Connective Tissue and Its Heritable Disorders

second edition

Contents

Preface

We were gratified by the reception accorded the first edition of this book, and delighted that it should have been found useful by so many. Nevertheless, given the passage of time and the intensity of advances in the field it was bound to become outdated sooner or later, and the need for a second edition became clear some time ago. With the encouragement of our colleagues, which we should, perhaps, have resisted had we appreciated at the time that to produce a second edition involved no less effort than to produce a first, and the support of John Wiley & Sons, we embarked upon our planning for this new edition some four years ago. Given the developments that occur almost weekly in some area or other of connective tissue research there is no "perfect moment" at which to produce a volume of the scope of this, but we have striven to ensure that it is as up to date as possible by giving all contributors the opportunity to add a section, "Recent Developments," to their respective chapters at the proofs stage to take account of the most recently made available information only shortly before publication.

The structure of the first edition is maintained in the second, although the content has considerably expanded. Part One, "Biology of Extracellular Matrix," addresses the morphological, physiological, and molecular biological aspects of the connective tissues and their constituents under normal conditions, while in Part Two, "Heritable Disorders of Connective Tissue," specific disorders, or groups of disorders, are extensively covered in dedicated chapters. A number of disorders have been added to those considered in the first edition, some of the less common or only recently defined of which are included in an additional chapter, "Miscellaneous Disorders," towards the end of the book. In all cases, all aspects of each disorder, whether scientific or clinical, are described in detail, and it is hoped that the reviews will prove useful to both researchers and medical practitioners alike. A new Appendix includes a chapter on collagen metabolites in body fluids, this being occasioned by the commercial availability of kits that may be diagnostically useful that were not on the market at the time of the first edition. Finally, we have been pleased to be able to add the reminiscences of Karl Piez in the collagen area to those of Victor McKusick as they relate to heritable connective tissue disorders. These two contributions not only make pleasant reading in themselves, but also help to provide a contextual foundation for the chapters that follow, and serve to emphasise how significant the progress that has been made subsequently in a relatively short space of time.

We would close by thanking all the contributors and expressing our hope that this second edition will not be found wanting.

January 2002

Acknowledgments

The financial support of the Swiss National Foundation (Grants 32-42-198.94 and 31-57-272.99, "Molecular Pathology of Connective Tissue Disorders") is gratefully acknowledged.

The Editors would thank the Marfan Foundation of Switzerland for further financial support and encouragement. For a number of years, the Foundation has supported research into Marfan syndrome and its delineation from related disorders such as congenital contractural arachnodactyly, Ehlers-Danlos syndrome, and cutis laxa, and promoted the exchange of knowledge between experts and lay persons.

Despite our innate reticence, it would be less than fair not to acknowledge our respective families for their tolerance during the preparation of this book, given the disruption it has occasioned to their lives.

Preface to the First Edition

Although it has become something of a cliché to talk in terms of an explosion of knowledge having occurred in a particular field, it is the case, nevertheless, that there have been dramatic advances in our understanding of the extracellular matrix and its components over the past two decades or so, and these have, in turn, enhanced our perception of the molecular and genetic basis of several of the heritable disorders of connective tissue. Despite this, however, certain conditions have stubbornly resisted the yielding up of their secrets, and there is still some way to go before we can claim full comprehension of them.

In 1988, when this volume was conceived, no comprehensive text covering the heritable disorders of connective tissue had appeared since the 4th edition of McKusick's *Heritable Disorders of Connective Tissue* in 1972, then long out of print, and the time seemed appropriate to begin planning a new book which would take account of developments that had occurred since then. Conscious of our illustrious predecessor, we were gratified to receive from Victor McKusick a personal view of the development of a field to which he has contributed so greatly, and this forms an introductory chapter to the current volume.

In selecting conditions for inclusion, we experienced some difficulty in deciding just where the line should be drawn. All those diseases classically regarded as inherited disorders of connective tissue, such as osteogenesis imperfecta, the Ehlers-Danlos syndrome, Marfan syndrome, the chondrodysplasias, cutis laxa, and defects in mineralization, are covered. We have also included a number of conditions in which connective tissues are only secondarily affected, such as homocystinuria, alcaptonuria, α1-antitrypsin deficiency, Menkes disease, and prolidase deficiency. On the other hand, common diseases such as osteoporosis or arthritis, for which there may be a genetic predisposition, are not included. This is partly to avoid encountering semantic problems, and partly because of the difficulty of their phenotypes overlapping with those of mildly expressed forms of osteogenesis imperfecta and chondrodysplasia. We have also excluded rheumatic diseases that do have a genetic component, on the grounds that they are not generally regarded as inherited disorders of connective tissue *sensu strictu*. One feature which might well be considered curious is the inclusion of disorders of keratinization and the forms of epidermolysis bullosa simplex, which was on the grounds of practicality and interest, rather than strict accuracy. Despite the different embryological origins of dermis and epidermis, we feel that an interest in skin is more likely to embrace the whole tissue than merely one or other part of it. Wherever possible, throughout the book, disorders have also been identified by their MIM numbers, these being the numbers assigned to them by McKusick in his *Mendelian Inheritance in Man: Catalogs of Autosomal Dominant, Autosomal Recessive, and X-Linked Phenotypes* (popularly referred to as "McKusick Index Medicus"), published by the Johns Hopkins University Press, Baltimore and London.

When drawing up an outline for the book, it very quickly became apparent that its usefulness would be greatly enhanced by the inclusion of a detailed coverage of the composition and biology of the extracellular matrix, and a series of appropriate reviews occupy a large part of its first half. With the addition of morphological descriptions of specific connective tissues, and of the principles of medical genetics, without which the disorders cannot be appreciated, either in terms of their behavior in populations, or at a molecular level, we should like to believe that we have succeeded in compiling a text which will be of benefit not only to clinical and associated personnel, but also to basic scientists, for whom the juxtaposition of basic and clinical reviews within one set of covers might aid an enhanced awareness of the functional significance of the molecules they are studying.

Despite the appeal of the ancient maxim that to be happy in one's work one should not do too much of it, we found during the editing of this book that such an option did not arise. Indeed, the task was far more arduous than ever we could have conceived.

Nevertheless, our dealings with all those various contributors, to whom we are deeply grateful, remained pleasant, and any modest success the book may enjoy is a tribute to all their hard work and amiability throughout.

Introduction, Part I

Research on Collagen in the Author's Laboratory, 1952–1982[1]

Karl A. Piez

National Institutes of Health, Bethesda, Maryland 20892

INTRODUCTION

I was trained as a chemist, receiving a Ph.D. from Northwestern University in 1952. The school had an excellent chemistry department. Irving Klotz, a professor there, was one of my heroes because of his rigorous science and clarity of thought. My thesis had two parts: a synthetic organic chemistry problem and paper chromatography of amino acids in some biological samples. I did not discover anything important. However, I found that I was at ease in the laboratory. Biochemistry was a rudimentary science that was poised to take off. Chromatographic methods, amino acid sequencing, protein crystallography, electron microscopy, and cell culture were the leading technologies. Protein structure, nucleic acid structure, and molecular interactions were the driving concepts. Enzymology was alive and well but soon to pass its zenith. Immunology was still an art. Molecular biology studied chemistry and structure of proteins and nucleic acids but did not include gene isolation and manipulation, which were 20 years away.

I must admit that I did not appreciate the biological implications of what was to happen, but I have never regretted my chemical bias. Chemistry is the hard part of biological chemistry. What good is it to find a mutation in DNA and not understand what this does to the three-dimensional structure of the coded protein? Or worse, not to have the basis for understanding when someone else explains it?

Before graduate school, I had worked briefly as a technician in the National Institute of Dental Research (NIDR, now the National Institute of Dental and Craniofacial Research) at the National Institutes of Health (NIH). It was natural that I return. I was one of the first scientists hired there with interests beyond applied dental problems. I did not serve a postdoctoral fellowship in the usual sense but was told to do what I thought was important. With a continuing interest in chromatography of amino acids, I showed that diastereoisomers of amino acids could be separated by ion exchange chromatography [2]. I built an amino acid analyzer following the model developed by Stanford Moore and William Stein, but with a single column and the ability to analyze hydroxyproline and hydroxylysine [3]. Because two of the diastereoisomeric amino acids are hydroxyproline and hydroxylysine, and both are essentially unique to collagen, I developed an early interest in collagen. Because collagen is the major protein of skin, tendon, bone, and tooth, this interest was also consistent with the mission of NIDR.

In those early years, I also entered into some collaborative studies with Harry Eagle in another institute at NIH. He was largely responsible for making a science out of what was then the art of cell culture. We studied some aspects of amino acid metabolism in cell culture. In the course of this collaboration, we unexpectedly found that ^{14}C-labeled amino acids traveled slightly faster on ion-exchange columns than the same nonlabeled species [4]. This was important because a cut from the center of a peak would have a lower specific activity than the whole peak, giving false values in labeling studies. I learned from Harry that technology was all well and good, indeed necessary, but to apply it to a significant problem was what really counted. Perhaps this experience served the role of a postdoctoral fellowship. I did not myself ever grow a cell in culture but I learned what was involved and how to interpret data.

My interest in collagen was cemented when I met Jerome Gross in the mid-1950s. Jerry had served a postdoctoral fellowship in the laboratory of F.O. Schmitt at Massachusetts Institute of Technology. By electron microscopy, the group had made major findings about collagen to which I will return. My point here is that this early meeting was the start of a long-term scientific collaboration and friendship. I well remember telling Jerry something like, "A good problem for me would be to determine the complete structure and amino acid sequence of collagen." Sanger had recently sequenced the first protein, insulin, but of course collagen was very much larger and even its chain structure was not known.

That is what I set out to do. It was a chemical problem with many biological consequences. Among them were the heritable diseases of connective tissue, some of which were already thought to be a consequence of mutations in collagen. Thus, this chapter in this book. What I propose to do is recount events in which my laboratory played a role in reaching this goal. In some cases, I will go farther afield for the sake of completion, but this should not be considered

[1] Some of the events summarized here have been recounted in a brief review [1] written from a somewhat different point of view.

Connective Tissue and Its Heritable Disorders, pages 1–11

a comprehensive review or, for that matter, a complete personal history. Contributions made by other laboratories can be found in the original references. I will stop at 1982, when I left full-time academic research. Molecular biology in its modern form had by then taken over and others are more competent than I to pick up the story there.

The reader will see that my approach was systematic. The problem was researched from the bottom up. Flashes of insight did occur but they always arose from the data, not the imagination. This may be viewed as a limitation, but it was my style. Surprises were common, as they should be in advancing into the unknown; the unexpected was what we welcomed to give us new leads.

TYPE I COLLAGEN — CHEMISTRY AND STRUCTURE, 1956

In 1956, only one collagen type was known, now type I collagen. The following was known about it at that time:

1. It had been discovered by French scientists in the early 1930s (see [5]) that collagen in some tissues could be dissolved in acid and reconstituted into fibers. This finding was later repeated and expanded by Orekhovitch and Shpikiter in Moscow [6].
2. The collagen fiber was shown by x-ray diffraction [7] and by electron microscopy [8] to be periodic, the period being about 64 nm and denoted the *D* period. Figure 1 shows a wide-angle x-ray diffraction pattern.
3. The total amino acid composition of collagen was determined by Bowes and Kenton in England [9]. The one-third mole percent glycine, the presence of about 10 mole percent each of proline and hydroxyproline, and the presence of hydroxylysine, unique to collagen, were remarkable.
4. Segment long-spacing (SLS) crystallites of collagen in which rod-like collagen molecules occurred in bundles

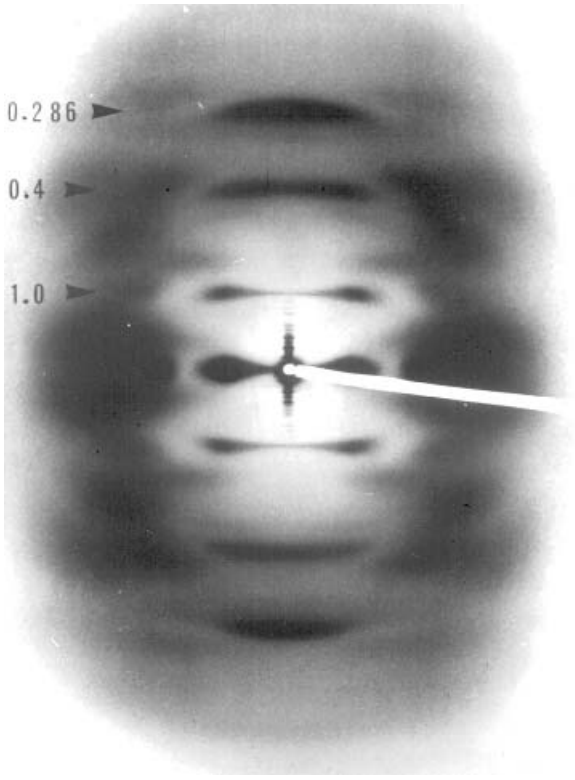

Figure 1. Wide-angle x-ray diffraction pattern of a collagen fiber. The short lines on the meridian near the center of the pattern arise from the *D* periodicity. These can be seen expanded on the medium-angle diffraction pattern in Figure 11. The layer lines at 1.0 and 0.4 nm arise from structural helices in the molecule. The reflection at 0.286 nm arises from the residue spacing. Photograph courtesy R.D.B. Fraser.

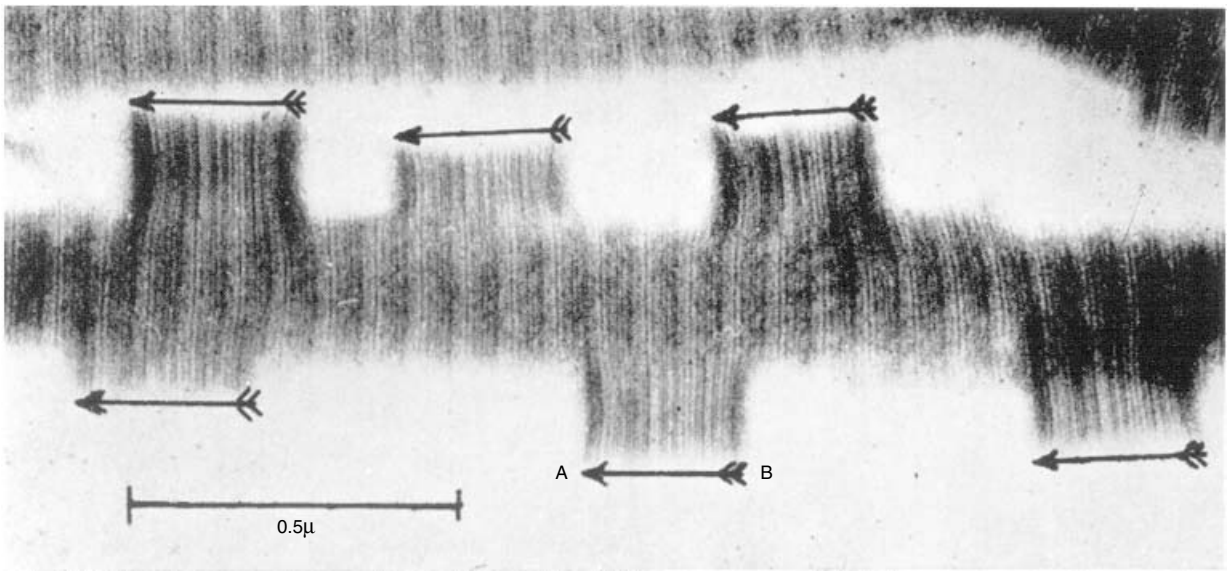

Figure 2. An electron micrograph of SLS crystallites formed on a collagen fibril. The crystallites are bundles of collagen molecules (arrows) with their ends aligned. They span about four periods in the fibril showing that molecules in the fibril must be parallel but staggered in a regular way. The A and B ends are now known to be the C- and N-terminal ends, respectively, of the three α chains comprising molecules. (From Hodge and Schmitt [11] with permission.)

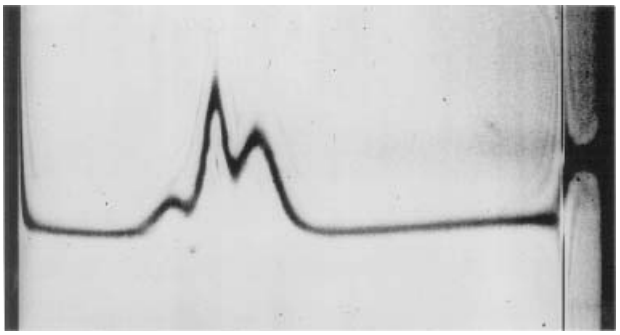

Figure 3. An ultracentrifuge pattern of denatured collagen extracted from shark skin [14]. Sedimentation right to left. Schlieren patterns formed by the α-, β-, and γ-components (right to left) can be seen. They have been shown to be single, double, and triple chains, the latter two containing cross-links.

with their ends aligned were observed by Schmitt et al. [10]. Because these bundles were about four times as long as the *D* period, it was concluded that collagen molecules must be overlapped in an ordered array in the fibril. A remarkable electron micrograph illustrating this result is shown in Figure 2. This led to the hypothesis by Gross et al. of a "tropocollagen particle" about 4*D* long and very thin [12]. Later refinement gave a value of 4.4*D*.

5. Orekhovitch and Shpikiter showed that denatured collagen contained two components of different sizes in the ultracentrifuge [13]. They called them the α- and β-components and believed them to be stoichiometrically related. Somewhat later, a still larger component, the γ-component, was reported by several groups. An ultracentrifuge pattern of these components is shown in Figure 3.
6. Rich and Crick [15] and Ramachandran and Kartha [16] independently showed that the wide-angle x-ray diffraction pattern of fibers of collagen (Fig. 1) could be explained by aggregates of molecules each a supercoiled triple helix with glycine residues in every third position in the center of the molecule. The other amino acid residues were on the outside of the molecule, where their side chains could direct the specific interactions between molecules to form fibrils and fibers. This structure is illustrated in Figure 4.
7. The first detailed physical chemical characterization of collagen in solution was done by Boedtker and Doty [17]. The dimensions of the molecule were correctly found to be 300 × 1.4 nm and the molecular weight was 345,000, somewhat higher than the correct value of about 300,000. These results were entirely consistent with the proposed "tropocollagen particle" of Schmitt and Gross. For the first time, the collagen molecule and its relationship to the fibril were defined.

CHAIN STRUCTURE OF THE COLLAGEN MOLECULE

My entry into collagen research, beginning in the middle 1950s, was to determine the chain structure of the type I molecule. Although x-ray diffraction indicated three polypeptide chains, this information applies only to local structure because the coherence of diffraction patterns of collagen is only about 10–20 nm whereas the molecule is about 300 nm long. Whether the chains were parallel or antiparallel, all or partly triple helix, folded or straight, and identical or nonidentical was not known. Complicating the picture was the presence of cross-linked components in all extractable collagens. The chemistry and location of these cross-links were unknown.

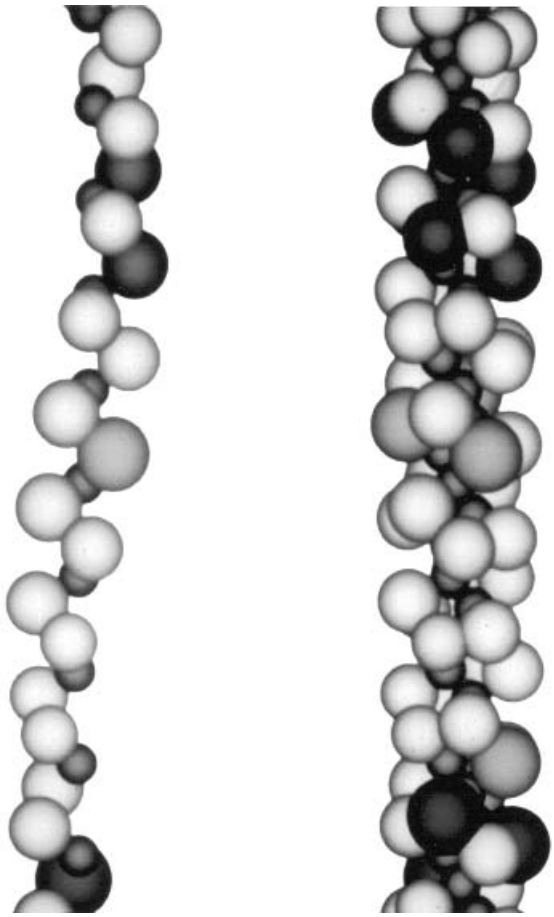

Figure 4. Ball models of segments of a collagen molecule (right) and of a single α chain (left) taken from the molecule. The small balls in the center of the molecule represent glycine residues occurring in every third position in each α chain. The side chains of other amino acid residues point outward. (Computer-drawn model by Benes Trus.)

The first surprise was that the ratio of α- to β-components varied with the type of sample, a result published with George Martin[2] and Jerome Gross[3] [18]. They were not stoichiometric subunits of the molecule as previously thought. Denatured salt-extracted collagen from vertebrate skin contained very little β-component whereas acid-extracted collagen contained a large amount. It was known

[2] George Martin had come into the laboratory, not under my auspices, somewhat before this time and we had begun to collaborate. He provided skills in cell culture and animal studies that I lacked. We have continued to collaborate, on and off, over the years.

[3] Jerome Gross provided major stimulus to me as a beginning scientist and helped immeasurably in the interpretation of data.

that salt-extracted collagen was recently synthesized whereas, acid-extracted collagen was older. In some samples, γ-components were found (Fig. 3). These results suggested that α-components were the basic polypeptide chains of the collagen molecule — now referred to as α chains — and that β- and γ-components were two and three, respectively, cross-linked α chains.

At that point we needed a way to separate α chains. Peterson and Sober [19] had recently invented the modified cellulose exchange resins that could be used to chromatograph proteins.[4] As these materials were not yet available commercially, we made our own carboxymethyl (CM)-cellulose and found that denatured collagen could be chromatographed [18,20].[5] To keep the components from reassociating, we kept the columns at 40°C. We monitored the effluent by ultraviolet absorption and analyzed fractions by ultracentrifugation and amino acid composition. We found that denatured vertebrate skin collagen from several species and collagen from fish swim bladder contained two types of α chains, named α1 and α2, in a 2:1 ratio, and two types of dimers of α chains, named β_{11} and β_{12}, the subscripts indicating the type(s) of α chain making up the dimer. An example of a CM-cellulose chromatogram of denatured collagen is shown in Figure 5.

The finding of two types of α chains in a 2:1 ratio was a major surprise. The unsymmetrical nature of type I collagen was bothersome. From time to time, we thought we had data for three different chains, but that turned out not to be true.

The molecular weights of the α chains were found to be about 95,000 and of the β-components twice that [21].[6] These values were consistent with three α chains, or one α chain and one β-component, per molecule in extractable collagen. The simplest model for the collagen molecule was then two identical chains and one similar but nonidentical chain, each extending the full length of the molecule. Of course, x-ray diffraction had shown that each chain was a helix with their axes probably parallel and supercoiled. This was shown by Andrew Kang[7] and Yutaka Nagai[8] to be correct [22] by cleaving the native molecule with the vertebrate collagenase of Gross and Lapière [23], separating the still helical one-quarter and three-quarter pieces, and characterizing the α chain fragments in them. The one-quarter piece of the molecule contained the C-terminal one-quarter of two α1 chains and one α2 chain and the three-quarter piece of the molecule contained the N-terminal three-quarters of the same chains. Molecular weights were as predicted by the model.

This story is not complete without mentioning the later discovery that collagen is synthesized and secreted as a precursor protein with propeptides at the N- and C-terminal ends. This was shown independently in the laboratories of Paul Bornstein [24] and George Martin [25].

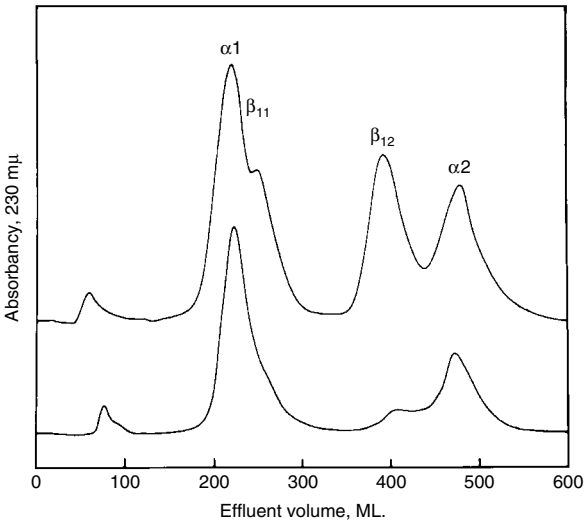

Figure 5. Chromatograms of denatured collagen fractionated on CM-cellulose at 40°C. The acid-extracted collagen (top) can be seen to have a greater proportion of β-components than the salt-extracted collagen (bottom). (Chromatograms by K.A. Piez.)

COLLAGEN CROSS-LINKS

With the chain structure of collagen known, we turned our attention to the characterization of cross-links in collagen, specifically in the β-components that we could isolate. Three discoveries came together to make this possible. First, Gross and Witkop [26] introduced the technique of cyanogen bromide (CNBr) cleavage of polypeptide chains. This chemical method cleaves at methionine residues yielding peptides with C-terminal homoserine the size of the distance between methionine residues in the original chain. Because the α chains of mammalian collagens contain 8–10 methionine residues, the number of peptides to be separated was manageable using ion-exchange chromatography.

The second discovery, made by Paul Gallop and his colleagues [27], was that collagen contained aldehydes. Although they did not correctly identify or locate them, they devised the methods to assay them. The third discovery, made in the laboratory of Miles Partridge [28], was that elastin contained pyridinium cross-links that, from their chemistry, probably arose from the condensation of four lysine residues through aldehyde intermediates, as shown

[4]The availability of this technology is an example of the early NIH where openness was the rule and collaboration easily obtained. Under modern pressures, that attitude has been largely lost.

[5]The first commercial samples of CM-cellulose were unreliable, which gave us an advantage over our competitors who could not repeat our results for some time. I have been reminded of this by Klaus Kühn whose group at the Max Planck Institut für Biochemie in München was making major contributions to our knowledge of collagen during this same period. At one point when I visited Klaus, he and Jürgen Engel brought out copies of my publications and grilled me on every fine point. I believe I passed that test.

[6]Marc Lewis and I taught ourselves ultracentrifugation with some help from colleagues such as William Carroll. Marc was much better at it than I, and became one of its strongest proponents.

[7]Andrew Kang was a physician choosing NIH over service in the armed forces. I remember Andy stating on his application that the only laboratory in NIDR that he would consider joining was mine. Many bright young physicians came to NIH as research associates during this period and went on to become leaders in medical science and education.

[8]Yutaka Nagai had come from a postdoctoral fellowship in Jerome Gross' laboratory where he had participated in collagenase characterization. He returned to Japan where he became a well-known professor. He recently retired but is active as a consultant.

later in my laboratory [29].[9] So we were on the lookout for lysine-derived aldehydes and cross-links arising from them.

At this point, Paul Bornstein came into the laboratory.[10] We devised chromatographic methods to separate the CNBr peptides of the α1 and α2 chains and the β_{12}-component of extracted rat skin collagen and examined them for aldehydes.[11] From the α1 chain, we found a small peptide in two forms, one containing a lysine residue and the other a simple aldehyde but no lysine. A similar situation existed in the α2 chain. From β_{12} these peptides were not found, but another that contained an α, β-unsaturated aldehyde was identified. It had the amino acid composition of the sum of the two aldehyde-containing peptides from the α1 and α2 chains. Schematics of the crucial chromatograms are reproduced in Figure 6. It could be deduced that the cross-link was the aldol condensation product of two lysine-derived aldehydes from the α1 and α2 chains [30,31]. The lysine-derived aldehyde has the chemical name δ-semialdehyde of α-aminoadipic acid. It has been given the trivial name allysine. Its hydroxylated counterpart, arising from hydroxylysine and named hydroxyallysine, also participates in cross-links.

This was the first cross-link identified in collagen.[12] Of course, the collagen fraction that we studied represented a small percentage of the total collagen and was not representative of mature collagen. Later studies from the laboratories of Bailey and Tanzer showed that aldimine cross-links and cross-links derived from other condensations are also present in more mature collagen [32,33]. Allysine and hydroxyallysine seem to be present only in the terminal nontriplet regions of the molecule. They condense with lysine, hydroxylysine, and histidine residues at sites in the helical region of adjacent molecules. More than two chains may be involved. It can be imagined that, in highly cross-linked collagens, multiple condensations tie together all the molecules in a fibril at periodic sites along the fibril.

The identification of aldehydes in collagen, and earlier evidence that collagen from lathyritic animals was deficient in cross-links, provided the basis for understanding this disease [31,34]. Lathyrism, characterized by fragile connective tissues, occurs in animals that eat the sweat pea, *Lathyrus odoratus*, and in experimental animals fed β-aminopropionitrile, the active component. This and related compounds are inhibitors of the enzyme lysyl oxidase, which converts lysine and hydroxylysine in peptide linkage to allysine and hydroxyallysine.

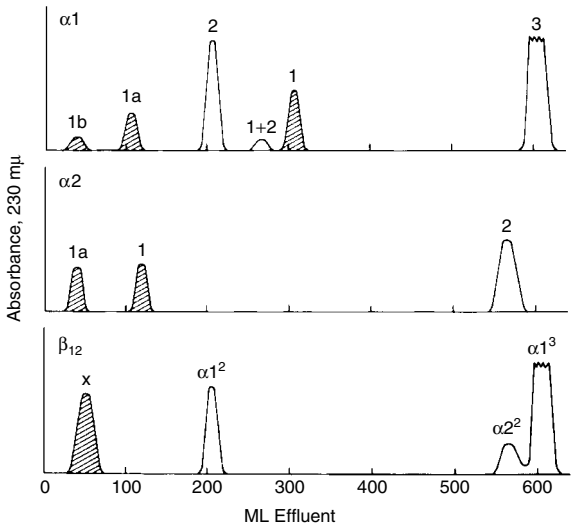

Figure 6. Schematics of the chromatograms on phosphocellulose of the small CNBr peptides from the α1, α2, and β_{12} chains of type I collagen [31]. Peaks 1 from α1 and α2 are lysine-containing peptides from the N-terminal ends of the α chains. Peaks 1a are aldehyde-containing peptides without lysine derived from peaks 1. Peak 1b is a small amount of peak 1a that did not bind to the column. Peak X on the β_{12} chromatogram is the sum of peaks 1a from α1 and α2 and contains an unsaturated aldol cross-link. The nonshaded peaks are other CNBr peptides not involved in cross-linking.

