adequately informed. However, the discovery of extensive variability of mutation constellations has consequences for the counseling of affected families. Compound heterozygosity for mutations in a large number of EB patients, and the fact that several families have combined dominant/recessive mutations, should induce (re)consideration of inheritance patterns and the recognition of rare genetic constellations, which seem to be more common in EB than in other genetic disorders. Therefore, the detection of one or two mutations in the index patient does not always allow unambiguous determination of the inheritance pattern or prognostic predictions. For these reasons, the genetic counseling of EB families should be cautious and performed in specialized centers by persons well-acquainted with the genetic and molecular complexity of EB. It is advisable to perform antigen mapping, determine the candidate genes, and identify the mutations in an EB family well before genetic counseling and prenatal diagnosis may be required. Mutation screening of several large candidate genes under time pressure, possibly during a pregnancy at risk for recurrence, is stressful and less likely to succeed.

Prenatal Diagnosis

The identification of specific gene mutations in EB has allowed the development of DNA-based prenatal testing in families at risk of recurrence for severe forms of this disease. Such testing can be performed on chorionic villus samples as early as the tenth week of gestation or on amniocentesis samples at the twelfth week. In fact, prenatal testing has already been applied to families at risk for severe recessive DEB, JEB Herlitz, and JEB with pyloric atresia [5,170–172]. Figure 14 shows verification of the DNA-based prenatal diagnosis of JEB Herlitz using antigen mapping of skin biopsies of the index patient and the aborted affected fetus.

An extension of prenatal testing is the development of preimplantation genetic diagnosis (PGD), a technique that has been successfully applied to a variety of other genetic diseases [173]. PGD is performed in conjunction with *in vitro* fertilization, fertilized embryos being allowed to grow to the eight-cell stage, at which time one cell is removed for mutation analysis. Embryos lacking tested mutation(s) can then be implanted into the uterus to establish pregnancy, which is performed as part of the *in vitro* fertilization procedure. It should be noted that PGD is not legal in all countries at the present time.

When a mutation is not known, prenatal diagnosis of EB using electron-microscopic examination of a fetal

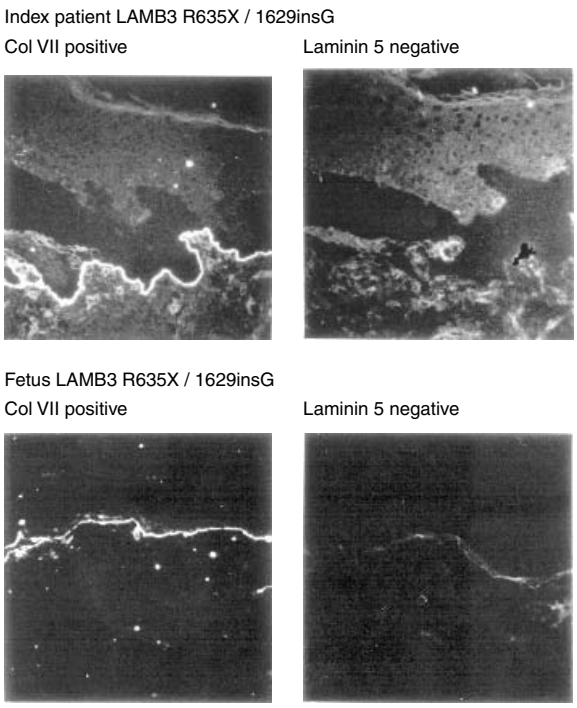

Figure 14. Prenatal diagnosis of JEB Herlitz. The index patient, who died at the age of 7 months, was compound heterozygous for *LAMB3* mutations R635X and 1629insG. Antigen mapping of the skin of this child showed junctional blistering with collagen VII in the blister base (**upper left panel**) and a complete lack of laminin 5 protein (**upper right panel**). Prenatal diagnosis using a chorionic villus sample obtained at the 11th week of the next pregnancy showed that the fetus carried both mutations. After termination of the pregnancy, the diagnosis was verified by antigen mapping of the fetal skin. This showed normal staining with collagen VII antibodies (**lower left panel**) but a negative reaction with antibodies to laminin 5 (**lower right panel**). The faint line visible in the lower right panel represents nonspecific staining of the horny layer.

skin biopsy serves to determine the presence of dermal-epidermal separation and to recognize specific ultrastructural defects. Prenatal diagnosis performed on a skin biopsy obtained by fetoscopy is not a screening method, and certain prerequisites for the tedious and not completely unrisky procedure are necessary [174,175]. The underlying defect must be morphologically demonstrable to allow unequivocal diagnosis, and the fetal skin must be sufficiently developed to allow morphological evaluation of the affected structures. For the DEJ this is the case between the sixteenth and twentieth weeks of pregnancy [176]. Prenatal evaluation is based on recognition of the characteristic ultrastructural abnormalities in fetal skin. Most experience has been obtained with the generalized recessive forms of JEB and DEB because these subtypes are severe enough to warrant the possible termination of pregnancy. Briefly, JEB exhibits detachment of the epidermis through the lamina lucida and defective hemidesmosomes. DEB shows blistering in the uppermost papillary dermis and an absence of anchoring fibrils. Clumping of tonofilaments in EBS herpetiformis and a paucity of anchoring fibrils in dominant DEB makes prenatal diagnosis of these subtypes conceivable as well. Expertise in taking the biopsy, preserving and processing the material, and establishing cell cultures, and great experience in evaluating normal and defective fetal skin, are imperative.

ANIMAL MODELS

Naturally Occurring Defects

Many rare heritable connective tissue disorders occur in domestic or laboratory animals. Such disorders can be used to provide a model system for studies of both normal and abnormal tissues. Although the eponyms of human diseases are not strictly applicable to the analogous diseases in animals, the causes and effects appear to be directly comparable. Affected animals offer opportunities for experimental analysis that are not possible in humans, such as experimental mating for genetic analysis or the provision of large amounts of tissue for biochemical investigations or for organ and cell cultures.

Clinical reports describe hereditary blistering disorders in dogs, bulls, foals, calves, and sheep (Table 4) [177,178], but not all of these have been characterized by electron microscopy or with molecular probes. An autosomal dominant EBS with basal cell cytolysis was found in Simmental bulls, a severe JEB with lamina lucida blistering in a toy poodle, and DEB with sub-basement membrane blistering in New Zealand sheep and Brangus calves. The latter animals presented with oral blistering and sloughing

TABLE 4. Animal Models of Heritable Blistering Disorders of the Skin

Species	Targeted Protein	Gene	Phenotype	Human Disease	Ref.
Dog	Laminin 5	*LAMA3* *LAMB3* *LAMC2*	Skin blistering	JEB Herlitz, JEB localisata, generalized atrophic benign EB	177
Sheep	Collagen VII	*COL7A1*	Severe blistering, exungulation	DEB generalisata mutilans	178
Mouse	Collagen VII	*COL7A1*	Severe blistering	DEB generalisata mutilans	184
Mouse	Keratin 14	*KRT14*	Severe blistering, tonofilament clumping	EBS generalisata	81
Mouse	BP230	*BPAG1*	Skin blistering, neural abnormalities	?	98
Mouse	Plectin	*PLEC1*	Skin blistering, muscular abnormalities	EBS with muscular dystrophy	179
Mouse	Laminin 5	*LAMB3*	Severe blistering, perinatally lethal	JEB Herlitz	180
Mouse	α6 integrin	*ITGA6*	Severe blistering, perinatally lethal	JEB with pyloric atresia	181
Mouse	β4 integrin	*ITGB4*	Severe blistering, perinatally lethal	JEB with pyloric atresia	182
Mouse	α3 integrin	*ITGA3*	Mild skin blistering	?	183

off of the hooves postnatally. Inbred Swiss white alpine sheep carried a severe form of this disorder [178] and developed blisters in the mouth, oral mucosa, tongue, esophagus, and skin areas with sparse hair within two days of birth. Exungulation occurred early, and oral erosions led to difficulty in feeding. Electron-microscopical examination revealed sublamina densa splitting and no identifiable anchoring fibrils. Antigen mapping demonstrated a complete absence of collagen VII in clinically uninvolved tissues of the DEB sheep, whereas in normal sheep skin a bright linear fluorescence at the DEJ was seen. Immunoblotting of dermal and epidermal extracts of EB sheep showed a lack of collagen VII, a phenotype similar to the DEB generalisata mutilans in humans [178].

Transgenic and Knockout Mice

More recently, gene ablation or manipulation in mice has delivered additional information about some DEJ proteins. The functional significance of a molecule can be assessed by elimination of the protein or by the introduction of mutations that cause dominant negative interference in genetically manipulated mice. In addition, in contrast to human mutations, animal models allow investigation of the consequences of gene mutations during embryonic development and assessment of the early consequences of lethal mutations. To date, several such knockout or transgenic mice exist for DEJ components and their cellular receptors, including keratin 14, plectin, BP230, α3, α6, and β4 integrins, the β3 chain of laminin 5, and collagen VII (Table 4).

The first indication of the involvement of keratins in the etiopathogenesis of EBS was derived from transgenic mice. An EBS-like disease was induced when a truncated keratin 14 gene was introduced into the germ line of the animals. Intraepidermal blistering and tonofilament clumping were the key features of the phenotype [81]. Thus, it was shown for the first time that keratin filaments form an essential supportive network in keratinocytes and that abnormalities of basal cell keratins can lead to EBS.

Ablation of the plectin gene in mice resulted in skin blistering due to degeneration of keratinocytes and death 2–3 days after birth [179]. Hemidesmosomes were significantly reduced in number, and their mechanical stability was altered. The skin phenotype of these mice was similar to that of patients with EBS with muscular dystrophy [89–94]. In addition, plectin (−/−) mice revealed abnormalities reminiscent of minicore myopathies in skeletal muscle and disintegration of intercalated disks in heart, suggesting a general role of plectin in the reinforcement of mechanically stressed cells.

BP230, or bullous pemphigoid antigen-1, is located in the inner plaque of the hemidesmosome and hence is likely to bind intermediate filaments. This was confirmed by generating mice with ablation of the *BPAG1* gene encoding BP230. Null mice exhibited a phenotype with a lack of the hemidesmosomal inner plaque, lack of intermediate filament binding, and cytolysis of basal cells. Surprisingly, the phenotype included neuromuscular abnormalities [98]. Molecular analysis of the mice disclosed two isoforms of BP230, an epidermis-specific isoform in the inner plaque of the hemidesmosome, which associates with the keratin intermediate filaments and a neuron-specific isoform, dystonin, that binds actin [99].

Similarly to human probands with JEB Herlitz and JEB with pyloric atresia, knockout mice for the β3 chain of laminin [180] and the α6 and β4 integrins exhibited severe blistering of the skin and other epithelia and postnatal demise [181,182]. In the integrin knockout mice, hemidesmosomes were absent from mutant tissue, but the basement membrane appeared normal. This suggests that these integrins are important for the assembly of hemidesmosomes, but not of the basement membrane proper. These mice provide valuable models for the molecular analysis of these disorders and are useful for developing novel therapeutic strategies.

In contrast, integrin α3-deficient mice revealed regions of disorganized basement membrane in the skin [183]. In neonatal skin, matrix disorganization was frequently accompanied by blistering at the DEJ. Laminin 5 and other matrix proteins remained associated with both the dermal and epidermal sides of blisters, suggesting rupture of the basement membrane itself rather than detachment of the epidermis from the basement membrane. The findings support a role for α3β1 integrin in maintenance of the integrity of the DEJ and establish the gene for α3 integrin as a novel candidate gene for EB.

A collagen VII deficient mouse has also been reported. Similarly to patients with DEB generalisata mutilans and to sheep with severe recessive DEB, the mice exhibited extensive sublamina densa blistering and an absence of anchoring fibrils. The mucocutaneous lesions led to the postnatal demise of the mice [184].

CONCLUDING REMARKS

The surprising heterogeneity of EB mutation constellations and their biological consequences has complicated the unambiguous diagnosis, classification, and prognostic predictions of the disease. Even in situations assumed to be unproblematic, variations have been found, for example, in pedigrees with combined recessive and dominant mutations. Analysis of known genetic aberrations shows that homozygosity is relatively rare and that most patients with recessive EB are compound heterozygotes for recessive, or recessive and dominant, gene defects. For genetic counseling, these findings have a major impact. The identification of one mutation does not suffice for diagnosis and genetic counseling; rather, it is necessary to know whether a second mutation exists and whether it causes a phenotype or acts as a modulator.

Novel genes causing additional EB subtypes are likely to be identified in the future, thereby extending the genotypic and phenotypic spectrum of the disease. A number of candidates have already been identified, such as BP230, α3 integrin, and some of the enzymes involved in the post-translational processing of the macromolecules of the DEJ.

Careful biochemical assessment of as many involved molecules as possible and their mutated counterparts will shed additional light on the molecular consequences of the mutations and help design novel gene therapy approaches for the treatment of EB. The EB subtypes caused by null alleles seem to be optimal diseases to be treated with such therapies, because no interference from endogenous mutant molecules need be expected. The skin is easily accessible for morphologic and biochemical control studies, and keratinocyte culture and transplantation techniques have been well-developed for the treatment of burns. Gene transfer into human keratinocytes *in vitro* has been successfully performed in many laboratories, and procedures for the enrichment of epidermal stem cell populations, stable transfection of the cells, and expression of correctly folded proteins are rapidly advancing. The future development of

successful therapies will also depend on progress in our understanding of suprastructure formation by structural DEJ macromolecules. This not only concerns the mechanism of aggregate formation but also the structural characteristics unique to each molecule. Further, functional redundancies of molecular components within supramolecular aggregates will have to be defined in greater detail than presently possible. This endeavor will not only be assisted by the elucidation of further genetic defects and their consequences in animal or human diseases, as well as the generation of transgenic animals as models for human diseases, but also by the analysis of aggregate formation by isolated matrix macromolecules or their mixtures *in vitro*. This combined information will not only help to understand and treat heritable skin diseases but also many common acquired disorders.

RECENT DEVELOPMENTS

Revised Classification of Epidermolysis Bullosa

At the second international consensus meeting on diagnosis and classification of epidermolysis bullosa, collective clinical, epidemiologic and laboratory data relating to inherited EB were reviewed and a revised classification suggested, better to reflect current knowledge [185]. Future clarification of the molecular abnormalities underlying EB could eventually lead to a completely different classification, but it is presently premature to base any system solely on molecular data.

In generating the new classification system, every attempt was made to simplify and clarify the group of disorders defined as EB, special attention being paid to the creation of a classification that could readily be used by practicing physicians, medical geneticists, and researchers. Several reported EB subtypes were eliminated because they were not considered to represent distinct entities following critical review of current molecular and clinical data, and some subtype names were simplified or renamed to increase consistency across the three major categories. Despite attempts to include the molecular basis of EB subtypes in the classification, a number of eponyms were retained for two particular reasons. First, some eponyms, such as Weber-Cockayne or Hallopeau-Siemens, evoke immediate visual images of highly specific clinical phenotypes, suggesting their continued utility in effective communication between clinicians and scientists all over the world. Second, the precipitous elimination of all eponyms would be counterproductive at this time, because it would impair any linkage with the existing medical literature on EB and result in confusion and, possibly, the generation of a series of alternative classification systems.

The new classification retains the three major EB categories, EBS, JEB and DEB (Table 5). The EBS group comprises EBS Weber-Cockayne (in this chapter, EBS localisata), EBS Koebner (EBS generalisata), EBS Dowling-Meara (EBS herpetiformis) and EBS with muscular dystrophy. The first three subtypes represent allelic variants of keratin 5 and keratin 14 gene mutations, the fourth is caused by mutations in the plectin gene. The new JEB category comprises only three subtypes, namely JEB Herlitz, caused by laminin 5 null mutations, JEB non-Herlitz (which includes JEB localisata and GABEB), caused by missense mutations in the genes for laminin 5 or by nonsense or missense mutations in the gene for type XVII collagen, and JEB with pyloric atresia, caused by mutations in the genes for α6β4 integrin. The new DEB group comprises three subtypes, dominant DEB (in this chapter, autosomal dominant DEB localisata and generalisata), recessive DEB Hallopeau-Siemens (DEB generalisata mutilans) and recessive DEB non-Hallopeau-Siemens (which includes autosomal recessive DEB localisata, autosomal recessive DEB inversa, and DEB generalisata non-mutilans, as described in this chapter). Each of these latter result from defects in the collagen VII gene.

Based on available molecular data relating to the gene defects underlying EB and on epidemiological studies [4], Pfendner et al. [186] have calculated the carrier frequency of EB in the US population as, for all JEB forms, 1/333 (expressed as a fraction); for JEB-Herlitz, 1/781; and for recessive DEB, 1/345. The estimates for dominant EBS and DEB were very low.

Unexpected and Minimal Epidermolysis Bullosa Phenotypes

Clarification of the genetic basis of EB in many more families has shown that minimal phenotypes and unusual symptom combinations may be more common than previously anticipated. It seems that the multitude of genetic and biological constellations in EB provide for a very broad spectrum of clinical manifestations, and that physicians and scientists dealing with EB need to pay particular attention to unexpected symptoms and their combinations in order not to overlook important indices. For example, a *COL17A1* mutation was found in a young child presenting with an EBS-like clinical picture and intraepidermal tissue separation [187]. *COL17A1* gene mutations are known to

TABLE 5. Revised Classification of Epidermolysis Bullosa*

Major EB type	Major EB Subtype	Abbreviation	Protein Involved
EB Simplex (EBS)	EBS Weber Cockayne	EBS-WC	Keratin 5, 14
	EBS Koebner	EBS-K	Keratin 5, 14
	EBS Dowling-Meara	EBS-DM	Keratin 5, 14
	EBS with muscular dystrophy	EBS-MD	Plectin
Junctional EB (JEB)	JEB Herlitz	JEB-H	Laminin 5
	JEB non-Herlitz	JEB-nH	Laminin 5; type XVII collagen
	JEB with pyloric atresia	JEB-PA	Integrin α6β 4
Dystrophic EB (DEB)	Dominant DEB	DDEB	Type VII collagen
	Recessive DEB Hallopeau-Siemens	RDEB-HS	Type VII collagen
	Recessive DEB non-Hallopeau-Siemens	RDEB-nHS	Type VII collagen

*Adapted from [185]

cause JEB, but in this case a large genomic deletion had led to extensive truncation of the intracellular domain of collagen XVII and impaired its interactions with other hemidesmosomal proteins and keratin filaments, leading to an EBS-like presentation. In another interesting case, pyloric atresia in a newborn with skin blistering was associated with dystrophic EB, instead of JEB-PA [188]. Yet another patient with severe JEB-PA experienced spontaneous, remarkable amelioration of skin blistering and subsequently had only very mild symptoms. The "transient severity" was shown to result from the modulation of abnormal splicing of integrin β4 pre-mRNA carrying a branch point mutation [189]. As regards DEB, several cases of *COL7A1* mutations leading to nail dystrophy, but not to skin blistering, have now been published [66,67, 190]. Dysphagia and esophageal stenosis without skin blistering have been shown to represent an extracutaneous form of DEB in a patient with mutations in the collagen VII gene (P. Zimmer, H. Schumann, S. Mecklenbeck, L. Bruckner-Tuderman, unpublished results). These observations extend the phenotypic spectrum of mutations in the genes for DEJ proteins and demonstrate that the clinical consequences of a given mutation depend on its biological effects at the molecular level.

Animal Models and New Candidate Genes

The generation of transgenic mice with ablation of genes encoding proteins of the DEJ has further expanded our knowledge of the molecular mechanisms of skin blistering. Targeted disruption of the *LAMA3* gene prevented the synthesis of both laminin 5 and laminin 6 molecules (both of which contain the laminin α3 chain), resulting in abnormal hemidesmosomes, lack of survival of mutant epithelial cells, severe junctional blistering, and perinathal lethality of the animals [191]. This mouse model also demonstrated that defects in the epithelial basement membrane caused abnormalities of ameloblast differentiation in developing teeth, thus laying a biological basis for understanding the enamel defects observed in JEB patients.

Knockout mice lacking perlecan, a major basement membrane proteoglycan, exhibited abnormalities in many tissues, including basement membranes [192]. Interestingly, the formation of basement membranes was not altered, but they deteriorated in regions under increased mechanical stress, such as myocardium or the skin, resulting in lethal cardiac abnormalities and skin blistering. Based on the severe phenotype in the mouse, perlecan null mutations cannot be expected in EB. Rather, it seems feasible that missense mutations in the perlecan gene may underlie some JEB or DEB subtypes.

Conditional ablation of β1 integrin in mouse skin resulted in severe defects in epidermal proliferation, hemidesmosome structure, basement membrane formation, and skin blistering [193,194]. Perhaps unexpectedly, the phenotype included massive dermal fibrosis and abnormal hair follicle invagination. Cell biological and biochemical analyses indicated that β1 integrin is important not only for hemidesmosome stability, epithelial cell proliferation and hair follicle morphogenesis, but also for the normal processing of basement membrane molecules and the maintenance of epithelial basement membranes [193]. The β1 integrin gene is therefore also a candidate gene for JEB.

In contrast to the above abnormalities, no pathologic phenotype was observed in mice with targeted ablation of the nidogen 1 gene [195]. This unexpected finding led to the assumption that nidogen 2 compensates functionally for the lack of nidogen 1 in the tissues and, therefore, more information on the functions of these ubiquitous basement membrane components can be expected from future double knockout mice lacking both nidogens 1 and 2.

A recent description of inherited DEB in inbred dogs may provide a naturally occurring animal model for somatic gene therapy [196]. The dogs exhibit relatively mild trauma-induced blistering in skin areas with sparse hair, such as the snout, the ears and mucous membranes, and can therefore survive with the disease. The genetic basis of the condition is a homozygous glycine substitution in the *COL7A1* gene [197]. The mild clinical symptoms of these dogs make them a suitable target for somatic gene therapy trials of the transplantation of genetically corrected keratinocyte sheets.

Advances in the Development of Gene Therapy for Epidermolysis Bullosa

Promising gene therapy approaches for EB are now being reported. The current strategy for gene therapy for severe recessive JEB and DEB is gene augmentation via an *ex vivo* approach [198–200]. This is based on the genetic modification of EB keratinocytes *in vitro*, culture of the cells into keratinocyte sheets, and subsequent transplantation of the keratinocyte sheets onto a patient's skin. The well developed techniques of keratinocyte transplantation for burns treatment and the easy access to the transplant offer valuable advantages. Efficient restoration of expression of the laminin 5 β3 chain in keratinocytes derived from several JEB patients was achieved using cDNA in a retroviral vector [201]. Importantly, the genetically corrected cells were fully functional in a skin transplant model in immune deficient mice; no blistering in the transplants was observed. Similarly, successful gene correction of *ITGB4* in keratinocytes from a patient with lethal JEB-PA showed that the corrected keratinocytes were indistinguishable from normal cells in terms of integrin α6β4 expression, the localization of hemidesmosomal components, and hemidesmosome structure and density, suggesting full genetic and functional correction of β4-null keratinocytes *in vitro* [202].

Successful gene therapy for DEB will depend on the restoration of collagen VII synthesis in DEB-Hallopeau-Siemens keratinocytes. Since collagen VII cDNA has a size of about 9.2 kb, it has been considered too large to fit into retroviral vectors. Therefore, a PAC (P1-artificial chromosome) vector containing the entire human *COL7A1* gene was tested [203]. The advantage of gene vectors is that, in addition to a gene, they accommodate the natural promoter and the necessary regulatory elements within the introns, thereby contributing to sustained expression of the transgene. Transfer of the *COL7A1*-PAC vector into an epidermal cell line, using a receptor-mediated, integrin-targeting, liposome-enhanced transfection system, increased collagen VII expression in the cells despite low transfection efficiency [203]. When the same vector was microinjected into immortalized collagen VII-deficient DEB keratinocytes, active synthesis of normal collagen VII was restored. Significantly, the collagen was fully triple helical and efficiently secreted from the cells, suggesting that it was functional (S. Mecklenbeck, S. Compton, R. Cervini, J. Meija, A. Hovnanian, L. Bruckner-Tuderman, Y. Barandon, unpublished results). In another approach, a cosmid clone containing the entire human *COL7A1* gene was used to generate transgenic mice [204]. The cosmid was capable of directing sustained and tissue-specific expression of human

collagen VII in the skin of fetal and adult transgenic mice, and human collagen VII was synthesized by cell cultures derived from the skin of 19-month-old transgenic mice [204], suggesting that the transgene expression was permanent.

Attempts to correct the DEB phenotype of keratinocytes using collagen VII cDNA have now been reported. Chen et al. delivered a truncated collagen VII cDNA into DEB keratinocytes and achieved synthesis of a minicollagen VII *in vitro* [205]. In comparison with parent DEB keratinocytes, the transfected DEB keratinocytes demonstrated enhanced cell-substratum adhesion, increased proliferative potential, and reduced cell motility, features that reversed the DEB phenotype toward normal. Whether the use of the minicollagen VII cDNA will prove a realistic strategy to correct the cellular manifestations of gene defects in DEB remains unclear, since many *COL7A1* deletions have been shown to be associated with pathologic DEB phenotypes. In spite of the large size of the collagen VII cDNA, Meneguzzi and coworkers have succeeded in inserting full-length canine collagen VII cDNA into a retroviral vector. Transduction with the vector induced collagen VII synthesis and secretion in DEB keratinocytes [197]. The advantages of retroviral vectors are high transfection efficiency and stable transgene expression after insertion of the retroviral vector into the genome. The above developments hold promise for the first gene therapy trials for JEB and DEB. At least in the cases of laminin 5 and collagen VII, the transgene products seem to be normal in terms of structure and folding, and can therefore be expected to be functional. After the above gene therapy approaches have been successfully tested in animal models, human treatment regimens using small keratinocyte transplants can be designed. These require careful long-term planning, since, in addition to the generation of genetically corrected skin transplants, extensive governmental approval procedures, the education of highly specialized medical personnel, and acceptance by EB patients will be necessary.

PATIENT SUPPORT GROUPS WORLDWIDE

The Dystrophic Epidermolysis Bullosa Research Associations of Europe and America have informative Web sites: http://www.debra.org.uk/ (DEBRA Europe) and http://www.debra.org/ (DebRA of America).

ACKNOWLEDGMENTS

The author's work was supported by grants Br 1475/1-2, Br 1475/2-3, Br 1475/3-2, and SFB 293/B3 and SFB492/A3 from the Deutsche Forschungsgemeinschaft (DFG), by the University of Münster IZKF 3/D17 grant from the Ministry for Education and Research, and by a grant from DEBRA Europe. The expert help of Sabine Mecklenbeck, Hauke Schumann, and Nadja Hammami-Hauasli with the illustrations is gratefully acknowledged.

Chapter 16

Prolidase Deficiency

Peter M. Royce and Beat Steinmann

Division of Metabolism and Molecular Pediatrics, Department of Pediatrics, University of Zurich, Switzerland

SUMMARY

- **Prolidase deficiency is a rare, autosomal recessively inherited disorder in which deficient activity of prolidase, which normally cleaves imidodipeptides containing a C-terminal prolyl or hydroxyprolyl residue, results in a massive urinary excretion of X–Pro and X–Hyp dipeptides derived from generalized protein breakdown, hyperimidodipeptiduria.**
- **The principal clinical feature of the disorder is chronic intractable ulceration of the skin, particularly that of the lower limbs. The phenotype is nevertheless somewhat variable and typically includes a degree of mental retardation and a susceptibility to recurrent respiratory infections.**

- **The prolidase gene, *PEPD*, is located on chromosome 19 at 19q12-q13.2, and several different mutations have been identified at this site in different prolidase-deficient individuals.**
- **An angiopathic pathogenesis has been suggested for the disorder, small vessels of the dermis frequently showing thickened walls surrounded by multiple basal laminae, and multiple microthromboses in bilateral cerebral white matter suggesting an abnormality of the cerebral vessels. One cause of the vascular anomalies might be superoxide production by neutrophils under the influence of X–Pro imidodipeptides.**
- **Prolidase deficiency may be suspected with a high degree of probability on the basis of hyperimidodipeptiduria and confirmed by measurement of prolidase activity in erythrocytes or leukocytes. Rapid urinary screening may be performed using paper or thin-layer chromatography or by high-voltage electrophoresis. The chromatography of untreated urine in an amino acid analyzer reveals the presence of several abnormal ninhydrin-positive peaks, and quantitative analysis after hydrolysis reveals a striking increase of Pro, Hyp, and Gly.**
- **Various therapeutic measures involving the topical application of glycine and proline, or the systemic or oral administration of various combinations of manganese and factors either stimulating collagen biosynthesis or inhibiting collagenase activity, have provided only occasional and transient relief. Similarly, repeated erythrocyte transfusions, either alone or in combination with $MnSO_4$ and ascorbic acid, have generally been found ineffective in the long term. There is thus little available other than the conservative management of ulcers that can be offered to patients at the present time.**

INTRODUCTION

Prolidase deficiency is a rare, autosomal recessively inherited disorder in which deficient activity of prolidase, which normally cleaves imidodipeptides containing a C-terminal prolyl or hydroxyprolyl residue, results in a massive urinary excretion of X–Pro and X–Hyp dipeptides, hyperimidodipeptiduria. The nature of the imidodipeptides excreted has led on occasion to the disorder erroneously being described as representing a specific defect in collagen metabolism; however, protein degradation in general is affected. The condition is associated with a somewhat variable clinical phenotype, which typically includes a degree of mental retardation and recurrent respiratory infections but of which the main feature is chronic, intractable ulceration of the skin, particularly that of the lower limbs. The pathogenetic mechanisms leading to the skin changes are poorly understood, and even less so are those resulting in mental retardation. To date, attempted therapy has met with little other than transient success.

CLINICAL FEATURES

Since the appearance of this chapter in the first edition of this volume [1], relatively few additional cases have been reported, and still only around just under 60 cases of confirmed prolidase deficiency have been described in the literature [2–4; 5–7; 8; 9–12; 13,14; 15–18; 19; 20,21; 22,23; 24–26; 27; 28; 29; 30,31; 32; 33; 34; 35; 36,37; 38; 39; 40; 41; 42; 43; 44–46; 47; 48; 49,50; 51; 52; 53; 54] (references relating to particular patients have been grouped

Connective Tissue and Its Heritable Disorders, pages 727–743

where appropriate, and as far as identities of patients in different publications have been possible to ascertain, and each is either a first report of a particular patient or carries a description of the patient's phenotype).

The clinical features of the disorder show some degree of variability, but certain features do appear to be fairly characteristic. Particular among these are chronic dermatitis with recurrent leg ulceration, a susceptibility to repeated upper respiratory tract infections, a somewhat characteristic facies, a mild to moderate degree of mental retardation, and hepatosplenomegaly.

Dermatological Manifestations

The dominant clinical problem associated with the disorder relates to its dermatological manifestations, and in the majority of cases chronic, repeated slow-healing ulcerations, mainly of the legs and feet (Fig. 1), are a feature. Ulceration of the upper limbs [14] and face [55] has also been reported, and in one case, that of a 17-year-old girl, although active ulcers were confined mainly to the legs, there was scarring from healed ulcers over most of her body [34]. The development of ulcers is often preceded by dermatological manifestations that may occur over the whole body and have been described variously as erythematous papular eruptions [11,40], telangiectasia with pruritus and photosensitivity [14], impetigo-like eruptions [18], pruritic eczematous lesions [19], and necrotic papules [21,35,41,42].

In the three cases reported by Ogata et al. [19], scar contractures had caused talipes equinus, also observed in one of the sisters described by Voigtländer et al. [35], and in one of the patients of Leoni et al. [33], the same condition was caused by a shortened Achilles tendon. In one case, a lesion on the right foot was so deep that the tendon was exposed and broken by the patient; after healing with scar formation, the foot was grossly deformed [11]. In a further case, the extent of ulceration was so severe that the amputation of both legs below the knee was required, but the patient still suffered from ulceration of the thighs and developed secondary infections of the stumps [36,37,56]. The risk of developing squamous cell carcinoma has been reported to be higher at the sites of venous leg ulcers [57], and one middle-aged prolidase-deficient patient with long-standing ulceration of the lower limbs developed a large, vegetating tumor on the anterior side of the lower right leg that required amputation of the leg above the knee [51].

In many cases, dermatological manifestations are restricted to the lower limbs, but telangiectasia has been reported in other areas including the face in some cases [11,18,19,22,23,35,39,41,43,44], and atrophic scar-like lesions on the face have been noted [11,19,21]. Hyperkeratosis over the elbows and knees has been mentioned in two cases [19,41], and ichthyosis was noted in one [38]. In contrast, several reports mention the thinness of the skin, particularly over the abdomen, with readily visible veins [11,18,19,40,51]. One patient was described as having a "curiously lax" skin with a spongy texture [24,26].

In a small number of patients not presenting with ulcers, perhaps because the clinical course of the disorder had not yet reached that stage, a chronic dermatitis was apparent, predominantly affecting the gluteal areas but also involving the arms, legs, and back and the soles of the feet and the palms of the hands [5,7,8,32].

Facial Features

Although one patient was specifically reported as having no unusual facial features [7], it does seem that most patients present with an "unusual," "peculiar," "characteristic," or "dysmorphic" facies [5,8,11,14,15,18–23,27,33,34,39,40,42–44,47]. Although not common to all patients, features described have included a low hairline and facial hirsutism, a saddle nose, ocular hypertelorism, ptosis, micrognathia, a high-arched palate, mandibular protrusion, and exophthalmos. Three patients have been described as having a "bird-like" facial appearance [24–26,44,46].

Mental Retardation

In several cases, moderate to severe mental retardation has been reported [5,7,11,14,15,19,23,27,31,34,40,42,44,46,49,52], while in another, intelligence was reported to be borderline [20,21]. In other cases, intelligence may be normal [25,44,46]. Epileptic seizures had been recorded in the history of one patient [42].

Other Features

Splenomegaly or hepatosplenomegaly is regularly described [5,7,8,14,18,27,31,33,34,40–42,47,49,50,52], and a tendency toward recurrent otitis media, sinusitis, pneumonia, and gastroenteritis and diarrhea is a frequent feature of the condition [5–8,14,19,27,32,35,42,45–47,49,50,52], although in several instances it has specifically been mentioned that there seemed to be no tendency toward recurrent infection [11,23,25]. On the basis of findings in one patient who suffered from recurrent erosive cystitis apparently unconnected with infection, it has been

suggested that urinary tract inflammation also be considered a consequence of the disease [26]. A degree of obesity has been noted in several patients [5,22,24,40,42]. Blood chemistry appears generally to be unremarkable except for an elevated γ-globulinemia in some cases [5,8,11,14,19,23,24,31,33,42,47,49,50] and occasional anemia [5,7,14,19,22,27,33,37,38,40–43,50]. One patient suffered greatly from lymphedema, which was suggested to have resulted from progressive damage to the lymphatic vessels [14]. In two cases, an association with systemic lupus erythematosus was noted, although it is not clear whether the association was fortuitous or direct [47,50]. Immune function was investigated in detail in one of these latter patients [49] who, in addition to hyper-γ-globulinemia, displayed low levels of complement C3 and C4 and a reduced CH50. In addition, neutrophil chemotaxis was abnormal.

Hypotonia [8,32,52] or muscular incoordination [5,27] has occurred in several patients, and there may also be signs of a generalized disturbance in connective tissue. Several cases of joint hyperextensibility have been reported [7,8,24,32,41], and one patient, displaying pronounced ligamentous laxity in the knees, was described as having a waddling gait, with external rotation of the femora [8]. Congenital dislocation of the hip was noted in the first year of life in two patients [11,43], and hip dislocation has been observed in two adult patients [19]. In one case, a hip dysplasia was operated on at 17 years of age [31].

Skeletal anomalies, which include a mild, diffuse demineralization of the long bones [5,40,41], scoliosis [33], and a retarded bone age [27], have been described. One patient is reported as having suffered frequent fractures of the forearm following only modest trauma from an early age [40]. However, in another case, bones appeared normal on x-ray examination [11], and a further patient was described as having no skeletal abnormalities [25]. Dental dysplasia and dysplasia of the dental enamel have also been described [41,42]. Trichiasis and associated corneal lesions were mentioned in the case of one patient [31].

Clinical Onset

The onset of clinical symptoms, which may not initially be dermatological, has been reported as occurring as early as shortly after birth or as late as 22 years of age; this may represent a genuine heterogeneity of the disorder or failure to recognize it, or it may simply be an artifact of reporting. Four prolidase-deficient individuals, the siblings of patients showing the full range of clinical manifestations, have been asymptomatic at the time of reporting. The first, a six-year-old girl [10], by the age of 15–18 years did go on to develop skin lesions [58–60]. The second, the 26-year-old brother of a severely affected female, was entirely asymptomatic [15], but his present condition and whereabouts are unknown (Dr. F. Gejyo, personal communication, 10 June 1991). The third such patient, asymptomatic at the time of study, was an eight-year-old boy [44], who did shortly after go on to develop small lesions on the feet (Dr. G. Cetta, personal communication, 11 June 1991, and [46]), while the fourth, the sibling of a severely affected child who died at an early age, was only four months old at the time of reporting, and it is not possible to predict the future clinical course [52]. Nevertheless, it does seem that, given time, the great majority of prolidase-deficient individuals do go on to develop symptoms of greater or lesser severity. One man, the brother of a female with confirmed prolidase deficiency, was found to be prolidase-deficient himself when he developed leg ulcerations for one month following a leg injury [25]. Trauma incurred in a road accident also seemed to be the stimulus for the appearance of ulcers on the ankles of a young female patient (Dr. G. Cetta, personal communication, 11 June 1991, and [46]).

Five cases of prolidase deficiency have been detected either directly or secondarily through the demonstration of glycylprolinuria in neonatal screening programs, and prolidase deficiency has been confirmed in four of them [28,29]. At the time of reporting of the three siblings described by Naughten et al. [28], the 19-month-old proband had mild hypotonia, and the two brothers, aged three and four years, had mild developmental delay but were otherwise asymptomatic. Until the age of seven years, the proband suffered chronic respiratory infections with severe neutropenia, which later resolved. At the ages of 13 and 14 years, the two brothers showed mild muscular hypotonia, and both had been hyperactive, with poor concentration and short attention spans, although the proband herself was not thus afflicted. All three sibs had a reduced IQ, to which language difficulties may have contributed, but none of the three had, at that time, gone on to develop the typical dermatological manifestations of the disorder (Dr. M. G. Ampola, personal communication, 13 June 1991; a more recent attempt to follow up the status of the three patients has been unsuccessful). The confirmed prolidase-deficient patient reported by Lemieux et al. [29] had no skin lesions at the age of nine years but did show a degree of impaired development, which may, however, have been secondary to a disturbed family life (Dr. C. R. Scriver, personal communication, 22 February 1991).