COLLAGEN TYPES

The question of whether the collagen from skin, tendon, and bone was the only collagen or whether there were other collagens derived from different genes was a matter of discussion in my laboratory and, I am sure, other laboratories. Edward J. Miller, in my laboratory but working on his own, gave the question a biological twist. If there are other collagens, they must have different biological roles. So the place to look is in a tissue with a unique function. He chose cartilage and found the first new collagen, designated type II [35]. It had only one kind of α chain, named α1(II), which had a different amino acid composition, and thus a different gene, from the chains of type I collagen, now known as α1(I) and α2(I).[13]

At about the same time, Erwin Epstein, working with me, did a CNBr digestion of whole skin. He isolated a CNBr peptide with a triplet sequence but not from type I or type II collagen [36]. We named the new collagen type III. When isolated later, it was found to have three identical α chains, named α1(III).

The question about different collagens was now answered. Types I, II, and III were shown to be fibrillar collagens with

[9]The British group was somewhat dismayed when, in a matter of weeks, we did the obvious experiment that showed that lysine was indeed the precursor of the cross-links in elastin. It just happened that we had the systems in place to do this. Elastin is an interesting protein and from time to time we did some experiments on it when we could think of an interesting one.

[10]Paul Bornstein had come into my laboratory as a physician on leave from his residency, having been deserted by Chris Anfinsen who had gone to Harvard for a year. Paul expressed ignorance about biochemistry and how to do research. I like to think I replied, "What is known you can read about. What is unknown you will participate in discovering." I was less eloquent, but that is what I meant and Paul did just that.

[11]I urged that we look first in the large CNBr peptides because statistically it was more likely that the cross-links would be there. Paul Bornstein, who was doing most of the experiments, opted for the small peptides because they would be easier to characterize if the cross-links were there. He was right even if illogical!

[12]During this period, there was considerable controversy among the several groups working on collagen cross-links. In the end, it was clear that everyone had made important contributions to the solution of a difficult chemical problem. However, there has been some confusion about credit, which I hope is clarified here.

[13]Many people were not happy about this nomenclature. Several informal committees were appointed at various times to come up with a better nomenclature. However, none was ever devised and the original has persisted.

similar structures. Other collagens have been found that are quite different in structure, as detailed elsewhere in this book. There are now about 19 collagens plus several other proteins with some triple-helical structure that might have been named collagens if they had been discovered by collagen chemists.

AMINO ACID SEQUENCING OF COLLAGEN

With the ability to isolate α chains and fragment them into CNBr peptides, it was possible to systematically sequence the various α chains. Some of this began in my laboratory [37] but was limited largely to the N-terminal nonhelical end where we had found the cross-link. The work was continued elsewhere by Paul Bornstein, Andrew Kang (with Jerome Gross), and the group in Klaus Kühn's laboratory. Eventually, it was possible to assemble a complete sequence of the α1(I) chain [38], although not all of it was derived from the same species.

About this time, a group from my laboratory made a trip to Johns Hopkins to talk to Victor McKusick. We felt that we were close to looking for mutations in collagen that would explain some of the heritable diseases of connective tissue. My laboratory never did this but we had helped to set the stage. This book makes it evident that this effort has gone far beyond the original dream.

During this period our interactions with Israeli scientists were a major factor in our progress.[14] Trips back and forth and collaborative projects were common. In 1971, Wolfie Traub and I published a review that brought into focus the current research at a critical time [39].

Of course, we were on the brink of the era of molecular biology. Manual and even automatic sequencing of polypeptide chains was about as tedious a task as one can imagine. It beggars the mind to think how we have gone from that technology to the DNA sequencing of today that has now given us the whole human genome.

PHYSICAL CHEMICAL STUDIES

Some people have thought that I was basically a physical chemist. That is not true, although the technology appealed to me and I have frequently used it, as has already been noted. One such study arose when Merry Sherman came into my laboratory about 1967. She brought with her a partially completed problem on mechanochemistry begun with Aharon Katchalsky[15] at the Weizmann Institute in Israel. Aharon had built a machine in which a cross-linked collagen tape was wound over several wheels and passed through two baths, one containing water and the other concentrated lithium bromide (LiBr). On entering the LiBr, which is a strong denaturing agent, the collagen triple helix would collapse and a section of tape would shrink. On reaching the water, the LiBr would be washed out, helix would reform, and the tape would return to its original length. Properly connected in the machine, the reversible shrinkage and stretching would make the wheels move continuously. To a casual observer, it would seem to be a perpetual motion machine, but of course the mechanical force was derived from the chemical energy of dilution of the LiBr as it was carried by the tape bound to denatured collagen from one bath to the other. It was a mechanochemical engine. Merry's task was to show that when collagen denatured it bound LiBr and released it when force was used to restore the triple helix. It was a neat problem successfully completed with complex thermodynamics that I did not fully understand. However, it made me a proud coauthor with Aharon and Merry [40].

Merry and I went on to study helix formation in a small CNBr peptide from α1(I). It was shown that this process could be treated as a reversible third-order chemical reaction [41,42] as opposed to the phase transition applied to the melting of whole collagen. The application of this result to biological questions is perhaps not obvious, but it brought a great deal of understanding to the problem in general.

FIBRIL STRUCTURE OF COLLAGEN

The period from about 1960 to 1970 was highly productive and exciting. It seemed as though each experiment suggested another in a never-ending stream — and most of them worked. It was the scientific method (hypothesis, experiment, proof) at its best. Having reached the original goal of characterization of the type I collagen molecule, it was natural to keep going and study fibril structure and assembly. To do this, I felt I needed to know more about the three-dimensional structure of proteins and the associated technologies.[16]

To accomplish this, I spent the academic year 1972–1973 in the laboratory of David Phillips (now Sir David Phillips) in Oxford, England, working with Andrew Miller and his students.[17] Andrew was analyzing in more detail than was previously possible the packing of collagen molecules in the fibril. He had been able to obtain improved x-ray diffraction patterns. I will return to these studies later. There were also extensive computational facilities and electron microscopy available. Most important, there were people who thought about and worked with proteins in three dimensions.

I had the composite sequence of the α1(I) chain with me. We discussed within Andrew's group the idea that there must be some evidence in the sequence of the *D* stagger between molecules. That is, because side chains interact between molecules to determine the *D* stagger, there must be complementarity (as opposed to homology, which was absent). We did what amounted to an autocorrelation analysis using, in one case, the sequence of charged amino acids and, in another, the sequence of amino acids with large hydrophobic side chains. These are the side chains that would interact. We called it an interaction analysis. The sequence

[14] I had many friends and colleagues at the Weizmann Institute in Rehovot and at the Hadassah Medical Center in Jerusalem, including Wolfie Traub, Ephraim Katchalsky, Shmuel Shoshan, and Jacob Menczel. These kinds of relationships are what make science a personal as well as an intellectual experience. My experiences in Israel could be the subject of another chapter.

[15] Aharon Katchalsky (later Katzir) was a well-known physical chemist specializing in irreversible thermodynamics. He was killed several years later in a random attack by Japanese terrorists at the airport near Tel Aviv. His brother, Ephraim Katchalsky-Katzir, was an equally well-known chemist (proteins), who later became president of Israel.

[16] I toyed with the idea of going to a laboratory where I could learn the techniques of cell and molecular biology. I decided that three-dimensional protein structure was closer to what I already knew and better for an old dog learning new tricks. I often wonder what would have happened if I had chosen the other course.

[17] This year was one of the most pleasant in my life. I need not state that scientists in the United Kingdom have every bit the same intellectual drive and ability as anywhere else, but they are more relaxed and do fewer experiments. The secret is that with more thoughtful planning, their success rate is higher than elsewhere.

was compared with itself as one chain was slid past itself one residue at a time. Wherever an amino acid of one charge on one chain was close to an amino acid of opposite charge on the other, a positive score was recorded and summed to give a total score for that stagger. The same was done for hydrophobic amino acids, but of course they are only of one kind. If at any stagger a maximum in the total score was seen, this would be evidence of complementarity and perhaps indicative of a real set of interactions.

The result is shown in Figure 7 [38].[18] There were indeed maxima in both analyses at staggers of 234, 468, 702, and 936 residues that were more prominent in the sum of the two curves. The *D* stagger must then be 234 amino acid residues. Because the residue spacing along the axis of the collagen fiber is known to be 0.286 nm and 0.286 × 234 is 66.9 nm, 234 amino acid residues is entirely consistent with x-ray and electron micrographic measurements of *D* but expressed in structural units. It was noted, and can be seen in Figure 7, that within the hydrophobic interaction curve there was additional structure. Analysis showed this to be based on an approximate 2 *D*/11 (42.5 residues) repeat of hydrophobic residues in the α1(I) sequence but its relationship to structure was unknown at that time. I will return to this surprising point later. This one-dimensional solution of fibril structure allowed us to reconstruct from the sequence the band pattern of the collagen fibril seen by electron microscopy [43]. This is illustrated in Figure 8.

At Oxford, we also prepared and analyzed electron micrographs of some polymorphic collagen fibrils prepared *in vitro*. These included centrosymmetric fibrils, diagonally banded fibrils, and checkerboard fibrils [43]. The result was that these fibrils could all be explained if there were a *D* periodic filamentous substructure arranged in various ways. The limit diameter could be calculated as about 4.0 nm. It has also been clear from electron micrographs of normal collagen fibrils that they appear to be composed of narrow filaments or microfibrils, as can be seen in Figure 9.

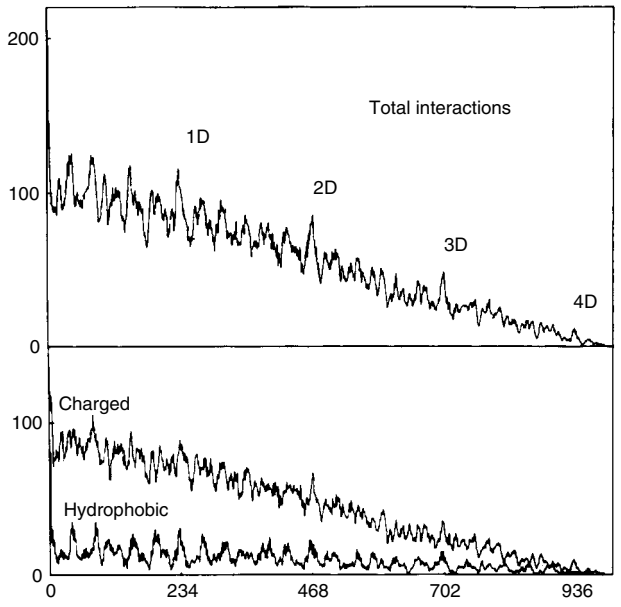

Figure 7. An interaction analysis of charged and hydrophobic side chains in the α1(I) chain [38]. The y-axis is the interaction score and the x-axis is the stagger. See text for explanation.

[18]It was the practice in many British laboratories in their search for equality to list authors alphabetically. I complained about this to David Phillips, feeling that I had been the major contributor to this project and should be first author. He was polite but obdurate. In any case, the group was very much a congenial team.

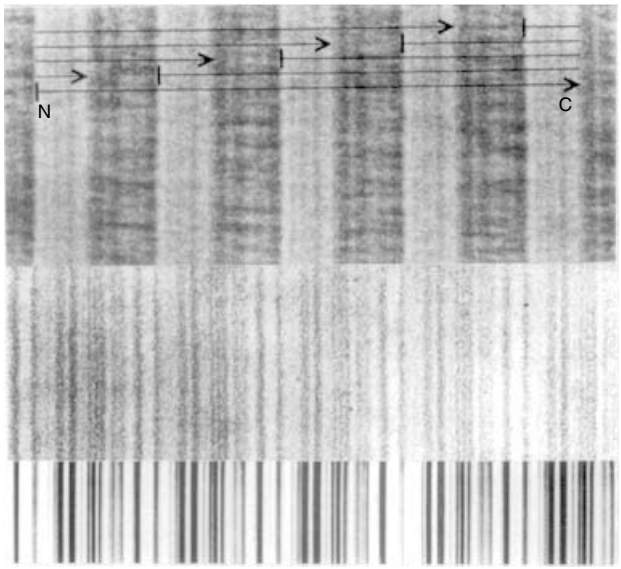

Figure 8. Reconstruction of the staining pattern seen in electron micrographs of a collagen fibril from the amino acid sequence using $D = 234$ amino acid residues [43]. **Top**: An electron micrograph of a fibril negatively stained with phosphotungstic acid. Superimposed is a representation of *D*-staggered collagen molecules showing gap and overlap regions. The gap regions take up more stain (darker) than the overlap regions and there is some positive staining. **Middle**: An electron micrograph of a fibril positively stained with phosphotungstic acid; only charged residues retain stain. **Bottom**: A print of charged residues in the sequence overlapped photographically by *D*. The correspondence among the patterns can best be seen by tilting the page.

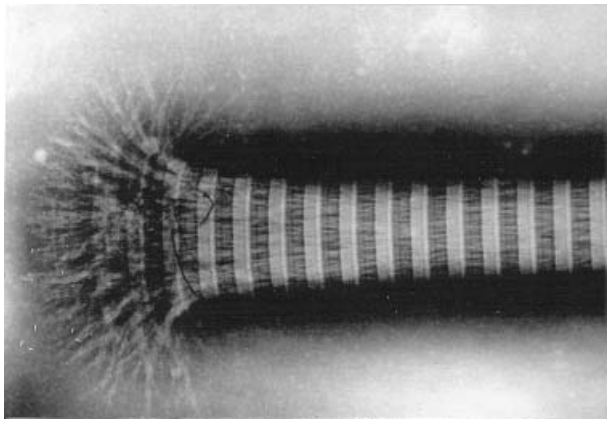

Figure 9. An electron micrograph of a fibril teased from rat tail tendon and cut across in a microtome. The fibril has flared at the end revealing a filamentous substructure that is continuous with the normal *D* periodicity. (Micrograph by K.A. Piez.)

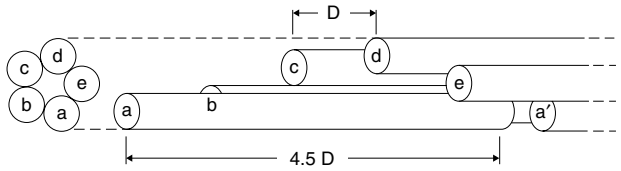

Figure 10. The Smith microfibril [44]. Collagen molecules are represented by rods much shortened for representation. Each molecule is staggered by 1 *D* and rotated by one-fifth of a circle so that the helix is closed after five molecules and the sixth molecule is in line with the first with a gap.

A possible explanation of these microfibrils lies in the structure proposed by Smith [44]. He reasoned that in as much as collagen molecules are 4.4 *D* long, if staggered by 1 *D* and rotated by one-fifth of a circle, they could form a closed five-fold helix of equivalent molecules. Overlap regions would have a cross-section of five molecules while gap regions had four. Such a helix is illustrated in Figure 10. This helix has a calculated diameter of about 4.0 nm and could be the microfibril deduced from electron micrographic evidence. That is, a fibril is a bundle of microfibrils, the number determining the diameter. I will return to this model in a moment, but must keep to chronological order to make clear the reasoning involved.

On returning to the NIH, my research focused first on *in vitro* fibril formation. The identification of an early intermediate was the goal. One was found both by light scattering [45] and by electron microscopy [46]. It contained up to about 100 molecules, but its structure was never determined in detail. It may be that it was not a true intermediate but rather a by-product of *in vitro* conditions. In any case, these studies were not very revealing.

When Benes Trus, an x-ray crystallographer, model builder, and computer scientist, came into the laboratory in about 1975, we returned to the sequence analysis begun in Oxford. That was a one-dimensional analysis. With both the α1(I) and α2(I) sequences now available, we could build molecules in the computer in three dimensions. We also reevaluated conclusions made from the x-ray diffraction data that others had obtained.

Our approach was to evaluate, by interaction curves and Fourier analysis, edges along a collagen molecule that could interact with edges on adjacent molecules. To do this, the supercoil pitch of the α chains had to be known. This can be understood if it is recognized that the amino acids along an edge arise from amino acids in the linear sequence of the α chains spaced apart by the number of residues in the supercoil. X-ray diffraction data at that time gave a value of the supercoil pitch in the range 30–40 residues. We tried many values and found that at 39 residues (*D*/6) the molecule became two-sided. One side was dominated by alternating charged and hydrophobic patches, each kind spaced *D*/6 apart. The other side was dominated by hydrophobic patches *D*/11 apart [47]. Thus, the earlier observation of a 2 *D*/11 repeat in the α1(I) sequence was apparently related to intermicrofibrillar interactions.

This could hardly be a coincidence, or could it? In any case, we proposed that this data fit a microfibril that was a right-handed helix of molecules given a left-handed twist. The *D*/6 sides of molecules would face into the center of the microfibril and define intramicrofibrillar interactions, whereas the *D*/11 hydrophobic sides would be on the outside where interactions between microfibrils would occur. If the twist was 30 *D*/11, the microfibril would have six-fold screw symmetry that would be consistent with hexagonal packing of microfibrils as would be expected [48]. In the microfibril model, there are, then, three levels of coiling, the three-residue left-handed helix of individual α chains, the 39-residue right-handed supercoil of the three α chains in the molecule, and the proposed 30 *D*/11 (638-residue) left-handed twist of the microfibril. These coils have opposite handedness — left, right, left — which is how a rope is made to prevent uncoiling. There may be a fourth level of coiling of microfibrils in the fibril.

The x-ray diffraction data were being refined by Andrew Miller and his colleagues [49,50] in Oxford and Grenoble and by Fraser and MacRae [51] in Melbourne. An example of the kind of diffraction patterns that were obtained is shown in Figure 11. The crystal model proposed by them consisted of molecules in cross-section placed on a near-hexagonal lattice in which the hexagonal planes were spaced by slightly different values. Molecules were related axially by *D* staggers and were straight-tilted by about 5°. The unit cell contained one collagen molecule.

This model certainly fit the diffraction data, but it had no provision for any substructure such as the microfibril that other data favored.[19] I felt that this was a fatal flaw. Furthermore, the supercoil pitch of α chains required by the diffraction data was 30 residues rather than the 39 residues suggested by sequence analysis. Remembering that the data on x-ray diffraction patterns show that coherence is only 10–20 nm — that is, regions of crystalline order may not be large — we proposed what we called a compressed microfibril model [48,52]. In this model, portions of molecules, specifically the overlap regions, were induced to be crystalline as a result of lateral compression arising from stretching or internal crystal energy. A near-hexagonal lattice of molecules in cross-section would be obtained, with systematic displacements explaining intensities of reflections on the x-ray diffraction pattern. Furthermore, the supercoil helix could be distorted by the compression to force ridges into grooves and give a value in crystalline regions of 30 residues but in a relaxed fibril would average 39 residues. The induced order would then be compensated for in the disordered gap regions of the microfibril. The model that we proposed is shown in Figure 12. It has the same unit cell as the refined model of Miller and Fraser [49–51] and fits the diffraction data at least as well. A final feature is that nuclear magnetic resonance spectroscopy (NMR) of relaxed fibrils has shown that, contrary to crystalline order, molecules are in continual motion rotating segmentally about their axes by as much as 30° [53].

We could not be sure that this model was correct, but it was consistent with all the data obtained by electron microscopy, x-ray diffraction, and sequence analysis. Today, 20 years later, there is very little additional data and no better model.

EPILOG

In 1982, I left the NIH and academic research and entered the biotechnology world, working first at Collagen

[19] It is my experience that x-ray crystallographers, with some notable exceptions, treat their data and models very narrowly. Protein crystals are artifacts, including crystalline order in collagen fibers, and may distort reality.

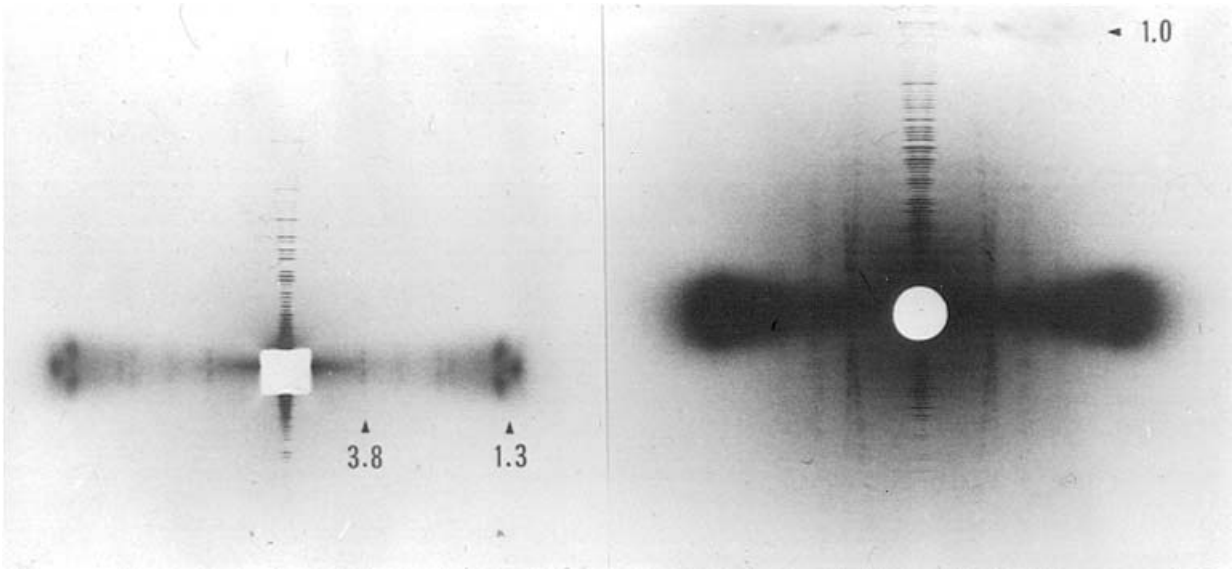

Figure 11. Medium-angle x-ray diffraction patterns of slightly stretched rat tail tendon collagen. **Left**: Unstained. **Right**: Lightly stained with phosphotungstic acid. The reflections along the meridian relate to molecular features sampled by the *D* periodicity. Reflections on and near the equator relate to lateral packing of molecules. Row lines can be seen to be split and sampled on the 1-nm layer line. (Photographs courtesy R.D.B. Fraser.)

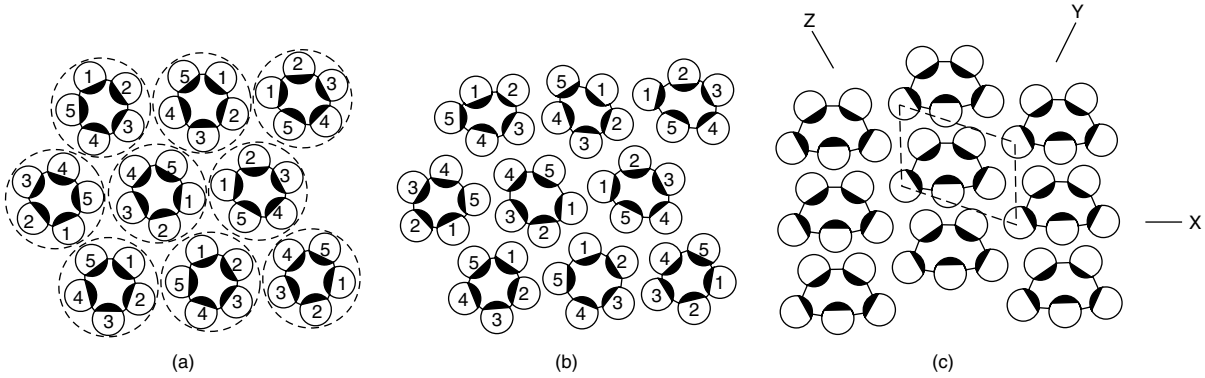

Figure 12. Proposed molecular packing of collagen molecules in cross section cut through the overlap region [48]. **a**: Hexagonally-packed five-fold microfibrils. One side of all the molecules faces to the inside of the microfibrils. **b**: The same microfibrils loosely packed to represent molecular motion in relaxed fibrils. **c**: The same microfibrils under tension (and compression) forcing overlap segments of molecules onto a near-hexagonal lattice with planes X, Y, and Z giving rise to the crystallographic unit cell indicated by dash lines.

Corporation[20] and then at Celtrix Pharmaceuticals[21] in California. We did many interesting things there including discovering transforming growth factor β2. I later played a small role in determining its three-dimensional structure by x-ray diffraction [54]. In 1991, I returned to the east coast as a Fogarty Scholar-in-Residence at the NIH and a part-time professor in Darwin Prockop's department at Thomas Jefferson University in Philadelphia. In 1996, I became scientist emeritus at NIH and remained an advisor to FibroGen, a biotechnology company in California and Europe whose scientific founders were Darwin Prockop, Kari Kivirikko, Sheldon Pinnell, and I. George Martin is Senior Vice President for Scientific Affairs. One of FibroGen's projects is to develop, and one day hopefully manufacture, recombinant human collagen to replace animal-source collagen in medical devices.

The story of collagen chemistry and structure has come a very long way. I can claim to have been a witness to much of it and sometimes to have contributed to its advance. Collagen, and connective tissue, has progressed from being viewed as an inert residence for cells, to an active player in development and disease, such as the heritable disorders of connective tissue discussed in this book.

[20]Collagen Corporation was founded by a group of physicians at Stanford, including John Daniels, who had worked with me as a research associate. John was particularly adept at methodology, which he was able to translate into manufacturing processes. He also had a good sense of entrepreneurship.

[21]Celtrix was a spin-off of the Research and Development Department from Collagen Corporation.

Introduction, Part II

Heritable Disorders of Connective Tissue: A Personal Account of the Origins, Evolution, Validation, and Expansion of a Concept

Victor A. McKusick

Johns Hopkins University School of Medicine and Johns Hopkins Hospital, Baltimore, Maryland 21205

INTRODUCTION

The concept that certain disorders represent generalized, single-gene-determined defects of one or another element of connective tissue is a simple one — especially when viewed from the perspective of 2001. The concept was heuristically powerful because it predicted the practicability of identifying a unitary "cause" at a biochemical, or, as we now say, a molecular level. (This is, in general, a strength of Mendelism.)

Weve, writing in Utrecht in 1931 [1], must have had the concept in mind when he referred to the Marfan syndrome as dystrophia mesodermalis congenita typus Marfan. Furthermore, Archibald Garrod in the same year, in his work *The Inborn Factors in Disease* [2], wrote as follows concerning osteogenesis imperfecta:

> ... the hereditary form of brittleness of the bones which has been observed in large numbers of the members of successive generations of some affected families. The fragility is apparently due to a defect of the mesenchyme, leading to an imperfect formation of connective tissues, rather than to any imperfect laying down of calcium salts in the bones; for the blue colour of the sclerotics of the eyes of those members of a family in which the condition occurs, is certainly due to imperfection of the fibrous tissue of the sclerotics, which, being less opaque than it should be, allows the black pigment of the choroid to show through it.

These writings were not the source of the concept for me, however. Rather, I can trace it to two colleagues at Johns Hopkins, Bentley Glass, who schooled me in the principle of pleiotropism, and Richard Follis, who, in essence, had the concept in relation to osteogenesis imperfecta.

My first published piece of clinical investigation concerned the syndrome of polyps and spots, which became known as the Peutz-Jeghers syndrome [3]. In the study of the five cases I collected and reported with the five that Harold Jeghers had observed in Boston, I sought the advice of Professor Glass in the Department of Biology at Johns Hopkins. He made it clear to me that genetic linkage was an unlikely cause of the syndrome and that pleiotropic expression of a single mutant gene was the probable explanation, even for such an improbable association as polyps and spots. That was in 1949 [4].

In a pathology conference at Johns Hopkins in 1950, Richard Follis, an associate professor of pathology, presented a case of lethal osteogenesis imperfecta congenita that he had studied in great detail because of his interest in bone disease. Histologically, he showed that not only the organic matrix of bone [5] but also connective tissue of the skin and sclera (and perhaps other structures) was defective [6,7].

It was soon thereafter that I began studies of the Marfan syndrome, when patients with this disorder were encountered in my experience as a cardiologist beginning in 1948. The designation "heritable disorder of connective tissue", and a formal statement of the concept, probably first appeared in print in March 1955 in an article in *Circulation* entitled, "The Cardiovascular Aspects of Marfan's Syndrome: A Heritable Disorder of Connective Tissue" [8].

Parenthetically, "heritable" was chosen, rather than "genetic" or "inherited", to convey the notion that the disorders are capable of being inherited, although in the individual instance they may have arisen by new mutation — another concept that Bentley Glass taught me.

Note that in March 1955 I wrote "Marfan's syndrome." Perhaps the editors of *Circulation* changed my usage. At any rate, when my full-dress article on the Marfan syndrome appeared in the *Journal of Chronic Diseases* in December 1955, the nonpossessive form of the eponym was used. Indeed, it is probably to the then-editor of this journal, J. Earle Moore,[1] that I owe my devotion to nonpossessives. He, in turn, got it from Morris Fishbein, longtime editor

[1] J. Earle Moore (1892–1957), a distinguished Johns Hopkins syphilologist, founded a multifaceted chronic disease clinic at Johns Hopkins as an outgrowth of his venereal disease clinic. It was that clinic I took over on July 1,1957, renamed the Moore Clinic, and developed into a medical genetics clinic that, at the same time, studied chronic diseases such as hypertension, systemic lupus erythematosus, sarcoidosis, and even cancer (the beginning of medical oncology at Johns Hopkins). In 1989, with the creation

Connective Tissue and Its Heritable Disorders, pages 13–18

of the *Journal of the American Medical Association* (AMA) who, in his manual on medical writing (and in his editing of AMA journals), insisted on the nonpossessive form. Amusingly, later editions of the *AMA Manual of Style* favored the possessive form. Over the years, I have had a difficult time over this issue with editors, who seem to have problems realizing that eponyms are convenient "handles," but not statements of property rights. However, the ninth and latest edition of the *AMA Manual of Style* (1998) recommends that the possessive form be avoided in eponymous terms.

The concept of heritable disorders of connective tissue, developed around the Marfan syndrome and osteogenesis imperfecta, logically suggested that there must be other disorders that fitted the category. The Ehlers-Danlos syndrome was an obvious one and pseudoxanthoma elasticum another. I undertook studies of these and of the Hurler syndrome in 1954 and 1955. The chapters of my monograph *Heritable Disorders of Connective Tissue* were first published serially in monthly issues of the *Journal of Chronic Diseases* from November 1955 to May 1956, inclusive. The collected chapters, with preface, acknowledgments, index, and a portrait of Archibald Garrod, to whom the book was dedicated, appeared in hardback in June 1956 [9]. J. Earle Moore advised the publisher that the book would be of limited interest, mainly to geneticists, for which reason only 1,000 copies were printed. All 1,000 were sold by Christmas of 1956. That was the only error of judgment in which I ever caught Dr. Moore.

The inclusion of the mucopolysaccharidoses among the heritable disorders of connective tissue was prompted mainly by a seminal paper by Brante [10], published in 1952, in which he pointed out that the storage material is mucopolysaccharide, not lipid. The disorder had been called lipochondrodystrophy by Washington [11] in the 1930s, on the basis of the mistaken impression that the storage material was lipid. The designation was, admittedly, an improvement on "gargoylism," which was used for a long time, especially in publications in English, on the basis of the clinical appearance of patients with the Hurler syndrome. Lipochondrodystrophy was the term adopted for the *Index Medicus*, which persisted in using it until well into the 1970s — several years after the nature of the disorders as lysosomal degradation defects had been thoroughly established.

ADDITIONAL HERITABLE DISORDERS OF CONNECTIVE TISSUE

From the first edition of *Heritable Disorders of Connective Tissue* (1956) [9], fibrodysplasia ossificans progressiva and some other disorders have been discussed as such conditions. Skeletal dysplasias, i.e., the "chondrodystrophies," were discussed mainly in relation to their differentiation from the Morquio syndrome and only to a limited extent in their own right, until the fourth edition (1972), when a fairly full discussion with abundant illustrations of individual types was given and the international classification was presented. (In fact, the Morquio syndrome was discussed only as part of the differentiation from the Hurler syndrome until the third edition [1966], when it became part of a six-way classification of the mucopolysaccharidoses.)

During the period 1962 to 1965, discovery of the simulation of the Marfan syndrome by the inborn error of metabolism, homocystinuria, drew attention to the fact that heritable disorders of connective tissue can be secondary in nature, the connective tissue becoming damaged as a result of a primary defect that leads to an accumulation of metabolites, a deficiency of metabolites, or both. A separate chapter on homocystinuria appeared in the third edition (1966). At the same time, a chapter was devoted to alkaptonuria, which, in its disabling clinical feature, namely the characteristic spondyloarthropathy, and perhaps valvular heart lesions, is a heritable disorder of connective tissue. Menkes disease is also a heritable disorder of connective tissue, although not a primary one; it found its way into the fourth edition (1972).

Cutis laxa, which should have had a separate chapter from the beginning, was elevated from being merely part of the differential diagnosis of the Ehlers-Danlos syndrome to separate-chapter status in the fourth edition (1972). Like the chondrodystrophies, epidermolysis bullosa also came to be recognized as a heritable disorder of connective tissue. Work so indicating was discussed as early as the first edition (p. 315).

The 1972 edition also had an extensive discussion of skeletal dysplasias as a separate chapter, but no other major chapters were added. With the molecular delineation of genetic disorders at an increasing pace during the last decade, the kinship of many other disorders to the classic heritable disorders of connective tissue has become evident, as reviewed in this volume.

THE IDENTIFICATION OF GENETIC HETEROGENEITY

The three main principles of clinical genetics relate to pleiotropism, genetic heterogeneity, and variability. The first has already been referred to. Repeatedly, in recent decades, when a particular phenotype ("disorder") has been studied in detail, two or more genetically separate, although clinically similar, entities have been found. Thus, the separation of homocystinuria from the Marfan syndrome was an example of the identification of genetic heterogeneity. Establishing subtypes of the "true" Marfan syndrome, in a convincing manner, has been difficult. In part, this is because of the third principle listed above, namely, variability. We have shown, for example, that even brothers can differ widely in the severity and even the nature of the manifestations. But, of course, the main reason it was difficult to establish heterogeneity was the lack of knowledge of the basic biochemical defect in the Marfan syndrome until 1991 (see below).

Genetic heterogeneity has been studied extensively in relation to the Ehlers-Danlos syndrome, osteogenesis imperfecta, the mucopolysaccharidoses, and the skeletal dysplasias. Of these categories, the genetic nosology (the delineation and classification of genetic disorders) of the mucopolysaccharidoses has been most satisfactory, simply because cell physiology and enzymology have provided methods for defining the basic defect in each. I have reviewed the nosology of these disorders elsewhere [12]. Two forms, the autosomal recessive Hurler syndrome and the X-linked Hunter syndrome, were recognized in 1956, although the chapter was entitled "The Hurler Syndrome." By the third edition of *Heritable Disorders of Connective Tissue* (1966), a six-way classification was possible. By the fourth edition

of the Center for Medical Genetics at Johns Hopkins in another site and the pressing problems of the AIDS epidemic, the Moore Clinic was restored in large part to its original function as a clinic for sexually transmitted diseases. In 1999, the Center for Medical Genetics became the Institute of Genetic Medicine.

(1972), mucopolysaccharidosis (MPS) V (Scheie syndrome) of the six-way classification had been recognized as an allelic variant of the Hurler syndrome, and presumed genetic compounds were identified; at least two subtypes of the Hunter syndrome (MPS II) and the Maroteaux-Lamy syndrome (MPS VI) were characterized on the basis of clinical severity; three clinically indistinguishable subtypes of MPS III (Sanfilippo syndrome) were identified on the basis of specific enzyme deficiencies; and MPS VII (Sly syndrome; β-glucuronidase deficiency) had been characterized. A fourth form of Sanfilippo syndrome (MPS IIID) and a form of Morquio syndrome due to β-galactosidase deficiency (MPS IVB) were found later in the 1970s.

The Ehlers-Danlos syndrome (EDS), defined as hyperextensible skin and joints, has been found to have extensive heterogeneity. For the most part, differentiation has been on clinical grounds, beginning with the five-way classification advanced by Beighton (1970) in his monograph [13]. As biochemical defects were identified, separate forms could be recognized. The first molecular defect to be found in a heritable disorder of connective tissue was deficiency of lysyl hydroxylase [14], in a form of the EDS that I called the ocular-scoliotic type (or type VI). Characterization of the clinical phenotype — marked fragility of the eyeball, leading to rupture from even minimal trauma, and severe scoliosis — was useful to the nosology, even though the enzyme deficiency could not be demonstrated in some clinically typical cases [15], indicating that heterogeneity exists even within one type. The identification of apparently persistent procollagen in a clinically characteristic form of EDS that had also been called arthrochalasis multiplex congenita strengthened the case for a further separate form, type VII [16]. With the proliferation of other forms, the classification reached a total of about a dozen types of EDS. EDS XI was called familial joint instability syndrome by Horton et al. [17] and some would question the necessity or desirability of classifying it as a form of EDS. All classifications need a category for cases (and their families) that defy precise pigeonholing; that is, type XII in some classifications of EDS. Some families with mitral valve prolapse as a predominant feature in multiple members in a dominant pedigree pattern have joint and skin changes that might qualify them either for the diagnosis of a form of EDS or for labeling as MASS (mitral, aorta, skin, skeleton) syndrome, an overlap disorder [18].

Over time, it became apparent that the diagnostic criteria established in 1986 and published in 1988 [19] failed to discriminate adequately between different types of EDS, and between different types of EDS and other phenotypically related conditions. In addition, elucidation of the molecular basis of several types of EDS has added a new dimension to the characterization of this group of disorders, and thus a revised classification of EDS, "the Villefranche nosology, 1997" was proposed, based primarily on the cause of each type [20]. This simplified classification into six major types, the guiding principle in the formulation of which was their usefulness to the generalist, and defines major and minor diagnostic criteria for each, complemented wherever possible with laboratory findings. It should aid the accurate diagnosis of EDS, thereby facilitating improvement in the following areas: (1) diagnostic uniformity for clinical and research purposes, (2) natural history, (3) management, (4) genetic counseling, and (5) potential areas of research.

From an early stage, osteogenesis imperfecta (OI) was recognized as occurring in two forms, congenita and tarda. The two forms were separately described in the nineteenth century, and based thereon were given separate eponyms, Vrolik and Lobstein, respectively. The most widely used classification in recent years has been that of Sillence [21–24], which recognizes four main types, with subtypes of type II, osteogenesis imperfecta congenita [22]. This clinically based classification, however, was shaken when it turned out that different (allelic) mutations in one and the same gene, i.e., that for the α1 chain of type I collagen, can result in any of several types of OI, from the mildest tarda to the most severe congenita and even result not in OI but in EDS. This should not have surprised us, because the experience with that other heteromeric protein, hemoglobin, had taught us precisely the same lesson.

Subclassification of pseudoxanthoma elasticum (PXE) was long unsatisfactory, again mainly because of lack of biochemical understanding. Pope [25,26] classified PXE into two autosomal dominant and two autosomal recessive forms, based on mode of inheritance and clinical characteristics. With the demonstration that the basic defect in PXE resides in the gene, *MRP6*, for the ATP-binding cassette protein, ABCC6 (MIM 603234), it has been found, however, that various mutations cause either autosomal recessive or autosomal dominant forms of the disorder; there is no evidence of nonallelic heterogeneity (see Chapter 11, this volume).

THE SEARCH FOR BASIC DEFECTS IN HERITABLE DISORDERS OF CONNECTIVE TISSUE

Fundamental to the concept of heritable disorders of connective tissue was, of course, the notion that a unitary defect involved primarily one element of connective tissue. Collagen was fairly clearly that element in the case of OI. Further pinpointing of the defects has had to await the development of methods and knowledge in the years since Follis's publications [5–7]; since that time, the specific collagen involved has been found to be "collagen vulgaris," or type I collagen, the predominant collagen of skin, tendon, and bone. Identification of the basic defect has come more slowly in the case of the other disorders of the fibrous elements of connective tissue.

If anyone had asked me in 1960, when the second edition of *Heritable Disorders of Connective Tissue* was published, how long it would take before the basic defect in the Marfan syndrome was known, I am sure I would have predicted a much shorter time than the 31 years it did in fact require to establish that it resided in *FBN1*, the gene for fibrillin-1 [27]. Because the 1957 work of Vernon Ingram had identified a single amino acid substitution in the β-globin molecule as the basis of sickle cell anemia [28], and because of the support this finding provided for the Pauling concept of molecular disease, we were thinking that sequencing of the collagen molecule(s) or the protein(s) of the elastic fiber would reveal a similar simple change in heritable disorders of connective tissue. Indeed, that proved to be the case, but demonstration thereof had to await methodologic advances for the study of genes and proteins that, in the case of the connective tissues, were many times larger than the globin genes and proteins.

> The demonstration that the anomaly in certain hemoglobin variants consists of substitution of one amino acid out of many making up the hemoglobin protein stimulates speculation about the nature of the fibrous proteins in heritable disorders of connective

> tissue. It is to be hoped that studies in the near future will explore the possibility, for example, that in osteogenesis imperfecta an anomalous species of collagen is produced which differs in only one amino acid from the collagen in persons free of the disease. (McKusick, *Heritable Disorders of Connective Tissue*, 1960, p. 317).

As stated earlier, lysyl hydroxylase deficiency in type VI EDS was the first specific defect to be found — the work of Krane, Pinnell, and Erbe [14]. Underhydroxylation of lysyl residues in collagen was the tip-off. Discovery of other defects in collagen in EDS followed thereafter: the demonstration of deficiency of type III collagen in type IV EDS [29] and the demonstration of structural defects in type I procollagen preventing its normal conversion to collagen in type VII EDS [30,31], rather than this disorder being caused by procollagen N-proteinase deficiency as originally suggested [16]. Elaboration of the molecular lesions present in these disorders is discussed elsewhere in this volume.

Molecular methods have permitted the proof of *de novo* dominant mutation as the basis of the overwhelming majority of cases of OI congenita. In those instances of more than one affected sib, gonadal mosaicism is suspected and, indeed, has been proved by analysis of DNA of the sperm of the father [32]. The curious fact that complete loss of one of the two types of polypeptide chain that make up the type I collagen molecule can be much less disruptive than deletion of a segment of one chain has been explained as a consequence of what Darwin Prockop has called "protein suicide" [33]: Because of the deletion, that chain does not associate appropriately into the triple-helical molecule and those molecules that are formed are unstable. Thus, even though only half of the chains are of the mutant type, a majority of the heteromeric molecules will be affected and the clinical picture will be severe.

Elucidation of the basic defects has been aided greatly by cell culture techniques. In the first edition of *Heritable Disorders of Connective Tissue* (1956), I suggested the usefulness of tissue culture to the study of this group of disorders, particularly to the study of the mucopolysaccharidoses.

> In connection with the heritable disorders of connective tissue, the first objective of tissue culture studies should be the *in vitro* replication of the morphological abnormalities. In osteogenesis imperfecta and in the Hurler syndrome one can with justification anticipate success in demonstrating morphologic abnormality, in the fibers formed in the first instance, possibly in the fibroblast itself in the second, i.e., the "gargoyle cell" may be demonstrable in culture (McKusick, *Heritable Disorders of Connective Tissue*, 1956, p. 210).

Danes and Bearn [34] demonstrated a cellular phenotype of the mucopolysaccharidoses, specifically cytoplasmic metachromasia, and concluded that heterozygotes for the Hunter syndrome show in culture two classes of cells: those with metachromasia (like that in the hemizygous affected male) and those without cytoplasmic metachromasia. But it remained for Elizabeth Neufeld and her colleagues to apply to cell cultures more refined measures of abnormality, namely the accumulation of ^{35}S and its impaired "washout" [35]. Their creative next step was to "nail down" the basic distinctiveness of several types of mucopolysaccharidosis by mixing experiments, which also served the purpose of demonstrating "correction factors" that are secreted from cells. The identification of a unique correction factor in each disorder was the basis for identifying the specific enzyme deficiencies.

The concept of lysosomal storage diseases was not advanced until 1964 [36]. In the third edition of *Heritable Disorders of Connective Tissue* (1966), the thinking that had prevailed up to that time — that there was an overproduction of mucopolysaccharides rather than defective degradation of them — was still echoed. It was even suggested by Dorfman at one time that there might be a change in the protein core of the mucopolysaccharides such that turnover did not occur properly, and regulation was disturbed [37].

In the late 1950s, the study of mucopolysaccharides excreted in the urine was a main method for identifying these disorders as mucopolysaccharidoses, and in the 1960s a main method for distinguishing them — on the basis of the specific pattern of mucopolysaccharides in the urine. It was puzzling that in both the Hurler and Hunter syndromes, clearly distinct entities, the same mucopolysaccharides were excreted in excess, namely dermatan sulfate and heparan sulfate. But the predominant excretion of heparan sulfate in the Sanfilippo syndrome was a strongly differentiating feature, as was also the excretion of keratan sulfate in the Morquio syndrome and the predominant excretion of dermatan sulfate in the Maroteaux-Lamy syndrome (MPS VI).

This volume discusses a number of newly elucidated diseases that any new edition of *Heritable Disorders of Connective Tissue* would need to discuss, even in separate chapters. One such condition is the Stickler syndrome. Demonstration that the defect in at least one form of the Stickler syndrome resides in type II collagen was established essentially by a reverse genetics approach; it was shown by Francomano et al. [38] that the clinical phenotype is linked (with no recombination) to the type II collagen gene. Because type II collagen, or cartilage collagen, occurs in cartilage, including the nucleus pulposus, and also in the vitreous of the eye and in the inner ear, the joint, spinal, ocular, and auditory features of the Stickler syndrome find ready explanation. Another example is Alport syndrome, the X-linked form of which results from defects in the $\alpha 5$ chain of type IV collagen [39]. Another form of Stickler syndrome has a defect in the $\alpha 1$ or $\alpha 2$ chains of type XI collagen, and an autosomal recessive form of Alport syndrome has a defect in the $\alpha 3$ chain of type IV collagen.

In the case of cutis laxa, mutations have been identified in two different genes, the elastin gene (which when deleted causes a different disorder, supravalvular aortic stenosis) and the X-linked gene, *ATP7A*, which causes neonatal cutis laxa and a special form of cutis laxa, the occipital horn syndrome. (Other mutations in *ATP7A* cause Menkes syndrome.)

The search for basic defects illustrates the evolution of methods in the last 45 years. Cell culture methods have already been noted; biochemical methods for the characterization of the several forms of collagen and other connective tissue proteins came along in the 1960s and 1970s, and still continue. Since 1980, methods for studying the genes themselves provided by recombinant DNA technology have made it easier in most instances to study the gene or the messenger RNA than to study the protein gene product.

Since 1989, in *Mendelian Inheritance in Man* (12th print edition in 1998) and in the continuously updated online version thereof (OMIM; www.ncbi.nlm.nih.gov/omim), we have been cataloging the intragenic lesions identified as the fundamental "causes" of various genetic diseases [40]. Called

allelic variants, these include point mutations and length mutations. The point mutations include nonsense mutations, missense mutations, initiator codon mutations, terminator codon mutations, promoter mutations, and splicing mutations. The length mutations include deletions, insertions, duplications, and rearrangements. The information now available reflects the extent to which methods for identifying mutations have advanced. Cataloging the information is considered important for the design of DNA diagnosis, as well as for theoretical analysis.

In summary, I have outlined the origin of the concept of heritable disorders of connective tissue, its evolution with the delineation of genetic heterogeneity and primary and secondary forms, and finally its validation by the definition of molecular defects. The concept is undergoing continuing expansion as susceptibility to common disorders of connective tissue, e.g., osteoporosis, osteoarthritis, and aneurysm, is being related to genetic differences in type I, type II, and type III collagen, respectively.

INTRODUCTION

In this chapter we focus on the organization of the connective tissue and the structure of other components in skin and tendon. Both have similar matrix composition, but they have dissimilar morphologies reflecting their very different functions. The skin is an organ that forms the "covering" of the body. It contains all of the tissues of the body and maintains a structural and functional barrier between the internal environment of the organism and the external environment, and thus has well-developed mechanisms to protect against radiant energy, mechanical trauma, microbial invasion and water loss. In contrast, the tendon is an internal, cylindrical or ribbonlike **structure** composed of fibrous connective tissue and cells organized to serve the specific function of mediating and sensing tension between muscle and bone. The organization of the connective tissue matrix in the skin and tendon illustrates the diversity of connective tissue matrix assemblies and their specialization to subserve specific functions. It is important to recognize, however, that these macro-matrix assemblies reflect tissue-specific matrix hierarchies and cell-matrix microenvironments, and that these contribute to the regulation of matrix organization as a whole. In the skin, for example, matrix molecules that exist on the surfaces of fibroblastic cells interact with elements of the cytoskeleton, thus influencing their shape, attachment, and migration, and determining their role in matrix synthesis and deposition. Our discussion of skin goes beyond the structure and composition of the matrix by reviewing the other tissues and structures which are part of the skin and which influence and interact with the dermal connective tissue.

SKIN

Epidermis

The Keratinocyte and Epidermal Layers

The epidermis is a 0.06–1.0 mm-thick, keratinized, stratified squamous epithelium that covers and is attached to the dermis (Fig. 1). It consists of viable (basal, spinous, granular) and nonviable (cornified) keratinocytes organized into layers. Other resident cell types migrate into the epidermis during embryogenesis or differentiate *in situ* in a pathway that is distinct from that of the keratinocyte. The basal layer of keratinocytes includes dividing cells. Some spinous cells may still belong to the proliferative pool of cells, but the majority of them, like the granular cells, are postmitotic. The cornified layer is comprised of dead, keratinized cells that form the protective outer layer of the skin. The various cells of the epidermal layers differ (at least) in size, shape, position, kinetic properties, mechanical strength, hydration, biochemical composition, and cytoplasmic and cell surface antigens. Many of these differences reflect the state of differentiation of the cells in their respective layers.

The basal cell layer. Basal keratinocytes of the stratum germinativum are cuboidal to columnar in shape (Fig. 1). They join with each other by desmosomal junctions and attach to the underlying basal lamina by hemidesmosomes and integrin receptors [1,2]. Both junctions are well characterized in terms of their structure and protein composition [3,4], although how they assemble and interact

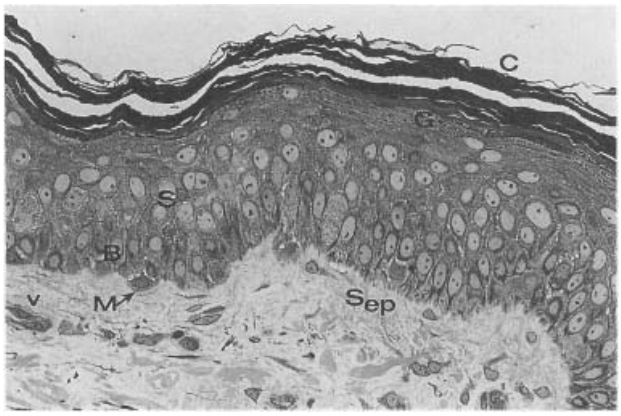

Figure 1. Histologic section of the full thickness adult upper arm epidermis showing basal (B), spinous (S), granular (G), and cornified (C) cell layers. A melanocyte (M) is indicated. Note the fine connective tissue of the subepidermal zone (S_{ep}), the vessels (v), and the abundance of cells in this portion of the papillary dermis. ×435.

Connective Tissue and Its Heritable Disorders, pages 19–39

(at the molecular level) with elements of the cytoskeleton is yet to be resolved. Fine bundles of low molecular weight, keratin intermediate filaments (50 and 58 kDa keratins, or K14 and K5 [5,6]) extend throughout the cytoplasm and insert into the attachment plaques of the desmosomes and hemidesmosomes at the cell periphery (Fig. 2). The keratin filaments, actin microfilaments, and microtubules form an integrated cytoskeleton that preserves the shape and structural integrity of the keratinocyte, yet which is sufficiently flexible to permit the cell to move out of the basal layer into the suprabasal compartment. The keratins account for approximately 30% of the total protein in basal cells [7].

Although all basal cells in normal human epidermis are similar morphologically, they are heterogeneous in function. Stem cells, transient amplifying cells, and postmitotic cells have been identified within the basal layer of monkey palm epidermis [8,9]. In this tissue, deep rete ridges alternate with thinner epidermal regions. Basal cells that are located in the deep rete ridges and have a smooth basal border are thought to be stem cells. They contain fewer keratin filaments, are heavily melaninized, divide slowly, and give rise to highly proliferative, suprabasal, transient amplifying cells. The latter cells become postmitotic in the differentiating cell compartment as they move toward the epidermal surface. In contrast, basal cells located in the shallower portions of the epidermis have serrated basal borders and a more extensively developed network of keratin filaments. They contain less pigment and have limited incorporation of ^{3}[H] thymidine and are suggested to attach the epidermis to the dermis. The marked differences between these two populations of basal cells in monkey palm are less apparent in palmar and other epidermal tissue of the human, but nonetheless can be demonstrated [8,9]. Other studies have also documented the presence of stem cells in human adult and fetal epidermis [10–12].

The spinous cell layer. Three to four layers of suprabasal keratinocytes constitute the stratum spinosum (Figs. 1 and 2). The name of this region is derived from the image of spines that is created when the cytoplasm between desmosomal attachments shrinks toward the nucleus as a result of chemical fixation and dehydration during histological preparation. The morphology and composition of spinous cells change between the lowermost (suprabasal) and uppermost (subgranular) layers. The cells immediately above the basal layer are polyhedral; those adjacent to the granular layer are flattened and appear rectangular in sectioned specimens. All spinous cells contain large, well-formed bundles of keratin filaments (Fig. 2) that include the K5 and K14 keratins synthesized in basal cells plus the pair of high molecular weight (56.5 and 67 kDa, or K1 and K10), differentiation-specific keratins [13] expressed as new gene products by these cells. Keratin accounts for a greater percentage of the total protein in the cell than it does in the basal keratinocyte (up to 85%) and is presumed to form a more rigid cytoskeleton.

Cells of the uppermost spinous layer contain other proteins characteristic of a more differentiated epidermal phenotype and organelles which participate in the events of terminal differentiation. Involucrin [14,15], keratolinin [16], loricrin [17], and the pancornulins [18] are proteins that will contribute to the cornified cell envelope (see below). They are first synthesized in the uppermost spinous cells. Small (100–500 μm diameter), membrane-bound organelles called lamellar granules are present in the cytoplasm. The contents of lamellar granules are arranged in alternating thick and thin lamellae that are thought to represent packing of either a series of flattened membrane disks or liposomelike structures [19]. The lipid-rich composition of lamellar granules — phospholipids, glycolipids, and free sterol — is accounted for by the membranes. Lamellar granules also contain proteolytic enzymes (lipases, proteases, glycosidases) which are thought to remodel the lipids once they are released into the extra-cellular space (see below) [20–22]. Other differentiation markers expressed by spinous layer

cells include the surface-associated pemphigus antigen, blood group antigens [23], various receptors and carbohydrate moieties [24], and membranous and intercellular lipids.

The granular cell layer. Keratin filaments form even larger bundles of filaments than in the spinous cells in cells of the two or three granular cell layers and they associate with an electron-dense protein, profilaggrin, to form keratohyalin granules (Fig. 3a). Profilaggrin, synthesized in the granular cell layer, is a high molecular weight (>400 kDa), histidine-rich, phosphorylated polymer of filaggrin monomers joined by link proteins [25,26]. It is synthesized only in keratinizing cells that express the high molecular weight keratin pair [27]. It is unclear whether, or how, the keratohyalin granules function in the granular cell layer; rather, their role appears to be related to organization of the cornified cell. Alterations in the synthesis and processing of profilaggrin with concomitant alterations in keratohyalin structure (or absence of keratohyalin granules altogether) occur in different forms of ichthyosis [28,29].

The protein constituents of the cornified cell envelope, identifiable in spinous cells, become cross-linked by calcium-dependent, epidermal transglutaminase enzymes within granular cells, even though the cornified cell envelope

Figure 3. Electron micrographs of the granular (**a**) and uppermost granular and first cornified cell layers (**b**). In (**a**), note the large, stellate keratohyalin granules (KHG) associated with intermediate filaments (arrow) and lamellar granules (LGs) in the cytoplasm. The lamellar granules in (**b**) are evident in clusters within the extracellular space between the granular and cornified cells. Note the cornified cell envelope (CCE) in the first cornified cell and the modified desmosome (D) present between the two cell layers. (a) ×16, 500; (b) ×61, 300.

itself is evident morphologically only in the cornified cell (Fig. 3b). A cytosolic form of epidermal transglutaminase present in granular layer cells and a particulate membrane-bound form present in spinous and granular layer cells [14,30], are believed to form ε (γ-glutamyl) lysine cross-links between envelope protein precursors in a sequential and reinforcing manner [reviewed in 31].

The lamellar granules are present within the cytoplasm and cluster at the periphery of the granular cell, where their membranes fuse with the plasma membrane for the release of their contents into the intercellular space (Fig. 3a,b). The corelease of lipids and enzymes is presumed to accomplish the remodeling of "probarrier" polar lipids from within the granules into the neutral lipids which organize into lamellae [22]. The lamellae form a hydrophobic seal at the granular layer–cornified layer interface that impedes the transport of polar substances across the epidermis and retards water loss [32–35]. Animals that are deficient in essential fatty acids and/or have reduced quantities of lamellar granules exhibit increased water loss through the skin [36]. The contents of the granule are also thought to contribute to the unique lipid surface composition of the cornified cell envelopes [31] and to be important in desquamation of the cornified cell [34]. Individuals affected with harlequin ichthyosis uniformly have abnormal lamellar granules in which the internal lamellae are disorganized or absent [29].

Granular cells are an interesting contradiction in that they are involved concurrently in the synthesis of new molecules and in the degradation of their nucleus, cytoplasmic organelles, and molecules, as they prepare to undergo terminal differentiation to the cornified cell layer. A viable, synthetically and metabolically active cell is transformed into a dense, dehydrated, nonviable cell that contains little other than proteinaceous material and that is bounded by a cornified cell envelope. This transition is poorly understood. Enzymes that are involved in the breakdown of DNA and RNA have been demonstrated biochemically and various morphologic stages of nuclear degradation have been described [37], but there is as yet no explanation for the abrupt and "clean" transition, i.e., how organelles and cytoplasm are remodeled and recycled without evidence of cell debris in either layer of the normal epidermis. Intermediate stages in the breakdown of granular cells, recognizable as "transitional cells," are seen occasionally in normal human epidermis, although they are a regular feature of certain other keratinizing epithelia [38]. Transitional cells retain some of the organelles characteristic of the granular cell and, like the cornified cell, they have a cornified cell envelope; the cytoplasm is typically dense and the nucleus is pyknotic or shows structural evidence of degradation.

The cornified cell layer. The cornified layer shows great variability in thickness, ranging from 15–25 cell layers in regions of the limbs and trunk (Fig. 1), to hundreds of cell layers in the thick skin of the palms and soles [39]. Individual cells of the stratum corneum are thin, flattened, and polyhedral in shape. They are nonviable and filled with disulfide-bonded, keratin intermediate filaments embedded in an electron-dense matrix. A thick (12–15 nm), rigid, resistant, cornified cell envelope protects the cell from degradation by solvents, keratinolytic agents, and other potentially damaging substances (Fig. 3b). The cornified cell envelope is the most insoluble component of the epidermal cells. Lipids unique to the stratum corneum are covalently bound to the outer surface of stratum corneum cells [31,40].