Three other patients apparently suffering from prolidase deficiency as determined by the urinary excretion of C-terminal proline-containing dipeptides, but in whom direct confirmation by enzyme assay is lacking, have also been reported. One of these, a five-year-old girl, the first cousin of a severely affected patient who died at eight years of age of septicemia, shortly after her first birthday developed clinical symptoms, including recurrent otitis media, chronic diarrhea, repeated respiratory infections, and abscesses of her face and neck, and later showed a facial rash with a butterfly distribution. She also was diagnosed with systemic lupus erythematosus on the basis of the results of immunological investigations [49,50]. Clinical details of a further such patient, a 22-year-old male, appear to be restricted to the information that he exhibited dermatological purpura [61], but the third patient [62,63], a mildly retarded 47-year-old male, is generally regarded as the first reported case of prolidase deficiency; his clinical symptoms were, however, not entirely typical of the disorder. Skin lesions were absent, although the skin of the lower extremities was described as "atrophic and broken down about the toes," and instead there appeared to be considerable skeletal involvement; there was generalized osteoporosis of the distal tibiae and fibulae and bones of the foot, with eversion of the talotibial joints; hyperostosis was noted in the frontal regions of the skull, but an iliac crest biopsy showed no bony abnormality, and neither was there any radiographic or histological evidence of osteomalacia or hyperparathyroidism. There was no reported increased susceptibility to infections, although the patient did die at about 50 years of age from influenza [63].

Metabolic Phenotype

The hallmark of prolidase deficiency is imidodipeptiduria, an excessive urinary excretion of X–Pro and

X–Hyp dipeptides. In a number of cases of both confirmed [5,7–9,13–15,20,21,23,33,50,64–67] and probable [61–63] prolidase deficiency in which the urinary dipeptides have been analyzed, it has been shown that the C-terminal of the two residues is usually proline, while that in the X position can be one of a number of different amino acids. Those that have been identified include Ala, Ser, Thr, Val, Phe, Ile, Leu, Pro, Asp/Asn, Glu/Gln, Lys, and Tyr, but in all cases the predominant dipeptide has been Gly–Pro, which generally accounts for 20–30% of the amount of all those excreted. Under normal circumstances, the excretion of Gly–Pro is negligible [66–71]. Because the concentration of imidodipeptides in the serum of patients with prolidase deficiency is so much lower than it is in urine, peptides other than Gly–Pro are not readily detectable [23,62]. Nevertheless, if methods are sufficiently sensitive, a variety of X–Pro imidodipeptides can be quantified [72]. Amino acid analysis of cerebrospinal fluid from the previously described case of probable prolidase deficiency was normal, and no peptides were detectable [62].

Despite the apparent relative paucity of hydroxyproline-containing urinary dipeptides, the urinary excretion of peptide-bound hydroxyproline has also been increased some six- to ten-fold in cases of both confirmed [2,5,7,14,20,21,33,64,67] and probable [62,63] prolidase deficiency, although in one patient no urinary hydroxyproline whatsoever was detected [34], a finding that is not readily understandable. The increased urinary excretion of hydroxyproline has been interpreted by some authors as indicative of an increased rate of body collagen turnover [2,5,14,62], but it would seem more reasonable to suppose that it is merely a reflection of the nonsusceptibility of hydroxyproline in peptide-bound form to degradation by hydroxyproline oxidase [63,73] as normally occurs [74]. That a proportion of the imidodipeptiduria is generated by the normal turnover of body protein is demonstrated by the excessive excretion of peptide-bound hydroxyproline by patients while on a gelatin-free diet [6,33,62,63], but gelatin-loading studies have demonstrated that in the absence of intestinal mucosal prolidase activity, dietary protein does contribute considerably, some 40–50% of the bound hydroxyproline ingested being able to cross the intestinal wall in peptide linkage to be excreted within 24 hours [6].

In one or two cases, the urinary excretion of tripeptides such as Gly–Pro–Pro [2,64] and Asx–Pro–Pro and Tyr–Pro–Pro [5] has been noted. Sheffield et al. [14] also note that a number of tripeptides were identified in the urine of their patient, but no details were given. Urinary hydroxyproline-containing tripeptides have been reported in normal individuals in very small amounts [75,76], but others have questioned their existence [77]. It is not clear by what means such tripeptides should escape normal degradation to dipeptides. It is similarly unclear why Pro–Gly should have been found in the urine of one patient [13,14] despite adequate activity of prolinase, this being the enzyme that cleaves dipeptides with an N-terminal Pro or Hyp residue.

INHERITANCE AND PREVALENCE

Prolidase deficiency is inherited in an autosomal recessive manner. In a number of pedigrees, parental consanguinity is evident [9,10,14,15,17,19,22,39,41,49,50,52], and the determination of prolidase in erythrocytes, leukocytes, and plasma of parents and other family members has demonstrated intermediate levels of activity consistent with heterozygosity for a recessive trait [3,5–7,10,15,17,19–21,27,29,32,34,40,47,52,67,78, 79], with the occasional exception [26]. Although originally assigned MIM no. 26413, indicative of its status as an autosomal recessive disorder, prolidase deficiency is currently included under MIM 170100 "Peptidase D; PEPD (prolidase; imidodipeptidase; prolidase deficiency, included)" [80], which reflects rather the codominant inheritance of benign variant alleles of the dimeric enzyme [81].

Although cases of prolidase deficiency have been reported from several ethnic groups, with a wide geographical distribution, the small number of cases reported in the literature makes it clear that it is an extremely rare disorder, although there may well be an element of underreporting as a result of physician unfamiliarity with the condition. Phang and Scriver [74] estimate an incidence of 1–2 per 1 million births, but Myara et al. [82] state that as much as 2% of the Japanese population is heterozygous for the disorder. Such a figure would result in there being over 10,000 cases in Japan and is clearly too high an estimate.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Diagnosis

The diagnosis of prolidase deficiency may be suspected on clinical grounds in pediatric or adolescent patients presenting with the symptoms described, suspicion which may be strengthened by the results of urinary amino acid analysis. Very rapid screening may be performed using paper or thin-layer chromatography or high-voltage paper electrophoresis [82]. High-voltage electrophoresis of urinary amino acids in one case showed a continuous band from Gly to Glu [25], while in another, a large spot that stained apple-green with ninhydrin was observed migrating between Gly and Ala, with a "continuous ninhydrin-positive cascade reaching the glutamine region" [13,14]. Thin-layer chromatography of urine [5,7,8,19] also shows the existence of abnormal spots, the most prominent of which migrates as authentic Gly–Pro. These abnormal ninhydrin-positive spots are not apparent if the urine is first hydrolyzed and, conversely, are still present upon the electrophoresis of urine from which free amino acids have been removed. Imidodipeptiduria may also be simply demonstrated by ion-exchange chromatography with an amino acid analyzer. The chromatography of untreated urine reveals the presence of several abnormal ninhydrin-positive peaks, which are not apparent if the urine is first hydrolyzed, and quantitative analysis reveals an increase in the content of many amino acids after hydrolysis, in particular Pro and Hyp, which are strikingly elevated [5,7,8,13–15,19–21,47,62–64]. Imidodipeptiduria has also been ascertained in a newborn screening program in which newborn urine samples impregnated on filter paper are eluted and analyzed by thin-layer chromatography [29]. The use of capillary zone electrophoresis promises to provide a rapid, simple, and reliable means of detecting imidodipeptides in only small amounts of urine [83], and a complete resolution of imidodipeptides has been achieved using micellar electrokinetic chromatography [84].

As noted above, the excretion of Gly–Pro is negligible under normal circumstances, but enzymatic confirmation of prolidase deficiency is strictly necessary, because the urinary excretion of Gly–Pro has been reported in cases of increased bone turnover, such as in patients with generalized osteopathy and greatly elevated levels of serum alkaline phosphatase [68,85], rickets [69,70], and patients

with osteomalacia and hyperparathyroidism resulting from a parathyroid adenoma [86] (and B. Steinmann, personal observation). Further, a peptide containing proline and hydroxyproline was detected in the urine of three patients with ataxia telangiectasia [87].

Prolidase activity is conveniently determined in erythrocytes or leukocytes. Whole cells should not be used because substrate transport through the plasma membrane is rate-limiting [65]. Cultured skin fibroblasts may also be used, but caution is required because there are large variations in prolidase specific activity in sonicates or homogenates related to cell number [88–90]. Prenatal diagnosis has been accomplished successfully using amniotic fluid cells [52]. A simple procedure suitable for use in mass screening programs has been described whereby activity is extracted from dried blood spots on filter paper [91], and this has been used in prospective ascertainment [28].

For diagnostic purposes, prolidase activity is best measured using Gly–Pro as substrate, and optimal reaction conditions have been described by Myara et al. [92], who have also briefly reviewed means of determining the release of glycine and proline from the substrate [82]. Clinically, a widely used means of determining proline release [10,20,30,32,34,35,46,78,79,91,93] has been the colorimetric procedure of Chinard [94]. Other amino acids, to some extent, interfere with this reaction, and the modification by Troll and Lindsley [95], which removes the basic amino acids lysine, hydroxylysine, and ornithine, has been used also [5]. Others have determined glycine, proline, and Gly–Pro using an amino acid analyzer [8,11,15,23,25,27,28,33,40,45]. A method of measuring dipeptidase activities based on the decrease in absorption at 220–222 nm as peptide bonds are hydrolyzed has been described [96,97] and used for the determination of prolidase activity in leukocytes [5]. A rapid high-performance liquid chromatography (HPLC) procedure has been described for determining the content of unhydrolyzed Gly–Pro in the reaction mixtures [98], and two methods that measure the simultaneous disappearance of substrate and appearance of product have been reported, one based on the difference between the ^{1}H nuclear magnetic resonance spectra of Gly–Pro and free Gly and free Pro [99] and the other on the isotachophoretic separation of Gly–Pro and free Gly [100].

Differential Diagnosis

A differential diagnosis must include familial leg ulcers of juvenile onset [101], an apparently autosomal dominantly inherited condition of unknown cause with expression only in males. In three patients with prolidase deficiency (two confirmed and one probable) in two families, clinical and immunological findings have led to a diagnosis of systemic lupus erythematosus (SLE) [47,50] and the suggestion that prolidase deficiency is likely to be a risk factor for the development of SLE and therefore that patients with SLE for whom there is a family history or childhood presentation of it specifically be investigated for prolidase deficiency because standard immunological or hematological investigations do not identify the biochemical abnormalities characteristic of the disorder [50].

BIOCHEMISTRY AND MOLECULAR GENETICS

Prolidase (imidodipeptidase; peptidase D) (EC 3.4.13.9) functions in the latter stages of catabolism of both endogenous and dietary protein to cleave imidodipeptides in which the imino residue is C-terminal. It is generally considered to be a cytosolic enzyme, but its possible existence at other locations (e.g., bound to the plasma membrane, either internally or externally), has not been excluded [97]. It has a wide tissue distribution, having been found in such diverse situations as intestinal mucosa, kidney, liver, brain, heart, thymus, uterus, and prostate, as well as in erythrocytes, leukocytes, dermal fibroblasts, and plasma [82,102–104]. Dipeptides containing N-terminal imino acid residues are cleaved by a different enzyme, prolinase (iminopeptidase) (EC 3.4.13.8), but there are no reported cases of its deficiency in man or other animals, and it is not considered here.

Prolidase has been purified to apparent homogeneity from several nonhuman sources [103] and in man from liver [105], kidney [106], erythrocytes [65,105,107], and fibroblasts [90] by chromatographic procedures. The native enzyme has an M_r of 97,000–116,000 by gel filtration, and a subunit M_r of 55,000–58,000 by SDS-polyacrylamide gel electrophoresis, consistent with the native enzyme being a dimer. A considerably more rapid and simplified immunoaffinity purification procedure using an immobilized monoclonal antibody to human liver prolidase results in a similar subunit M_r of 56,000 upon SDS-polyacrylamide gel electrophoresis [108]. Analysis of cDNA coding for the entire protein, and protein sequence analysis [109–111], demonstrate that the mature enzyme is composed of 492 residues and has an M_r of 54,305 [110]. Secondary structure predictions indicate the presence of α-helices, β-sheets, and potential β-turns in the protein, with hydrophobic and hydrophilic regions distributed evenly throughout [110]. Comparison of amino acid sequences further suggests that prolidase is related to *Escherichia coli* methionine aminopeptidase (EC 3.4.11.18), the tertiary structure of which comprises a so-called "pita bread" fold with two bivalent metal ion-binding regions within the centrally located active site [112,113].

The optimum pH of the human enzyme is 7.6–7.8 [65]. A relatively early study suggested that there is a specific requirement for Mn^{2+}, which was thought to be bound by a thiol residue [114]. Others also noted the likelihood of a thiol group being involved in enzyme-substrate interaction [115], but the lack of any inhibition of activity by the cysteine-specific reagent 2,2′-dipyridyl disulfide would argue against this [116]. Proposed models of the active site have been suggested and involve a binding site for Mn^{2+}, essential for activity, which interacts with the peptide bond carbonyl group of the dipeptide substrate [117,118] and with the carboxylate group of the prolyl residue in *trans* imidodipeptides in such a manner that the dipeptide functions as a bidentate ligand toward the Mn^{2+} [118,119]. Using the evidence of phenylglyoxal and carbodiimide inactivation, with protection conferred by proline derivatives, Mock and Zhuang [116] deduced the presence of arginine and carboxylate (aspartic/glutamic acid) residues at the active site of prolidase. From a comparison of the amino acid sequences of prolidase and human skin collagenase, they further suggested an evolutionary relationship between the two [116]. Mock and Liu [120] have proposed a catalytic cleavage mechanism for prolidase involving chelative activation of the substrate by one of the pair of active-site metal ions, with nucleophilic addition to the susceptible carbonyl group by the second metal hydroxide. Hechtman et al. [121] and Richter et al. [107], in studies of human erythrocyte prolidase, have presented evidence to suggest that only about 6–30% of the total enzyme within the cells is present in the active holoenzyme form,

possibly corresponding to the low levels of Mn^{2+}, the rest being in an apoenzyme form that can only become active on stimulation by Mn^{2+}. The presence of Mn^{2+} also affects the thermal stability of the enzyme because when crude human erythrocyte lysate is heated at 50°C for 1 hour in the absence of added $MnCl_2$, activity is almost completely lost, whereas, following similar treatment in the presence of $MnCl_2$, full activity is retained [107].

In contrast to the generally held view that Mn^{2+} is necessary for prolidase activity, Mock and colleagues question whether it is in fact an obligatory active site component, pointing out that divalent transition metal ions with similar chemical properties are functionally interchangeable in other metalloproteinases [120,122]. Hechtman [103], however, describes a dramatic loss of activity of prolidase in which Mn^{2+} had been replaced by Zn^{2+} and provides evidence that optimal activity is very clearly achieved with Mn^{2+} over a range of other divalent metal ions. Furthermore, Zn^{2+}-prolidase was thermolabile in comparison with the Mn^{2+}-enzyme, which was thermostable, and although there was little difference in K_m values for different imidodipeptide substrates, V_{max} values were greatly decreased with the Zn^{2+}-enzyme [103]. Nevertheless, Mock and Liu [120] state that they are unable to obtain any benefit from the Mn^{2+} activation procedure widely used during purification of the enzyme.

The prolidase (peptidase D) gene, *PEPD*, is located on chromosome 19 at 19q12-q13.2 [103] and consists of 15 exons ranging from 45 to 528 bases in length and 14 introns ranging in size from 1 to 50 kb, which make up some 98% of the gene, the whole comprising over 130 kb of genomic DNA [123,124].

Several investigators have reported the existence of two forms of prolidase, I and II, separable by ion-exchange chromatography [46,103,104,125–131]. Prolidase I corresponds to the major form described above, while prolidase II is a labile enzyme that would not have survived the preliminary heat inactivation steps of Richter et al. [107] and Boright et al. [90] or the preliminary procedures of Endo et al. [105]. Only prolidase I activity is present in human plasma [131]. The two forms of the enzyme differ in their response to Mn^{2+}, their thermostability, their response to inhibition by *p*-hydroxymercuribenzoate, and their substrate specificity [125,126,128,130,131], in particular, prolidase I having greater activity toward Ala–Pro, Phe–Pro, and especially Gly–Pro than prolidase II [125,126,128–130]. Support for the existence of two forms of prolidase is provided by the failure of antibodies to highly purified prolidase to inhibit all the activity in extracts of cultured skin fibroblasts [59,90]. M_rs of 151,000–185,000 and 95,000 for the native form and subunit, respectively, of prolidase II, as compared with corresponding M_rs of 105,000–112,000 and 56,000 for prolidase I, have been reported [128–130], but it is highly unlikely that prolidase II is a precursor or differently post-translationally modified form of prolidase I encoded either partially or completely by the locus for prolidase on chromosome 19 because there is no immunological cross-reactivity between the two forms [59,90,108]. In prolidase deficiency, the activity of prolidase against Gly–Pro in various cells and tissues, including erythrocytes, leukocytes, plasma, serum, fibroblasts, and cultured lymphoid cells, is reduced to levels ranging from undetectable to less than 7–10% of control values [5–8,10,11,14,15,19–21,23,25,27,29,30,32,33–35,44, 45,47,50,59,65,93,127,130,132]. The level of activity against certain other X–Pro substrates, such as Met–Pro, Phe–Pro, Ala–Pro, Val–Pro, and Leu–Pro, however, may not be completely eliminated and may be reduced by only a moderate extent [32,59,78,79,90,132]. The residual activity may represent the labile prolidase II enzyme [46,59,90,128,130].

Several mutations have been identified in the *PEPD* gene in prolidase-deficient individuals. Those reported at the time of writing are summarized in Table 1. Immunochemical studies of cultured fibroblasts, lymphoblastoid cells, and erythrocytes, using monospecific antiserum or monoclonal antibodies, have revealed that these mutations give rise to a degree of molecular heterogeneity in the polypeptide phenotype in prolidase-deficient patients [59,90,105,109,135] in that both patients who are CRM^- (cross-reacting material negative) and patients who are CRM^+ (cross-reacting material positive) have been identified. Northern blot analysis using a prolidase cDNA probe has shown an absence of prolidase mRNA in CRM^- cells [59].

The first mutation to be identified, in two unrelated CRM^+ patients, resulted in an Asp > Asn amino acid substitution at residue 276, which would predict a change in the secondary structure of the prolidase subunit from α-helix to β-sheet [133]. Bazan et al. [113] note that this residue corresponds to Asp97 in *E. coli* methionine aminopeptidase, a cobalt ligand in the active site of the enzyme. Confirmation that the mutation within the prolidase gene and not some other defect was the cause of the prolidase deficiency was provided by transfection experiments in which plasmids containing either a normal or the mutant prolidase cDNA were incorporated in NIH 3T3 mouse fibroblasts.

In both cases, the synthesis of immunologically cross-reacting material was observed, but active human enzyme was only detected in cells transfected with normal prolidase cDNA [133]. Restriction fragment analysis indicated that the two patients were homozygous for the G826A substitution,

TABLE 1. Mutations in the Prolidase Gene, *PEPD*, in Prolidase Deficiency

Mutation	Exon/Intron	Effect	Notes	Reference
IVS4-1G>C	Intron 4	del exon 5		129

G1342A	Exon 14	Gly448Arg	In two unrelated patients.	129
del 774 bp	Exon 14	del exon 14	In two sisters.	123,134
del 3 bp	Exon 15	del Glu452/Glu453		129

*Both of these mutations were detected in a single asymptomatic patient.

which resulted in the elimination of a *Taq*I cleavage site from genomic DNA [133]. In a number of other patients, who were CRM^-, the *Taq*I restriction fragment pattern of exon 12 was similar to that of controls, indicating the probability of different mutations being responsible [133]. Complementation analysis by Boright et al. [90] did, however, indicate that all of the CRM^- and CRM^+ mutations that they studied mapped to a single locus.