The organization of the contents of cornified cells varies with their position within the stratum corneum. The matrix between the filaments is filaggrin; the 37 kDa protein subunits result from dephosphorylation and proteolysis of profilaggrin during the granular-cornified cell transition [41]. Filaggrin is thought to facilitate alignment of the keratin filaments [42,43], thus resulting in a structure referred to by Brody [44] as the "keratin pattern." The presumed function of filaggrin is called into question, however, because patients affected with ichthyosis vulgaris lack profilaggrin–filaggrin, yet demonstrate a normal keratin pattern in the stratum corneum [28]. Filaments are compact and aligned in the layers most proximal to the granular cell layer, but as the cells are pushed further toward the epidermal surface their contents decrease in density and the filaments become more random within the cell. This may occur as a result of further breakdown of filaggrin into pyrrolidone-carboxylic acid and urocanic acid, and, ultimately, into component amino acids [45]. The dissociation of filaggrin may be important in the water-binding capacity of cornified cells that are present on the outer surface of the skin.

Desquamation of the cell layers of the stratum corneum is essential for the epidermis to maintain a consistent thickness. The enzymatic contents of the lamellar granules and membrane-bound enzymes of the stratum corneum are thought to promote desquamation by remodeling the lipids in the intercellular spaces at the granular cornified cell interface and within the stratum corneum. Lipases and proteases degrade adhesive lipids and proteins, including those related to the modified desmosomal junctions [46]. Certain polar lipids are nonetheless present within some regions of the stratum corneum and have been demonstrated to act as another mechanism for water binding within these layers [47].

Although we have described unique phenotypes and functions of keratinocytes in accord with their positions within the epidermal strata, and the strata as separate compartments, it should be emphasized that the cells are a continuum and that the links are not only structural but also physiological. The cells communicate by gap junctions [48]. The number and position of cells in a vertically stratified, physiologically integrated unit have been recognized by microinjecting intracellularly the fluorescent, membrane-impermeable, gap-junction permeable Lucifer Yellow dye, and following its distribution into adjacent cells. Communication among cells of varying stages of differentiation is likely to be important in the integrated control of cell activities [49].

Melanocytes, Langerhans cells, and Merkel cells. Cells other than keratinocytes are also found in the epidermis, either as resident populations or in response to a transient condition. Melanocytes, Langerhans cells, and Merkel cells are components of normal epidermis. They migrate into the epidermis early in embryogenesis (melanocytes and Langerhans cells) or differentiate *in situ*, probably from an ectodermal/keratinocyte progenitor cell (Merkel cell). Lymphocytes and polymorphonuclear leukocytes are also recognized in the epidermis under abnormal conditions.

Melanocytes are dendritic cells which typically reside in the basal epidermal layer (Figs. 1,4). They migrate into the epidermis from the neural crest at around 50 days estimated gestation age and increase in number during the first trimester to a density that is approximately the same as in adult epidermis. Melanin synthesis begins in the third month of fetal development and melanosomes

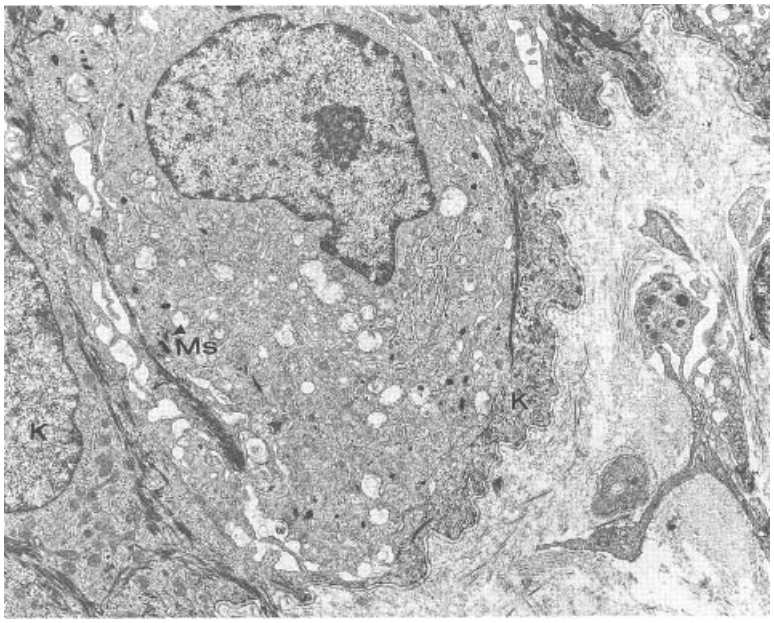

Figure 4. Electron micrograph of a mature melanocyte within the adult epidermis. Surrounded by keratinocytes, the melanocyte shows abundant mitochondria, rough endoplasmic reticulum, and melanosomes (Ms) (arrowhead) in varying stages of maturation. Keratin filaments are present in adjacent keratinocytes (K). ×8, 330.

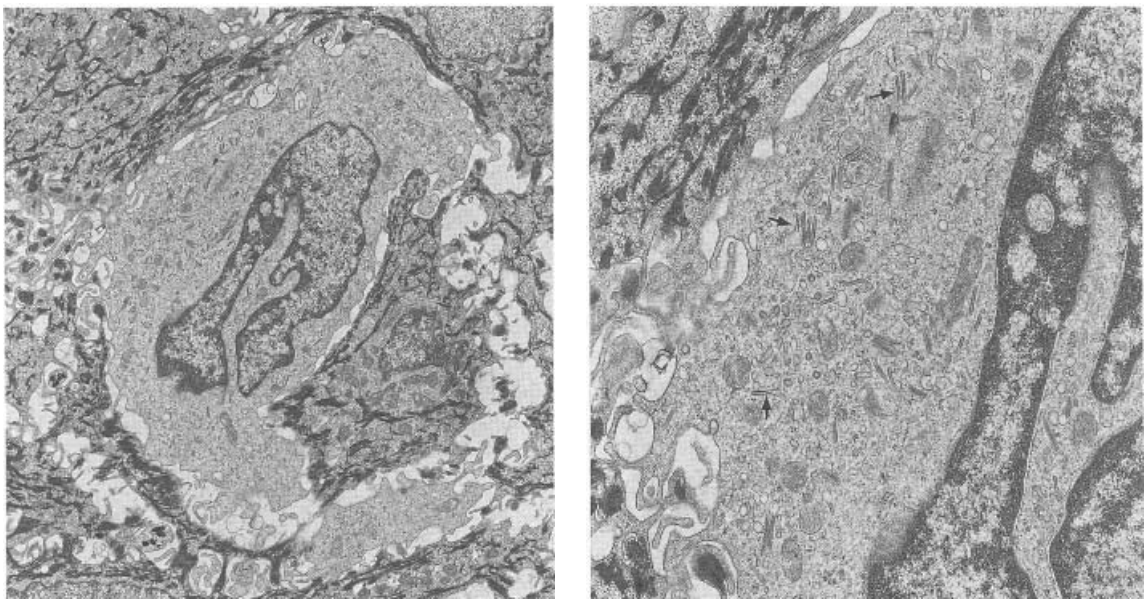
are transferred by phagocytosis to basal keratinocytes in the fifth month [50]. Melanocytes in adult skin are easily seen at the light microscopic level as more lightly stained cells that often "protrude" from the basal surface of the epidermis toward the dermis (Fig. 1). They do not form junctions with other cells of the epidermis nor with the basal lamina, although melanocytes and keratinocytes interact via soluble mediators. Melanocytes contain fine, vimentin intermediate filaments that occur individually within the cytoplasm (compared with bundles of keratin filaments seen in keratinocytes) and the characteristic membrane-bound melanosome in which melanin pigment is synthesized. Immature melanosomes are recognized by a lattice like protein scaffolding within the organelles. This structure is obliterated when the melanosomes become actively involved in melanin synthesis. Mature melanosomes often occur in greater density in keratinocytes than in melanocytes because the phagocytosed melanosomes are collected in membrane-bound vacuoles known as melanosome complexes. Thus melanin pigment becomes distributed throughout cells of the basal epidermal layer, providing the skin reasonably uniform protection from ultraviolet radiation. Pigmentation is under endocrine control and varies with the type of melanin produced and the amount and distribution of melanosomes. As keratinocytes move into the first suprabasal layers, the melanosomes they contain are degraded by lysosomes, although occasionally melanosomes can still be recognized in stratum corneum cells. There is a growing body of work that defines paracrine and even autocrine regulation of melanocyte activities in the epidermis [51].

Langerhans cells are bone marrow-derived, antigen-presenting cells of the immune system. They migrate into the embryonic epidermis early in development, where they are recognizable, typically, in suprabasal layers by a few of their characteristic surface and cytoplasmic antigens (HLA-DR and ATPase reactivity) [52]. In adult epidermis, Langerhans cells account for about 2–6% of the total epidermal cell population [53]. Like melanocytes, Langerhans cells are dendritic, but they are easily distinguished from them by their suprabasal location, pale cytoplasm, and lobulated nucleus (Fig. 5a). Langerhans cells are also recognized by a number of characteristic surface markers (e.g., CD1, CD4, CD45, S100, T200, Fc-lgG and C3b receptors, HLA-DR, HLA-DQ, and HLA-DP [for detailed summary, see 54]) that can be demonstrated by immunohistochemical staining of epidermal sheets or sections of skin. Langerhans cells present soluble antigens and haptens to sensitized T-cells.

Langerhans cells also contain short, rodlike Langerhans cell granules (Fig. 5b). The ultrastructure of the granule gives the impression of a racquet-shaped organelle in sectioned tissue, but when the granules are reconstructed in three dimensions they are found to be flattened disks with the two sides of the disk spaced widely apart at one site. An appropriate section through both the parallel and expanded regions gives the image seen in section. The granule has been shown to form by internalization (endocytosis) of membrane-bound antigen [55].

Merkel cells, members of the paraneuronal cell system, are the third population of nonkeratinocytes present among basal cells in glabrous skin of the digital surfaces, lips, and gingiva and in the nail bed — all sites of high tactile sensitivity. They are found in lower frequency in hairy skin. Descriptive and experimental studies have led to the tentative conclusion that keratinocytes are the progenitors of Merkel cells [56,57]. Both cells are joined by desmosomes and contain keratins in their cytoplasm. K18 found in the Merkel cell is not present, however, in epidermal keratinocytes but rather is characteristic of simple epithelia [58]. Merkel cells are inconspicuous in histologic sections unless detected by an immunohistochemical reaction. At the ultrastructural level, they are easily distinguished by the presence of 100–140 nm-diameter, dense-core granules in the cytoplasm proximal to



a b

Figure 5. Electron micrograph of a Langerhans cell surrounded by keratinocytes within the epidermis (**a**) and an enlarged portion of the Langerhans cell showing the characteristic granules (small arrows) (**b**). (a) ×6, 270; (b) ×17, 325.

Figure 6. Electron micrograph of a Merkel cell (Me) among basal keratinocytes (K). The cell is identified easily by the presence of dense-core granules in the cytoplasm. A neurite (N) that is presumably associated with the Merkel cell is seen proximal to it, just below the basal lamina. ×8, 085.

the Golgi apparatus and adjacent to the site of apposition of a related intraepidermal neurite (Fig. 6). A junction with the structural features of a synapse may occur between the neurite and the Merkel cell, but there is no physiological evidence that transmitters are released. These sites may simply be specialized for adhesion.

The dense-core granules are similar in morphology to monoamine-storing granules in other cells; they contain the peptide transmitter substances met-enkephalin, vasoactive intestinal peptide (VIP), chromogranin A, and neuron-specific enolase [reviewed in 59,60]. Synaptophysin is also present in the Merkel cell on the surface of membrane-bound vesicles of variable size (hence not likely to be the dense-core granules) [61]; this last compound, along with neuron-specific enolase, suggests that the Merkel cell belongs to the diffuse neuroendocrine tissue of the body, and hence counters

evidence for a keratinocyte origin and suggests that instead Merkel cells may be derived from neural crest. The nature of the granule contents provides a basis for hypothesizing functions of the cell. Merkel cells are currently thought to be slow adapting type I mechanoreceptors that receive information when the keratinocytes they are in contact with are deformed. It is not clear, however, whether signal transduction is initiated at the keratinocyte or the neurite [62].

Epidermal organization. An interesting organization of epidermal cells is noted when epidermis is treated with strong alkali or hypotonic buffer solutions that cause the cells to swell. Under these conditions, one sees the cells aligned in columnar patterns, referred to as cell stacking [63,64]. Stacking is best seen in rodent epidermis, where there is evidence that the columns of cells are derived from the progeny of individual stem cells [11]. Cell stacking is also somewhat evident in normal adult human epidermis that is of typical body thickness, although the pattern is most apparent within the stratum corneum. Thick skin of the palms and soles and hyperplastic epidermis of healing wounds show no evidence of stacking. Higher rates of epidermal proliferation are thought to interfere with this organization. The stacking morphology may be important in barrier properties of the epidermis, because regions or conditions under which the stacking pattern is absent (normal or pathologic causes) permit greater epidermal water loss [64].

Epidermal appendages. The pilosebaceous structures, eccrine and apocrine sweat glands, nails, and teeth develop as appendages of the epidermis. Each of them begins to form during the fetal period soon after the embryonic–fetal transition (2 months' estimated gestational age), and requires the collaboration of epidermal and dermal cells. They are recognized in their earliest stages as clusters, cords or folds of epidermal cells that push downward into the dermis [65]. With few exceptions, the appendages form only during embryogenesis; regions of skin which lose follicles and sweat glands (in a burn wound, for example) will not spontaneously regenerate these structures with healing, although they can be reformed experimentally, indicating the potential still exists, assuming the right set of circumstances.

The Dermal–Epidermal Junction (DEJ)

Basement membranes or basement membrane zones are boundaries or interfaces between epithelia and connective tissue compartments assembled by collaboration of the two involved tissues, each contributing different structural, molecular, and antigenic components. The structural elaboration of the basement membrane zone appears to correlate with the mechanical stresses on the tissues joined and thus the presumed attachment strength required to maintain integrity at the interface. An epithelium, like the epidermis, that is subjected to significant physical stress typically develops mechanisms of attachment at the basement membrane zone ranging from modifications in tissue organization (rete pegs, rete ridges, microprojections of the basal surfaces of keratinocytes) to the formation of subcellular junctions (hemidesmosomes and anchoring fibrils).

The basement membrane between the epidermis and dermis is known as the dermal–epidermal junction or DEJ (Figs. 4,6,7). The DEJ separates these two distinct compartments of the skin and provides for adhesion between them, thus effecting the overall integrity of the skin. The DEJ excludes the transit of molecules based on size and charge, but it permits passage of migrating and invading cells under normal (e.g., melanocytes, Langerhans cells) or pathologic (e.g., lymphocytes, polymorphonuclear leukocytes, and tumor cells) conditions. All the nutrients needed by the epidermis, conveyed via the circulation, must cross the DEJ. The DEJ also supports the epidermis and influences the behavior of keratinocytes by modulating cell polarity, proliferation, spreading, migration, and differentiation. The last functions are particularly important during ontogeny, wound repair, and remodeling of the tissue.

Morphology

The ultrastructural morphology of the DEJ can be described in four planes (1) the basalmost borders of the basal keratinocytes; (2) the lamina lucida, an electron-lucent plane that lies beneath the epidermis and superficial to the lamina densa; (3) the lamina densa, an electron-dense plane also known as the basal lamina; and (4) the reticular lamina or subepidermal zone consisting of the connective tissue immediately subjacent to the epidermis (Fig. 7).

Hemidesmosomes join the epidermis to the dermis (Fig. 7). They span the keratinocyte plasma membrane, linking to other structures and molecules of the DEJ that promote attachment. The attachment plaque of the hemidesmosome is located along the basal cell plasma membrane. A few of the plaque proteins are common to the hemidesmosome and the desmosome [3,4]; others are unique to each structure. The bullous pemphigoid antigen (BPA) is associated with the attachment plaque of the hemidesmosomes where it appears to colocalize with the $\alpha 6\beta 4$ integrin receptor [2]. This combination of antigen and matrix receptor is believed

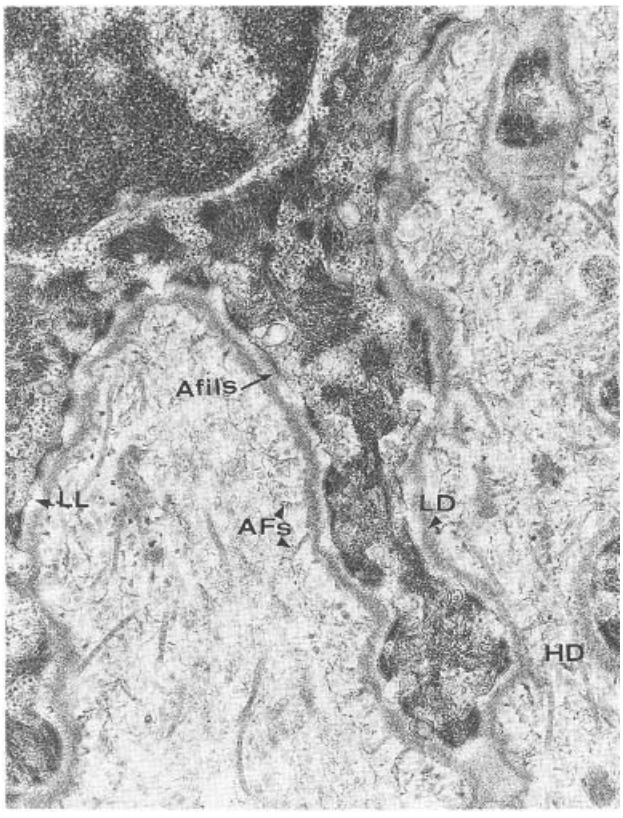


Figure 7. Electron micrograph of the dermal epidermal junction showing hemidesmosomes (HD), lamina lucida (LL), anchoring filaments (Afils), and anchoring fibrils (AFs). ×28, 350.

to provide a stable contact between epidermal cells and a yet-uncharacterized ligand in the basement membrane. There is some evidence that BPA may also be present in the lamina lucida adjacent to the hemidesmosome [66–68]. Keratin filaments of the basal keratinocyte insert into the attachment plaques, thus connecting the cytoskeleton with the cell surface and, ultimately, with the matrix of the papillary dermis. Juxtaposed to the attachment plaque, in the plane of the lamina lucida, is the subbasal dense plate (SBDP). Anchoring filaments that span the lamina lucida are usually increased in density beneath the hemidesmosomes (Fig. 7). From the dermal side of the lamina densa, banded, anchoring fibrils project into and loop through the reticular lamina network of loose fibrillar collagen (Fig. 7). Anchoring fibrils assemble from aligned dimers of type VII collagen. In most regions of the skin, both ends are embedded in the lamina densa [69–71]. In other regions, particularly notable in newborn foreskin, only one end of the type VII collagen dimer is embedded in the lamina densa, the other extending into the dermis, where it terminates in a small aggregation of type IV collagen and laminin termed an anchoring plaque [72].

The DEJ in human skin has the same general structure in all parts of the body, although there are certain age- and sex-related differences, and regional variation in the density and distribution of structures [73]. It is plastic and readily remodeled during wound healing and at sites of morphogenetic events (e.g., follicle formation).

Composition

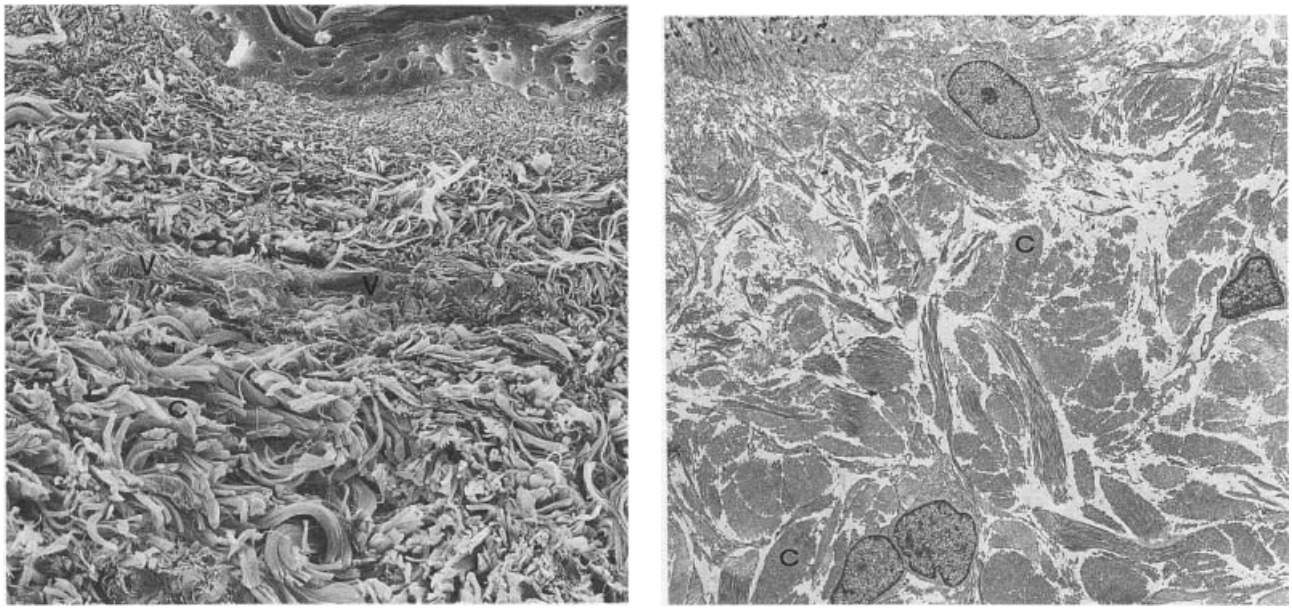
Several of the molecules of basement membranes (type IV collagen, laminin, and heparan sulfate proteoglycan) are common to all basement membranes, regardless of their position in the body or of species. Others are unique and may be tissue specific. The ubiquitous components may be the minimum essential requirements for adhesion between an epithelium and a connective tissue. The unique components may enhance the integrity required by the specific tissue, or they may provide additional functions. The molecular composition of many structures of the DEJ is understood, although the complexity of the region probably has only barely begun to be appreciated. Keratinocytes and fibroblasts both contribute molecules to the DEJ. Plaque proteins of the hemidesmosome, BPA, type IV collagen (lamina densa), type V collagen (lamina densa and reticular lamina), laminin (lamina lucida and lamina densa), heparan sulfate proteoglycan and chondroitin 6-sulfate proteoglycan (lamina densa), entactin/nidogen (lamina lucida [74,75]), and type VII collagen (anchoring fibril) are all products of the basal keratinocyte.

Fibroblasts of the papillary dermis contribute type V collagen [76] and fibronectin to the lamina densa, and types I, III, and V collagen to the reticular lamina. Oxytalan fibers, bundles of microfibrils of the elastin network, are also products of fibroblasts. These fibers originate in the lamina densa and project into the papillary dermis, where they join a horizontal network of elaunin-type elastic fibers (see below). Collagenase, a molecule which may be important in remodeling the DEJ and other matrix components of the dermis (see also Chapter 15, this volume), is synthesized by both keratinocytes and fibroblasts.

Dermis

Organization of the Dermis

The dermis is organized into regions on the basis of differences in connective tissue density and arrangement. The papillary dermis underlies the epidermis and is approximately two times its thickness (Fig. 8a,b). Small, collagen fiber



a b

Figure 8. Scanning (**a**) and transmission (**b**) electron micrographs of a portion of the epidermis (a and b), papillary dermis (a and b), and intermediate dermis (a). The vessel (V) in the scanning micrograph demonstrates the approximate boundary between the papillary and upper reticular (intermediate) dermis. In both micrographs, note the very fine bundles of collagen fibrils immediately beneath the epidermis and the increasingly larger collagen bundles (C) deeper in the dermis. (a) ×500; (b) ×2, 500.

bundles provide compliance to the tissue, accommodating deformation of the skin at its surface. Zones of the papillary dermis are recognized variously among individuals. In some, a subepidermal reticular lamina of densely organized connective tissue is seen prominently in stained sections of skin; in others, this region may be poorly developed and therefore cannot be delineated from the remainder of the papillary dermis. Projections of the dermis (termed dermal papillae) reciprocal to the epidermal rete ridges and pegs contain capillary loops and free nerve endings that terminate in close apposition to the DEJ. In some regions of specialized skin, such as the thick skin of palms and soles, encapsulated nerve endings are also present in the papillary dermis.

Fibroblastic cells are more abundant in the papillary dermis than in the reticular dermis and have unique properties: a higher rate of metabolic activity, an enhanced capacity for proliferation, and a longer replicative life span [77,78]; they also demonstrate increased plating efficiency, a higher cell density *in vitro*, and reach confluence more rapidly than fibroblasts isolated from the reticular dermis [79,80].

Matrix with the same consistency and organization as the papillary dermis surrounds the pilosebaceous structures as they extend deeply into the dermis. This connective tissue, known as the periadnexal dermis, is clearly different from the papillary dermis during embryonic development both in terms of cell types and matrix components, but it becomes more similar once the appendage attains adult characteristics. The deep boundary of the papillary dermis appears to correlate with the position of a vascular plane, the subpapillary plexus (Fig. 8a).

The reticular dermis provides the bulk of the dermis and of the skin as a whole. It is characterized by large, interwoven collagen fiber bundles and mature elastic fibers. Although differences in matrix organization are recognized abruptly at the transition between papillary and reticular regions, there is an increasing gradation in size of the collagen fiber bundles toward the hypodermis (Fig. 8a,b). As in the papillary dermis, these differences may be exaggerated, allowing different regions of the reticular dermis to be recognized. In some individuals an intermediate zone of the dermis is distinct from the deeper reticular dermis. Differences in the organization, mechanical properties, state of maturation of matrix components, and selective loss of elastic fibers from this region in certain disease states [81] provide additional evidence for the uniqueness of the region. Collagen fibrils are often heterogeneous in cross-sectional diameter in the intermediate dermis but homogeneous in the deep reticular dermis; collagen fibers and fiber bundles in this area are intermediate in size and density between the small bundles of the papillary dermis and the larger bundles of the deep reticular dermis. Elaunin elastic fibers (see below) are characteristic of the intermediate dermis, while mature elastic fibers are found deeper in the tissue, and, because of its relationship to the subpapillary vascular plexus, the intermediate dermis also has an abundance of cells belonging to varied populations. Compared with the papillary dermis, cells and vessels are relatively sparse in the deeper reticular dermis.

It is not clear what factors account for the structural and compositional differences between the papillary and the reticular dermis. It is well known, however, that there is communication between the epidermis and the dermis via soluble molecules and cells; thus it is possible that the structure and composition of the papillary dermis are regulated by these interactions. If this is correct, the papillary dermis may represent a zone of influence of the epidermis that corresponds to a minimum effective concentration of diffusible substances from keratinocytes. Similar interactions also may exist between cells in the deeper dermis and the hypodermis, although such interactions would involve fewer cells and the nature of the interactions is less apparent.

Extracellular Matrix

There is a rich variety of matrix molecules in the dermis, including several types of collagen molecules, elastic fibers of variable structure and composition, proteoglycans, and glycoproteins. The composition, ratios, and structural organization of these molecules vary with the specific region. Interstitial fibrillar collagen throughout the dermis is composed of types I and III collagens which may assemble together, and with type V collagen, into the same periodically banded fibrils [82]. Molecules of type V collagen may regulate fibril diameter in instances where they are incorporated with type I [83]. Type I collagen molecules that retain their amino terminal propeptide extensions (pN-collagen) are present specifically in the upper papillary dermis, where they form small-diameter fibrils [84]. Retention of the propeptide extensions is suggested to be one of the mechanisms which regulate fibril diameter [85]. Type V collagen is enriched in the papillary dermis and in the loose connective tissue sheaths surrounding nerves and vessels [76]. Based on the amounts of different collagens extracted from isolated dermal preparations, the relative proportions of these collagens in adult skin are estimated to be 80–90% type I collagen, 8–12% type III collagen, and less than 5% type V collagen. The high proportion of type I collagen contributes to the great tensile strength of the dermis and its ability to withstand deformation. In fetal and neonatal skin, type I collagen represents a smaller proportion of the total collagen [86,87]. Type VI collagen is also abundant within the dermis, where it is organized into 3 nm beaded filaments that are interwoven among the banded collagen fibrils and are within the diffuse matrix milieu between fiber bundles [88,89]. The widespread distribution of type VI collagen suggests it may play a role in organizing other matrix components of the dermis [90]. Ontogenetic studies demonstrating the early expression of type VI collagen in embryonic and fetal skin lend support to this hypothesis [91].

The elastic connective tissue fibers in the dermis organize in a continuous network that can be isolated when the skin is treated with strong alkali and autoclaved to digest all structures other than elastic fibers [92] (Fig. 9). Elastic fibers are composed of varying proportions of microfibrillar elements and elastin, depending upon the region of the skin. Vitronectin [93], fibronectin [94], amyloid P [95,96], and decay-accelerating factor [97] may also be associated with elastic fibers. The microfibrils establish a template of the elastic fiber network in the skin, while elastin imparts the elastic qualities. Oxytalan fibers, consisting of bundles of 10–12 nm microfibrils, are the elastic connective tissue components of the papillary dermis [98]. They extend perpendicularly from the DEJ into the papillary dermis, where they merge with elaunin fibers in the deep papillary and intermediate dermis. The microfibrils throughout the elastic fiber system have been shown to contain fibrillin, a 350 kDa glycoprotein [99] and an immunologically distinct 31 kDa microfibrillar-associated glycoprotein (MAGP)[100]. Other glycoproteins have also been revealed in microfibrils using monoclonal antibodies.

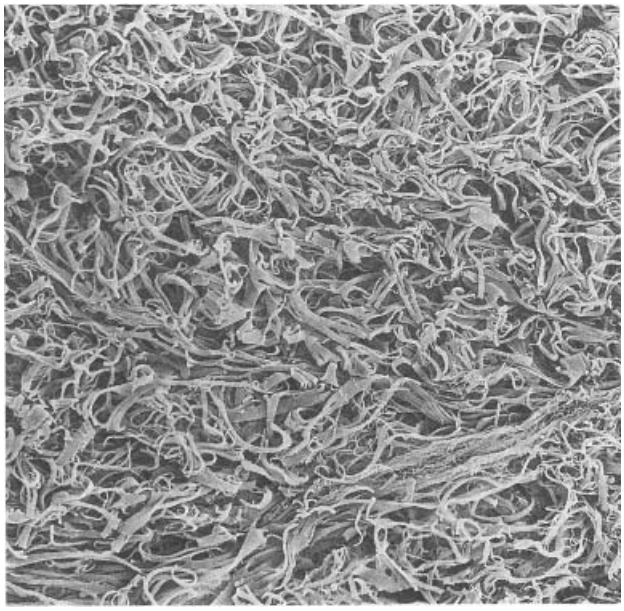


Figure 9. Scanning electron micrograph of the elastic network that remains after all of the other components of the dermis are removed by autoclaving. ×280.

Soluble elastin is deposited on the microfibrillar scaffolding of even the oxytalan fiber, as recognized by immunostaining with antielastin antibody [101]. Cross-linked, insoluble elastin is associated with elaunin fibers in the intermediate dermis [100]. Elaunin fibers, in turn, join with the "mature" fibers of the deeper reticular dermis. The latter fibers have the greatest proportion of elastin of all elements of the elastic fiber system (up to 90% [102]); microfibrils are evident only on the surface and embedded within the electron-lucent fiber, where they appear as densities. Mature elastic fibers are flat, branching structures that have the appearance of broad rubber bands (Fig. 9). They are responsible for the elastic recoil of stretched skin. Turnover of elastic fibers is relatively slow in normal dermis. They are susceptible to damage by ultraviolet radiation and particularly prone to changes with aging [103]; sun-exposed skin shows cumulative effects of radiation damage that result in matted, dysmorphic fibers that cease to function in maintaining skin elasticity [104]. There is great variability in the structural alterations of elastic fibers (fragmentation, granular degeneration, separate deposition of elastin and microfibrillar components, etc.) in the skin of patients with inherited disorders of connective tissue that involve both elastic (e.g., cutis laxa, the Buschke-Ollendorff syndrome, pseudoxanthoma elasticum) and collagenous (osteogenesis imperfecta, Ehlers-Danlos syndrome) connective tissue [105,106]. These changes appear to occur as both synthetic and degradative phenomena.

Proteoglycan, glycosaminoglycan (GAG), and glycoprotein molecules form a continuous matrix phase that surrounds and embeds the fibrillar components and cells of the dermis, and the structures of the DEJ. The proteoglycans are large molecules (100–2,500 kDa) that have several functional domains and attachment sites for from one to a large number of GAG molecules. All proteoglycans have a core protein which is characteristic for the specific molecule and determines, by its primary structure, the nature of the bound GAGs. The core protein may bind to hyaluronate. Proteoglycans bind cells to matrix molecules and in this capacity are involved in adhesion, regulation of proliferation, differentiation of cells, tissue repair (wound healing), and embryogenesis/morphogenesis (e.g., follicle formation); they bind growth factors (e.g., fibroblast and endothelial growth factors) and connect fibrillar (collagens and elastic fibers) and filamentous (e.g., fibronectin, laminin, vitronectin, and thrombospondin) matrix components via their GAG constituents, thus assisting in organizing the components of the extracellular matrix. Proteoglycans also bind water and thus are important space-filling molecules in the interstitium; the hydration of proteoglycans regulates the volume of the tissue and the compressibility of the skin. In addition to their position within the extracellular matrix, proteoglycans are also present on cell surfaces and in the basement membrane [107].

Proteoglycan molecules are visualized ultrastructurally as granules when the tissue is treated with cationic dyes (e.g., ruthenium red, alcian blue) that interact with anionic binding sites on the molecules (Fig. 10). They are recognized in routinely processed tissue only in certain connective tissue disorders (e.g., spondyloepiphyseal dysplasia) where there are abnormal proportions of the classes of proteoglycans in the dermis, or an excessive quantity of them. In these cases, flocculent material and filaments (presumably hyaluronate) are seen around collagen fibrils and in the usually "clear" interstitial spaces (Fig. 10). Immunohistochemical recognition of different proteoglycan species has been more difficult for other matrix molecules because the GAGs are not specific to any one proteoglycan and because the distinctive core proteins are well protected by the GAG side chains. Nonetheless, it has been achieved after "demasking" of the GAGs by enzymic digestion [108–110].

The major GAGs/proteoglycans in mammalian skin are hyaluronic acid (which exists free in the tissue as a GAG, heparin/heparan sulfate proteoglycan [111], and a chondroitin-6-sulfate proteoglycan [108] (restricted primarily to basement membranes), chondroitin sulfate/dermatan sulfate (assembled into large and small proteoglycans in the dermal matrix), and keratan sulfate (present in very low quantities). Dermatan sulfate represents 30–40% of dermal proteoglycans [109]. The small interstitial dermatan sulfate proteoglycan (PG II or decorin) associates primarily with type I collagen, where it binds, via its core protein, at regular periodicities along the length of collagen fibrils and with fibronectin [112]. These molecules are thought to influence the lateral growth of collagen fibrils, but they are not incorporated within the fibrils *per se* [113,114]. A second small proteoglycan, PG I or biglycan, seems to be absent from dermal matrix but is expressed by other cells in the skin such as keratinocytes and capillary endothelial cells. Fetal skin contains a higher content of hyaluronic acid [115] than adult skin, which correlates with a high rate of cell migration and inhibition of fibrillar matrix deposition. The nature of this tissue environment is thought to explain why embryonic and early fetal cutaneous wounds heal without scarring [116]. The transition from a hyaluronic acid-rich to a sulfated GAG-rich environment favors differentiation and stabilization of cells within the matrix and an increased accumulation of fibrous connective tissue.

Several glycoproteins in the dermis, laminin, fibronectin, thrombospondin, vitronectin, and epibolin, interact with the dermal proteoglycans, either by binding directly to their GAG moieties or as part of a complex involving both cells and proteoglycans. Specific matrix-binding and cell-binding

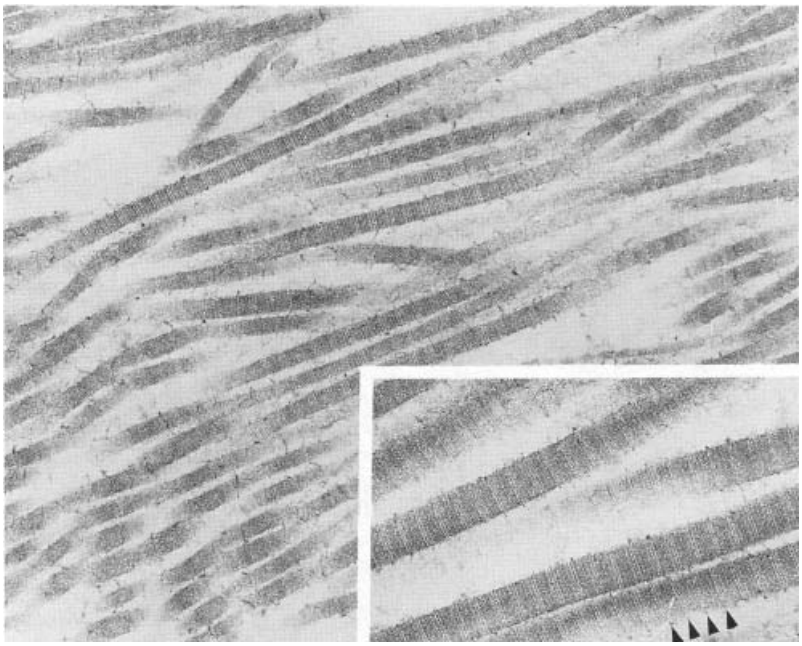

Figure 10. Transmission electron micrographs of collagen fibrils in the intermediate (**a**) and reticular (**b**) dermis fixed in the presence of ruthenium red. The glycosaminoglycan moieties (GAGs) of the proteoglycans associated with the fibrils are retained by binding with ruthenium red. GAGs decorate the surface of collagen fibrils (a) and can be seen in periodic association with regular banding patterns (b) (arrow-heads). (a) ×57, 000; (b) ×66, 700.

domains of the glycoprotein interact with integrin receptors on the cells (see below) to effect these interactions. Insoluble (cellular) fibronectin, for example, is abundant throughout the dermis, where it binds to collagen, fibrin, heparin, and cells. Cell–fibronectin complexes *in vivo* and *in vitro* are involved in tissue repair, wound healing, and embryogenesis. Fibronectin associated with cells also regulates cell migration, proliferation, and orientation.

It is apparent from the foregoing discussion that dermal fibroblasts are involved at various levels with the matrix. They are responsible for the synthesis and degradation of matrix molecules and they (and other cells of the skin, including keratinocytes and phagocytic and inflammatory cells) attach and interact with the matrix through a family of matrix receptors. The integrin matrix receptors are noncovalently-linked, heterodimeric, transmembrane proteins consisting of specific α and β subunits that, when assembled in various combinations, have specificities for matrix laminin, fibronectin, vitronectin, and collagens types I and IV [117,118]. Small intracellular domains of the integrin molecules are thought to interact with proteins of the cytoskeleton [118]. The binding of cells to matrix through integrin receptors thus establishes a continuous link with the cells' cytoskeletons, influencing their activity and function in the tissue.

Cutaneous Vasculature (Blood and Lymphatics)

Blood Vessels. Cutaneous vessels are important sites for the exchange of metabolites and cells in the skin. They play crucial roles in wound repair and various immunologic events. Like other regions and structures of the skin, a general pattern of the vasculature is characteristic for this organ (Fig. 11), but it is modified according to the region and

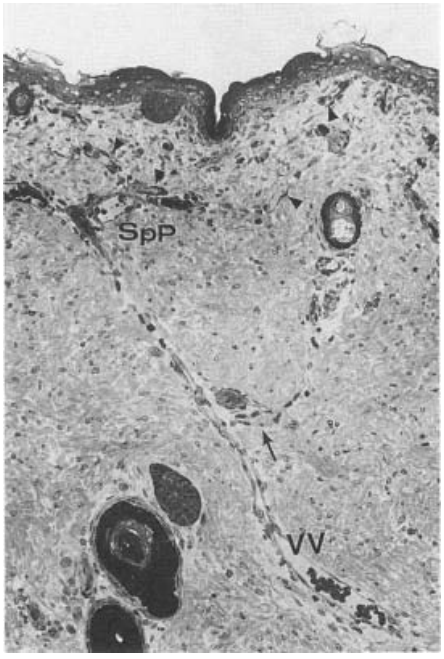

Figure 11. Histologic section of skin from a third-trimester human fetus showing the pattern of vasculature that is characteristic for late fetal and adult skin. Note the vertical vessel (VV) that either supplies or drains the subpapillary plexus (SpP) located at the boundary between the papillary and reticular dermis. Branches of the ascending vessels (arrow) supply the epidermal appendages and branches from the subpapillary plexus (capillaries) (arrowheads) supply the papillary dermis and epidermis. ×160.

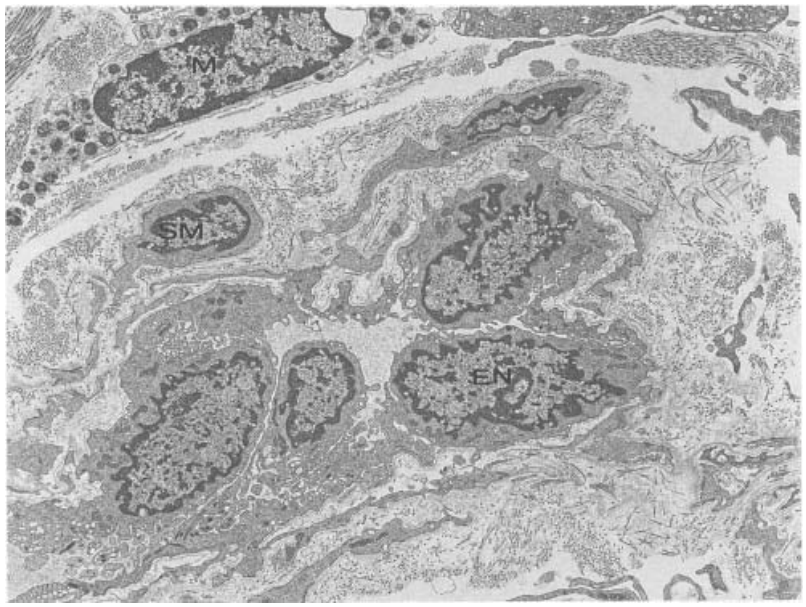
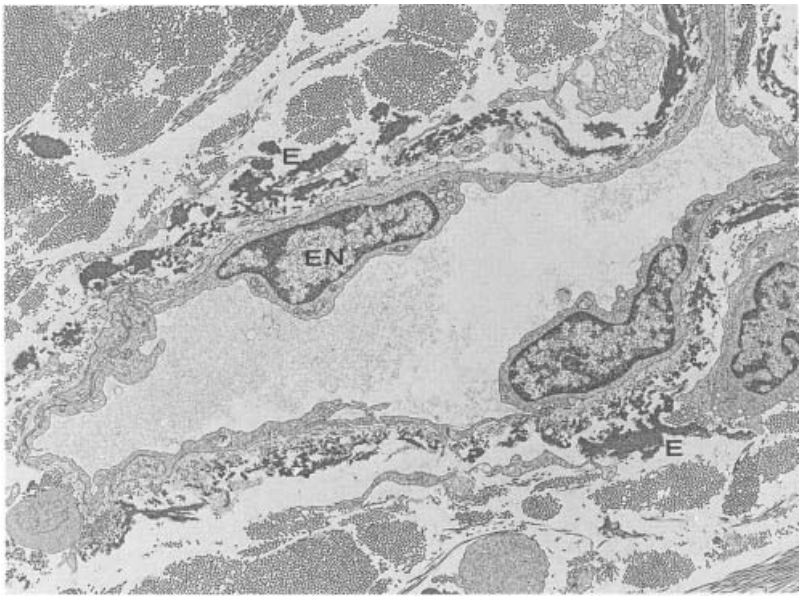
age, environmental injury, and disease. The microvasculature (arterioles, venules, and capillaries) of the dermis originates from musculocutaneous vessels in the subcutaneous fat and muscle of the body wall. Vessels enter the skin and form a horizontal plexus at the junction between the hypodermis and deep reticular dermis. Arterioles extend vertically from the deep plexus toward the skin surface. They connect with one another by lateral branches, give rise to vessels which will supply the epidermal appendages, then terminate in the subpapillary plexus located at the approximate boundary between papillary and reticular dermis [119](Figs. 8a,12a). The structure of the vessel wall in this position permits easy migration of cells into the tissue, hence this plexus is commonly the site of an inflammatory reaction. Capillary loops extend from the subpapillary plexus toward the epidermis. Ascending and descending (arterial or venous) limbs of the loops differ in their wall structure [120]. Venous capillaries leave the dermal papilla to join postcapillary



a



b

Figure 12. Electron micrographs of a postcapillary venule (**a**) and a lymphatic vessel (**b**) in the subpapillary plexus. A few smooth muscle cells (SM) surround the postcapillary venule and multiple layers of basal lamina are evident. Note the mast cell (M) adjacent to the vessel. The most conspicuous components in the wall of the lymphatic vessel are the elastic fibers (E). Note the flattened endothelial (EN) cells, in contrast to those of the venule, and the absence of other cells in the lymphatic wall. (a) ×5,200; (b) ×3,570.

venules in the horizontal plexus. The latter vessels are drained by venules, positioned in parallel with the ascending arterioles, that empty directly into the larger diameter venules of the dermal–subcutaneous horizontal plexus. Direct connections between arterial and venous segments of the microvasculature allow for bypass of congested capillary beds. In palms and soles, such connecting vessels have unusually well-developed smooth muscle layers and are referred to as glomus bodies. The most dense vasculature is found in the uppermost 1–2 μm of the skin [121,122].

Different vessels and regional segments of the microvasculature can be distinguished by size and position, external and internal vessel diameter, thickness of the vessel wall, and fine structure of the endothelial cells, basement membrane, and cells forming the vessel wall [121,123–125]. The papillary and intermediate dermis contain only vessels in the size range of the terminal arterioles, arterial and venous capillaries, and postcapillary venules. Larger diameter arterioles and venules with thicker walls are characteristic of the reticular dermis and subcutaneous fat [121]. Venules in the horizontal plexus at the dermal–subcutaneous interface have valves [126]. Venous capillaries associated with eccrine sweat glands and the hair bulb have bridged fenestrations of the endothelial wall which allow for rapid exchange of materials between the vessel and adjacent tissues. Such structures are not apparent in the capillaries of other regions of the skin in healthy individuals but are common in the skin of patients with psoriasis [127].

Lymphatic vessels. Lymphatic vessels, although less complex in organization and structure, are arranged in parallel with the venous network. Except for a few blind-ending lymphatic tubules (prelymphatics), lymph channels are absent from the normal papillary dermis. A prominent horizontal plexus of initial lymph vessels, so named because they are the origin of the lymphatic channels in the skin [128], is organized deep to the subpapillary venous plexus. In comparison with adjacent postcapillary venules, lymph vessels have a larger luminal diameter (not always apparent because of the normally collapsed state of the lymph capillaries), thinner walls lined by flattened, discontinuous endothelial cells, poorly developed structure of the basement membrane, and valves [129]. The endothelial cells do not show an immunopositive reaction with antibodies against factor VIII-related antigen (a prominent feature of endothelial cells of postcapillary venules) and only rarely contain Weibel-Palade bodies as ultrastructural markers in the cytoplasm. Lymph vessels are reinforced minimally with collagen fibers, but elastic fibers are conspicuous and characteristic as the major supporting elements of the wall (Fig. 12b). Bundles of filaments, called lymphatic anchoring fibrils, that have the morphology of elastin fiber microfilaments, appear to anchor the endothelial cells into the associated collagen matrix [130]. Continuity between the elastic fibers of the lymph vessel and the elastic network within the dermis may provide pathways along which fluid can track toward the lymph vessel; additionally, the elastic fiber systems may aid in movement of fluid in the lymphatics away from the skin [reviewed in 131]. Lymph vessels in the deep reticular dermis also have some smooth muscle cells as part of the vessel wall [131].

Lymph vessels in the superficial plexus are the primary sites for collection of extracellular fluid, soluble tissue debris, and proteins; they provide for the exit of macrophages and transient lymphocytes [129]. Fluid is passed quite rapidly through collecting lymphatics to lymph vessels in a deeper plexus at the junction between the deep reticular dermis and the subcutaneous tissue, then to another plexus of lymph vessels within the subcutaneous fat. Lymph appears to be cleared slowly from this site.

Cutaneous Innervation

Nerves that enter the skin are branches of large, myelinated, segmental, musculocutaneous branches of spinal nerves (cranial nerve V to the face) (Fig. 13a). Once within the skin, the fibers branch extensively, following pathways in parallel with the vasculature. Boundaries between segmental units of fibers are imprecise and each area receives overlapping innervation from more than one spinal nerve. The skin contains somatic sensory and autonomic nerve fibers that are distributed generally throughout the dermis and terminate as "bare" nerve endings (fibers surrounded by a Schwann cell sheath and basal lamina but lacking myelin) beneath and sometimes within the epidermis (Fig. 13b) (often associated with Merkel cells), within the dermal matrix and in specific relationships with sweat glands, pilosebaceous structures, and blood and lymphatic vessels. Other fibers end in encapsulated receptors, such as Meissner's corpuscles (touch receptors) of the papillary dermis and Pacinian corpuscles (pressure receptors) in the subcutaneous fat. These receptors, characteristic of ridged, nonhairy skin like the palm and sole, augment sensory reception by the bare nerve endings. Cutaneous sensory nerves receive mechanical, thermal, and chemical stimuli. Autonomic motor fibers influence secretion of sweat and sebaceous glands and supply the walls of vessels.

Nerves in the skin have traditionally been demonstrated by silver staining techniques or with routine dyes. More recently, immunohistochemical techniques and antibodies that recognize specific molecules in and on neuronal and non-neuronal cells have been used in conjunction with experimental procedures that delete specific populations of nerves according to their function. The results of these combined approaches have demonstrated that the innervation of the skin is remarkably complex and that the nerve fibers within this organ can be classified into *overlapping* categories on the basis of the following structural, compositional, and functional criteria:

1. General type of fiber (sensory or autonomic);
2. Size, degree of myelination, and density of the nerve fibers (large-diameter, myelinated, sensory A-α fibers are associated primarily with encapsulated receptors, whereas the smaller diameter, more sparsely myelinated, A-δ fibers and unmyelinated C-fibers are distributed generally and respond to heterogeneous sensory stimuli [132];
3. Pattern of distribution within the skin; i.e., within a specific portion of a structure of the skin (e.g., fiber or lamellar portion of a receptor, fiber or Merkel cell of the complex) or within a region of a neuronal or nonneuronal cell;
4. Enzymes and structural proteins expressed by neuronal cells;
5. Neurotransmitter and neuromodulatory substances released by neuronal cells;
6. Receptors expressed on neuronal and associated nonneuronal cells;
7. Functional activity of the nerve fiber.

Function is often predicted by the nature of the neuropeptides in the fibers, but the role of these substances in

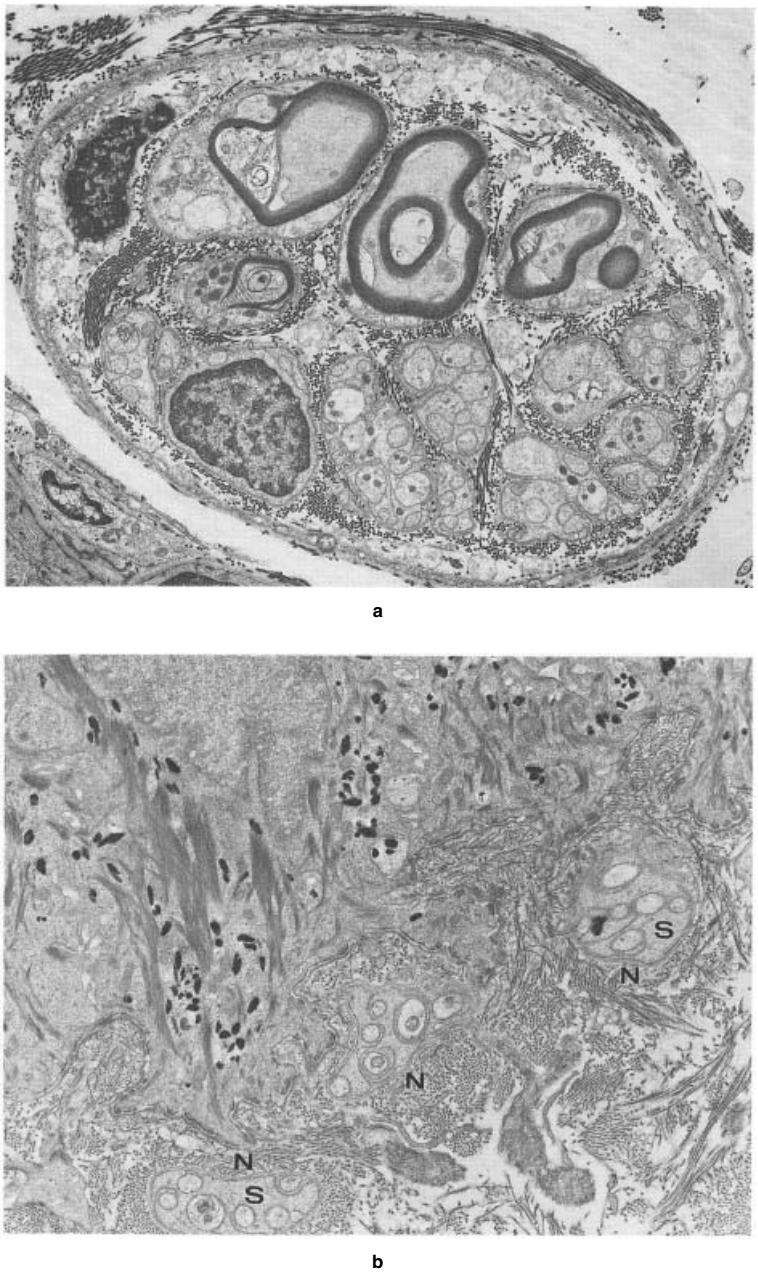


Figure 13. Electron micrographs of a large mixed nerve (**a**) and small unmyelinated nerves (**b**) in the reticular (a) and papillary (b) dermis. **a**: Nerve fibers contain myelinated and unmyelinated axons with investing Schwann cells. The endoneurium includes fibrillar collagen. The perineurium is composed of cells and basement membrane. **b**: The unmyelinated terminals (N) end immediately beneath the epidermis. Schwann cells (S) enclose the bare nerve fibers. (a) ×7, 220; (b) ×7, 670.

fibers of the skin is not always clear even though their roles may be well defined in other tissues. For example, acetyl cholinesterase is recognized immunohistochemically in areas innervated by sensory nerves, although how it acts in these sites is unknown [133]. Moreover, the effect evoked by the fiber may be secondary, as in the case of substance P, which stimulates the release of histamine from mast cells. Histamine in turn triggers the release of more substance P from the nerve fiber (axon reflex), causing itch, flare, and weal in the skin in a dose-dependent manner [134].

Any one structure of the skin may be innervated by different types of fibers and individual fibers may express more than one chemical substance. Small, unmyelinated sensory axons in the papillary dermis, for example, can contain both calcitonin gene-related protein (CGRP) and somatostatin, or CGRP and substance P [135], and may release them simultaneously. Substance P, neurokinin A, and CGRP all may be released from sensory fibers in response to physical or chemical irritation [134]. The description of fiber type and distribution and density for

one region may be inaccurate for another (e.g., hairy versus nonhairy skin).

Sensory fibers in the skin innervate the epidermis (sometimes via intraepidermal endings), the dermis, sweat glands, pilosebaceous structures, blood and lymphatic vessels, single cell receptors (Merkel cells), and encapsulated receptors (e.g., Meissner's corpuscles). They are immunoreactive for synaptophysin and somatostatin [132], substance P (transfer of nociceptive information), neurokinin A, vasoactive intestinal peptide, neuron-specific enolase, myelin basic protein, S-100, and an antineurofilament antibody [136] (Table 1). Blood vessels and lymph vessels, sweat glands, sebaceous glands, and the erector pili muscles also receive autonomic innervation [136]. Autonomic fibers to large blood vessels and to sweat glands are recognized in sections stained immunohistochemically with antibodies to neuropeptide Y (a vasoconstrictor), tyrosine hydroxylase (involved in the synthesis of catecholamines), vasoactive intestinal peptide (may increase sweat gland secretion and vasodilation, and thus play a role in thermoregulation), neuron-specific enolase, myelin basic protein, S-100 [136], and possibly somatostatin [132]. Nerves to sweat glands in particular are also immunoreactive for atrial natriuretic peptide, a substance which acts as a diuretic and vasodilatory substance in other tissues and which is therefore suggested to play a role in regulating water and electrolyte balance in the eccrine sweat glands of the skin [137]. Schwann cells, Meissner's corpuscles, and large nerve bundles are identified by antimyelin basic protein and anti-S-100 [136] (Table 1). Antinerve growth factor receptor antibody also stains Schwann cells of cutaneous nerves [138].

Hypodermis

The subcutaneous region, or hypodermis, is distinct from the dermis throughout life. Even in early embryonic skin, when there is little differentiation of body wall tissues into skin, subcutaneous connective tissue, and skeletal muscle, differences between the regions are recognized first by different densities and orientations of mesenchymal cells (embryo), then by differences in the orientation and composition of fibrous and diffuse connective tissues (fetus). Although the dermal and hypodermal regions are structurally distinct, they are well integrated through nerve, blood vascular, and lymphatic networks, and because the terminal portions of the anagen hair follicles and eccrine sweat glands are embedded deeply within the fat.

The distinguishing characteristic of the subcutaneous region is the presence of fat stores. These develop early in the second trimester within a finely constructed, fibrillar collagen stroma organized in a lobular pattern [65,139]. Assemblies of fat occur primarily at sites that are rich in blood vessels and lymphatics. Fibroblastic-appearing cells colonize the matrix and develop the differentiated adipocyte phenotype as they accumulate refractile lipid droplets within the cytoplasm. Individual lipid droplets coalesce into a large central lipid vacuole and the cells enlarge. A fine casing of connective tissue fibers surrounds individual fat cells, giving each cell the appearance of a ball of yarn.

In newborns, the fat lobules are well developed and measurements of skinfold thickness from a large population of infants between birth and the first year of life reveals a correlation between fat deposition, sex, and birth weight of the infant [140]. Subcutaneous fat deposition continues throughout life, increasing in mass either through the hyperproliferation of fat cells, recruitment of undifferentiated mesenchymal cells into adipocytes, and/or hypertrophy of existing adipocytes [141]. The size of fat cells increases with age and, accordingly, lipid synthesis increases in the larger cells. The latter is a property, however, primarily of growing individuals compared with mature individuals [142].

The thickness of subcutaneous fat can be measured as a function of skinfold thickness using skin calipers, computerized tomography (CT) [143], magnetic resonance imaging (MRI), radiography, and ultrasound [144,145]. The imaging modalities have been used, in particular, to determine whether correlations exist between the extent of

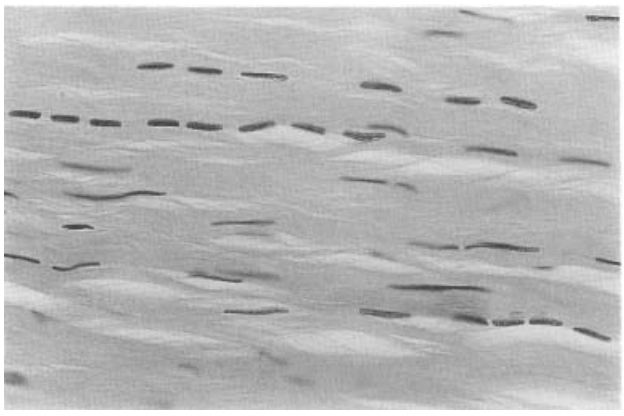
subcutaneous fat, body density, and visceral fat depots of males and females of different age groups. The purpose of these determinations is to assess whether the extent of subcutaneous fat correlates with the quantity of visceral fat and whether body fat distribution can be used to predict metabolic complications of obesity. The data at present are ambiguous and may depend upon the method used for data collection [143,144].

Fat in the skin is an important store of energy in the form of triglycerides. As a tissue, the adipose layer insulates the body, cushions the skin, and molds body contours. Absence of subcutaneous fat in certain disorders of the skin, such as Werner's syndrome, brings the dermis in direct contact with connective tissue of the bone. The absence of this richly vascularized tissue accounts for chronic ulcers that heal very slowly, very poorly, or not at all.