In two further prolidase-deficient sisters, the offspring of consanguineous parents from whom they inherited the mutation, Tanoue et al. [123,134] detected a genomic deletion of 774 bp including exon 14, which resulted in the production of mRNA lacking 192 bp of sequence corresponding to exon 14. Transfection and expression analysis using mutant prolidase cDNA resulted in the presence of an inactive mutant protein of M_r 49,000 [134,138]. At the deletion breakpoints there were 7 bp of short repeats, and the mechanism of "slipped mispairing," whereby the repeat sequences misrepair during DNA replication, leading to the formation of a single-stranded loop that is then excised, was suggested as being the cause of the deletion [134].

Ledoux et al. [135,136] subsequently identified six novel alleles from prolidase-deficient patients, listed in Table 1, and Kikuchi et al. [137] have reported a further novel mutation in a Japanese patient. This last mutation, generating a stop codon at amino acid position 184, would be expected to result in the production of a truncated polypeptide, but any mutant protein may have been very unstable because none was detectable [59]. Kikuchi et al. [137] note that the mutation, occurring at nucleotide position 551, involves the CpG dinucleotide, a known hotspot for point mutations. Interestingly, although the patient of Kikuchi et al. [137] was severely affected from birth, the case reported by Ledoux et al. [136], who had a missense mutation at the same position, had residual prolidase activity and was asymptomatic. Position 184 is located in a nonconserved region of the protein, distal to the active site [116], and it would seem that the nonsense mutation (stop) affects the stability of the catalytically inactive enzyme, whereas the missense mutation at the same position does not affect stability and allows the production of a partially active enzyme.

Endo et al. [59] attempted to relate the polypeptide and mRNA phenotypes they observed to clinical phenotype but without success. The only possible correlation observed was that mental retardation occurred only in CRM^- patients, in whom the biochemical defect might be regarded as most severe. However, it did not occur in all CRM^- patients studied. The variable nature of the clinical symptoms observed in prolidase deficiency, especially in affected siblings, has long been puzzling, but the finding of the same gene deletion in two sisters, one of whom developed skin lesions at the age of 19 months but the other of whom did not do so until 18 years of age, makes it clear that factors unrelated to the prolidase gene product influence the course of the disease [134].

In one of the cases reported by Ledoux et al. [136], two novel alleles were detected in a single prolidase-deficient individual, still asymptomatic at the age of 11 years, one carrying a G551A transition in exon 8, resulting in the Arg184Gln substitution mentioned above, and the other carrying a G833A transition in exon 12, resulting in a Gly278Asp substitution. Direct sequencing demonstrated the proband to be a genetic compound for the two mutant alleles on homologous chromosomes, one being paternal in origin and the other maternal, and expression of the mutant alleles in a COS-1 expression system demonstrated that the Arg184Gln mutation was associated with 7.4% residual activity, while the Gly278Asp substitution resulted in inactive enzyme, although in both cases a normal amount of immunoreactive protein of the expected size was detected by western analysis [136]. The expression of mutant alleles previously identified, G1342A (Gly448Arg) and ΔGlu452/453 [135], in the same system resulted in undetectable enzyme activity in each case [136]. Although the former mutation allowed the detection of stable immunoreactive material, the latter did not, being associated with a mutant protein that was synthesized but rapidly degraded [136]. The Gly278Asp and Gly448Arg substitutions both introduce charged side chains in close proximity to the negatively charged active site metal-binding residues Asp276 and Glu452, and Ledoux et al. [136] speculate that the function of these metal-binding residues might be affected by steric and/or electronic hindrance as a result of these mutations, with consequent loss of enzyme activity. Although the ΔGlu452 mutation removes one of the metal-coordinating residues, Ledoux et al. [136] suggest that its destabilizing effect is more likely due to a reversal of polarity in the distribution of residues within the β-motif proximal to the mutation.

Several authors have speculated on the role of the labile prolidase II enzyme in relation to the severity of the clinical phenotype. Butterworth and Priestman [125] first observed a virtual absence of prolidase I in prolidase deficiency and observed that the properties of prolidase II were altered, implying a structural relationship between the two forms. The simplest explanation was that they shared a common subunit that was altered in the disease, but, as noted above, immunochemical studies have shown the two forms not to be immunologically cross-reactive, and Endo et al. [59] could find no correlation between the severity of the clinical phenotype and the residual level of enzyme activity representing prolidase II, concluding that it seemed to be largely irrelevant as a modifier of the clinical phenotype.

The finding of an increased manganese content of erythrocytes from one patient, together with deficient activity of prolidase and arginase, both Mn^{2+}-dependent enzymes, raised the question of there being an entirely different cause of prolidase deficiency in some patients, namely a defect in cellular manganese handling that renders manganese unavailable for Mn^{2+}-dependent enzymes [32], in a manner analogous to the disturbance in copper handling that reduces the availability of copper to Cu-dependent enzymes in Menkes disease and the occipital horn syndrome (see Chapter 14, this volume). However, this particular patient was one of those in whom an Asp276Asn substitution was later detected [133].

PATHOLOGY

The patient initially reported by Isemura et al. [15] died at 25 years of age from cerebral hematoma following an unsuccessful skin-grafting operation and was examined at autopsy by Sekiya et al. [18]. Abdominal and breast skin was thinner than normal, and in some parts the epidermis consisted of only two or three layers of squamous cells. The lamina densa of the epidermal basement membrane displayed irregular disruption, and the basement membrane of the small vessels of the dermis was lamellated and showed interruptions. The basement membranes of the renal tubules

and glomerular capillaries were thickened, irregularly in the first site and with splitting in the second. Both the tubular basement membrane and the vascular basement membranes of the interstitium were highly lamellated. Thickened dermal vessel basement membranes were also observed in five patients by Pasquali Ronchetti and her colleagues [44,139].

In the patients reported by Leoni et al. [33] and Ogata et al. [19], the epidermis appeared to be normal. However, in the two patients described in the former report, dermal fibroblasts and myofibroblasts showed a poorly developed rough endoplasmic reticulum and Golgi apparatus. Vesicles containing heterogeneous electron-dense material were noted, and lysosomes appeared to be abnormally abundant. The dermal fibroblasts observed in skin biopsies of unaffected skin by Quaglino et al. [139] were also characterized by lysosomal inclusions, but the rough endoplasmic reticulum was well-developed and sometimes abnormally dilated. However, in both studies [33,139], the dermis contained numerous macrophages with convoluted plasma membranes and containing numerous lysosomes and vesicles filled with heterogeneous material. In the two patients described by Leoni et al. [33], the small vessels of the dermis were thick-walled because of the presence of aggregates of microfilaments associated with endothelial and smooth muscle cell basement membranes. Histological examination of the spleen of the probable, but atypical, case of prolidase deficiency reported by Goodman et al. [62] revealed moderately widened cords of Billroth, swollen sinusoidal lining cells, and thickened arteriole walls.

Ultrastructural studies of clinically unaffected skin from the thigh have shown both normal [33] and reduced [139] contents of dermal collagen and elastin, but there does seem to be a tendency toward a smaller than normal mean collagen fibril diameter, with a greater size distribution and disturbed packing into fiber bundles, and an abnormal shape and unusually high degree of branching of elastin fibers, indicative of disturbed fibrogenesis [33,44,139]. These changes appear less marked in clinically unaffected forearm skin [44]. Disturbances of collagen and elastin fibers have also been reported in the probable case of Goodman et al. [62], and in both apparently normal skin [4] and skin around leg ulcers [19] in confirmed patients, although Arata et al. [11] and Sekiya et al. [18] mention that no morphological abnormalities of collagen or elastin fibers were apparent in the cases they studied.

The examination of early ulcerations on the legs indicated that they resulted from occlusion by amyloid of the medium-sized vessels of the dermal-hypodermal junction [4]. The overlying epidermis was necrotic, and an infiltrate of neutrophils destroyed the surrounding connective tissue, leading to deep ulceration. The ulcer floor showed dense granulation tissue infiltrated with neutrophils and plasma cells, possibly indicative of a repair attempt, with an increase in the number of fibroblasts as scarring developed. An accumulation of amyloid fibrils around the capillaries in the dermis around leg ulcers was also noted by Ogata et al. [19], and generalized amyloidosis was noted in the patient autopsied by Sekiya et al. [18].

Amyloid was not at all a feature, however, in mild, initial cutaneous lesions in a 19-year-old prolidase-deficient girl who had been asymptomatic at the time of first reporting at seven years of age [11] but had since developed crops of annular erythematous macules with marginal scales on her thighs and buttocks, and atrophies blanches or small ulcers on her lower legs [12]. Blood vessels in the middle to deep dermis of an annular erythema revealed what was described as mild homogenization of their walls, with perivascular edema. Examination of an atrophie blanche without a preceding ulcer demonstrated marked dilatation of capillaries with thickened, hyalinized walls that showed evidence of collagen "homogenization" and had a narrowed or occluded lumen. Multilayered basal laminae were found around small vessels, and capillary endothelial cells had some lysosome-like structures, many mitochondria, and a highly developed endoplasmic reticulum.

PROGNOSIS AND MANAGEMENT

Prognosis

Because the clinical symptoms of prolidase deficiency do not necessarily manifest themselves until late childhood, or even late adolescence or early adulthood, it is not easy to be precise about the prognosis in any particular patient. Only one patient described in the literature, the brother of the autopsy case [18] described above, appears to have remained entirely asymptomatic by the age of 26 years [15], and his present status is unknown. A further late-onset case did not show skin lesions and ulcers until 30 years of age, although he had suffered frequent infections with chronic bronchitis since the age of 10 years [54]. Consequently, it is reasonable to expect that any patient who is prospectively ascertained through routine neonatal urinary screening, for example, will become clinically affected, most probably before the age of 10 years or so. Developmental delay would be apparent before this age.

Although in the majority of instances prolidase deficiency might be seen as severely discomfiting rather than life-threatening, as experience with the disorder grows it does seem that there is a tendency for it to be associated with a reduced life expectancy, at least seven cases out of the approximately 60 reported having suffered premature death. The patient reported by Lapière et al. [2,3], as noted by Endo et al. [59], died at 36 years of age; this was following rehospitalization with very large ulcers up to the thighs, which were deeply infected with *Pseudomonas aeruginosa*. She presented with septic shock and died of an intravascular coagulation syndrome (Dr. Ch. M. Lapière, personal communication, 13 June 1991).

The female patient first reported by Isemura et al. [15] died at 25 years of age [18] and is the patient whose autopsy findings are described above. An unpublished case died at 15 years of age of terminal liver failure and cardiac failure [38], while a further patient died of sepsis in her late twenties [56]. One patient died at 16 years of age of adult respiratory distress syndrome following treatment for cellulitis of the leg [47], and one eight-year-old boy died despite intensive care, plasmapheresis, and high-dose steroids after having been admitted to hospital suffering abdominal pain and subsequently developing septicemia severe enough to require respiratory support [50]. A further severely affected child died at age four years [52], and, in addition, the probable case of prolidase deficiency reported by Goodman et al. [62] died of influenza at around the age of 50 years [63].

Management

Powell et al. [5] suggested that the massive loss of proline and other bound amino acids might result in the decreased availability of the respective amino acids for reuse in protein synthesis, and Jackson et al. [8] proposed that the clinical symptoms of prolidase deficiency resulted from a

"collagen deficit" arising specifically from the excessive urinary loss of proline that would otherwise be available for reuse in new collagen biosynthesis. On this basis, oral proline therapy might reasonably be expected to alleviate symptoms, but results have been disappointing. Although a diet supplemented with 10 g/day of proline, twice the estimated daily loss of 5 g, elevated the serum proline level from the lower limit of normal to the upper limit in one patient [14], no definite benefit was apparent other than the subjective assessment that the patient felt better than before and attended school more regularly. The treatment of a female patient by oral therapy with 4 g of proline/day for a month did not improve her clinical condition [15], and neither did longer-term oral therapy of a further case with 6 g/day of proline in conjunction with wet proline dressings [19] alleviate clinical symptoms.

Although the topical application of an ointment containing 5% glycine and 5% proline was claimed to result in a considerable improvement in the ulcers of three patients [39,140,141], in other cases the same result has not been achieved [47]. It should be noted that proline is not an essential amino acid and that each cell of the body is capable of synthesizing it in sufficient amount.

Sheffield et al. [14] suggested that the therapeutic potential of the manganese cofactor of prolidase might be tested, as might that of drugs that stimulate collagen synthesis or inhibit collagenase, and several workers have tried various combinations of compounds with rather mixed results. Based on the erroneous belief that the condition in their patient represented a genetically determined deficiency of prolyl hydroxylase, Lapière and Nusgens [2] investigated the use of high doses of ascorbic acid, a cofactor of this enzyme, both intravenously and orally, but were unable to demonstrate any improvement or any modification of the urinary excretion of hydroxyproline. The intramuscular injection of ferrous ion, a cofactor of collagen prolyl and lysyl hydroxylases, was similarly unsuccessful. In contrast, De Rijcke et al. [42] reported that a daily oral dose of 4 g of ascorbic acid resulted in healing of their patient's ulcers and a normalization of the previously rough, dry hair. They further reported that when, after two years, the patient discontinued this therapy for psychological reasons, the ulcers reappeared.

Using a combination of oral ascorbate, Mn^{2+}, diphenylhydantoin, and N-acetyl-hydroxyproline, Charpentier and her colleagues [20,21] were able to reduce the urinary excretion of Gly–Pro by their patient by about one-half, although, despite the fact that the treatment prevented the occurrence of further inflammatory rashes, there was no improvement in the patient's leg ulcerations. The effects observed apparently were not related to any restoration of prolidase activity [93]. The antibacterial agent dapsone, administered at a dosage of 75 mg/day in one patient, resulted in accelerated epithelialization of ulcers, but healing was no more rapid [19].

The treatment of one patient, a four-year-old girl, with $MnCl_2$, proline, and ascorbic acid over a nine-month period was, however, accompanied by an apparently dramatic clinical improvement [27]. The skin was almost normalized, growth was normal, bone age increased rapidly, muscular coordination became normal, and IQ was substantially increased. These improvements were accompanied by no great alteration in the urinary excretion of dipeptides during the treatment period. Similar treatment with hydroxyproline instead of proline also resulted in a slight improvement in the condition of the two patients of Voigtländer et al., with an absence of new ulcer formation [35]. The treatment of a further patient with ascorbic acid, diphenylhydantoin, and N-acetyl-hydroxyproline is also reported to have brought about a considerable improvement of skin ulcers to the extent that he was able to resume walking [40].

Repeated erythrocyte transfusions, either alone [3,17,65] or in combination with $MnSO_4$ and ascorbic acid, have generally been found to be ineffective in either altering the pattern of imidodipeptiduria or alleviating clinical symptoms. Hechtman et al. [121] have suggested that such failure is a consequence of prolidase occurring to a large extent in an inactive apoenzyme form in human erythrocytes and propose the use of erythrocytes in which prolidase has previously been activated by preincubation of the cells with Mn^{2+}. In their studies, hemolysates of normal erythrocytes that had been incubated overnight in the presence of 1 mM $MnCl_2$ showed a more than 30-fold increase in prolidase activity, and the intact cells themselves showed a 10–20-fold increase in the rate at which they were able to degrade Gly–Pro. No information is available on whether the procedure has been used successfully in the treatment of prolidase-deficient patients, but given the fact that erythrocytes treated in such a manner retained high levels of enzymatic activity for at least two weeks, the procedure clearly has significant potential. Berardesca et al. [45] reported a dramatic improvement in one 15-year-old Italian patient whose ulcers had worsened to the extent that he was no longer able to walk but in whom, after four transfusions of concentrated erythrocytes at bimonthly intervals, the ulcers showed an improvement such that he was able to resume walking. However, there was no alteration in the level of excretion of urinary imidodipeptides. In this case, the transfused erythrocytes had not previously been activated.

More recent reports suggest the beneficial effects of corticosteroid therapy in managing prolidase deficiency. The patient with probable prolidase deficiency described by Shrinath et al. was apparently making good progress with oral prednisolone, which had prevented further new infections, although her facial rash persisted [50]. Yasuda et al. [55], in contrast, found that oral prednisolone alone was ineffective against skin ulcers in one of their patients but did find that corticosteroid pulse therapy performed using intravenous drip infusion of methylprednisolone (1,000 mg/day) for three days, followed each time by oral prednisolone (30 mg/day), repeated three times over two years resulted in almost complete regression of preulcerative lesions and ulcers 1–2 months after each pulse course. Finally, the topical application of an ointment containing growth hormone to one 13-year-old prolidase-deficient boy in whom growth hormone deficiency had been diagnosed resulted in a complete but transitory healing of the boy's foot ulcers, which was attributed principally to the growth-promoting effects of growth hormone on dermal connective tissue [142].

Although patients with prolidase deficiency are clear candidates for gene replacement therapy [133], on the whole at the present time there is little in the way of treatment confirmed to be effective that can be recommended other than the conservative management of ulcers combined with measures to prevent infection. As an example of this, Ogata et al. [19] used hydrotherapy of ulcers followed by the application of wet dressings containing antibiotics effective against *Pseudomonas aeruginosa*. Split-thickness skin grafting has been found to be unsuccessful [18,19].

As far as genetic counseling is concerned, the risk of a couple of which one member has prolidase deficiency having

an affected infant is almost zero, but the risk of a couple each of whom is heterozygous for the disorder having an affected infant is the same as for any other recessively inherited disorder (i.e., there is a 1 in 4 probability). The activity of prolidase in chorionic villus biopsies appears not yet to have been investigated, but its known expression by amniotic fluid cells [27,89] has permitted the prenatal diagnosis of an affected infant, the sibling of a seriously affected child who died at the age of four years. The diagnosis was later confirmed using the baby's leukocytes [52]. Excessive levels of imidodipeptides might also be apparent in amniotic fluid but, as cautioned earlier, their presence alone would not necessarily be confirmatory of prolidase deficiency.

PATHOGENESIS

The pathogenesis of the clinical manifestations apparent in this disorder is not at all well-understood. An elevated "dermal aldehyde" content, suggested as resulting from an inability of the aldehyde groups to participate in collagen intermolecular cross-links, led Goodman et al. [62] to describe the condition in their patient, a probable case of prolidase deficiency [63], as resembling lathyrism (this being the condition resulting from the inhibition of lysyl oxidase, the enzyme responsible for initiating the cross-linking of both collagen and elastin; see Chapter 9, this volume). In fact, the condition as described bears no resemblance to lathyrism, either biochemically or clinically.

Connective Tissue

The elevated urinary proline:hydroxyproline ratio in their patient, only later confirmed as being prolidase-deficient, initially led Lapière and his colleagues to suspect deficient activity of prolyl hydroxylase (the enzyme responsible for the post-translational modification of specific prolyl residues within the collagen α chains) [2,64,143]. However, the finding of a normal extent of prolyl hydroxylation in collagen produced by cultured fibroblasts from patients with imidodipeptiduria and prolidase deficiency disposed of this possibility [73,93], and Isemura et al. [15] found a normal amino acid content of dermis in their patient, with normal extents of prolyl and lysyl hydroxylation and of hydroxylysyl glycosylation. Nevertheless, the above-mentioned reports [2,62,64,143] may have served to cause an undue amount of attention to be focused on collagen to the extent that in one instance it was felt justifiable to describe prolidase deficiency as an "inborn error of collagen metabolism" [22].

Actual studies of collagen in prolidase deficiency, however, are few. Minimal increases in the ratio of collagen type III to collagen type I have been reported in both dermis [17] and fibroblasts [93], although another study on dermal fibroblasts found an equally minimal decrease [144]. The ratio of the reduced collagen cross-links dihydroxylysinonorleucine:hydroxylysinonorleucine was reported to be elevated in the dermis of one patient [17], but the significance of this is not certain. It is not clear from which region the skin was obtained, and the increased dihydroxylysinonorleucine content may reflect the normal pattern seen in scar or granulation tissue [145]. The most striking observation in studies with cultured fibroblasts from prolidase-deficient patients has been an elevation in the extent of intracellular degradation of newly synthesized collagen [93,144]; however, no such elevation was found in another study [146]. Isemura et al. [15] reported a slightly decreased ratio of the collagen hydroxylysyl glycosides Glc–Gal–Hyl:Gal–Hyl in the urine of their patient, but Leoni et al. [33] in their two patients found a normal content of hydroxylysyl glycosides in urine and a normal diglycoside:monoglycoside ratio, which would indicate a quantitatively normal level of catabolism of collagen. The elevated lysyl aldehyde content of dermal collagen from the patient of Goodman et al. [62] is consistent with reports of disturbed fibrillogenesis and may be a reflection of disturbed alignment of tropocollagen molecules for some reason such that normal cross-linking cannot occur, although it must be said that if alignment and fibrillogenesis were seriously disturbed it would be unlikely that lysyl oxidase could function. In conclusion, one must therefore say that biochemical evidence of any change in collagen metabolism is minimal and that if any such changes do occur they are likely to be secondary to the basic metabolic disturbance.

Because of the frequent occurrence of Gly–Pro sequences in collagen, the occurrence of Gly–Pro as the predominant dipeptide in the urine in prolidase deficiency has also led to possibly greater emphasis than justified being placed on collagen as the principal or even the sole source of the urinary dipeptides [2,5,8,11,13,20,21,62,64,144]. However, several authors have pointed out that the greatly elevated urinary Pro:Hyp ratio, which may be as high as 5:1 or more, indicates that the urinary dipeptides are from sources other than solely the breakdown of body collagen [7,14,15,22,27,73,82,107,121]. It is clear that exogenous protein does contribute to the imidodipeptiduria [6], and Hechtman et al. [121] expressed the view that the principal source of urinary dipeptides is likely to be the absorption of peptides derived from dietary protein.

As mentioned earlier, it has been suggested that the connective tissue alterations might result from a proline "deficit" [8]. Because the C1q component of complement also contains collagen-like sequences, it has also been suggested that there is somehow an immunological deficit related to this fact [8]; however, C1q levels have been found to be normal [21,25], as have levels of plasma acetylcholinesterase [21], another protein with collagen-like amino acid sequences. However, as mentioned above, there are frequently elevated levels of IgG and IgA in plasma from patients. There is a possibility that the frequently observed susceptibility to repeated respiratory infections might result from a failure of IgG function brought about in some way by an elevated concentration of plasma dipeptides. However, Gly–Pro is the principal imidodipeptide to be detectable in the plasma of patients [23,62,72], and although several Gly–X peptides have been examined for their effect on the binding of human IgG to bacterial Fc receptors, none was found [147]. Gly–Pro and X–Pro dipeptides, however, were not examined in this regard.

Piérard et al. [4], in a histological study of the process of dermal ulceration in a prolidase-deficient patient, described developing ulcers as initially appearing as isolated papules resulting from the occlusion of medium-sized vessels of the dermal-hypodermal junction by amyloid. A dense infiltration of neutrophils was above the main vascular alteration, surrounding a core of connective tissue that was eliminated by the neutrophils to form a deep ulceration. The precursors of the fibrous amyloid deposits associated with chronic inflammatory disorders are the serum amyloid A proteins. Mitchell et al. [148] demonstrated the production by rabbit synovial fibroblasts treated with inflammatory mediators of serum amyloid A3 that had the effect of inducing collagenase synthesis by these cells. It is therefore conceivable that such

a mechanism of tissue damage might be operative in the present condition.

Arata et al. [60] examined the cutaneous lesions of one case, a 19-year-old girl who had remained asymptomatic until 15–18 years of age, by light and electron microscopy. Small vessels of the dermis frequently showed thickened walls surrounded by multiple basal laminae, although there were no amyloid deposits, and an angiopathic pathogenesis was suggested. Severe edema of the scrotum and lower limbs, or of just the lower limbs, was specifically noted to be a problem in two patients [14,26] and suggested as resulting from progressive damage to the lymphatic vessels [14]. In the case of both blood and lymphatic vessels, however, the mechanism by which vascular damage might initially be induced is unknown, although there are several indications that collagen-derived peptides are involved in inflammation, and the X–Pro imidodipeptides, some of which will be collagen-derived, may have similar effects.

The small peptide degradation products of bacterial collagenase digestion of acid-soluble calf skin collagen have been found to have a number of bradykinin-like properties. For example, when injected intradermally in rats, they result in an increased permeability of skin capillaries [149] and this may be related to the edema sometimes observed in prolidase deficiency (see above). The same degradation products, when injected into the brain ventricle of rats, depress locomotor activity [149] and have also been shown to cause the release of rat mast cell histamine [150]. Further, dipeptides containing proline and hydroxyproline also induce the release of histamine from isolated mast cells and collagenase from polymorphonuclear leukocytes [151]. In addition to these findings, the intratracheal instillation of collagen peptides resulting from the action of bacterial collagenase on collagen results in an influx of neutrophils into the lungs of rats [152].

High-molecular-weight ($M_r \sim 200$ kDa) fragments derived from mild alkali treatment of insoluble collagen have been reported as being both chemotactic for polymorphonuclear leukocytes and stimulators of neutrophil respiratory bursts with concomitant release of superoxide radicals, lysis, and release of hydrolytic enzymes [153]. The large size of the fragments indicates that the stimulant is either collagen or very large fragments of it. It may be the case in prolidase deficiency that collagen, especially if previously damaged by inflammatory cell enzyme release, might act as a mediator of further inflammation. The tripeptide Pro–Gly–Pro generated by alkali degradation of whole cornea also functions as a chemoattractant toward polymorphonuclear leukocytes [154], and it may be that the imidodipeptides generated in prolidase deficiency have a similar effect.

There is some evidence that the imidodipeptides that accumulate in prolidase deficiency do themselves exert a deleterious effect. Watanabe et al. [155] demonstrated that Pro–Pro, Gly–Pro, and Ala–Pro primed N-formyl-methionyl-leucyl-phenylalanine (fMLP)-induced superoxide generation by polymorphonuclear leukocytes from normal, healthy individuals, and Yasuda et al. [55] subsequently examined the process using neutrophils from two prolidase-deficient sisters. The extent of superoxide generation by these neutrophils correlated with the level of several serum imidodipeptides, which, in turn, were highest at periods of active ulcer formation. Pretreatment with Pro–Pro of neutrophils isolated from blood collected at times when serum imidodipeptide levels were comparatively low resulted in a significant enhancement of superoxide generation following fMLP challenge but had no such effect on neutrophils isolated from blood collected at times when serum imidodipeptide levels were elevated, suggesting that they were already fully primed under such circumstances. Yasuda et al. [55] suggested that superoxide production by neutrophils was the direct cause of vascular thickening and inflammatory skin lesions. They further noted that the extent of neutrophil superoxide production was greater in the more severely affected of the two sisters and suggested that clinical severity may depend on the response of neutrophils to the imidodipeptides.

There may also be some involvement of neuropeptides in the dermal ulceration. In the fluid from spontaneous blisters in inflamed skin in a number of disorders, there are significant amounts of substance P, vasoactive intestinal peptide, calcitonin gene-related peptide, somatostatin, and neuropeptide Y [156], and each of these when injected intracutaneously induces flaring, in some cases accompanied by whealing and itching [156–159]. This appears to result from the ability of these substances to elicit histamine release, as demonstrated with rat peritoneal mast cells [157,159], and, in addition, calcitonin gene-related peptide is a potent vasodilator [158]. Substance P is quite likely a mediator of the local inflammatory response [160], is chemotactic for neutrophils and stimulates lysosomal enzyme release from them [161], and enhances the phagocytic activity of both neutrophils and macrophages [162].

Mental Retardation

The pathogenesis of mental retardation is intriguing and has not yet been approached by clinical investigations. However, it is worthy of note that prolidase is normally present in brain at levels 10–100 times higher than would be required for the measured rate of protein turnover in this tissue [117]. Most neuroactive peptides (e.g., thyrotropin releasing hormone, MIF, β-MSH, substance P, β-lipotropin, oxytocin, vasopressin, angiotensin) contain proline in their structure and are thus resistant to the action of conventional amino and carboxyl peptidases. Thus, in addition to its role in protein turnover, prolidase is likely to terminate the activity of proline-containing neuropeptides [163]. One might speculate therefore that deficiency of prolidase might cause significant pathophysiological changes. As mentioned previously, there may be some correlation between the presence of mental retardation and the extent of enzyme deficiency in that of eight patients studied by Endo et al. [59], mental retardation was only apparent in three of the six who exhibited a CRM^- phenotype.

To the best of our knowledge, the examination of cerebrospinal fluid has been performed only in one patient, that with probable prolidase deficiency reported by Goodman et al. in 1968 [62], in which case the amino acid analysis was normal and no peptides were detectable. A broader study to investigate whether imidodipeptides were present in excessive amounts in cerebrospinal fluid would be of interest and might indicate whether one or more functioned as a neurotransmitter or neuromodulator. Furthermore, brain tissue obtained at autopsy from prolidase-deficient patients has not been examined with respect to the extent of residual enzyme activity or the content of free imidodipeptides. However, magnetic resonance imaging of the brain of one of the two siblings initially reported by Arata et al. [11], superoxide production by whose neutrophils was examined by Yasuda et al. [55], demonstrated multiple microthromboses in bilateral cerebral white matter [12]. This finding suggested an abnormality of the cerebral vessels,

consistent with the angiopathic pathogenesis proposed by Arata et al. [12], to which imidodipeptide-induced superoxide production may have contributed [55], and may explain the occurrence of mental retardation in prolidase deficiency [12].

ANIMAL MODEL

No animal model of prolidase deficiency, either naturally occurring or experimentally generated, has yet been described. However, opportunities do present themselves for the creation of an experimental model in which the pathogenesis of the disorder might be investigated by virtue of the fact that the antihypertensive captopril is an inhibitor of prolidase in extracts of various rat and human tissues [164,165], although this effect is weak as far as porcine kidney prolidase is concerned [119] and minimal with respect to erythrocyte prolidase [164]. There is a striking similarity between captopril, N-(3-mercapto-2-methyl-1-oxopropyl-L-proline), and X–Pro dipeptides, and the oral administration of captopril to the rat resulted in the increased excretion of peptide-bound hydroxyproline, suggesting that *in vivo* inhibition of tissue prolidase had occurred [164], although it should be noted that this finding does not necessarily equate with imidodipeptiduria, and, significantly, there was no increase in the urinary excretion of Gly–Pro, normally the most abundant urinary imidodipeptide in prolidase deficiency. The clinical use of captopril has several side effects, including dermatological manifestations similar to those seen in prolidase deficiency [166,167]. Other mechanisms for the development of these cutaneous lesions have been suggested (summarized in [164]), but suspicion must fall on the inhibition of tissue prolidase.

Other inhibitors of prolidase that might be useful in developing an experimental animal model of prolidase deficiency are the naturally occurring glycolytic intermediate, phosphoenolpyruvate, and analogs of it, an effective inhibitor of pig kidney prolidase [97,168], and N-benzyloxycarbonyl-L-pipecolic acid and N-benzyloxycarbonyl-L-proline [119].

Chapter 17

α_1-Antitrypsin Deficiency

Diane Wilson Cox

Departments of Medical Genetics and Pediatrics, University of Alberta, Edmonton, Canada

SUMMARY

- **α_1-antitrypsin (α_1-antiproteinase, α1AT), the most abundant plasma proteinase inhibitor, is a serine protease inhibitor important in the control of tissue proteolysis, particularly in the lungs.**
- **An inherited deficiency of α1AT is associated with an increased risk of chronic obstructive lung disease, liver disease, and tissue destruction in inflammatory conditions such as rheumatoid arthritis.**
- **The locus encoding α1AT (*PI, SERPINA1*) is located at 14q32.1 in a cluster of serine proteases that may also be involved in tissue destruction and/or inflammation.**
- **There are numerous genetic changes in the 392 amino acid residues of α1AT, leading to more than 70 genetic variants, with at least 15 resulting in a reduced plasma concentration.**
- **The most common deficiency variant or PI type is PI*Z. Individuals of PI type ZZ occur as about one in 3,000 to 7,000 in Caucasian populations. The plasma concentration of α1AT in PI ZZ individuals is about 15–20% of normal.**
- **There are other rare variants leading to a reduced concentration of α1AT, some resulting in no detectable α1AT (null variants).**
- **PI Z results in deficiency because of its tendency to polymerize in the liver, which then results in the formation of typical inclusions.**
- **The greatest risk for patients with α1AT deficiency is chronic obstructive pulmonary disease. Smoking has a profound effect on the age of onset and prognosis.**
- **About 3% of all PI ZZ individuals develop severe progressive liver disease in childhood, although about 14% develop signs of liver abnormality that resolve during the early years of life. There is an increased risk of liver disease in adult life.**
- **Avoidance of smoking is important preventative therapy. Replacement therapy, using purified α1AT, is available. The benefit of such therapy is not well-established because of confounding with other factors that may influence the rate of lung degradation. Gene therapy is also under investigation. Antioxidants may aid in tissue preservation; their role needs to be explored. Lung or liver transplantation offers potential therapy for end-stage organ destruction.**

INTRODUCTION

α_1-Antitrypsin (α_1-antiproteinase, α1AT) is a major plasma proteinase inhibitor that plays an important role in the control of connective tissue proteolysis. An inherited deficiency of α1AT is associated predominantly with an increased risk of abnormally rapid degradation of lung elastin, leading to emphysema, and with destruction of the liver in both children and adults. Susceptibility to an increase in joint damage in rheumatoid arthritis and to tissue destruction in inflammatory conditions has also been suggested.

Tissue integrity is dependent on an appropriate balance between proteolytic enzymes, which can facilitate tissue remodeling when required, and inhibitors of these proteinases. The array of proteinases and their inhibitors is extensive. A number of classes of proteinases are involved in forming and maintaining extracellular matrix, including thiol proteinases, carboxyl proteinases, a large group of metalloproteinases, and an even larger group of serine proteinases. Control of proteinases is largely maintained by a variety of proteinase inhibitors. An imbalance between any one of these proteinases and its inhibitors could lead to abnormal tissue destruction (see Chapter 7, this volume).

The Serpins

α1AT, the most abundant plasma proteinase inhibitor on a molar basis, is a serine proteinase inhibitor. Its plasma concentration is similar to that of the much larger proteinase inhibitor α_2-macroglobulin, which inhibits a variety of proteinases by an entrapment mechanism. Of the large number of proteinases and inhibitors found in human tissues and plasma, α1AT, which has been particularly well-studied, can be regarded as part of a model system. Deficiencies of other plasma and tissue proteinase inhibitors may prove to be equally destructive when more is known about their function and deficiency states. The class of serine proteinase inhibitors, referred to as "serpins," typically have a reactive center formed by an X–Ser that acts as the substrate for the target proteinase [1]. The serpins are a superfamily of proteins found in viruses, plants, and animals [2] (see also Chapter 7, this volume). Several of them, such as α_1-antichymotrypsin,

Connective Tissue and Its Heritable Disorders, pages 745–763

antithrombin III, C1 inhibitor, and α_2-antiplasmin, are major inhibitors of the inflammatory cascade.

Historical Background

α1AT, first isolated by Schultze et al. [3], was later named α_1-antitrypsin because most of the trypsin inhibitory activity in plasma was associated with the α_1-globulin fraction and particularly with the protein they had initially isolated [3]. The name α_1-antitrypsin has been commonly used since that time and is maintained in this chapter for historical reasons. However, it is now well-recognized that trypsin inhibition is not the major function of this protein, and α_1-proteinase inhibitor has been suggested as an alternate designation.

α1AT deficiency was first noted by C.-B. Laurell, in a number of patients with early-onset emphysema, as an abnormal protein pattern on electrophoresis [4]. Subsequent studies confirmed the presence of early-onset emphysema in individuals homozygous for the deficiency gene [5]. At about the same time, Fagerhol and Briand in Norway [6] observed variable protein bands on acid starch gel electrophoresis, which were shown to be α1AT [7]. A number of variants were observed on starch gels and were named Pi (now PI) for proteinase inhibitor [6] in recognition of the fact that α1AT was an inhibitor of other proteinases in addition to trypsin. The involvement of α1AT deficiency in liver disease in children was recognized by Sharp and colleagues in 1969 [8].

STRUCTURE AND FUNCTION OF α_1-ANTITRYPSIN

Protein Structure

α1AT is a 52 kDa glycoprotein consisting of a single polypeptide chain of 392 amino acid residues and three carbohydrate side chains. The protein is homologous in amino acid sequence to several other plasma proteinase inhibitors: α_1-antichymotrypsin (42% homology), antithrombin III (28%), and C1 inhibitor (27%) [9]. The relatively small size of α1AT permits its diffusion through interstitial body fluids.

The structure of human α1AT, known from x-ray crystallography [10], shows a well-defined secondary conformation, including three β sheets and eight α helices. An inactive, relaxed form of α1AT, proteolytically cleaved at the active site, has been crystallized. α1AT contains only one cysteine residue and therefore does not form an intramolecular disulfide bridge. However, the cysteine residue can form a disulfide bond with other proteins and with thiol compounds. There is microheterogeneity among the α1AT molecules, depending on the type of carbohydrate side chain (biantennary or triantennary). This results in a typical microheterogeneity on isoelectric focusing in which the various protein types have pIs of 4.42–4.67, with the two major bands being at 4.48 and 4.55 [11].

The reactive site of α1AT involves Met and Ser residues at positions 358 and 359, respectively. These two residues are widely separated in the relaxed molecule, which has been crystallized. In the native inhibitor, these residues are adjacent on an exposed loop of approximately 16 residues [1]. This exposed loop then becomes the site for forming a tightly bound one-to-one complex with a target proteinase, particularly neutrophil elastase. This is a common mechanism for serine proteinase inhibitors [12]. The methionine residue, important for functional activity [13], is apparently also crucial for specificity because substitution of Met 358 by Arg in the genetic variant called PI Pittsburgh causes loss of inhibition of elastase. Arginine is present at the identical position in antithrombin III, and this mutant α1AT protein is active as an inhibitor of thrombin [14].

The exposed position of the reactive methionine residue readily allows its oxidation to methionine sulfoxide, which will no longer accommodate the physical complexing between elastase and α1AT [14]. This inactivation of methionine by oxidation could be harmful in individuals already deficient in α1AT but has been proposed to be advantageous in situations of tissue inflammation, where local tissue breakdown would be enhanced [1].

Location and Organization of the Gene

The gene encoding α1AT (commonly known as *PI* for proteinase inhibitor, now officially *SERPINA1*) is 10.2 kb in length and contains four introns [15]. Control of expression and cell specificity requires the region 700 base pairs 5′ upstream of the transcription start site [16], and the specific proteins that bind to this region have been identified [17]. Although the most abundant expression of α1AT occurs in the liver, the gene is also expressed in monocytes [18]. An additional transcription start site 5′ to the hepatocyte initiation site controls expression in macrophages and monocytes [19]. Studies of α1AT in transgenic mice have demonstrated its expression in thymus, chondrocytes, lymphoid tissue of the small intestine, gastric and small intestinal crypt epithelial cells, renal distal tubule brush border, and the lining of pulmonary alveoli [20,21]. The macrophage-specific promoter, and consequently macrophage expression, are reported to be absent in the mouse [22].