TENDON

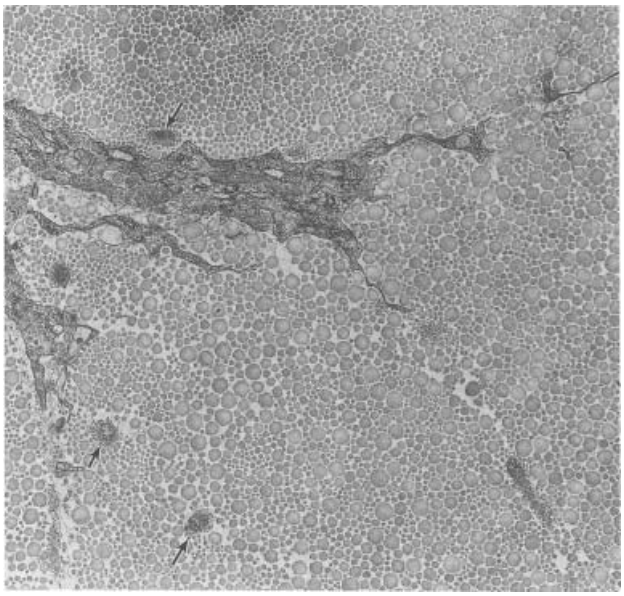
Tendons are connective tissue structures that link muscle to bone. They have great tensile strength, a degree of pliability, and a component of elasticity. Whereas muscle can withstand mechanical forces up to 77 lbs./sq. in. (531 kPa), the average tensile strength of human tendons ranges from 4,000 to 18,000 lbs./sq. in. (27,600–124,000 kPa) [146]. Tendons have a relatively sparse supply of blood and lymphatic vessels in contrast to muscle and bone with which they associate.

The characteristic structural units of tendon are densely packed parallel bundles of fibrous collagen that extend between the myotendinous and osteotendinous junctions. A tendon fascicle consists of groups of collagen fiber bundles and associated tendon cells, surrounded by a fine layer of loose connective tissue, referred to as the endotendon or endotenon. Within each fascicle, rows of elongated and flattened fibroblasts extend the length of the collagen fiber bundles (Fig. 14a) [147]. Groups of tendon fascicles are surrounded by a tendon sheath or epitenon. In certain specialized regions, tendon sheaths form synovia. Synovial sheaths surround the tendons and lubricate and nourish them, especially where they pass over joints.



a

Figure 14. Light (**a**) and electron (**b**) micrographs of adult human Achilles tendon. **a**: Artifactual separation of tendon fibers reveals the parallel organization of collagen matrix and linear alignment of tendon cells. **b**: Bimodal sizes of collagen fibrils are seen in cross section, along with small areas of elastin and microfibrils (arrows). (a) ×435; (b) ×15, 580.



b

Figure 14. (*Continued*)

Tendons may be very short relative to their width or they may be long and slender. Shorter, broader tendons include the attachments for the major muscles of the trunk, limbs, and head. The long, slender tendons that serve the digits of the hands and feet have special modifications. Vincula are shorter tendinous fibers that extend from the body of digital tendons to the associated bone, helping to keep the tendon aligned.

Collagen fibrils of the tendon fascicles are bimodal in diameter: Large fibrils are 150–200 nm in diameter and smaller fibrils are 40–80 nm in diameter (Fig. 14b). The relative proportions of the two sizes vary throughout a tendon. The collagen fibrils of tendon sheaths, however, show a narrower range of diameters and an average of 60 nm in diameter. They do not align in parallel, but are loosely interwoven in multiple orientations. Tendon sheaths contain primarily type I collagen, but they are relatively enriched with type III collagen compared to tendon fascicles. The organization of the tendon bundles ensheathed by loose connective tissue helps to keep the tendon matrix flexible and resistant to disruption by pulling. The loose connective tissue presents a potential path for cellular activity in maintenance and repair of tendon matrix. Small bundles of microfibrils also contribute to the tendon matrix, and these correspond to fine fibrillin-positive fibers observed by immunolabeling [99]. Tendon sheaths have more detectable amounts of elastic fibers (elastin and microfibrils) than the tendon matrix.

Scanning electron microscopy and polarization microscopy have demonstrated that tendon fibers have crimped, not helical, planar undulations, giving the appearance of wavy or zigzagged ribbons. This configuration appears to correspond to the nonlinear portion of the stress-strain curve when the contractile force of the muscle is applied to the tendon [148]. The crimped architecture is not observed in samples that have been treated with hyaluronidase [149], suggesting that hyaluronic acid and

perhaps other glycosaminoglycans may be important in maintaining this level of organization of tendon fibers. Dermatan sulfate, keratan sulfate, and chondroitin sulfate chains are found in varying proportions in different anatomical regions of tendons [150,151]. Decorin, dermatan sulfate proteoglycan II, is associated with the surface of tendon collagen fibrils and in periodic gaps along the fibril length, as it is in the skin [152].

Chapter 1, Part II

Morphology and Chemical Composition of Connective Tissue: Cartilage

Nicholas P. Morris, Douglas R. Keene, and William A. Horton
Research Center, Shriners Hospital for Children, Portland, Oregon 97201

INTRODUCTION

Cartilage is a highly specialized connective tissue that is distributed throughout the body. It performs many functions which, in general, help the body to withstand compressive forces and, to a lesser extent, resist shearing and torsional forces. It is essentially avascular and comprised primarily of extracellular matrix. Although various schemes have been used to classify different types of cartilage, i.e., embryonic versus permanent, calcified versus noncalcified, skeletal versus nonskeletal, it is most commonly divided into hyaline, elastic, and fibrocartilage based on its morphologic appearance and the composition of its extracellular matrix.

The cells that elaborate cartilage matrix have been called chondroblasts or chondrocytes, depending upon the amount of matrix surrounding the cells and the implied relative maturity of the cells [1]. Because this distinction is arbitrary, the term chondrocyte is employed in this chapter. It should be emphasized, however, that chondrocytes behave differently depending upon the particular circumstances. The sum total of this behavior, i.e., morphology, genes expressed, etc., is referred to as the phenotype [2]. Thus, chondrocytes have the capacity to express different phenotypes.

The macromolecules that comprise cartilage extracellular matrix are addressed in more detail in other chapters. This chapter focuses primarily on cartilage morphology and attempts to relate structure to development, since so many inherited disorders of cartilage are developmental in nature. Changes in molecular composition of the matrix and the identification of developmental control mechanisms are provided as examples and are not intended to be comprehensive.

DEVELOPMENTAL ASPECTS

Cartilage plays a central role in the formation and growth of the vertebrate skeleton because many bones form first as cartilaginous models that are only later replaced by bone tissue in a process called endochondral ossification. The current biological model of this process is derived from studies of limb development in lower vertebrates, especially the chick. Limb development begins early in embryogenesis with the formation of the limb buds comprised of mesenchymal tissue covered by a layer of ectoderm, the apical ectodermal ridge (AER) [3] (Fig. 1). Under the influence of the AER, the underlying mesenchymal cells form a progress zone where they remain undifferentiated, proliferate, and extend the limb bud distally [4]. The timing, location, and pattern of skeletal element formation are under the control of a variety of transcription factors, in particular the *Hox* genes and intercellular signaling or growth factor molecules such as sonic hedgehog, bone morphogenetic proteins (BMPs), fibroblast growth factors (FGFs), and Wnt7. In the limb, the latter originate from three signaling centers, the AER in the distal ectoderm, the zone of polarizing activity (ZPA) in the posterior mesenchyme, and the dorsal ectoderm. These maintain the proximo-distal, anterior-posterior, and dorsal-ventral axes of development, respectively [5].

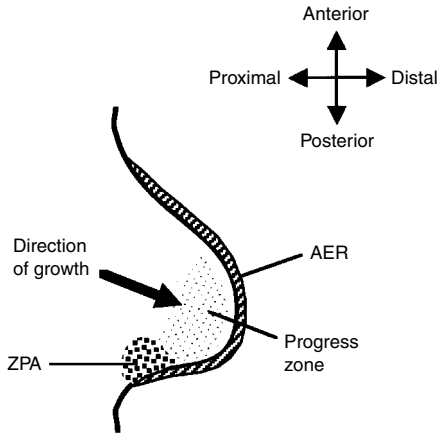

Figure 1. Regulation of early limb development. The proximal-distal axis is controlled by the apical ectodermal ridge (AER), which secretes fibroblast growth factors (FGFs) that maintain the outgrowth of proliferating mesenchymal cells in the progress zone. The anterior-posterior axis is determined by the zone of polarizing activity (ZPA), which is located in the posterior mesoderm and which utilizes signaling by Sonic hedgehog (Shh). The dorsal-ventral axis (perpendicular to the plane of the diagram) is determined by the dorsal ectoderm utilizing intercellular signaling by Wnt 7 molecules. These three signaling centers also require feedback from each other to be maintained.

Connective Tissue and Its Heritable Disorders, pages 41–65

Beginning proximally, the mesenchymal cells in areas destined to become bone form condensations, a process that represents a key step in skeletal formation [6]. Chondrogenesis proceeds directly from these condensations as the cells differentiate into chondrocytes. Thus, the location, number and shape of the condensations initially define the endochondral skeleton. Aggregation of cells is mediated by the cell surface adhesion molecules, NCAM (neural cell adhesion molecule) [7] and N-cadherin [8], and includes the formation of gap junctions [9]. The size of the initial condensation appears to be determined more by the extent of recruitment of cells to the condensation than the proliferation of cells after condensation [6].

Modulation of the extracellular matrix is also required for condensation and chondrogenesis. The extracellular matrix produced by the poorly differentiated mesenchymal cells in the early limb bud contains collagen types I and III, fibronectin, and small amounts of noncartilaginous proteoglycans of small hydrodynamic size [3,10,11]. The expression of fibronectin, tenascin, versican, and syndecan 3, for example, increases during condensation, while the amount of hyaluronan decreases. The precise roles of these molecules are unclear but may be to enhance the migration of mesenchymal cells, as well as promote their response to growth factors or signaling molecules [6]. Some matrix changes associated with condensation involve modulation of matrix protein structure by alternative splicing of structural domains. Fibronectin contains multiple tandem type III structural modules, two of which are regulated by alternative splicing. Inclusion of one of these, extra domain A (EDA), appears to be essential for condensation, while its exclusion from the molecule appears to be necessary for subsequent differentiation to chondrocytes [12–15]. Coincident with condensation is the appearance of mRNAs for cartilage-specific proteins, including type II collagen and cartilage (large aggregating) proteoglycan (aggrecan) core protein [16,17]. An alternatively spliced form of type II collagen, type IIA, is characteristic of prechondrocytes or chondroblasts [18], and is expressed throughout the area of condensation [19–21]. Overt chondrogenesis, sustained by BMP signaling [22], begins at the middle of forming bones shortly after condensation with the synthesis and secretion of matrix rich in these macromolecules and others, including types IX and XI collagen, small proteoglycans, link protein, and cartilage matrix protein (CMP) [16,17,23–25]. Differentiation to the chondrocyte phenotype is accompanied by a switch to the collagen type IIB splice form as well as changes in the structure of type XI collagen brought about by alternative splicing [26–30]. Synthesis of noncartilaginous proteins, such as type I collagen, ceases. This process forms the *anlagen*, or models, of the future skeleton.

Cartilage formation (chondrogenesis), is followed by hypertrophy, degradation, and replacement of the cartilage by bone, a process called endochondral ossification. At the single cell level it can be viewed as the product of a differentiation pathway involving the sequential expression of three chondrocytic phenotypes: committed (prechondrocytic) mesenchymal cell, differentiated chondrocyte, and hypertrophic, or terminally differentiated chondrocyte. For the purpose of this chapter, the shaft of a long bone will be referred to as the diaphysis and its rounded ends, the epiphyses, at all stages of development.

To accomplish transformation from cartilage to bone, chondrocytes in the center of the diaphysis of the cartilage *anlage* enlarge and begin to synthesize molecules atypical of hyaline cartilage matrix, including type X collagen and fibronectin, and express activity of carbonic anhydrase and alkaline phosphatase [31–37]. These changes signal the expression of the hypertrophic chondrocyte phenotype, which is also characterized by reduced synthesis of type II collagen and possibly also that of cartilage proteoglycans, proteoglycan link protein, and protease inhibitors that prevent vascular invasion [31–39]. The net effect is that hypertrophic cartilage is degraded by invading vascular tissue, the hypertrophic chondrocytes undergo programmed cell death (apoptosis), and osteoblasts associated with the invasion deposit bone matrix in the space previously occupied by hypertrophic cartilage.

This transformation is accompanied by the formation of a layer of bone by osteoblasts in the perichondrium (periosteum) around the region of hypertrophic chondrocytes in the mid-diaphysis [40]. Because this bone forms from a layer of osteoblasts adjacent to the cartilage, but not by replacement of cartilage, it is called membranous or periosteal bone. This membranous bone may serve as a staging area and may be a prerequisite for vascular invasion of the underlying hypertrophic cartilage. In mice lacking the function of the transcription factor, Cbfa1, the overt expression of the osteoblastic phenotype is blocked, as is the formation of mineralized bone tissue [41,42]. Vascular invasion is also prevented, and the bone remains entirely cartilaginous, suggesting an interdependence of these two processes. Much of the cartilage is calcified and hypertrophic in appearance, showing that the hypertrophic chondrocyte can be a stable endpoint in chondrocyte differentiation and that apoptosis is not obligatory.

Once established in the center of a bone (mid-diaphysis), the ossification process spreads centrifugally as a front. Chondrocytes adjacent to the front terminally differentiate to hypertrophic chondrocytes, which, as above, facilitate the hypertrophy, degradation, and replacement of the cartilage. Much of the cartilage *anlage* is consumed by this process. However, as this front nears the ends of the bone (epiphyses), chondrocytes adjacent to the hypertrophic cells proliferate, producing new cells that synthesize cartilage matrix before they in turn hypertrophy. In other words, the source of cartilage that is replaced by bone changes from cartilage originally derived from mesenchyme to that produced by newly proliferated chondrocytes. This switch allows the epiphyseal cartilages at the ends of the bones to be pushed apart without being consumed. This proliferation-hypertrophy-replacement process becomes structurally organized into the so-called growth plate and occupies a narrow space between the epiphyseal cartilage and the expanding bone [43]. Once formed, the growth plate is responsible for linear skeletal growth. The mature growth plate can be viewed functionally as a dynamic structure with a leading edge where cells are born that synthesize cartilage template and a trailing edge where this template is replaced by bone. The coordination of these events is under precise and complex regulatory control, both autocrine and paracrine, involving signals from the perichondrium, from within the growth plate and from the newly formed bone.

Epiphyseal cartilage is not permanent. Specialization occurs at the surface to form articular cartilage, while secondary ossification centers develop in the center of the cartilage [44]. These centers correspond to the ''epiphyses'' seen on radiographs. They arise and grow through the same process that occurs in primary ossification, i.e., cartilage hypertrophy, vascular invasion, and replacement of cartilage

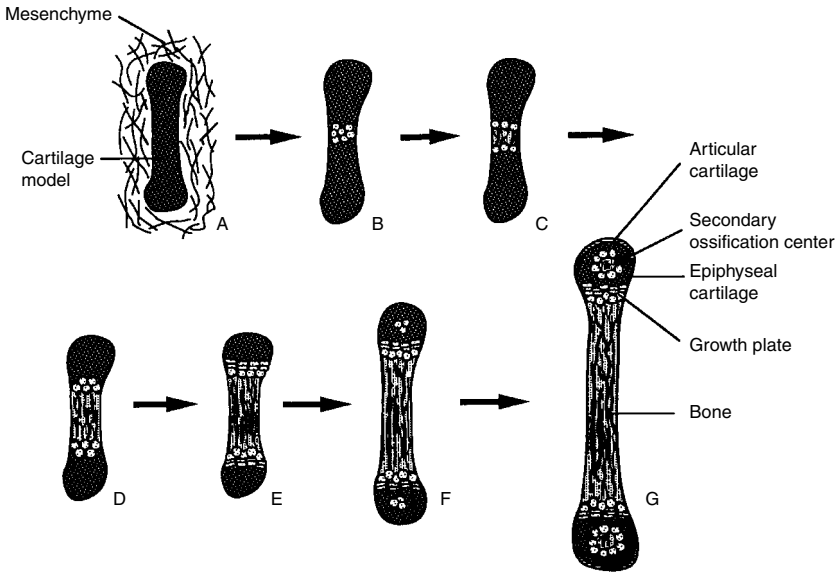

Figure 2. Schematic representation of bone formation and growth. **A:** The initial condensation of mesenchymal cells and their differentiation to chondrocytes defines the cartilage model. **B:** The differentiation of chondrocytes to prehypertrophic and then to hypertrophic chondrocytes (indicated as individual cells in the diagram) initiates in the diaphysis at the mid point of the long axis of the cartilage model. **C, D:** The differentiation to hypertrophic chondrocytes proceeds distally in a wave along the diaphysis. Differentiation of the loose mesenchyme surrounding the cartilage model into the perichondrium also begins at this midpoint and mirrors the differentiation of the underlying cartilage. As the wave of chondrocyte hypertrophy proceeds distally, a bony collar forms in the perichondrium adjacent to the cartilage, again beginning at the midpoint of the diaphysis. From here, blood vessels invade the cartilage model and cartilage is replaced by bone. **E:** The concerted wave of chondrocyte hypertrophy and bone formation proceeds along the diaphysis until the metaphyseal growth plates are formed. A steady state is reached where chondrocyte proliferation matches replacement by bone permitting regulated longitudinal bone growth while the epiphyses remain cartilage. **F, G:** As longitudinal bone growth proceeds, vascularization of the epiphyses by cartilage canals increases and chondrocytes in the center of the epiphyses become hypertrophic and are replaced by bone, forming the secondary ossification centers. In a process not yet understood, the articular cartilage is protected from ossification. Longitudinal growth ends when the metaphyseal growth plates are no long sustained and the primary and secondary ossification fronts fuse.

by bone [45,46]. Eventually, the entire epiphyseal cartilage is replaced by bone.

Skeletal formation occurs early in human development. For example, mesenchymal condensation is evident by 6.5 weeks of gestation, and the cartilage *anlage* of the tibia is formed by 8 weeks. Structural elements of the growth plate can be identified by 16 weeks, when approximately 60–70% of the cartilage *anlage* has been replaced by bone [47–49]. The growth plate brings about linear bone growth from this time through the end of puberty [43,48,49]. The formation and linear growth of a long bone is depicted schematically in Figure 2.

Permanent hyaline cartilage, other than articular cartilage, such as that in the nose, larynx, trachea, and bronchi, derives from local mesenchyme in a fashion similar to the formation of the cartilaginous models of the skeleton, but the chondrocytes do not progress to the hypertrophic stage [44]. The developmental history of other types of cartilage, such as the elastic cartilage of the ear, Eustachian tube, epiglottis, and certain laryngeal structures, and fibrocartilage, found in the intervertebral disks, symphysis pubis, and articular disks of many joints, is not as well defined as for hyaline cartilage [44,50].

STRUCTURE

Hyaline Cartilage

As the most abundant cartilage in the body, hyaline cartilage provides a good starting point to examine cartilage structure. At the molecular level, a great degree of complexity of the extracellular matrix is disguised by the simpler morphology. In addition to the many collagens, proteoglycans, and other proteins found abundantly or uniquely in cartilage, many gene products not typically associated with cartilage, such as basement membrane components [51–53] and complement proteins [54,55], are also expressed during the development of this tissue. Nevertheless, the defining feature of hyaline cartilage is an abundant extracellular matrix composed of an extensive system of collagen fibrils in which a network of aggregating proteoglycans is embedded. In combination, they impart the unique biomechanical properties typical of cartilage, rigidity without brittleness, and resistance to compression and shear. It must be pointed out that the structure, and especially the ultrastructure, of cartilage varies substantially according to the species, location, sublocation, and age of the cartilage, as well as to how it was prepared for study. A thorough description of all of these variations is beyond the scope of this chapter. Therefore, the general structure of hyaline cartilage is presented, with some emphasis on developmental cartilage, although a number of important deviations are addressed.

Hyaline cartilage appears glossy and almost translucent to the naked eye. At lower magnification, chondrocytes typically appear ovoid, but range in shape from round to flat (Fig. 3). Rounder cells tend to be found in the center of a cartilage structure, while flatter chondrocytes reside

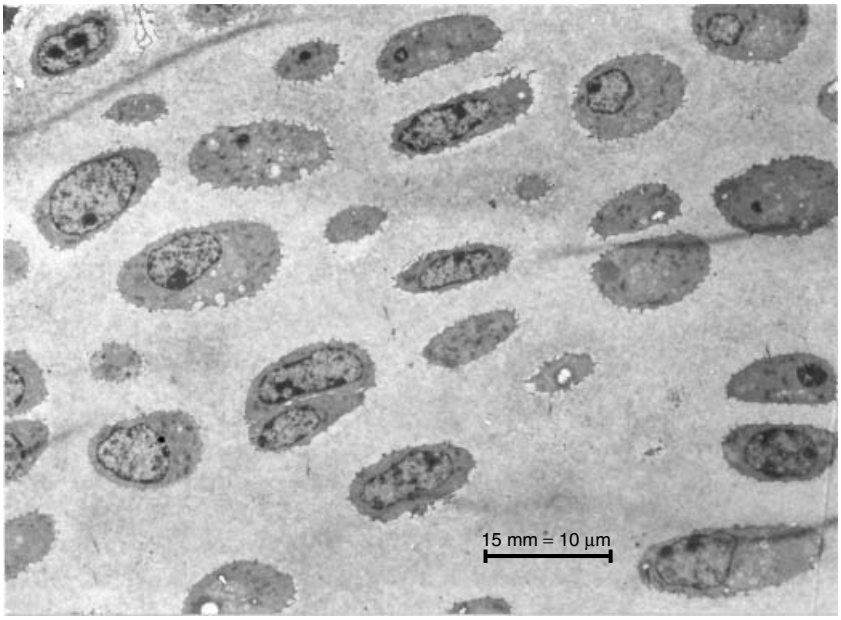

Figure 3. Transmission electron micrograph of epiphyseal cartilage from a newborn mouse. The cells have an even distribution, and the matrix stains relatively homogeneously, except for the region immediately surrounding the cells. Scale bar: 15 mm = 10 μm.

near borders, such as the perichondrium [56]. The nuclei are relatively large, usually centrally placed, and conform to the shape of the cell. Lipid droplets and poorly defined cytoplasmic structures may be seen. The distribution of cells in hyaline cartilage varies from relatively even to quite uneven. The space occupied by a chondrocyte and defined by the rim of extracellular matrix adjacent to the cell is often referred to as a lacuna. Two, or occasionally more, chondrocytes may occupy a single lacuna in hyaline cartilage, especially in young individuals, implying their recent division. The extracellular matrix appears relatively homogeneous by many stains. However, those that indicate the distribution of the cartilage proteoglycan, i.e., cationic dyes that form complexes with the glycosaminoglycan component of the macromolecules (toluidine blue, azure A), reveal a compartmental organization [56,57]. A densely staining pericellular compartment surrounds each cell or group of cells. This zone is circumscribed by a moderately dense-staining territorial matrix compartment, and a less intensely staining interterritorial matrix compartment occupies the intervening space. There may be a poorly staining ring called the border zone between the territorial and interterritorial compartments. An idealized chondrocyte and its matrix compartments are illustrated in Figure 4.

The fine structure of chondrocytes and matrix organization is much better defined by transmission electron microscopy (Fig. 5) [56,58,59]. The cytoplasm contains abundant rough endoplasmic reticulum, Golgi complexes, and secretory vesicles, which vary in relative amount according to the synthetic activity of the cell. Mitochondria are typically seen, as are fat droplets and glycogen deposits. Filamentous structures are extensive in some chondrocytes, and most cells contain a few microtubules. The plasma membrane is scalloped with many processes containing microfilaments, which may extend 1–2 μm into the matrix. Small invaginations called caveolae are prominent along the surface. A single small cilium may be detected in many chondrocytes, especially those from fetal cartilage.

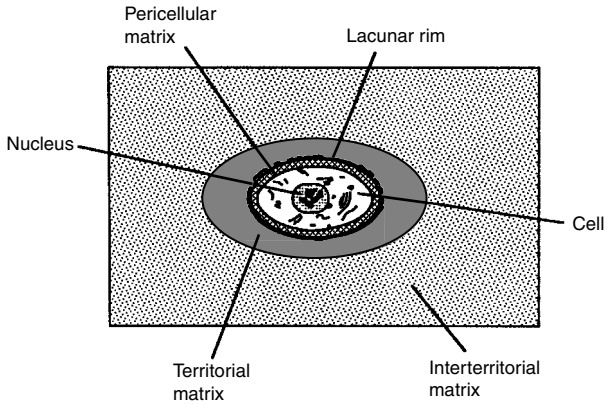

Figure 4. Idealized chondrocyte, depicting surrounding matrix compartments and other landmarks.

The fine structural organization of matrix compartments surrounding chondrocytes has been difficult to define for technical reasons, and the issue has been further clouded by the remarkable inconsistency in terminology that has been used. In some instances, the same structures have been given different names because they do not appear the same after different fixation procedures. In other instances, the same term has been applied to different structures. The nomenclature employed here is that given in Figure 4; it is consistent with that employed in reports of investigations in which the fine structure of the matrix has been well preserved [59–63].

Observations of tissues fixed by conventional chemical methods have implied the existence of a delicate lacunar

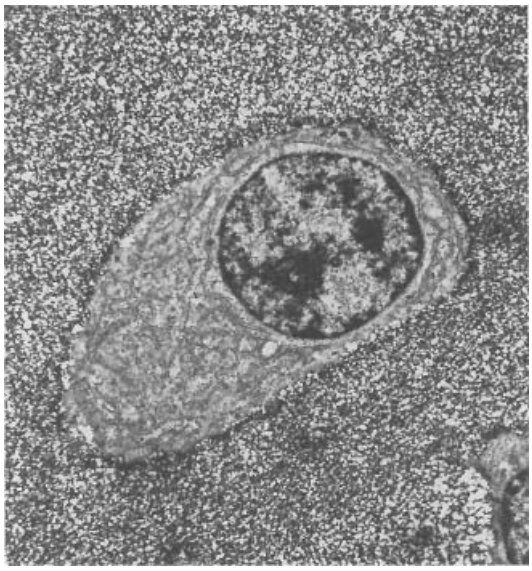

Figure 5. Transmission electron micrograph of an epiphyseal chondrocyte from a 9-day-old rabbit. Note the eccentrically placed nucleus and abundant rough endoplasmic reticulum. The section was stained with ruthenium red to demonstrate condensed proteoglycan granules, which obscure collagen fibrils. Note the slightly greater staining intensity of pericellular matrix. ×5600.

matrix occupying the space between the chondrocyte surface and the inner border of the lacuna [64]. The space has been called the lacuna, moat, halo, corona, and capsule [65–69]. However, fixation methods that preserve pericellular proteoglycans indicate that this space is an artifact of fixation, resulting from detachment and retraction of the cell membrane from the lacunar wall [65]. Fixation with substances that completely precipitate these proteoglycans, e.g., ruthenium hexamine trichloride, shows that the plasma membrane is contiguous with a dense proteoglycan coat that forms a pericellular envelope [60,62]. The collapsed proteoglycans are visualized as dense granules within this pericellular matrix compartment. The thickness of this compartment varies from cell to cell and from one region to another of the same cell and can be absent entirely [70]. Typically, few discernible collagen fibrils are seen. Fixation with ruthenium hexamine trichloride also indicates that the distribution of proteoglycans is relatively uniform in cartilage and thus the matrix compartments of cartilage are better defined and described by the organization and distribution of collagen fibrils [60].

Surrounding the pericellular envelope is a basket-like network of fine collagen fibrils aligned parallel to the surface of the chondrocyte which comprises the inner layer of the territorial matrix compartment [60,62], and is sometimes called the lacunar rim [56]. The fibrils are generally thin and some show faint 64-nm periodic banding, although others do not. Fine filamentous, as well as amorphous, structures can also be seen [71]. This capsular structure and its contents, referred to as a chondron, can be physically isolated from the tissue by mechanical shear or by enzymatic digestion. The structure of chondrons has been most extensively described in adult articular cartilage and they have been proposed to be the functional units of hyaline cartilage [57,72].

The remaining territorial matrix consists of randomly oriented bundles of collagen fibrils, which may exhibit faint periodic banding [73,74]. Specimens fixed in proteoglycan-precipitating agents show dense granules dispersed throughout the matrix [75] that, in many instances, are in close proximity to collagen fibrils. The interterritorial matrix is distinguished ultrastructurally by collagen fibrils, which may be oriented differently from those of the territorial matrix, depending on location [73,74], and which are, in general, thicker than those in the territorial matrix compartment. Proteoglycan granules are more abundant and are observed along and between collagen fibers. After cryotechnical preparation, an additional ultrastructural feature consisting of fine filaments, 10–15 nm in diameter and with crossbanding similar to collagen fibrils, has been observed in all matrix compartments [76]. However, the biochemical nature of these filaments is as yet undefined.

Fetal cartilage is characterized by a rather open network of collagen fibrils with diameters less than 25 nm and larger interfibrillar spaces that are filled with proteoglycan. In such a preparation fixed with ruthenium compounds, collagen fibrils are readily visible (Fig. 6A). Typically, the fibrils are individual rather than bundled as in adult cartilage and most other tissues and often show little preferred orientation. At times, fibrils of the territorial matrix near the chondrocyte run parallel to the plasma membrane in a concentric fashion, especially in the growth plate [60] and in developing articular cartilage [77]. After cryotechnical preservation, by which both the cell and the matrix are optimally preserved [78], no distinct pericellular envelope is visible and collagen fibrils are not excluded from the region adjacent to the plasma membrane (Fig. 6B). Fibrils are difficult to see embedded in the proteoglycan gel, but their distribution is not altered near the cell and the uniformity of appearance of the matrix is remarkable in light of previous studies using other methods of ultrastructural preservation.