The *PI* gene is located in the distal region of chromosome 14 at 14q32.1 and lies within a cluster of homologous genes with some sequence and structural similarities. Members of this cluster, which are involved in blood coagulation, inflammation, and blood pressure control, include corticosteroid-binding globulin (*CBG*), α_1-antichymotrypsin (*AACT*), blood coagulation factor C1 inhibitor (*PCI*), and kallistatin (*PI4*), all of which map within a region of about 300 kb [23–25] (Fig. 1). A *PI*-related gene for which the functional status is not known, designated *PIL* (for PI-like), lies adjacent to *PI* [26]. The close physical proximity of these related genes could have clinical significance. The disease associations ascribed to variants of α1AT could be due to effects of proteins encoded by neighboring genes.

Function of α_1-Antitrypsin

α1AT shows a broad substrate specificity for serum proteinases. The inhibition of pancreatic trypsin, which was the first substrate identified [27], is not considered to be physiologically important. Other serine proteinases inhibited include pancreatic and neutrophil elastase, neutrophil cathepsin G, pancreatic chymotrypsin, collagenase from skin and synovium, acrosin, kallikrein, urokinase, and renin [12]. Proteases within the clotting and fibrinolytic systems (plasmin, thrombin, factor XI, and Hageman factor cofactor) are also inhibited. However, some of these inhibitory activities may be *in vitro* phenomena only. The activity of physiological importance lies in the inhibition of neutrophil elastase. α1AT provides approximately 90% of the antielastase activity in plasma. It gains access to the lower respiratory tract more readily than does α_2-macroglobulin, the other major inhibitor of elastase, although the latter is produced by lung fibroblasts [28]. Inhibition of the clotting cascade does not seem to be of major physiological significance, probably because of other more effective inhibitors.

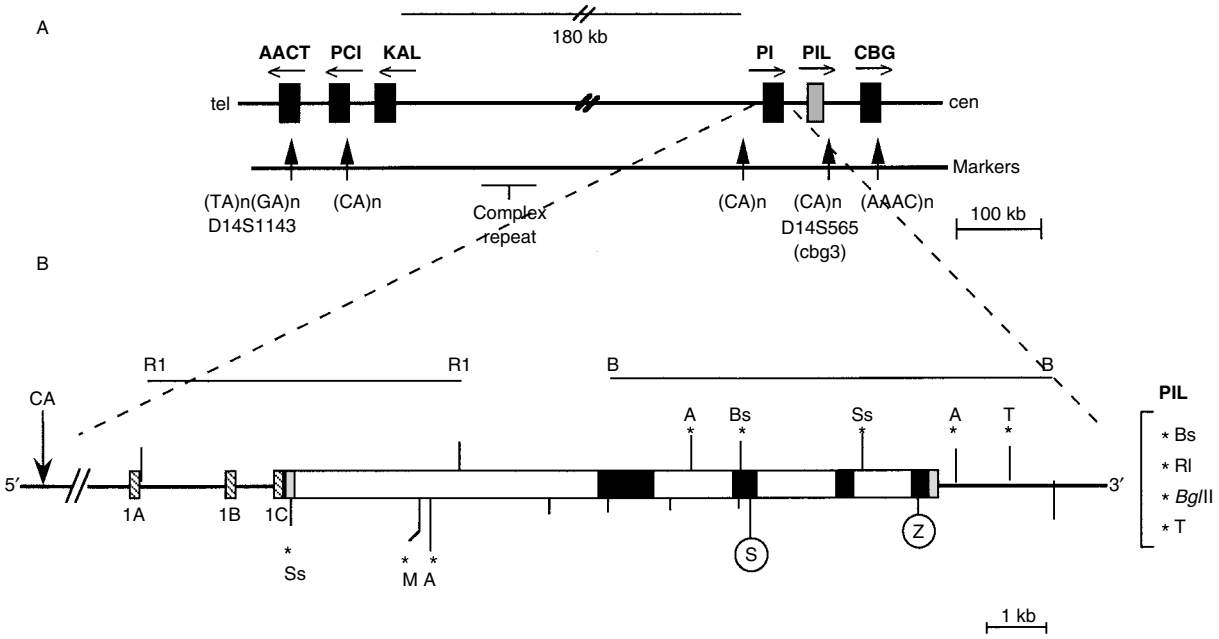

Figure 1. A. Cluster of PI and other loci in the serpin superfamily cluster on chromosome 14, as determined by pulsed field gel electrophoresis [23–25]. AACT: α_1-antichymotrypsin (*SERPINA3*); PCI: protein C inhibitor (*SERPINA5*); KAL: kallistatin (*SERPINA4*); PI: α_1-antitrypsin (*SERPINA1*); PIL: PI-1 like (*SERPINA2*); CBG: corticosteroid-binding globulin (*SERPINA6*). New names, in parentheses, have been assigned by the HUGO Nomenclature Committee. **B**. α1AT gene and flanking regions. Coding regions are solid, introns open, untranslated dotted rectangles. Cross-hatched regions are exons of macrophage DNA. Asterisks indicate sites of polymorphisms (SNPs) identified with the following restriction enzymes (those in square brackets at the right indicate polymorphisms in the PIL locus): A — *Ava*II; B — *Bam*H1; Bs — *Bst*II; T — *Taq*I; RI — *Eco*RI; Ss — *Sst* sites [46]; S and Z circled — sites of mutations in PI*S and PI*Z, respectively. Positions of CA repeats are indicated by arrows in A and B.

GENETIC VARIATION

Many variants of α1AT (PI, or proteinase inhibitor, types; MIM 107400) have been identified by electrophoretic methods. These variants were initially identified by the acid starch gel electrophoresis method developed by Fagerhol [29]. Variants were named according to their relative mobilities in the acid starch gel system: F (fast), M (medium), S (slow), and Z (the most cathodal). Several variants, including the Z deficiency variant, were also recognized by agarose electrophoresis [30]. In most populations, about 90% of the alleles are of the M type. Over 70 alleles, most of them rare, have been described [31–33]; 40 are listed under MIM 107400 [34]. These variants are now identified by their position in polyacrylamide isoelectric focusing (PIEF) gels. Their names have been designated by letters of the alphabet, from the most anodal (presently B) to the most cathodal (Z) in position on the PIEF gel, in addition to a place name designation [32]. PI types are designated MZ, MS, and so forth; alleles are designated *PI*M*, *PI*null*, and so on. PIEF [35] is the most commonly used method for identification of genetic variants, and many modifications have been developed. Names can be replaced by specific sequence designations as sequences of the variants become available.

Normal Variants

Most of the PI variants are associated with a normal concentration of α1AT. The normal mean concentration is 1.32 g/L [36]. PI MM individuals usually have plasma concentrations of 80–120% of this mean. There are several common subtypes of the normal M variant: M1, M2, M3, and others. Typically, the M1 subvariant is most common, at a frequency of about 0.70, then M2 at about 0.15, and M3 at about 0.12. Frequencies are similar in all of the major racial groups [37]. Although there are isolated reports of possible disease association with various M subtypes, these may represent sporadic findings because all of the normal subtypes seem to have a normal concentration and inhibitor activity [38]. Normal variants with a somewhat reduced concentration of α1AT are PI I and PI S, both of which are associated with about 60% of the normal concentration of α1AT [39,40]. These two variants can be considered normal because their presence in the heterozygous state, or even in combination with Z, does not appear to result in a significantly increased risk of disease.

The rare PI P variant, which has also been called Plowell [41,42], is associated with a plasma concentration of α1AT of about 30% of normal [43]. This variant is on the borderline for classification as a deficiency variant because it appears to lead to increased risk of emphysema when combined with the Z allele [42]. There are a number of variants that show a position similar to PI P on IEF that are not deficiency alleles [32,42].

All of these variants are inherited in a codominant manner in that the products of each allele can be visualized on PIEF. This is in contrast to the deficiency state, which is inherited in a recessive manner.

Deficiency Variants

The deficiency alleles can be considered as those associated with less than about 30% of the normal concentration of

α1AT, a concentration at which disease risk is increased. By far the most common deficiency allele, usually representing about 95% of all deficiency alleles, is *PI*Z*. Individuals of PI type ZZ generally have only about 18% of the normal concentration of α1AT. Interestingly, this variant is found in northern European populations and not in blacks or Asians, except through racial admixture [37]. A feature of the Z allele is that it is associated with the formation of liver inclusions due to storage of the abnormal α1AT in dilated endoplasmic reticulum [44].

A number of other rare deficiency alleles make up the remaining 5% of all deficiency alleles in white populations. The mean plasma concentration of α1AT associated with these other rare variants ranges from 0 to about 15% of normal [45]. In addition to the Z variant, there are at least eight rare deficiency variants that produce some measurable product and at least 12 variants for which no product can be detected in plasma. The null (Q0) alleles, by definition, are associated with no detectable α1AT in plasma and are therefore at one end of the spectrum of deficiency alleles. The frequency of all of the null alleles combined was estimated to be 1.4×10^{-4} in a white North American population [45], and the individual Q0 alleles are even more rare. The rare deficiency mutations and their characteristics have been summarized [45,46]. A number of these mutations have been identified by DNA sequencing and indicate various causes for the plasma deficiency. Mmalton [47] and Mnichinan [48] variants produce about 15% of the normal concentration of plasma α1AT, similar to that occurring with the *Z* allele. Both of these have a deletion of the phenylalanine residue at position 52, which results in accumulation of α1AT in inclusions as for the Z gene product. Most of the null variants have base changes that result in a premature stop codon, resulting in intracellular degradation of the abnormal product as observed with one of the more common null alleles, Q0bellingham [49]. Study of the specific mutations involved provides information on factors required for both protein secretion and stability.

The recognition of null alleles has practical significance because null homozygotes seem to have an increased risk of emphysema even in comparison with PI ZZ homozygotes [50]. These affected individuals may be the most likely to benefit from replacement therapy.

DNA Polymorphisms

In addition to the protein variants, both normal and deficiency, found by electrophoretic methods, further variation has been identified in the DNA sequence within and surrounding the α1AT gene. A number of DNA restriction fragment length polymorphisms (RFLPs) have been used to show that the *PI*Z* allele arose about 5,000 years ago, after the divergence of the major racial groups, and has spread extensively through northern European populations [51]. RFLPs have also been used to identify the evolutionary pathway of normal variants [46,52]. Because of extensive linkage disequilibrium throughout the region, the combination of markers, or haplotype, is usually specific for each of the rare deficiency variants and has been used to guide their identification [45]. A polymorphism at a *Taq*I restriction site 3′ of the α1AT gene is suggested to lie in an enhancer region, resulting in an impaired interleukin (IL)-6 acute phase response, thus predisposing to lung disease [53]. All of these RFLPs belong to a subset of SNPs (single-nucleotide polymorphisms) that can be converted for detection using the polymerase chain reaction (PCR).

Highly polymorphic dinucleotide (CA) repeats have been identified close to the PI α_1-antichymotrypsin (AACT) and C1 inhibitor (PCI) loci [24]. Other variants in the serine proteinase cluster are included in marker and SNP databases.

DIAGNOSTIC METHODS

Plasma Concentration of α_1-Antitrypsin

The plasma concentration of α1AT can be measured by immunological or functional methods. Detailed protocols and appropriate references are available [54]. Immunological assays are usually preferred in clinical laboratories, where automated nephelometry is used for the measurement of a variety of proteins. The results of immunological assays can vary considerably between laboratories because of the use of different standards. Many of the commercially available standards have an abnormally high normal range (1.5–3.0 g/L). For this reason, laboratories may express normal values as a percentage of a normal pool, which is established as 100%. A standard from the American Pathological Association can be purchased commercially. This standard has been calibrated against a highly purified preparation of α1AT, which indicates that the normal mean is 1.32 g/L [36].

Functional assays can also be used and usually correlate well with immunological results. However, the inhibitor activity in plasma also includes that due to α_2-macroglobulin. Results can be misleading, particularly in testing children, in whom the α_2-macroglobulin plasma concentration is elevated. As a result, these assays tend to be used only for special investigations. The functional assays evaluate the inhibition of trypsin or elastase using synthetic substrates.

Most of the quantitative variation between individuals is accounted for by PI type [55]. Normal ranges of PI types commonly found in the population and for selected deficiency types, measured immunologically, are shown in Table 1, expressed both as a percentage of a normal pool and as g/L [40,56]. Expressed on a molar basis, the normal mean is 25μM. The measurement of plasma α1AT is the appropriate first test for the diagnosis of deficiency. Any values below 50% of the normal mean require PI typing for verification of genetic status. A low level of α1AT can also occur for nongenetic reasons such as in respiratory distress syndrome in newborns, conditions of severe protein loss, terminal liver failure, and during the course of cystic fibrosis. The plasma concentration of α1AT associated with PI type ZZ is about 18% of normal (range 9–27%) [45,57]. However, in infants and children with liver disease, the concentration of α1AT is frequently elevated to as much as 40% of normal [58].

TABLE 1. Plasma Concentrations of α_1-Antitrypsin Associated with Various PI Types

	α1AT Concentration		Increased Disease Risk	
PI Type	Mean ± SD (% normal)	Mean (mg/dL)	Lung	Liver
MM	100 ± 23	1.32	no	no
MS	86 ± 20	1.12	no	no
MZ	65 ± 15	0.84	no	no
SZ	45 ± 11	0.58	slight	no
ZZ	18 ± 5	0.23	yes	yes
Q0Q0(null)	<1	<0.01	yes	?

Values are from [40] and [56].

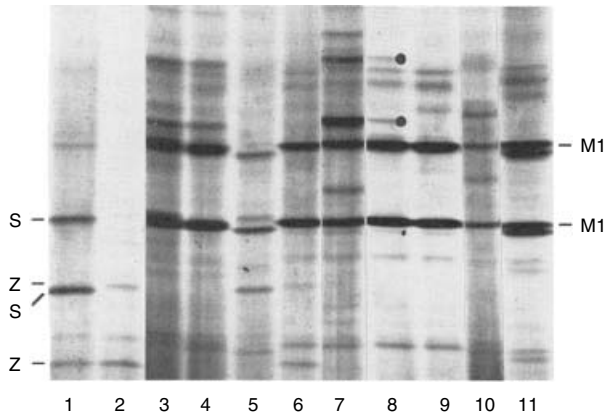

Figure 2. PI types determined by isoelectric focusing, in polyacrylamide gel, pH 4.2–4.9. Lane 1—SZ; 2—ZZ; 3—M1M3 (aged sample, not reduced); 4—M1M3—sample as for 3 but cysteine reduced; 5—M2S; 6—M1Z; 7—IM1; 8—M1 (on penicillamine treatment); 9—M1; 10—FM1; 11—M1M2. The two major bands are indicated for M1, S, and Z. Dots indicate extra bands sometimes observed in patients treated with penicillamine. The anode is at the top.

Measurement of plasma α1AT is not always reliable for the identification of heterozygotes. α1AT is an acute-phase protein that can show a marked increase (up to fourfold) in a wide range of inflammatory conditions, cancer, and liver disease. Pregnancy and estrogen therapy also produce modest increases.

Determination of PI Type

Isoelectric focusing (PIEF) provides confirmation of genetic α1AT deficiency (Fig. 2). Different carbohydrate side chains result in a multibanded pattern. This method identifies a large number of variants; however, most are not clinically significant. The concentration of α1AT below which samples are tested by PIEF will depend on the particular purpose of the test. In general, all samples with a concentration of less than 50% of normal should be further tested by PIEF. This is likely to detect both adults and children of PI type ZZ. If one wishes to detect every PI MZ heterozygote, then all samples must be PI typed. α1AT, as an acute-phase reactant, can easily be elevated into the normal range in PI MZ individuals. In rheumatoid arthritis, the concentration of α1AT in PI MZ individuals was found to be $148 \pm 46\%$ of normal, with some values threefold the normal mean [59]. Agarose electrophoresis, IEF in agarose, or PIEF are all suitable for confirmation of a deficiency state, with the best resolution obtained with an ultrathin PIEF gel and a narrow pH range (pH 4.2 to 4.9) [35]. Commercially available narrow pH gradients, for example 4.2 to 4.9, are typically used with ultrathin PIEF gels to obtain excellent resolution [60]. Similar resolution is also obtained with immobilized pH gradients [61]. Immunofixation following PIEF is appropriate to identify rare variants of α1AT [35].

Occasionally, variants detected by isoelectric focusing are not due to genetic variation. These include a band cathodal to PI Z, which is sometimes seen in liver disease, absent bands due to bacterial degradation, additional bands in aged samples, which can be removed by reduction with an agent such as cysteine, or binding to other proteins or to thiol compounds. Patients on penicillamine therapy show an additional anodal band, which could be interpreted as one of the anodal variants such as F (see Fig. 2). In addition to this anodal band, a cathodal component has also been seen in such patients [62].

Recombinant DNA Methods

Identification of Variants

DNA methods are used in some laboratories in place of PI typing by isoelectric focusing. The appropriate region of exon 5 in the α1AT gene can be amplified using PCR and the Z mutation tested using labeled oligonucleotide probes [63,64]. Another approach is to use a primer with a nucleotide substitution to create a *Taq*I site in the normal allele but not in the Z allele [65,66]. A similar approach has been developed for detection of the S mutation [66]. A disadvantage of this molecular approach is the potential for misclassification. Using specific tests for PI S and Z, the rare deficiency alleles would all provide a "normal" test result. A deficient individual could be classified as PI type MM, particularly if the concentration in the plasma were not taken into consideration. The isoelectric focusing method of PI typing is therefore preferable because a large number of variants can be identified and a deficient allele will not be misclassified. Furthermore, serum is generally a more simple source for testing than DNA, and the procedure is more economical. Rapid methods for mutation detection may make DNA methods more reliable, although probably more expensive, in the future.

Prenatal Diagnosis by DNA Analysis

The molecular approach is preferred for prenatal diagnosis. PCR requires very small quantities of DNA, so that amniotic cells or chorionic villus samples can be assayed conveniently. As with any prenatal diagnosis involving PCR, caution must be taken to avoid maternal contamination. The family must be studied before prenatal diagnosis to identify whether Z or a rare deficiency allele is present. If the mutant allele is known, appropriate specific identification can then be made.

Liver Inclusions

Intracytoplasmic inclusions were one of the first characteristic features to be described in α1AT deficiency [8]. α1AT inclusions are easily visualized as bright pink globules of various sizes, observed with periodic acid-Schiff (PAS) stain following diastase treatment (PAS-D) [8] (Fig. 3). In infants with α1AT deficiency, inclusions may be fine and granular and difficult to visualize. Large inclusions stain brick red with Masson trichrome stain and dark purple with phosphotungstic acid-hematoxylin (PTAH) stain [67]. Although the presence of typical liver inclusions is not the usual way to establish a diagnosis, such inclusions are sometimes discovered in liver biopsies when α1AT deficiency has not been suspected. For null alleles and some of the other rare deficiency alleles, no inclusions are observed in the liver.