The collagen fibrils are predominantly composed of the fibrillar collagen, type II, with lesser amounts of the related type XI collagen and the fibril-associated collagen (FACIT), type IX [79]. Polymerization of collagen molecules to form this structural unit of cartilage is complex and many factors may function in concert to maintain the small fibril diameter found in developing cartilage. Among these are the rate and order of processing of the propeptide domains [80], the presence of the fibril-associated proteins/proteoglycans decorin and biglycan [81] and fibromodulin [82], and the incorporation of the minor collagens, types IX and XI [83,84]. Mice with a perinatally lethal mutation in one of the genes for type XI collagen (COL11A1) fail to synthesize type XI collagen and produce a soft cartilage with compromised biomechanical integrity [85]. The cartilage extracellular matrix contains more sparsely distributed collagen fibrils with very large diameters suggesting an *in vivo* role for type XI collagen in maintaining (limiting) fibril diameter. The large amino-terminal noncollagenous domain of type XI collagen has been shown to be localized to the surface of thin cartilage fibrils [84], and it is likely that this domain sterically limits lateral growth of fibrils. The severe phenotype of this mutation demonstrates the fundamental importance of regulating such morphologic parameters.

Specific intermolecular interactions have been proposed to stabilize the proteoglycan-collagen fibril system beyond physical entanglement. Proteoglycan has been localized at regular intervals along collagen fibrils [86]. Recent evidence

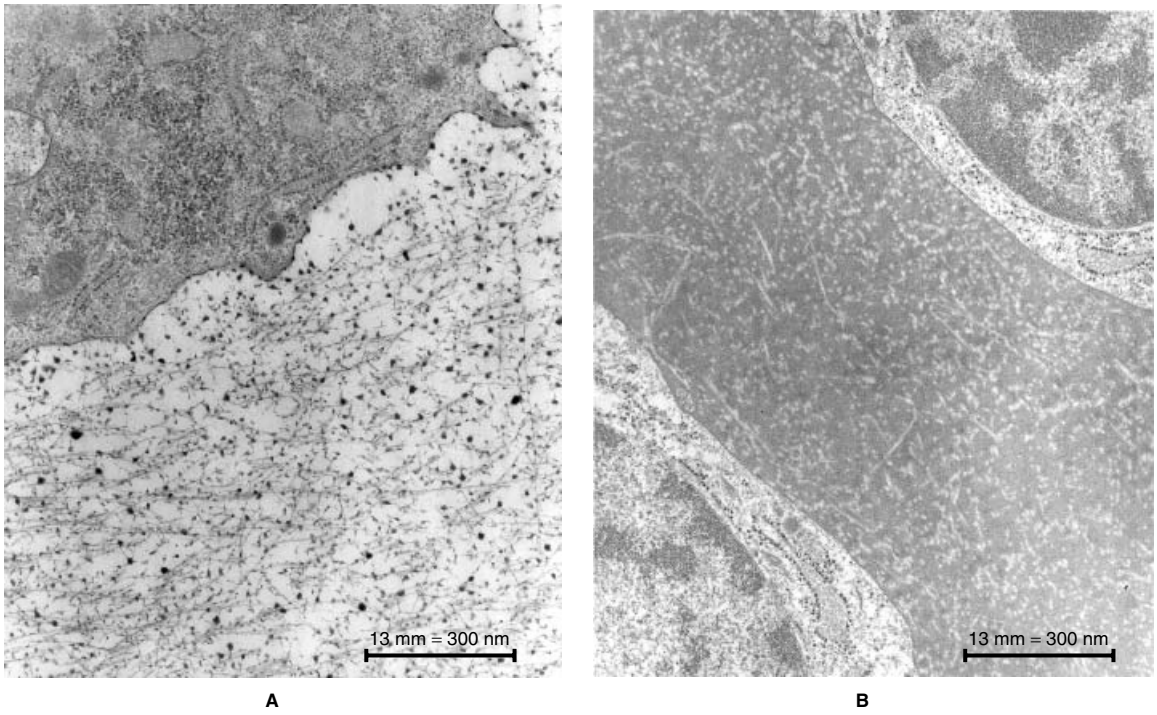

Figure 6. Transmission electron micrograph of 17-day fetal chick sternal cartilage, typical of nonpermanent fetal cartilage. **A:** The section was prepared by conventional aldehyde fixation and stained with ruthenium. It shows a somewhat higher magnification of the matrix than the previous figure. The collagen fibrils are thin and randomly oriented except very near the cell where they tend to run more parallel to the cell surface. Proteoglycans are collapsed into electron dense granules by this preparation revealing ''spaces'' between the fibrils. Combined with cell shrinkage, it suggests exclusion of fibrils from the immediate vicinity of the cell. The condensed proteoglycan granules appear associated with collagen fibrils in the matrix and perhaps slightly concentrated in the pericellular space created by cell shrinkage. **B:** The same tissue was prepared by high pressure cryotechnical fixation. The proteoglycans are not condensed so the area between fibrils appears electron dense, with no ''spaces.'' The matrix abuts directly on the plasma membrane of both cells because there is no cell shrinkage. Collagen fibrils (appearing light by this technique) are not excluded from the matrix near the cell surface and again tend to run parallel to it (seen mostly in cross section). Scale bar: 13 mm = 300 nm.

for an interaction between collagen molecules and the keratan sulfate domain of aggrecan occurring in the gap regions of the fibrils provides a putative mechanism for such a stabilizing connection [87]. Type IX collagen is located on the surface of the fibrils covalently associated with itself and type II collagen [88]. It contains a large globular domain, which can protrude from the fibril [89]. Type IX molecules interact with other type IX molecules via this domain [90] supporting the proposition that type IX collagen stabilizes inter-fibril interactions [91]. Mice lacking type IX collagen show normal skeletal development, but a progressive loss of structural integrity is evident from the early and severe osteoarthritis that develops [92]. There are many other proteins associated with the fibril surface; it is possible that one or more mediates similar interactions between the fibrils and the aggrecan complex. Finally, matrix-stabilizing interactions may be provided by the activity of transglutaminase which has been implicated in cross-linking cartilage extracellular matrix components, especially in the hypertrophic zone of the growth plate [93,94].

Despite the presence of matrix compartments and differing organization of collagen fibrils, histochemical and immunohistochemical staining of fetal cartilage suggest the composition of the matrix is consistent and homogeneous. Thus, the fibrillar components, collagen types II, IX, and XI, and the aggrecan network are found throughout fetal cartilage. Noncollagenous proteins such as cartilage oligomeric matrix protein (COMP) and CMP are rather evenly distributed as well [25]. However, there are exceptions and changes occur as the skeleton matures. For example, type XI collagen is found throughout the matrix of fetal cartilage, but the protein isoform containing the peptide encoded by exon 6B of *Col11a1* is found preferentially in diaphyseal cartilage but not in epiphyseal cartilage (Fig. 7). In fetal bovine cartilage, the FACIT collagens, types XII and XIV, are found more abundantly near the articular surface and around cartilage canals, and staining diminishes toward the growth plate [95]. The glycosaminoglycan component of cartilage proteoglycans appears to differ in the territorial and interterritorial compartments. The territorial compartment is relatively enriched in chondroitin sulfate compared with keratan sulfate side chains, whereas the opposite is observed in the interterritorial compartment [33,56]. CMP is present in fetal cartilage but is absent from developing and adult articular cartilage [25]. In a complementary fashion, fibromodulin is preferentially localized in developing articular cartilage [25,96]. Lumican, which is difficult to detect in early fetal cartilage, is present in neonatal/juvenile cartilage and is abundant in adult cartilage [97]. These and other modulations of matrix composition suggest that not all chondrocytes and their associated matrices are functionally equivalent.

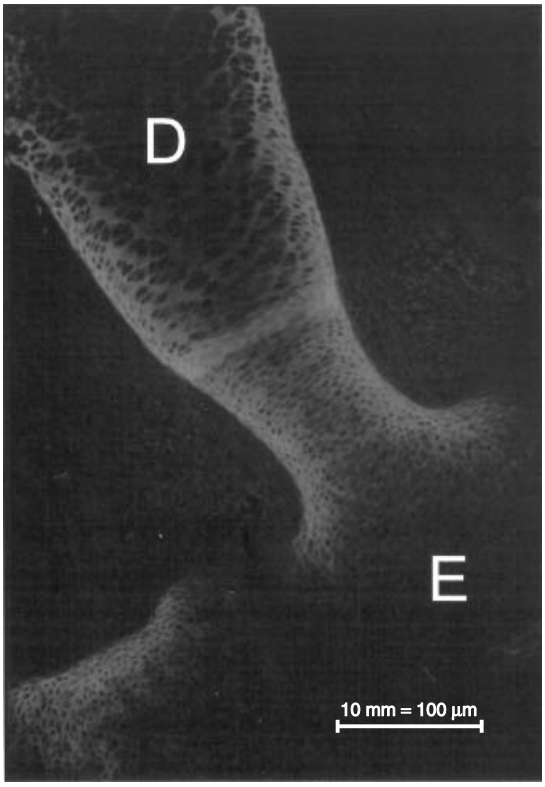

Figure 7. Indirect immunofluorescence staining of 18-day fetal rat elbow cartilage with antibodies to type XI collagen. Antiserum recognizing all isoforms of type XI collagen stains the cartilage uniformly. Staining with a monoclonal antibody specific to the isoform of type XI collagen containing the peptide encoded by exon 6B of the α1(XI) chain shows that in the humerus, this isoform is restricted to diaphyseal regions, D, adjacent to the perichondrium and is not found in the epiphysis, E, at this stage. Although the function of this isoform is unknown, this observation reveals complexity and nonuniformity of the cartilage matrix that are not readily apparent from morphology or ultrastructure alone. The ulna is at the lower left. Scale bar: 10 mm = 100 μm.

Perichondrium

The surface of most cartilage is covered by a fibrous covering known as the perichondrium. This is continuous with the periosteal cover of bone and blends into surrounding fibrous connective tissue [56]. The articular surface and cartilage-bone interfaces of articular cartilage and the growth plate lack a perichondrium. The structure is usually divided into an outer fibrous and an inner chondrogenic layer. The outer layer contains bundles of typical banded collagen fibrils and elastin. Types I, III, and V collagen have been localized by antibodies to this layer, whereas staining for proteoglycans is much less intense than in cartilage matrix [33]. Fibroblasts are detected between the fibrous bundles, and blood vessels are frequently seen. The inner layer of perichondrium blends into the subperichondrial cartilage. Chondrocytes in this region are flat and aligned tangentially with the cartilage margin. The cell density is higher here than deeper in the cartilage; the gradual change in density correlates with a change in cell shape from flat to ovoid (Fig. 8).

The development of the perichondrium begins at the middle of the embryonic bone as a concentration of polygonal cells that covers the cartilage *anlage* [98,99]. Indeed, each successive stage of development is first detected at this point; it then propagates distally in both directions correlating with the state of differentiation of the underlying chondrocytes. As the chondrocytes become hypertrophic, the perichondrial cells adjacent to them elongate in the direction of the long axis of the bone. These cells form overlapping layers and then develop cell-cell contacts or syncytia. Finally, the outer layers of cells form a fibrous extracellular matrix that separates the cells. The most differentiated perichondrium is associated with mature or hypertrophic chondrocytes. The more distal proliferative regions of developing cartilage have a less developed perichondrium. The epiphyseal regions do not have a true perichondrium as defined morphologically. The fact that the most organized perichondrium is associated with the narrowest parts of the developing bone suggests that the perichondrium imposes a physical constraint on the lateral growth of the rudiment. Such a constraint would promote longitudinal growth as chondrocytes in the center produced matrix or enlarged as a result of hypertrophy, as well as contribute to the difference between the width of the cartilage at the diaphysis and epiphysis [98]. It has also been suggested that the perichondrium provides an inhibitory signal for chondrocyte proliferation [100].

During development, the perichondrium immunohistochemically and by *in situ* hybridization stains intensely for a variety of extracellular matrix proteins, including types XII and XIV collagen [101,102], fibrillin [103], and tenascin and the cell surface proteoglycan, syndecan 3 [104]. Their specific roles are unknown, but it is likely that fibrillin and type XII collagen contribute to mechanical constraints and that syndecan 3, the expression of which is localized to the perichondrium of proliferating regions of cartilage, contributes to growth factor function [105]. It is now clear that the perichondrium is much more than a passive restraint and covering. Components of many molecular signaling systems such as BMPs [106,107], Indian hedgehog (Ihh) [108], transforming growth factor-β (TGF-β) [109], and retinoic acid [110,111], which have pronounced effects on chondrocyte differentiation, can be found in the perichondrium.

Vascular Canals

Some hyaline cartilages, including epiphyseal, costal, and laryngeal cartilages, contain vascular canals [56]. These enter from perichondrial vessels and penetrate the cartilage, occasionally forming anastomoses. A typical cartilage canal is comprised of capillaries surrounding a central arteriole and venule (Fig. 9) [56,112]. A variable amount of interstitial connective tissue is usually present, and banded collagen fibrils can be seen in bundles. Types I and III collagen and fibronectin localize immunohistochemically to the interstitial tissue and vessel walls [33]. The chondrocytes in the immediate vicinity of the vascular canals are often larger than typical chondrocytes, and some resemble hypertrophic chondrocytes. The cartilage matrix around vascular canals is enriched in type XII collagen [95]. Younger cartilage (i.e., fetal, newborn) tends to contain more canals than older cartilage. They are often located in the vicinity of the growth plate, and "communicating canals" between the epiphyseal and metaphyseal vessels may sometimes be detected in the growth plate [113].

Growth Plate

The growth plate, or physis, is a very specialized form of hyaline cartilage that is responsible for linear

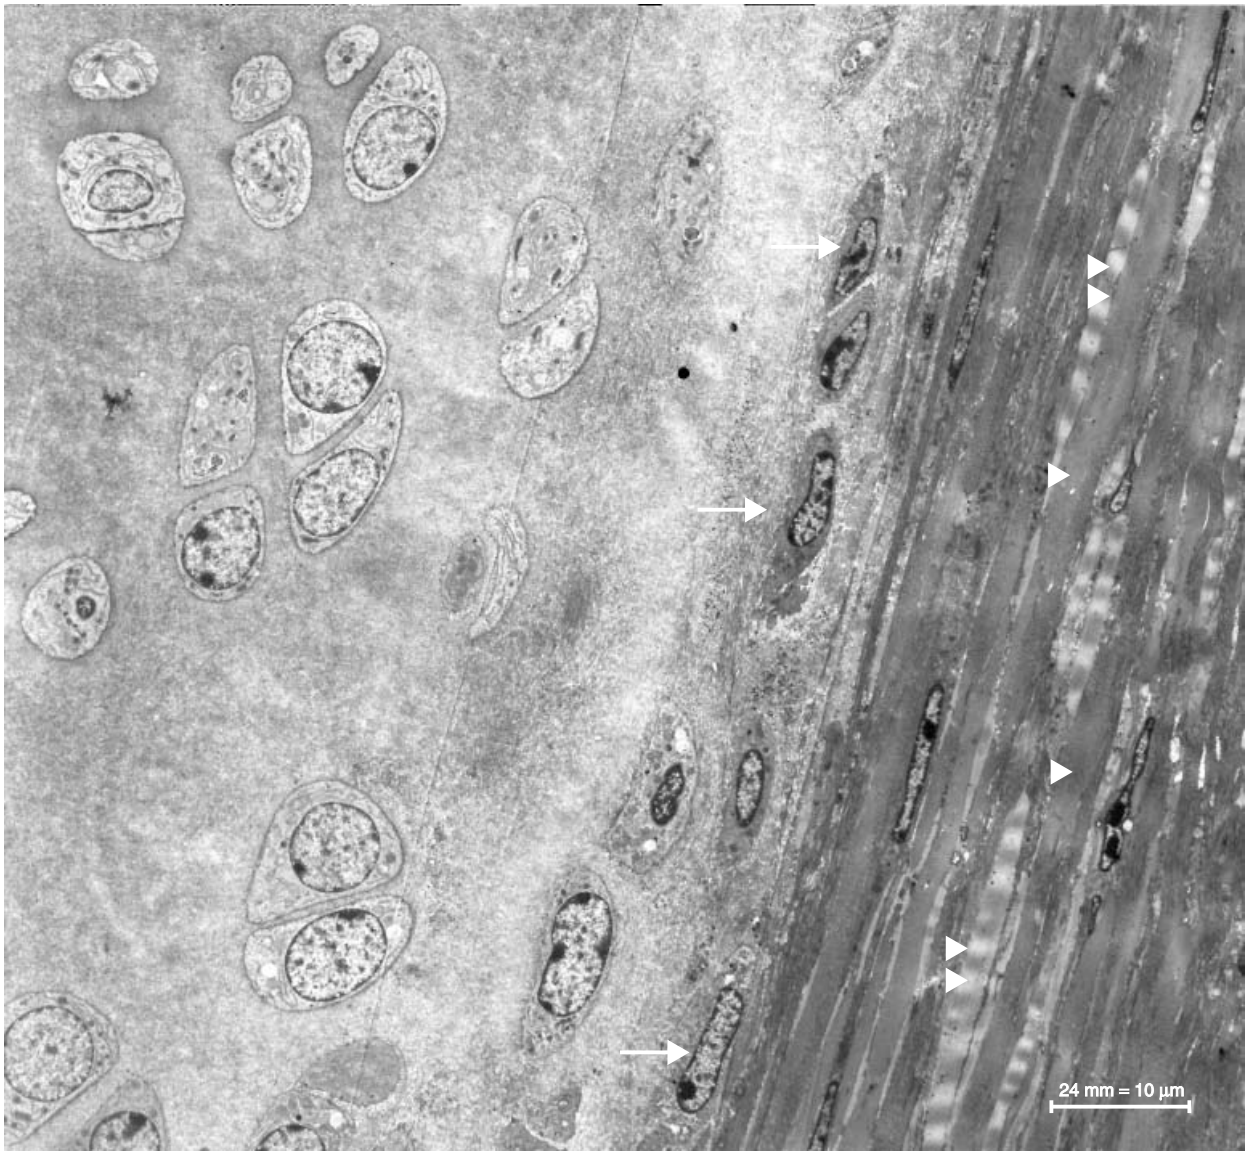

Figure 8. Transmission electron micrograph of newborn rat perichondrium. The perichondrium consists of flattened cells and very dense bundles of collagen fibrils running more in parallel to the section (arrowheads) or more in cross section (double arrowheads) (see also Fig. 14). The chondrocytes adjacent to the perichondrium (arrows) are more flattened than those farther into the cartilage. The matrix around them appears coarser due to larger, more densely arranged collagen fibrils indicating a transitional matrix containing cartilage and non-cartilage components. Scale bar: 24 mm = 10 μm.

skeletal growth. It has been the subject of several lengthy reviews [43,47–49,114]. Its structure is shown in Figure 10. The growth plate is a transition tissue that occupies only a few millimeters of space between the epiphyseal cartilage at the ends of growing bones and the bone proper. Chondrocytes in the growth plate play out the latter stages of the differentiation scheme outlined earlier. After proliferating in the direction of bone growth, chondrocytes enter a maturational or prehypertrophic stage where they actively secrete matrix, which pushes the cells apart from one another. As they complete terminal differentiation, the growth plate chondrocytes enlarge, taking on the form of hypertrophic chondrocytes. These cells alter the matrix, so that some areas become mineralized, while others become degraded. Finally, the hypertrophic chondrocytes die and are replaced by osteoblasts that deposit bone in place of cartilage. For any one cell, this sequence of events occurs at one site over time. However, because the bone is growing, these temporal events are represented spatially in the tissue. The chondrocytes at the earliest stages of the scheme are furthest from, and those at the latest stages closest to, the ossification front where bone is formed. Since neighboring chondrocytes are at approximately the same stage of the scheme, they tend to be the same distance from the front. This arrangement creates the appearance of columns or elongated clusters of cells aligned parallel to the direction of growth and zones of cells with similar characteristics perpendicular to this axis. The names of

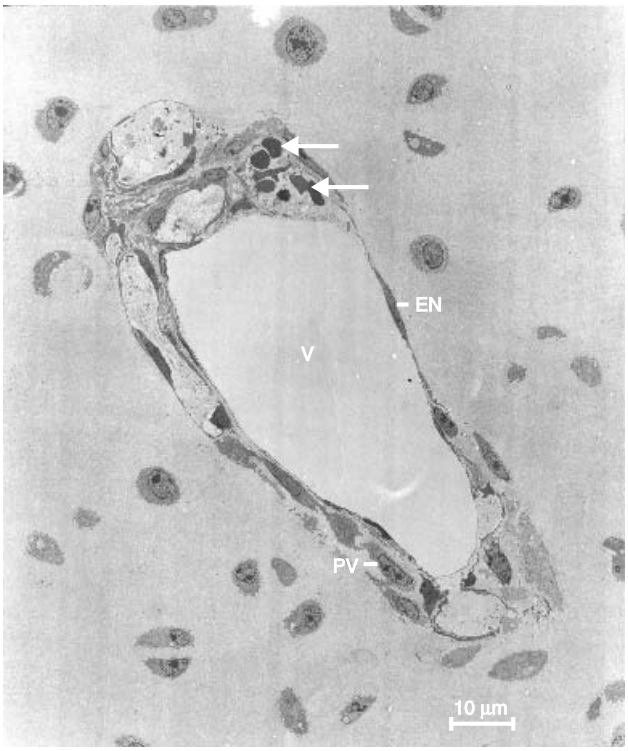

Figure 9. Transmission electron micrograph of a vascular canal from an early second trimester fetal calf. A cartilage canal contains an arteriole, one or more venules (V) and associated capillaries. Note the endothelial (EN) and perivascular (PV) cells. A few capillaries containing red blood cells are indicated by arrows. Scale bar: 15 mm = 10 µm.

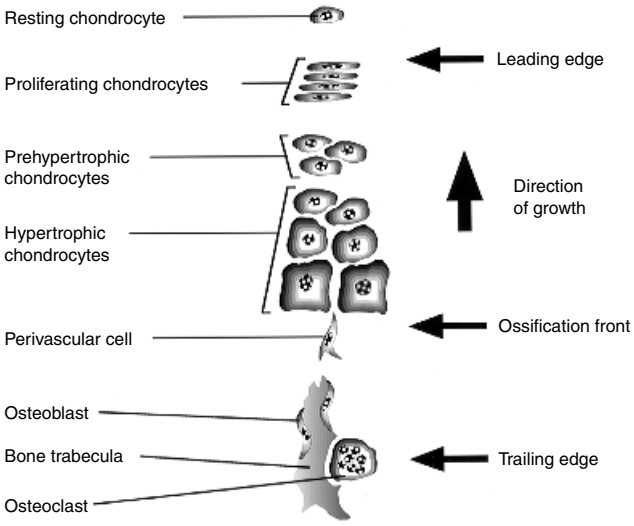

Figure 10. Schematic representation showing the different zones of the growth plate in relationship to bone growth and ossification. Also depicted are the changes in growth plate structure with time, and the life cycle of a single chondrocyte. The cell starts as a resting chondrocyte, differentiates to a hypertrophic chondrocyte, and finally dies as the ossification front approaches and passes through the site occupied by the cell.

the zones reflect their predominant activity, i.e., reserve or resting, proliferative, maturational or prehypertrophic, and hypertrophic, schematically represented in Figure 10 and shown in the photomicrograph in Figure 11. It must be emphasized, however, that the borders between

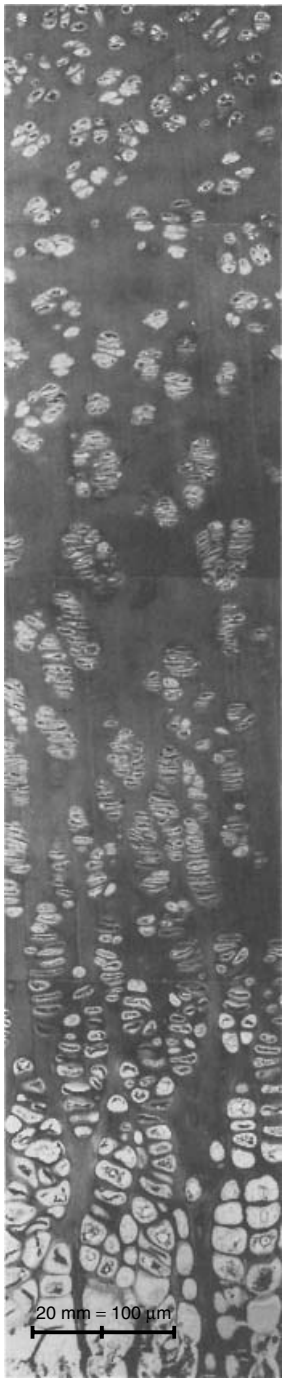

Figure 11. Light photomicrograph (composite) of a rib growth plate from a newborn infant. Note the gradual transition from the reserve zone at the top to the zone of vascular invasion at the bottom, where the invasion of several chondrocyte lacunae can be seen. Methylene blue/basic fuchsin. Scale bar: 20 mm = 100 µm.

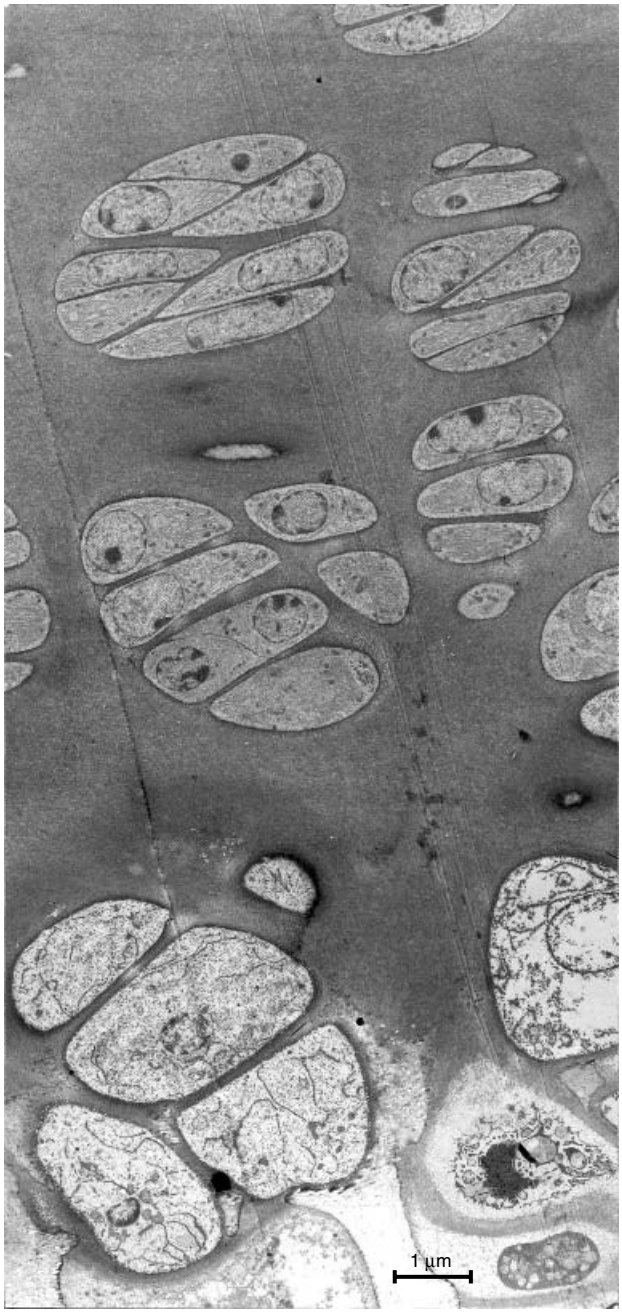
these zones are not precise and that the cellular and matrix changes that occur in the growth plate happen gradually, rather than in distinct steps, as implied by zonal designations.

Although all growth plates share the same general structure, they differ slightly from site to site and from species to species, as documented in the literature and in the experience of the authors. Growth plates from fast-growing bones are wider than those from slow-growing bones [115]. Hence, a femoral growth plate from a fetus or infant will be wider than one from an older child, and a femoral growth plate will be wider than an iliac crest or vertebral body growth plate from the same child. Similarly, the growth plates of fast-growing bones, such as a tibia or femur, tend to exhibit the columnar arrangement of cells, whereas the elongated cluster arrangement is more typical of slowly growing bones, e.g., iliac crest. Fetal growth plates are not as well organized as those from newborn infants or older children; the younger the fetus, the less the organization. It is not clear whether this reflects the faster growth rate or the "immaturity" of the fetal bone.

A



B

Figure 12. Transmission electron micrographs of chondrocytes from the growth plate proliferative **(A)** and hypertrophic **(B)** zones. In the proliferative zone **(A)**, note the distinct, more amorphous-appearing territorial matrices that fuse together to create transverse septa, and the vertical alignment of collagen fibrils along the lateral borders of the micrograph, which correspond to longitudinal septa of the growth plate. The hypertrophic zone **(B)** shown in this micrograph illustrates that the proliferative cells, prehypertrophic cells, and hypertrophic cells can appear as asymmetric clusters rather than distinct columns. Scale bars: **(A)** 24 mm = 10 μm; **(B)** 15 mm = 1 μm.

Figure 12. (*Continued*)

The zone farthest from the center of the growing bone is the zone of reserve or resting chondrocytes. It merges with the epiphyseal cartilage, which it closely resembles except for the orientation of the ovoid-shaped chondrocytes. Their long axes are oriented perpendicularly to the axis of bone growth.

As shown in Figure 12A, the proliferative zone contains flattened chondrocytes in columns or clusters parallel to the axis of growth [33,49]. The cells are close together, implying

recent division; however, mitotic cells are difficult to detect. Uptake of ^{3}H-thymidine or the deoxynucleotide analogue, bromodeoxyuridine (BrdU), reflecting DNA synthesis and cell replication, is restricted mainly to this zone of the growth plate [116,117]. The cells are rarely separated by only their plasma membranes; more commonly, each cell is surrounded by its own territorial matrix compartment, which may merge with that of an adjacent cell [60]. Chondrocytes in the lower proliferative zone contain relatively more rough endoplasmic reticulum, Golgi complexes, and secretory vesicles than cells in the upper part of the zone [65]. Single cells and surrounding territorial matrices in the lower proliferative zone are separated by interterritorial matrix with the ultrastructural characteristics described earlier; however, all the chondrocytes within a cluster share a common territorial matrix [33,60]. Thus, a cluster of cells in this region with its shared territorial matrix compartment is the chondron, or functional unit, of the growth plate. It is comprised of the daughter cells of a single differentiated cell in the reserve or upper proliferative zone, i.e., a clone.