It is important to note that these inclusions are present in individuals who carry only one Z allele (e.g., PI MZ). In individuals heterozygous for α1AT deficiency, numerous and large inclusions may be observed in association with liver disease or other inflammatory conditions. The presence of inclusions in periportal granules in patients with chronic liver disease is almost always due to the presence of Z α1AT or other deficiency types of polymerizing protein such as Mmalton. This is not the case in end-stage liver disease or in nonhepatic cancer, in which tumor necrosis factor can stimulate production of α1AT, leading to inclusion formation [68]. Typical inclusions can be observed in any

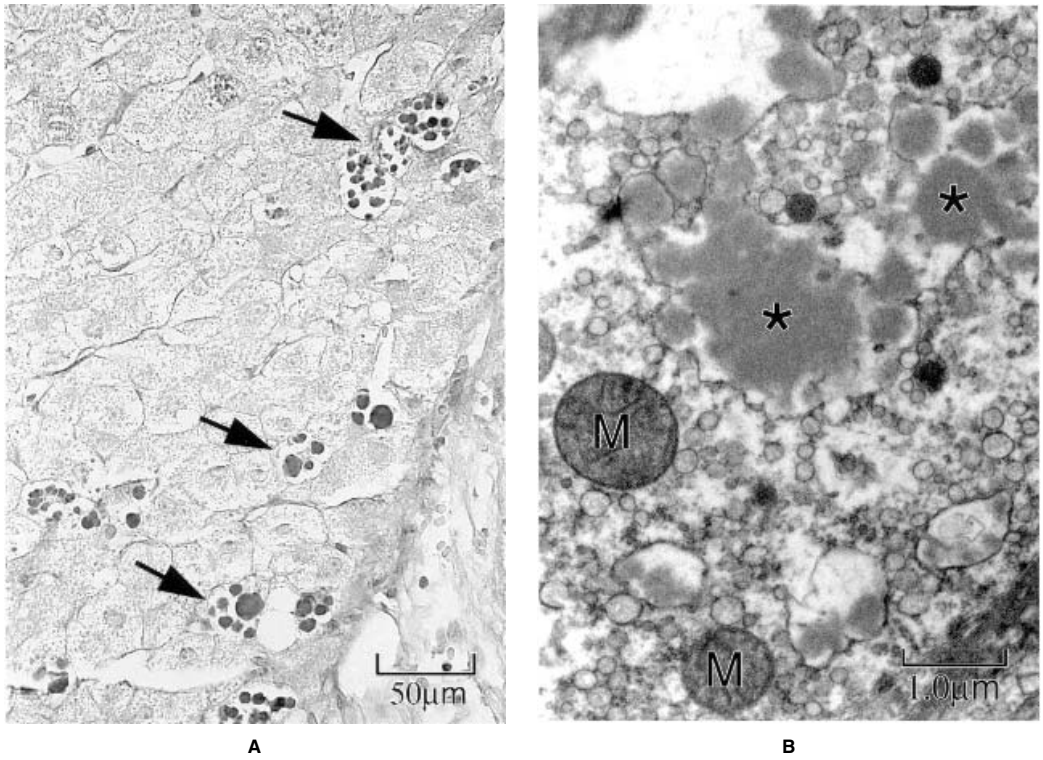

Figure 3. Hepatocyte inclusions seen in α1AT deficiency, PI type ZZ. The mutant Z protein self-aggregates, forming inclusions in the endoplasmic reticulum. **A**. Inclusions (arrows) seen with PAS-diastase stain. **B**. *—inclusion within the dilated cisternae of endoplasmic reticulum, M—mitochondria, as seen by electron microscopy. (Photographs kindly provided by Dr. Laurence D. Jewell, University of Alberta.)

severe systemic disease in which the rate of α1AT synthesis exceeds the capacity of processing enzymes involved in secretion [69,70].

CLINICAL FEATURES AND PROGNOSIS

Obstructive Lung Disease

The major disease risk associated with α1AT deficiency is chronic obstructive pulmonary disease (COPD), specifically emphysema. The incidence of COPD in males is at least twice as high as in females [71], which may be related to smoking exposure. The early observation from Sweden [4] associating α1AT deficiency with early onset of symptoms of COPD has been confirmed in many studies. However, those early studies suggested that 60% of individuals developed COPD before 40 years of age and 90% below 50 years of age. These and subsequent studies have all been plagued by the problem of biased ascertainment because patients are generally ascertained through clinical illness. Although we are now aware that nonsmokers with α1AT deficiency have a much better prognosis, we still do not know the true risks of developing clinically significant disease.

In emphysema associated with α1AT deficiency, the lower portions of the lungs are more severely involved. In patients with well-established emphysema, thoracic x-rays show a symmetric decrease in peripheral vasculature, particularly in the lower lungs [72]. As in emphysema due to other causes, changes in lung mechanics are noted, with reduction in lung volumes and expiratory flow rates. The decreased expiratory flow is due to loss of elastic recoil, which in turn is due to destruction of the elastin fibers. The most sensitive parameters for detecting abnormalities in α1AT-deficient patients with no clinical symptoms are reported to be closing volume, nitrogen washout volume, and lung mechanics, as for other types of emphysema. Evidence suggests that CT scans may be particularly sensitive for detecting changes [73].

The age of onset and severity of disease are highly variable, probably due in part to both genetic and environmental factors. Nonsmokers can maintain normal lung function to at least 30 years of age [50], and the course of the lung destruction is generally long and slow. In a large Swedish study of 246 adult nonsmokers with the deficiency, the age of onset of dyspnea was 53 years in males and 54 years in females, with symptoms rarely occurring before 43 years of age [74].

Effect of Smoking

Smoking is the most important known factor in determining the rate of deterioration of lung function and the ultimate prognosis. In the Swedish study quoted previously [74], the age of onset of dyspnea for male smokers was 40 years and for female smokers 39 years. In the majority, symptoms were rarely observed before 29 years of age. Lung function deteriorates continually as the elastin matrix of alveolar walls is destroyed. In a study of 65 PI ZZ Danish patients (60% of whom were identified because of symptoms), the age at which 50% of FEV_1 (forced expiratory volume in 1 second) predicted for age and height was reached was 17 years greater in those who had never smoked than in smokers [75]. A large proportion of individuals with α1AT deficiency may never come to medical attention because of mildness or absence of symptoms. Data from the α1AT

Registry in the U.S. show a mean decline of 57.5 mL per year in FEV_1 among 208 nonsmokers, 52.0 mL per year in 697 ex-smokers, and 104.8 mL per year in 22 current smokers [76]. Males showed a greater decline than females. Initiation of smoking during adolescence is likely to be particularly detrimental because attainment of maximal lung function is prevented even in normal individuals [77].

Although true survival figures are difficult to obtain, again because of biased ascertainment, the most extensive data are available from the Swedish study, as summarized in Figure 4. At 55 years of age, the survival rates for patients with α1AT deficiency were found to be 83% for nonsmokers and 22% for smokers [74].

A study of 52 patients with α1AT deficiency, about half ascertained through family studies rather than through the presence of COPD, indicates that the risk of developing COPD has been overestimated because of study biases [78]. Of those deficient patients not ascertained through COPD and between 30 and 60 years of age, only one-third, almost all of them smokers, had developed COPD. In addition to the pronounced effect of cigarette smoking on lung function, the possibility was raised that the presence of emphysema in a parent, or the presence of asthma, might also increase the risk of individuals with α1AT deficiency developing COPD.

Risk of Lung Disease in Heterozygotes

Knowledge of the potential risk of developing COPD is important because of the high incidence, about 2–5%, of heterozygotes in most populations. Early studies, which have been reviewed [56], reached varying conclusions. There appear to be no significant differences in lung function between PI MZ and MM nonsmokers [79]. However, PI MZ smokers show a decrease in lung function parameters, which reflects a loss of elastic recoil [79,80]. Over a six-year period, MZ smokers showed a significantly increased mean annual reduction in FEV_1 of 75 mL/year in comparison with 40 mL/year for nonsmoking MZ individuals [81]. This suggests, in comparison with data presented above, that the loss in elastic recoil for an MZ smoker is similar to that of a PI ZZ nonsmoker.

Liver Disease

Childhood Onset

The first report of liver disease in infants and children with α1AT deficiency suggested that a poor prognosis was typical [8]. Based on a follow-up study of 120 PI ZZ children ascertained from the screening of 200,000 Swedish newborns [82], we now have a more accurate concept of the prognosis. Although approximately 17% of PI ZZ children developed clinically recognized liver abnormalities, of which more than half were prolonged jaundice, a follow-up of these infants up to 12 years of age indicated that only 2.4% of the PI ZZ infants developed liver cirrhosis with early death, corresponding to 13.6% of those with clinically obvious liver abnormalities in infancy [82].

In infants, the most common sign of liver abnormality associated with α1AT deficiency is jaundice, with increased conjugated bilirubinemia and raised serum aminotransferase levels in the early days and months of life. α1AT deficiency is a common cause of the "neonatal hepatitis syndrome". In infants presenting with hyperbilirubinemia, histopathological features include intrahepatic cholestasis, varying degrees of hepatocellular injury, and moderate fibrosis with inflammatory cells in portal areas [67]. The reason for the continued liver destruction leading to cirrhosis in a small proportion of children with early hyperbilirubinemia is not known. While the serum level of liver enzymes (alanine aminotransferase and glutamyl transpeptidase) tends to remain somewhat elevated in a large percentage of PI ZZ children, persistent elevation at greater than three times the normal upper limit tends to be associated with a poor prognosis [83,84].

The typical PAS-D positive inclusions may be scarce in young infants and show no correlation with the severity of the liver disease. Confirmation of the deposits as α1AT can be made by immunofluorescence microscopy, which usually shows the presence of stored material in asymptomatic children when very little can be observed by PAS-D staining. Although the presence of these typical inclusion bodies is a diagnostic feature, the diagnosis is made more easily and reliably by PI typing of a serum sample.

The overall risk of an individual of PI type Z developing severe liver disease in childhood, although generally low (about 2%), is higher among sibs of PI ZZ children with liver disease. The frequency of recurrence of severe liver disease in a subsequent sib varies considerably among studies. However, the overall conclusion from all studies indicates a risk dependent on the severity of liver disease in the index patient. When liver abnormalities are mild and resolve, the risk of liver disease in a subsequent PI ZZ sib seems to be about 13%. When liver disease is severe in the index patient, the risk in subsequent PI ZZ sibs may be about 40% [85].

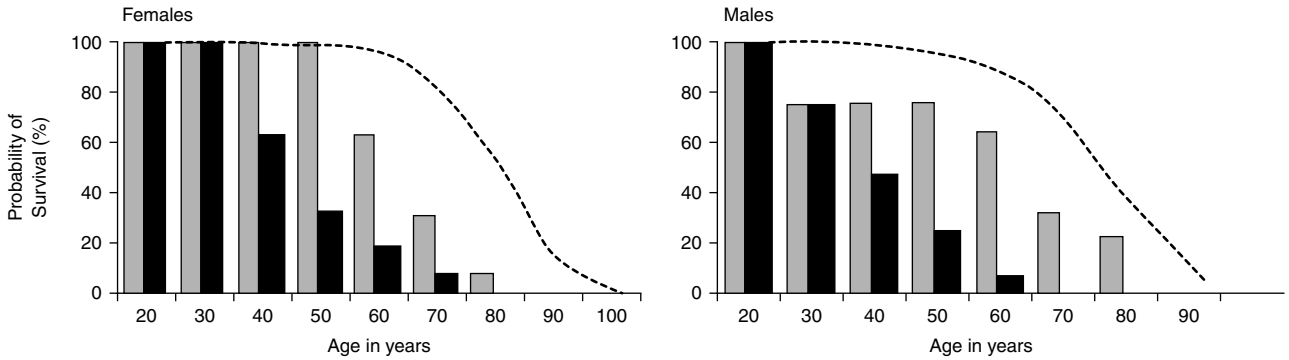

Figure 4. Survival curves for 141 males and 105 females with α1AT deficiency compared with the normal population. Dotted line indicates survival curve (percentage surviving at each age shown in years) for normal males and females in the Swedish population. Stippled bars, nonsmokers; solid bars, smokers, Based on data from [74].

Adult Onset

Soon after the discovery of the association of α1AT deficiency with lung disease, an association with hepatic cirrhosis and fibrosis was documented in Swedish adults [86]. Liver disease in adults does not seem to be associated with a history of neonatal hepatitis. The incidence of liver disease apparently increases with age and is higher in males. Among PI ZZ individuals over 50 years of age, 15–19% develop cirrhosis [74,87]. The risk of liver disease at 20–40 years of age has been reported to be about 2% and at 41–50 years of age about 4% [87]. Destruction of the liver is exceedingly rapid when onset occurs in adults. Risk of the development of hepatocellular carcinoma (hepatoma) has been reported for males [88], but an excess of patients with α1AT deficiency has not been found among hepatoma patients [89].

PI MZ and SZ Heterozygotes

The risk of liver disease in individuals heterozygous for α1AT deficiency seems to be low. There could be a slightly increased risk for PI SZ adults and for PI MZ individuals because two or three times the normal frequency of MZ individuals has been found in patients with liver disease [90]. There is unlikely to be a significantly increased risk of liver disease in PI SZ children beyond that expected by chance. At least some cases reported in the literature have been due to a mistyping of PI ZZ as PI SZ. The strongest support for the lack of association with liver disease comes from the Swedish newborn screening program [83].

Rheumatoid Arthritis

Reduced plasma α1AT probably contributes to the progression rather than the initiation of rheumatoid arthritis. Of 246 Swedish patients with α1AT deficiency, 4.4% had rheumatoid arthritis, and a further 3% had considerable joint pain [74]. While there could be an increased tendency toward rheumatoid arthritis in homozygotes, most studies have focused on heterozygotes.

An increased prevalence of PI MZ among adult patients with rheumatoid arthritis was first observed in 1976, when a prevalence rate of 9% was found in 55 patients studied [91]. When the size of this patient group was increased, 9.3% were Z heterozygotes (PI MZ and SZ) among patients with classical rheumatoid arthritis who had joint erosions radiologically [59]. Among female patients with onset of arthritis before to 42 years of age, 8 of 46 (17.4%) were Z heterozygotes. Possibly the increased prevalence of Z heterozygosity is associated with more severe disease because nine out of ten Z heterozygotes had stage 3 or 4 rheumatoid arthritis [59]. In patients with both rheumatoid arthritis and pulmonary disease, no increased frequency of Z heterozygotes has been observed [92,93]. Such studies could be biased, however; for example, in the latter study, patients were required to be sufficiently ambulatory to be able to volunteer to take part in extensive tests of pulmonary function.

There have now been at least 14 studies carried out on the frequency of PI types associated with rheumatoid arthritis in several countries, including Canada, Sweden, Switzerland, the U.K., and the U.S. An increased prevalence of Z heterozygotes has been observed in some studies [94–96] but not in others [97,98]. Possibly the differences between these studies represent differences in the patient populations. In summary, it seems that no association with Z heterozygotes is found when patients are drawn from a general arthritis clinic population, whereas an increase of three to four times that found in the normal population is found when patients are selected for erosive rheumatoid arthritis. This is demonstrated, for example, in Swedish studies, where the heterozygote frequency was found not to be increased in random patients from a clinic [97], while in a study of 200 patients with erosive rheumatoid arthritis, 6.1% were found to be Z heterozygotes versus 2.1% in controls [95]. We can conclude that Z heterozygosity does not necessarily predispose to initiation of rheumatoid arthritis. However, although the risk to Z heterozygotes is relatively low, at least some of these individuals may undergo particularly extensive joint destruction.

In one study, an increased frequency of the rare F variant α1AT in FM heterozygotes was reported [98]: a prevalence of 2.1% compared with about 0.4% in the control population. This association has not been noted in most other studies, except that by Beckman et al. [95]. The second cysteine residue, resulting from the mutation in the F variant [99], could in some way impair inhibitor activity in the inflamed joint tissue. These cases may have been mistaken as having the unusual IEF pattern observed in patients treated on penicillamine [62], which is frequently administered to patients with rheumatoid arthritis.

In Canadian children with juvenile rheumatoid arthritis, a numerical but nonsignificant increase in Z heterozygotes was found [59]. More severely affected British children showed a significant increase of PI type MZ to 10.4% versus 1.6% in a control population [100].

There is reason to assume that a reduced amount of α1AT might be more conducive to severe degradation of the joint. α1AT is a potent inhibitor of elastase and other proteolytic enzymes released by neutrophils, which would occur particularly at the site of inflamed joints. Therefore, although not initiating the rheumatoid process, a reduced concentration of α1AT, as in MZ heterozygotes, could contribute to increased destruction of the proteoglycans, collagen, and other connective tissue components in the joints. This hypothesis is discussed further in the section on disease mechanisms.

Vascular Disease

Data from several studies suggest that α1AT may play an important role in the protection of blood vessels. Various disorders affecting arterial integrity have been described [101]. In a study of 47 patients with infrarenal abdominal aortic aneurysms, five (11%) were of PI type MZ phenotype, where about 2% would have been expected [102]. A male patient with emphysema and deficiency (PI ZZ) was reported to have a ruptured colic artery aneurysm and multiple other small aneurysms of a middle colic artery [103]. An increase in intracranial aneurysms has also been suggested. In an examination of the medical records of 362 patients with α1AT deficiency, including both PI MZ and homozygous (PI ZZ) deficiency, a ruptured intracranial aneurysm was found in one PI ZZ patient and two Z heterozygotes [104]. An additional PI MZ heterozygote had spontaneous dissection of the cervical internal carotid artery. In a study of a larger series of patients with intracranial aneurysms, 6,696 patients had a post-mortem examination, and six were recorded as having α1AT deficiency (four PI ZZ, one PI MZ, and one not PI typed), although it appears that PI typing was carried out on only a small proportion of the patients [105]. Interestingly, arterial fibromuscular dysplasia was found in two of the six patients, both with the PI ZZ phenotype and hepatic or pulmonary failure. Fibromuscular dysplasia is reported in about 12% of patients with spontaneous cervical artery dissection and

up to 20% of those with ruptured intracranial aneurysms. Two of three women with bilateral internal carotid artery stenosis due to fibromuscular dysplasia were found to be of PI type MZ [106]. Fibromuscular dysplasia involving a cerebral artery was found in a PI ZZ child with decreased antioxidant status [107], and this observation may indicate an underlying tendency to arteriopathy later in life in PI ZZ individuals. The stiffness of the abdominal aorta in 19 men with α1AT deficiency was reduced in comparison with normal controls; however, no difference was found for 17 women in the study [108]. These observations provide additional evidence for an effect on the connective tissue of blood vessels.

Both plasma α1AT and plasma α_1-antichymotrypsin (a cathepsin G inhibitor) are bound to the surface of endothelium [109]. Neutrophils release proteinases, such as elastase and cathepsin G, to the endothelium at the time of an occlusion. Therefore, it might be predicted that if the concentrations of inhibitors were inadequate, tissue damage could result. The arterial weakening and fibromuscular dysplasia may represent a response to damage of the vascular endothelial matrix due to inadequate inhibition of proteinases. A history of smoking may be especially important because of the impaired function of α1AT that occurs as a consequence of oxidation of the critical methionine residue. More studies are needed to document the extent of vascular defects and also the potential preventative role of antioxidants.

Kidney Disease

Membranoproliferative glomerulonephritis (MPGN) has been identified in PI ZZ children who also have liver disease [58,110]. The kidney abnormality may be a consequence of the liver disease. Nephropathy was observed in 79% of 19 patients of PI type ZZ who had chronic liver disease [111]. However, among 246 Swedish PI ZZ patients, only 15% showed signs of renal glomerular damage, manifested by proteinurea or hematuria [74]. Some of these may have been mild and not have advanced to MPGN. In two-thirds of those affected, there was no coexisting liver cirrhosis. The abnormal Z α1AT probably plays a role in the formation of the immune complex in the kidney. Concentration of Z α1AT at the glomerular membrane could lead to its polymerization, with subsequent formation of antibody to the foreign aggregate. A role for Z α1AT is supported by the report of one patient with liver disease whose MPGN was cured following liver transplantation [112]. A PI ZZ adult with IgA glomerulonephritis and hypertension as well as cirrhosis was reported to have sudden deterioration of renal function [113]. Immune complex deposition may play some, but not necessarily the only, role in producing symptoms of kidney damage. α1AT deficiency is apparently not a frequent cause of MPGN. In one study of 53 patients with idiopathic MPGN, none were homozygous or heterozygous for PI Z [110].

Other Diseases with an Inflammatory or Immune Component

There are reports of a number of other inflammatory conditions associated with α1AT deficiency. Panniculitis is characterized by inflammation of the panniculus adiposus, the fat layer under the dermis. Although the risk of patients with α1AT deficiency developing panniculitis must be relatively small, there may be other predisposing factors in certain individuals to cause the disease. A number of cases have now been reported of severe ulcerative panniculitis associated with α1AT deficiency. Two of five patients with panniculitis were found to have α1AT deficiency [114]. In a survey of 96 patients with panniculitis, 15.6% were found to be α1AT-deficient, as defined by serum concentration [115]. Recognition of such patients is important for successful treatment. Administration of purified α1AT has been successful for the treatment of severe cases, and deoxycycline, a tetracycline that inhibits collagenase activity, has also been effective [116,117]. Histoplasmosis has been suggested as one of the triggering agents that might lead to panniculitis in individuals of PI type ZZ [118]. Further studies on this association are required.

Anterior uveitis, an immunologically mediated inflammatory eye disease, has been associated with an increased frequency of Z heterozygotes [119,120]. Two of 16 patients with posterior uveitis were of PI type MZ [121]. Corneal ulceration was observed in a PI ZZ child, who had markedly reduced α1AT in tears [122]. Testing of individuals with severe corneal ulceration might be productive and lead to improved therapy because α1AT is normally expressed in the cornea [122].

Other inflammatory conditions reported in association with α1AT deficiency are systemic necrotizing vasculitis [123] and persistent cutaneous vasculitis [124]. A fatal case of Wegener granulomatosis has been reported [125]. Panarteritis in association with emphysema and glomerulonephritis [126] and Hashimoto thyroiditis [127] has been reported in PI ZZ individuals.

PATHOLOGY AND DISEASE MECHANISMS

The Basic Defect

The Z deficiency allele is associated with typical inclusions in the liver and PAS-D globules within the endoplasmic reticulum, which show positive fluorescence with α1AT antibodies. These inclusions result from a defect in secretion of the abnormal Z α1AT. The protein within the liver inclusions has an abnormal carbohydrate composition, with a mannose-rich core, typical of incompletely processed glycoproteins. However, this incomplete processing is a secondary effect because impaired secretion also occurs when Z mRNA is injected into *Xenopus* oocytes [128]. The portion of Z α1AT that is secreted may have decreased specific elastase inhibitor capacity [129]. Z α1AT has a normal rate of synthesis [130] and a half-life of 5.2 days, identical to that of M α1AT [131].

The mutation in the Z protein is Glu342Lys [132,133]. Examination of the three-dimensional crystallographic structure indicates that this residue is involved in a salt bridge that is important for stabilization of the molecule and occurs at a sharp bend in the major β sheet [10]. A series of site-directed mutagenesis experiments, in which the salt bridge was altered and replaced, suggest that the salt bridge defect has only a modest effect on the stability of Z α1AT, and the lack of secretion seems to be due to a change to a positive charge at amino acid residue 342, resulting in an alteration in tertiary structure [17]. The Glu342 residue of M α1AT is located at a hinge region of the reactive center loop. This loop is mobile and can adopt varying configurations. With mild denaturation, the loop locks into a structural sheet (A sheet) within the protein, forming a thermostable inactive protein [134]. Under the same conditions, when the temperature is elevated to 37 °C, the reactive center loop inserts into the A sheet of a second molecule, a phenomenon that has been called loop-sheet polymerization [135]. Substitution of the hinge residue 342 in Z α1AT makes the molecule a receptor for a second Z molecule and results in dimerization and finally

aggregation of the protein [136]. The same type of self-aggregation, or polymerization, occurs spontaneously with the deficiency variant PI Mmalton, which has a deletion of residue 52, phenylalanine [137]. Like the Z type α1AT, Mmalton forms hepatic inclusions. Because polymerization is increased at higher temperatures, elevated body temperatures associated with inflammation could be predicted to enhance the formation of inclusions.

In addition to polymerization, inclusion formation by the abnormal protein could involve the abnormal binding or the lack of binding of proteins required for secretion. There is evidence that heat shock proteins, produced in cells under stress, could be involved (reviewed in [138]). Heat shock proteins have been shown both to bind to secretory proteins until the assembly of the proteins is complete [139] and to be induced by the presence of abnormal proteins [140]. Further, the synthesis of stress proteins has been shown to be increased in PI ZZ individuals with liver disease [141]. However, it is not clear whether such proteins induce damage or are innocuous bystanders involved only in degradation of the abnormal protein. There is variability among PI ZZ individuals in their tendency to develop liver disease. Some individuals may have an inherently different metabolism, increasing their susceptibility to liver damage. Studies have been carried out on cell fibroblasts from patients with and without liver disease and transfected with a mutant *PI Z* gene. In cell lines from patients with liver disease, protein degradation lags, suggesting an inadequate mechanism for degrading abnormally folded protein [17]. The liver injury probably results from a combination of a slow degradation pathway, inadequate antioxidant protection from the effects of absorbed uninhibited proteinases, subsequent damage to the cell membrane due to oxidant free radicals, further destruction of weakened cells by the presence of inclusions, and possibly autoimmune effects.

Pathogenesis of Lung Disease

Elastin, the major component of the tissue matrix of the lung, can be destroyed by neutrophil elastase. A reasonable explanation for the destruction of elastin tissue in α1AT deficiency has been supported by several types of data. The alveolar destruction leading to emphysema can be explained by an imbalance between proteolytic enzymes, particularly elastase, and their inhibitors. α1AT has been demonstrated to be the major inhibitor of elastase at the epithelial surface by studies of a homozygous null individual who had less than 15% of normal inhibitor capacity against neutrophil elastase in lavage fluid [142]. This suggests that other elastase inhibitors in lung tissue, such as low-molecular-weight proteinase inhibitor or α_2-macroglobulin, make only a minor contribution. α1AT enters lung tissue readily because of its small molecular size and can be recovered in lavage fluid. The plasma deficiency found in patients of PI type ZZ is also reflected in a low concentration in the lung alveoli, as reflected in bronchiolar lavage fluid [143]. A number of experimental studies have been carried out in animals that demonstrate that experimental emphysema can be produced by administration of porcine pancreatic elastase [144] and human neutrophil elastase [145,146]. The extensive studies that support this hypothesis and the role of neutrophils have been reviewed [147,148].

Effect of Smoking on Enhancement of Lung Destruction

The destructive effects of smoking on lung tissue are even more enhanced in individuals with α1AT deficiency. One of the major mechanisms of increased destruction seems to be the effect of oxidation. Methionine residue 358 of α1AT, when oxidized, is unable to complex with elastase. A direct effect of smoke can occur through the oxidizing agents found in the gas phase of tobacco smoke (reviewed in [147]). No consistently reproducible effect has been shown in studies examining the elastase inhibitor capacity in the serum of smokers and nonsmokers, which is not surprising in view of the generous supply of antioxidants in plasma. However, inactivation of α1AT has been noted in lavage fluid after smoking, and oxidized α1AT with a reduced inhibitor activity has been recovered from the lungs of smokers [149]. In addition to oxidation of α1AT, smoke triggers the release of elastase and also causes the release from neutrophils of myeloperoxidase, which inactivates α1AT [150]. Any excess elastase produces complexes with α1AT and cleaves the α1AT to an inactive form. A local imbalance between elastase and α1AT inhibitor will therefore lead to enhanced tissue destruction.

Pathogenesis of Liver Disease

One hypothesis for the liver disease associated with α1AT deficiency is that the α1AT accumulated in the endoplasmic reticulum of liver cells directly causes liver injury. Mouse models have provided equivocal results. In one study, transgenic hepatitis-free mouse lines containing multiple copies of human M or Z α1AT genes per mouse were established [151]. There were no differences between M and Z mice at five copies of gene per mouse genome. In a Z line with 12 copies, abundant material accumulated in the liver, resulting in areas of liver necrosis. However, this excessive overexpression of the Z allele does not represent the human situation in early neonatal life. In another study in which one, ten, and more than ten copies of the Z gene were present, inflammation and necrosis occurred to the same degree in both M and Z mice, possibly relating to the presence of hepatitis virus in the colony [152]. There was an increase in inflammation and necrosis in mice with ten or more copies of the Z gene, although the difference was not significant. In a more recent study in which large numbers of transgenic M and Z mice were produced, accumulation of Z protein was achieved in the liver but no evidence of cirrhosis or fibrosis was seen in any animal. This study suggested that the mouse model was most useful for investigating the liver manifestations occurring in ZZ adults but that other factors must be involved in neonatal liver disease [153].

Further arguing against this hypothesis is the observation that infants with α1AT deficiency and liver symptoms have very little accumulated α1AT in their hepatocytes. On the other hand, adults with α1AT deficiency frequently have numerous and large inclusions and yet may be free of liver disease. The intracellular accumulation of α1AT has been shown to increase hepatic lysosomal enzyme activity [154]. This could cause the elevation of liver enzymes frequently observed in apparently clinically well children and adults with the deficiency. The extensive accumulation, equivalent to that seen in the transgenic mice, could play some role in adult liver disease. However, given the very slight amount of α1AT stored in the livers of newborns and infants, the accumulation may not be the only cause of early liver destruction.

Another hypothesis for the cause of liver injury is a lack of circulating α1AT, particularly as a cause of liver disease in young infants. The typical PAS-D positive inclusions

are often difficult to identify in percutaneous liver biopsy specimens from infants [67]. The amount and size of liver inclusions show no clear correlation with the severity of liver disease; severe liver disease in the early months of life can be associated with only very sparse liver inclusions. An apparent lack of liver disease in null homozygotes cannot be used as evidence against a lack of α1AT as the causative factor for liver disease. Null homozygotes are present at only 1/1,000 the frequency of PI ZZ individuals. Therefore, if only 2% of PI ZZ individuals were affected with severe and fatal liver disease in childhood, the dozen or so null homozygotes described to date would not, by chance, be expected to have liver disease in infancy. α1AT is expressed in human jejunal epithelium [155]. Secretion from this source could be important in combating exogenous proteinases in the gut, as proposed below in discussion of the role of breast-feeding.

The choice between these two hypotheses is important for therapy. If the liver inclusions cause damage, then infusion of additional α1AT would not be a rational therapy. However, if the damage occurs because of lack of α1AT, there is potential for the use of α1AT as therapy for liver disease, at least during the early sensitive weeks. At the present time, such therapy is not warranted, pending the availability of further information on the basic disease mechanism.

Pathogenesis of Disorders with an Autoimmune or Inflammatory Component

In rheumatoid arthritis, the Z heterozygote may have inadequate α1AT present in the joint fluid to prevent leukocyte elastase, cathepsin G, and collagenase from attacking the structural proteins of joint cartilage [95]. In addition to its role as an antiproteinase, α1AT may also reduce inflammation through the inhibition of hydrogen peroxide oxidation [156], and the deficiency state could therefore ineffectively control inflammation. However, it is not clear whether this effect occurs *in vivo*, where α1AT may be inactivated by exposure to hydroxyl radicals generated from hydrogen peroxide [157].

Several of the abnormalities in inflammatory response also have an autoimmune component. It is not clear whether a deficiency of α1AT has an effect on the immune response or whether disease results entirely from an inability to handle inflammation adequately. An inappropriate immunological response could be triggered by a lack of proteinase inhibitor to exert its effect on cell-bound proteinases. Proteinases such as trypsin, neutrophil elastase, and cathepsin G can substitute for helper T-cells in B-cell mitogen assays [158]. Increased T-helper cell activity and B-cell inactivation could trigger exaggerated cell-mediated immunity. Alternatively, the wide variety of inflammatory abnormalities may result entirely from inadequate handling of the proteinases released during the inflammatory response in various tissues. Individuals who develop such disorders may have some additional predisposing factor. However, recognition of PI deficiency in individuals with any of these severe inflammatory disorders is important because of the potential for treatment with purified α1AT.

Another possible reason for these disease associations could be the effect of impairment in function of adjacent genes in the serine proteinase inhibitor cluster. Particularly noteworthy is the close association with corticosteroid-binding globulin, which is involved in control of the immune response.

THERAPY

Preventative Therapy

Avoidance of Smoking

An effective way to prevent the lung destruction of α1AT deficiency is to avoid smoking and exposure to other agents from the environment that can damage the alveolar connective tissue. Given the high incidence of α1AT deficiency in the population, a large percentage of affected individuals may never come to medical attention. For some individuals, the lung destruction will be sufficiently slow that a relatively normal life span can be achieved. This complicates the assessment of any therapy because it will not necessarily be possible to determine whether a particular rate of decline is altered by that therapy. The dramatic effect of smoking in accelerating the rate of lung destruction has been described previously in this chapter.

If the establishment of smoking behavior is to be avoided, patients must be recognized before the age when smoking usually begins. Population (newborn) screening has been shown to be feasible using dried blood samples on filter paper [159]. The wisdom of population newborn screening is a topic of lively debate [160]. The goal of such a screening program would be to counsel parents to encourage their affected children to avoid smoking completely. For the best effect, parents of children with α1AT deficiency should also be advised to avoid smoking. In Sweden, however, studies showed that about one-third of parents will continue their smoking [83]. Negative attitudes in parents regarding their child's illness were shown to last for at least five to seven years [161], stressing the necessity for extensive education to accompany the screening. Screening during the teen years is an alternative, although usually less practical. Although parents were unlikely to be persuaded to give up smoking, the Swedish screening program did have an impact on smoking by affected children [162]. Of 50 children followed, 18–20 years after their initial diagnosis in the newborn screening program, only 12% were previous or current smokers compared with 36% of 48 control children. Five of the six affected smoking children had one or both parents who smoked.

Antioxidant Therapy

Because excessive free radicals from any source can lead to tissue damage, antioxidants might be expected to modify or even prevent tissue damage. There is evidence that an excess of pro-oxidants can damage both liver and lung [163–165]. Tissue exposure to oxidants will be dependent on genetic variation in metabolic pathways as well as antioxidant intake. Optimal antioxidant activity should be maintained in lung and liver tissue to help prevent tissue damage. Vitamin E status might be important in determining individual susceptibility to liver or lung destruction. Vitamin E, administered in doses adequate to cover daily requirements, may help to protect tissues and should be considered as a possibility for preventative therapy. Because this is an inexpensive approach to therapy, data need to be collected and evaluated in appropriate trials.

Other Therapies

Because the cause of liver disease in a small percentage of PI ZZ individuals is unknown, preventative measures are uncertain. Given the hepatotoxicity of alcohol, avoidance or limitation of intake would seem to be prudent for α1AT-deficient individuals. For liver disease of infancy, breast-feeding during the early months of life may offer

some protection from liver disease. A significant difference was found between breast-fed and nonbreast-fed infants in developing clinical signs of liver disease in the early months of life, although breast-feeding did not necessarily prevent the development of cirrhosis [166,167]. The rationale for the effectiveness of breast-feeding is that proteinase inhibitors in human milk help limit proteinase uptake and reduce their transport to the liver via the portal circulation [168]. Human milk has high concentrations of α1AT, particularly in the first week of lactation, and a breast-fed infant can have an intake in the range of 100–400 mg/24 hours [169]. Although there are inadequate data to prove the effectiveness of breast-feeding, this is a subject requiring further study.

Replacement of α_1-Antitrypsin

Replacement by Infusion

The destruction of lung tissue in patients of PI ZZ results from the uninhibited activity of proteases in the lung. Effective therapy must prevent this tissue destruction, because the adult human lung has a limited capacity for self-repair. The goal of augmentation therapy is to increase the α1AT plasma concentration sufficiently to delay the accelerated rate of lung deterioration found in α1AT-deficient patients. Because PI MZ and even SZ heterozygotes, with 60% and 35%, respectively, of the normal amount of α1AT are unlikely to be at increased risk of lung disease, maintenance of a partial level (about 35% of normal) through augmentation therapy should prevent excessive lung destruction. The protective plasma level is calculated to be about 0.52 g/L according to the internationally established standards [170,171].

Augmentation of serum levels by the infusion of purified human α1AT is the only currently approved therapy for α1AT deficiency. In initial studies, administration of 60 mg/kg weekly was shown to increase α1AT and antineutrophil elastase levels in lung and serum to appropriate protective levels [172]. Clear evidence for significant benefit from this therapy has not yet been established. A randomized clinical trial, predicted to require 500 patients and controls for a three-year period to show a 40% decrease in the decline of FEV_1, was not considered to be feasible [173]. A more sensitive way to measure decline in lung function, possibly by CT scan [73], could make random trials more feasible. As an alternative, patient registries have been established in the U.S. and Europe to monitor α1AT-deficient patients receiving augmentation therapy by infusion. In a study of 927 patients from the U.S. registry, among whom 10% of those treated were current smokers and 389 received continuous therapy, survival over a period of at least six months was assessed. Significant improvement was shown only for patients with an FEV_1 of 35–49% and not for those with lower or higher FEV_1 values. However, it is noteworthy that the change in relative risk was slight in comparison with the effects of education, which presumably reflects socioeconomic status. Initial FEV_1 was a high predictor of survival. Those on augmentation therapy showed a decreased relative risk for mortality overall. A significant difference in the decline of FEV_1 was shown only in those with an initial FEV_1 of 35–79% predicted. However, these results cannot easily be interpreted because there is a strong possibility that differences were due to other factors such as socioeconomic status. Another comparison is available from Europe, although the controls and patients are from different populations. A German group of patients received therapy, and a Danish group who received no therapy were used as controls. Again, those in the mid-range of initial FEV_1 showed a slowed rate of decline in lung function (83–93 mL/year with no treatment, 64–66 mL/year with treatment). No effects of therapy were observed in those with higher or lower FEV_1 values. There is a suggestion that augmentation therapy may be useful in some individuals; however, there are many questions still unanswered. Of particular importance is the possible effect of socioeconomic status, perhaps reflecting improved nutrition. All figures in these studies had large standard deviations. Because of the high degree of variability in decline of lung function, baseline data on the rate of decline of lung function in any particular patient will be critical in deciding when and if therapy will be warranted.

No data are available to indicate whether the protective level must be maintained at all times. Patients with α1AT deficiency have been shown to have free elastase activity, as measured by lung lavage, only during periods of respiratory infection [174]. Augmentation therefore may be effective when administered only during times of infection [175]. The patients in these studies have no documentation of their nutritional and antioxidant status, which may well be important factors in maintaining a slow decline in lung function.

Because an unknown proportion of nonsmoking individuals of PI type ZZ maintain relatively normal lung function for many decades, there will be some individuals who have a relatively normal life span even without therapy. For this reason, it would seem appropriate to monitor the rate of decline of lung function, if possible over a one- or two-year period, to assess the rate of progression of lung destruction. This may help in rationally deciding who will benefit most from the therapy. Replacement therapy is costly, so consideration needs to be given to the initial slow rate of decline in some patients who may not require continuous therapy for effective results. Assessment of therapy only in times of respiratory stress also needs evaluation.

Replacement by Aerosol

More direct targeting of α1AT specifically to the lungs, the only major organ to be significantly damaged by elastase degradation, could avoid the large requirement for purified α1AT. The challenge for effective aerosol therapy is to deliver appropriate-sized droplets into the lung alveoli. Aerosolized α1AT has been shown in sheep to pass through the lower respiratory tract epithelium, gaining access to the alveolar walls, and in individuals with PI type ZZ to be absorbed into the serum [176]. Administration of 100 mg twice daily appears to be safe and effective in raising the lung epithelial lining fluid levels of α1AT to protective levels [176]. The half-life of α1AT in the lungs after a single dose of 200 mg is 69.2 hours and that of its antineutrophil elastase activity is 53.2 hours [177]. This approach requires only about 10% of the purified α1AT used for intravenous administration and could provide an economically feasible approach, in combination with antioxidant administration, for the treatment of α1AT deficiency.

Use Of Recombinant α_1-Antitrypsin