Although the histochemically defined differences between the territorial and interterritorial matrix compartments of typical hyaline cartilage (including epiphyseal cartilage and the growth plate reserve zone) are the same in the proliferative zone, the orientation of collagen fibers changes from random to the direction of growth (longitudinal or vertical by convention) in the interterritorial matrix. This presumably results from stretching of this compartment by the directional cell division and compression from the accompanying secretion of new matrix. The net result is the formation of septa between the chondrons, which exhibit a longitudinal or sometimes diagonal orientation. This interterritorial matrix is continuous with that of the reserve and epiphyseal cartilage. Small membrane-bound structures called matrix vesicles are found in these septa [118,119]. They measure approximately 100–200 nm in diameter and occasionally contain ribosomes. They are thought to be derived from the cell processes of nearby cells and participate in mineralization of the matrix in the lower growth plate. Matrix vesicles are not normally found in the transverse septa that separate individual cells, which is composed of territorial matrix [60].

As one moves to the hypertrophic zone, there is a gradual increase in cell size that corresponds to the expression of the hypertrophic chondrocyte phenotype (Fig. 12B). Earlier studies, using conventional chemical fixation, suggested that cells in the lower hypertrophic zone degenerated. However, studies employing cryofixation combined with methods to preserve matrix proteoglycans indicate that they remain intact throughout the hypertrophic zone to the point of metaphyseal vascular invasion [60,61,63,120]. Using this approach and stereologic procedures, Hunziker et al. were able to quantify and compare a number of parameters of chondrocytes of the proliferative and lower hypertrophic zones of the rat tibia [61]. Hypertrophy was associated with increases in cell volume and surface area of approximately ten- and fourfold, respectively. The increases were due mainly to changes in vertical diameter. The absolute amounts of rough endoplasmic reticulum, Golgi complexes, and mitochondria increased in the hypertrophic chondrocytes two-, four-, and threefold, respectively. However, the relative amounts of these organelles per cell volume decreased, suggesting a large influx of fluid during the process. Although the absolute numbers differed, Buckwalter et al. reached the same conclusions using a somewhat different methodology to examine the mouse tibial growth plate [63]. These observations illustrate the dramatic changes in cell morphology that occur during chondrocyte hypertrophy.

More extensive morphometric analysis of the hypertrophic zone indicates that extracellular matrix changes also contribute to longitudinal growth, albeit to a lesser extent than changes in cellular volume. The collagen content and the volume of both the territorial and interterritorial matrix compartments are expanded relative to the proliferative zone, with the territorial matrix making the larger contribution [121]. These matrix changes are accompanied by extensive remodeling, especially in the longitudinal septa, as evidenced by the turnover of type II collagen predominantly in this region [122].

The structural organization of matrix compartments in the hypertrophic zone is similar to that in the proliferative zone. By light microscopy, the septa appear more compressed by the enlarging cells, but electron microscopy shows that the collagen fibrils of the territorial matrix are arranged parallel to the cell surface and are more tightly packed than the longitudinally aligned fibrils of the interterritorial matrix [60]. Mineralization can be detected by electron microscopy as crystalline needles of apatite inside matrix vesicles in the septa of the upper hypertrophic zone [119]. In the middle of the zone, the crystals protrude from the vesicles and clusters of crystal needles extend outside the matrix vesicles. Coalescence of the clusters is detected in the lower hypertrophic zone, where the mineralization is visible by light microscopy [33]. Mineralization occurs normally only in the interterritorial matrix of the longitudinal septa (Fig. 13A). The territorial matrix and thus the transverse septa, which are composed of common or adjacent territorial matrices, are not mineralized (Fig.13B) [60,118]. The restricted pattern of mineralization is likely to be due in part to the production by lower hypertrophic chondrocytes of matrix Gla protein, a calcium-binding protein that inhibits mineralization [123]. The mineralization of cartilage matrix is often called provisional calcification.

Histochemical methods have shown changes in the matrix of the hypertrophic zone that are not evident morphologically. These changes are mainly in the territorial matrix of the hypertrophic cells. Most notable is the presence of type X collagen, a collagen that appears to be synthesized only by hypertrophic chondrocytes in the growth plate [31]. There is also evidence that this collagen is also expressed in articular cartilage in mouse, pig, and human late in development or in mature tissue [124,125]. Nevertheless, type X collagen is typically used as a marker for hypertrophic chondrocytes and the hypertrophic zone. The organization of type X collagen in the matrix is not entirely clear. Type X collagen forms a filamentous network in association with collagen fibrils near cells [126], and it contains typical lysine-derived collagen cross-links [127]. Type X collagen can also form a more elaborate hexagonal network *in vitro* [128] and so it can both self-associate and presumably interact with other collagens. It has also been shown to interact with proteoglycans [129,130]. The function of type X collagen is unclear, but changes in the organization of proteoglycans, matrix vesicles, and subchondral trabecular bone have been observed in type X-null mice [131].

Type I collagen and fibronectin have been localized intracellularly and in the pericellular region of cells in the lower hypertrophic zone [33]. Also, several other proteins more often associated with bone matrix are produced

by hypertrophic chondrocytes. These include osteocalcin, osteopontin, bone sialoprotein, and osteonectin [40,132], and alkaline phosphatase activity is associated with cell membranes and matrix vesicles in the same region [118,133]. It is possible that expression of these proteins by both hypertrophic chondrocytes and osteoblasts reflects a convergent requirement for the mineralization of their respective matrices [132]. However, it is also possible that some hypertrophic chondrocytes in appropriate circumstances escape apoptosis and functionally become osteoblasts [40,134,135].

B

Figure 13. Transmission electron micrograph showing the zone of provisional calcification. **(A)** The calcified areas appear black (arrowhead) and are found primarily in the longitudinal septa composed of interterritorial matrix between columns/clusters of lower hypertrophic chondrocytes. As the ossification front advances, this calcified cartilage forms the trabeculae (arrow) in the subchondral bone. The territorial matrix that lies adjacent to the longitudinal septa and the fused territorial matrices that form the tranverse septa are not mineralized. This is readily seen at higher magnification **(B)**, where the hydroxyapatite crystals, dark area (left), are excluded from the territorial matrix (center) of the hypertrophic chondrocyte (right). Scale bars: **(A)** 12 mm = 30 μm; **(B)** 13 mm = 300 nm.

Figure 13. (*Continued*)

Compared to the interterritorial matrix in the septa of the lower hypertrophic zone, the adjacent territorial compartment appears to stain less intensely with antibodies to type II collagen, proteoglycan, and proteoglycan link protein; however, this may be an artifact of compression [33].

Metaphyseal blood vessels penetrate the transverse septa and lacunae of the last (terminal) hypertrophic chondrocytes in the zone of vascular invasion. This can be seen at the bottom of Figure 11. Capillary sprouts and perivascular cells resembling macrophages are seen in direct contact with the transverse septa [136]. Partially degraded transverse septa can be identified in some instances, while dissolution of the septa with protrusion of the capillary sprouts into the lacunae can be seen in others. Extravasated red blood cells and platelets may be found in perforated lacunae. Degeneration of the terminal chondrocytes, i.e., contraction and rupture of the plasma membrane, may be observed in some lacunae in which the transverse septa are partially intact. Degradation of the territorial matrix of the terminal hypertrophic chondrocytes and neighboring longitudinal septa in some cases is also seen.

The normal and timely advance of blood vessels into the cartilage matrix is dependent on the expression of the matrix metalloproteinase, MMP-9 (gelatinase B). Analysis of MMP-9-null mice has provided insight into the regulation of cartilage degradation and bone formation in the growth plate [137]. Observations suggest that MMP-9 is produced by a cartilage-degrading cell, or chondroclast, originating in the bone marrow. The activity of MMP-9 leads to the release of angiogenic factors and promotes apoptosis

of hypertrophic chondrocytes. In the model derived from the MMP-9-null mouse, chondroclasts from the vascular bed of newly forming bone arrive at this last layer of hypertrophic chondrocytes initiating a degradative cascade by the secretion of MMP-9. This degradation provides both access and stimulus for further vascularization. The destruction of cartilage and/or the approach of capillaries induce the apoptosis of nearby hypertrophic chondrocytes that is observed near invading capillaries [120,138]. Finally, the capillaries introduce osteoblasts that deposit osteoid (bone matrix) in the remodeling matrix and lacunae vacated by the terminal chondrocytes. Not surprisingly, the highest levels of expression of interstitial collagenase (MMP-1) [139,140] and collagenase-3 (MMP-13) [141] during embryonic development occur at this interface of hypertrophic cartilage and forming bone.

Proximal (metaphyseal) to vascular invasion is the so-called primary spongiosa or zone of primary ossification [114]. Trabeculae oriented in the direction of growth contain an inner core of cartilage matrix that is frequently contiguous with the longitudinal septa of the growth plate, and which corresponds to the interterritorial matrix that was not degraded by vascular invasion [39]. Osteoblasts deposit bone matrix, osteoid, on these cartilaginous cores immediately beneath the sites of vascular invasion. The cartilage cores are gradually replaced by bone matrix during remodeling of metaphyseal bone [114]. Thus, the extensions of the longitudinal septa into the metaphyseal bone provide scaffolding for the deposition of bone matrix in subchondral bone, physically anchor the growth plate to the bone, and, in essence, provide continuity between cartilage and bone elements of the growing skeleton.

Much of the growth plate is bordered peripherally by a structure called the perichondrial ossification groove (of Ranvier) [48,142]. It encircles the lower growth plate and extends to the proliferative zone, where the groove is deepest (Fig. 14). The outer fibrous layer is continuous with the periosteum and, to a large extent, with the perichondrium. The innermost cells are densely packed and are thought to be mesenchymal precursor cells. It has been proposed that in the lower growth plate they become osteoblasts, which give rise to the sheaths of so-called "bone bark" that surround the zone of vascular invasion and part of the hypertrophic zone. In the upper growth plate, they may differentiate along chondrocytic lines and contribute to appositional growth of epiphyseal cartilage [142].

There has been much recent progress in understanding how the growth plate is regulated. This has focused on the control of chondrocyte proliferation and terminal differentiation because these events ultimately determine the rate at which terminally differentiated hypertrophic chondrocytes are presented to the ossification front. At least three mechanisms have been identified. The best defined is a regulatory circuit in the form of a negative feedback loop, involving FGFs, Ihh, PTH-related peptide

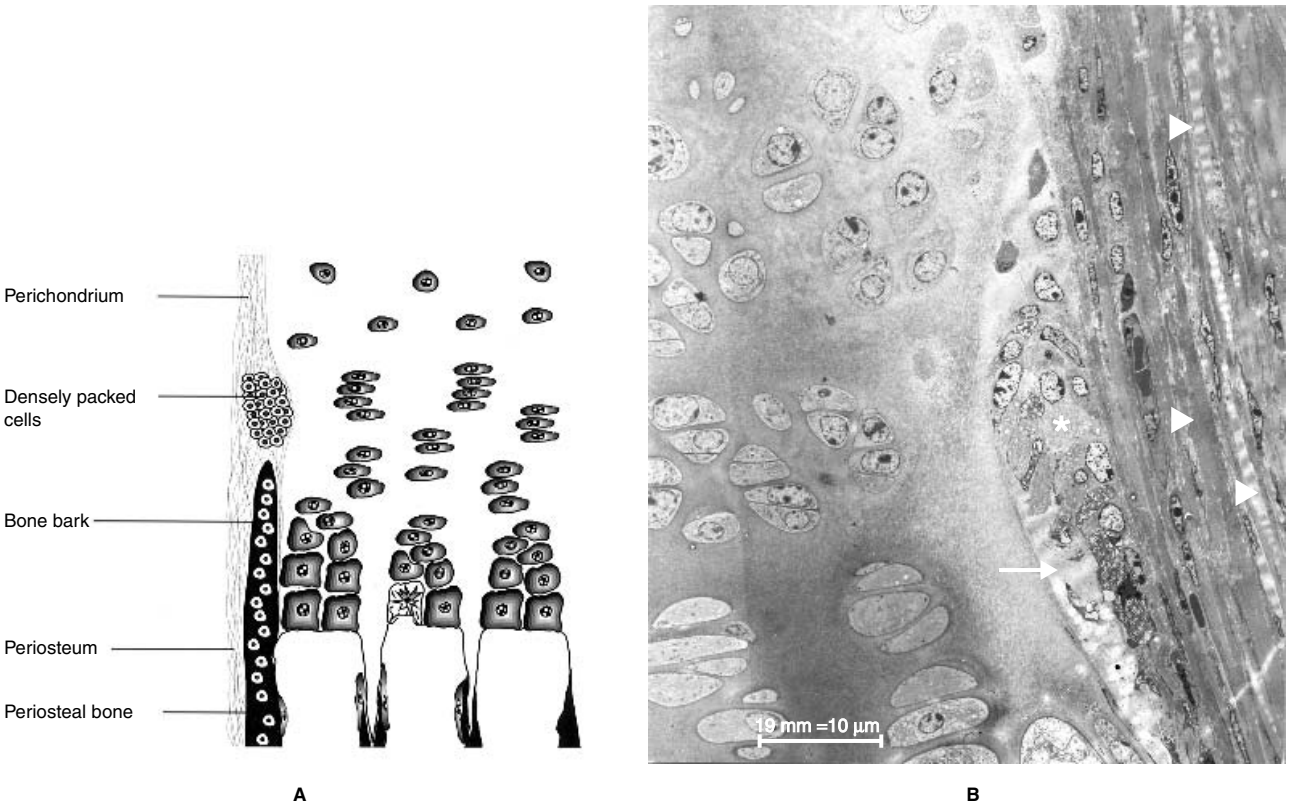

Figure 14. Schematic representation of the lateral border of a growth plate, showing the ossification groove (of Ranvier) and its components (bone bark and zone of densely packed cells). A transmission electron micrograph of the ossification groove is on the right. In this micrograph, the densely packed cells (asterisk) lacking extracellular matrix can be seen adjacent to the perichondrium. The mineralized bone bark is light in color (arrow). Note the thick bundles of collagen fibrils in the outer perichondrium (arrowheads). Scale bar: 19 mm = 10 μm.

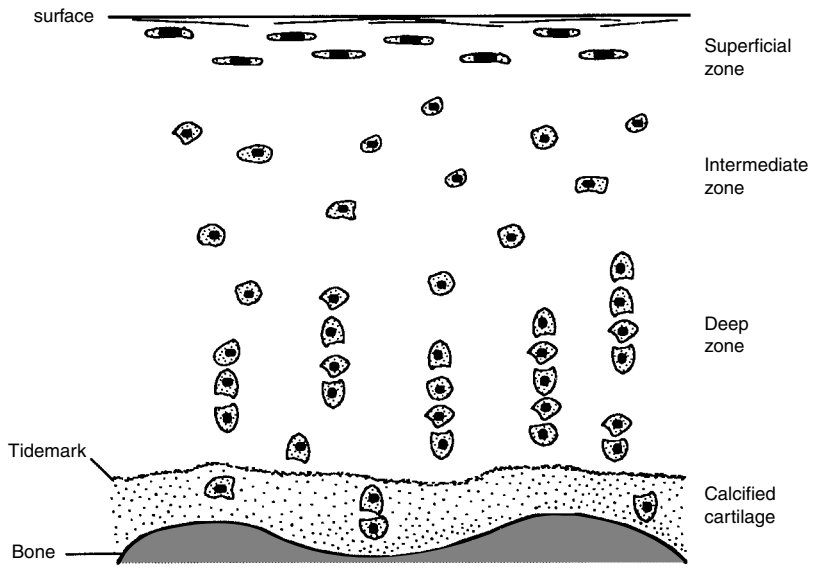

Figure 15. Schematic representation of adult articular cartilage, showing the zones and organization of articular chondrocytes.

(PTHrP) and, possibly, BMPs that controls the rate of formation of prehypertrophic cells [108]. FGFs acting through FGF receptors, especially FGFR3, constitute the second mechanism. FGFR3 activation inhibits bone growth, most likely through blocking both proliferation and terminal differentiation of growth plate chondrocytes [143]. The third mechanism involves extracellular matrix proteins that appear to affect chondrocyte proliferation and terminal differentiation by influencing the diffusion and presentation of growth factors to cells and by directly interacting with receptors on cell surfaces [144].

Articular Cartilage

Articular cartilage is usually divided into four zones: superficial (tangential), intermediate (transitional), deep (radial), and calcified (Fig. 15). The alternative designations reflect the alignment of collagen fibers as visualized by light microscopy [59]. The zones are sometimes referred to as zones I–IV, respectively. As with other cartilages, there are differences in cellular and matrix morphology depending on joint location, degree of weight bearing, and age and species of the cartilage. For example, it is difficult to distinguish the intermediate from the deep zone in young cartilage compared with articular cartilage from an adult [74]. Similarly, the articular cartilage of a growing bone does not have a calcified zone; rather, it blends into epiphyseal cartilage that resides between the articular surface and the growth plate (Fig. 16). This is more evident in species with large bones (and large epiphyseal cartilages), such as man, and becomes less apparent as secondary ossification centers in the epiphyseal cartilage encroach upon the articular region. Despite these differences, articular cartilages share many features with each other as well as with other cartilages. With the variations noted below, the ultrastructure of the chondrocytes and matrix, the organization of matrix into compartments, and cell-matrix relationships are similar to what has already been described.

The superficial zone is thinnest along the articular surface and widest at the articular margin, where it merges with the perichondrium. The articular surface is comprised of a thin layer of densely packed, fine collagen fibrils running parallel to the surface [73]. The fibrils have characteristic periodic banding, and many form bundles [71,74]. There are no cells in this fibrous layer. However, the lower part of the superficial zone contains flattened cells aligned parallel to the surface. These chondrocytes exhibit a cell-surface polarity [59,73]. The cell membrane facing the surface tends to be smooth and to contain prominent invaginations, or caveolae, while many cytoplasmic processes are found on the other (basal) side of the cell. Rough endoplasmic reticulum and Golgi complexes are sparse [73]. The typical basket-like pericellular capsule and territorial matrix compartment are not prominent in this zone. Cationic dyes reveal less proteoglycan than in deeper zones; however, proteoglycans and proteoglycan link protein can be detected by immunostaining [59,86]. The chondrocytes of the intermediate zone are more spherical, and the surface polarity seen in the superficial zone is much less apparent [59,73]. The cells have more prominent perinuclear filaments, and rough endoplasmic reticulum and Golgi complexes are more abundant. The organization of matrix compartments is more typical, and chondrons with concentric capsular layers are evident [62,71]. Collagen fibrils are thinner and more widely spaced, and may exhibit faint periodic banding. Their orientation tends to be random, and bundles are rarely observed [74]. The matrix of the intermediate zone stains intensely with cationic dyes for glycosaminoglycans [56].

The deep zone, when present, is distinguished by the tendency of the cells to align themselves perpendicularly to the joint surface and of the collagen fibrils of the interterritorial compartment, which are thicker than in the intermediate zone, to exhibit the same orientation [59,86]. Rough endoplasmic reticulum and Golgi complexes are prominent in the chondrocytes [73,75]. Cationic stains and immunostaining show abundant proteoglycan in this zone [86]. Schenk and colleagues have noted that the cells of the upper deep zone (closest to the articular surface) are rich in intermediate filaments and glycogen deposits compared with the cells of the lower deep zone near the border of this zone and the calcified cartilage zone, the so-called tidemark [59]. Matrix vesicles can be identified in the

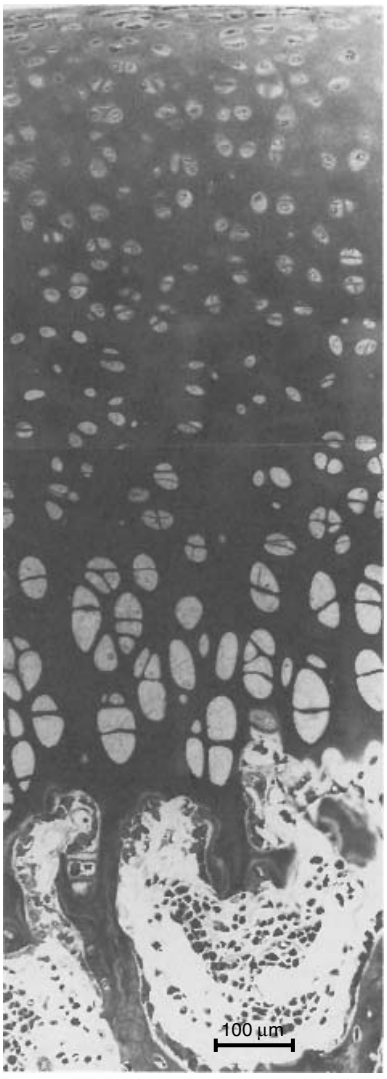

Figure 16. Light photomicrograph of articular cartilage from the femur of a 9-day-old rabbit. The articular surface, with flattened chondrocytes, is seen at the top. Since the rabbit is still growing, the articular cartilage merges into the growth plate at the bottom. Toluidine blue. Scale bar 20 mm = 100 μm.

interterritorial matrix of the deep, as well as the superficial and intermediate zones, but they are not mineralized [71].

The tidemark, which demarcates the deep from the calcified zone in adult articular cartilage, is a narrow band of fine vertical striations that corresponds to aggregates of mineral associated with matrix vesicles that protrude a short distance into the interfibrillar spaces of the lower deep zone [59]. They resemble cement lines of bone. The appearance of mineral in the calcified cartilage zone of articular cartilage closely resembles that in the lower growth plate, although matrix vesicles appear to be less numerous. As in the growth plate, mineralization occurs only in the interterritorial matrix compartment. There is less intense cationic dye staining of proteoglycan in the calcified cartilage zone than in the intermediate and deep zones [56].

Molecular heterogeneity contributes to the complexity of the articular cartilage matrix. The extracellular matrix of the superficial zone contains specialized proteins, superficial zone protein (SZP) [145,146] and lubricin [147], not found in the deeper zones. SZP is also made by synovial cells and both proteins are found in synovial fluid, suggesting that they may contribute a lubricating function. A novel cartilage glycoprotein, cartilage intermediate layer protein (CILP), is found in the territorial matrix only in the intermediate zone [148,149], suggesting a distinction between chondrocytes in this zone and those in the superficial and deeper layers. The changes in fibril diameters associated with different regions of articular cartilage are accompanied by a heterogeneous composition of the fibrils. The small proteoglycan, decorin, is preferentially associated with the population of fibrils with larger diameters, while type IX collagen is associated with the thinner fibrils [150].

Articular cartilage develops after the initial condensation defines the bone. Mesenchymal cells in the interzone, the space between the adjacent ends of developing bones that will eventually become the joint space, progressively differentiate into chondrocytes and thus form a subset of cells distinct from the rest of the epiphyseal cartilage [151]. In rabbit, the articular cartilage can be distinguished from the underlying epiphyseal cartilage at birth by the vertical orientation of collagen fibrils and at 2 weeks by the vertical and linear columns of chondrocytes or chondrons [77]. Formation of articular cartilage is independent of the secondary ossification center in the epiphysis, and growth of the articular cartilage to keep pace with the rest of the bone occurs by cell division in the vertical columns of cells and by the production of matrix.

Elastic Cartilage

Elastic cartilage has many of the characteristics of hyaline cartilage [50]. The cells are round to ovoid and may occasionally contain two nuclei. Fat droplets and glycogen aggregates may be extensive and, in such cases, the chondrocytes come to resemble typical adipose cells [152]. Otherwise, the cellular ultrastructure is similar to that of other chondrocytes [153,154]. Extracellular matrix compartments have not been as well defined as in hyaline cartilage. Collagen fibrils are relatively thin and do not show periodic banding. The most distinctive feature is the presence of a dense network of elastin, which can be selectively stained by orcein for light microscopy. By electron microscopy, elastin appears as irregular strands of amorphous material associated with poorly defined peripheral microfibrils [56,153] (Fig. 17). The cells near the perichondrium have a flattened shape, and faintly banded collagen fibrils can be detected. The elastic fiber component of elastic cartilage is produced by the chondrocytes. This appears to be a general capability of chondrocytes in as much as chondrocytes isolated from hyaline cartilage, which lacks elastic fibers, synthesize elastin and fibrillin within 24 hours of cell culture [155]. However, the elastic component is poorly regenerated during repair [152]. Elastic cartilage develops from a condensation of mesenchyme. The production of elastin, like chondrogenesis, is dependent on this condensation phase and coincides with the differentiation of mesenchymal cells to chondrocytes and the expression of the typical cartilage components, aggrecan and type II collagen [156].

Fibrocartilage

Fibrocartilage has been considered an intermediate tissue between hyaline cartilage and dense fibrous tissue and morphologically can vary between these two extremes [56,58]. It

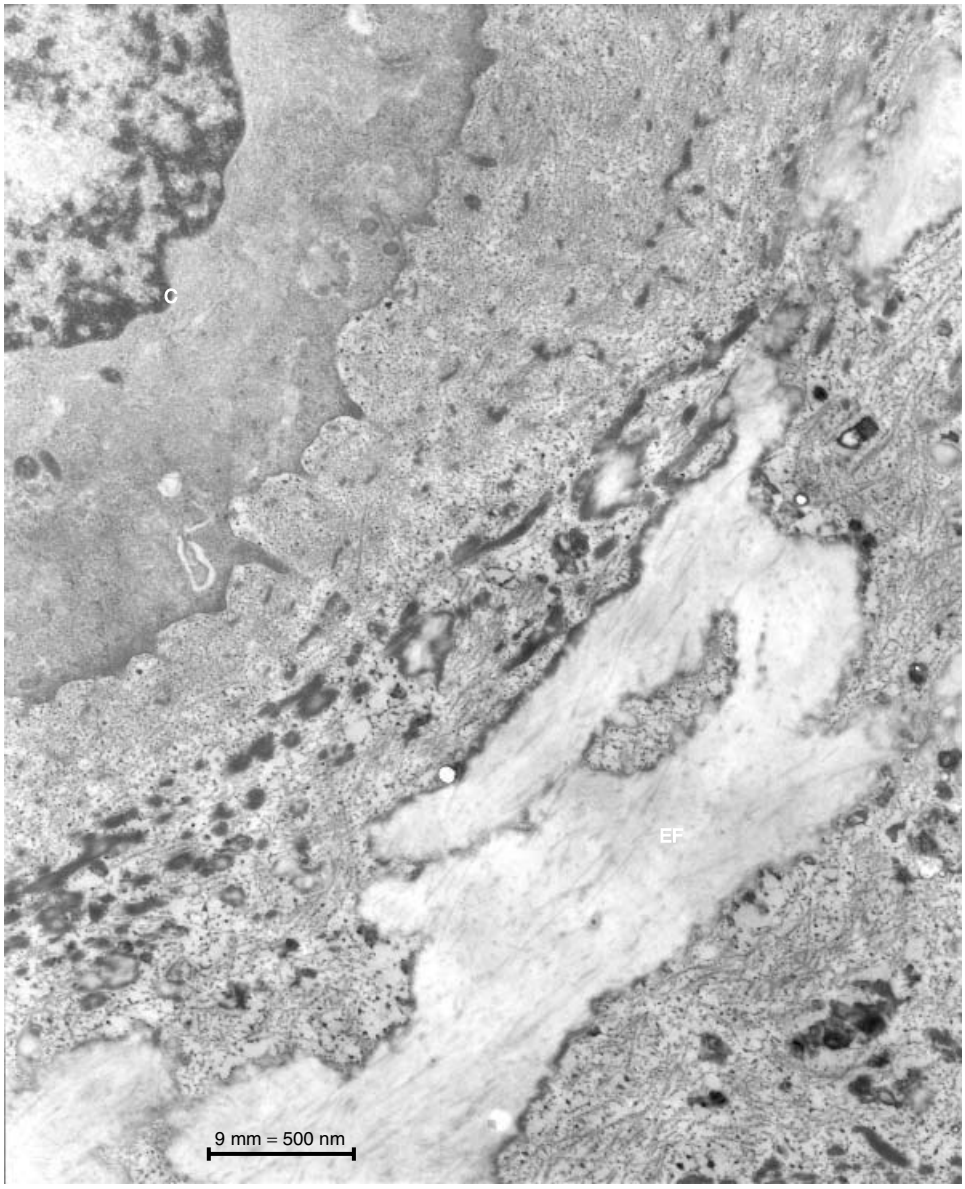

Figure 17. Transmission electron micrograph of elastic cartilage of the human ear. The extracellular matrix closest to the chondrocyte, C, has the more typical appearance of cartilage while the matrix more distant from the cell is a little coarser. The large elastic fibers, EF, occupy a considerable portion of the extracellular matrix. Scale bar: 9 mm = 500 nm.

is never found alone, but merges gradually with neighboring dense fibrous tissue or hyaline cartilage [50]. Fibrocartilage combines the properties of resistance to compression like cartilage with resistance to shear as in tendon [157]. Not surprisingly, both of these properties of fibrocartilage are intermediate in magnitude between cartilage and tendon. Fibrocartilage is typically found in areas where both of these properties are required, such as the intervertebral discs, menisci of the knees, and at the articular surfaces in the coracoclavicular and temporomandibular joints. Fibrocartilage is also found at the sites of tendon attachment to long bones but only at the epiphyses. Here the fibrocartilage is calcified to provide additional stabilization to this connection. The chondrocytes are interspersed, sometimes in rows, between dense fibrous bundles containing type I collagen. The territorial matrix around the cells is cartilage-like, containing collagen types II, IX, and XI [158] and proteoglycan, while the remaining extracellular space is occupied by thick interwoven bundles of collagen fibrils with the characteristic banding pattern (Fig. 18). The cells are round to elongated and resemble other chondrocytes ultrastructurally. Some fibrochondrocytes at the ligament- or tendon-bone interfaces express type X collagen [159,160] even though they do not appear hypertrophic. Fibrocartilage contains no definite perichondrium. Like hyaline cartilage, fibrocartilage is mostly avascular. Where they occur, blood vessels are limited to the periphery of the fibrocartilage. The nutritional state of the cells is maintained by diffusion aided by compression of

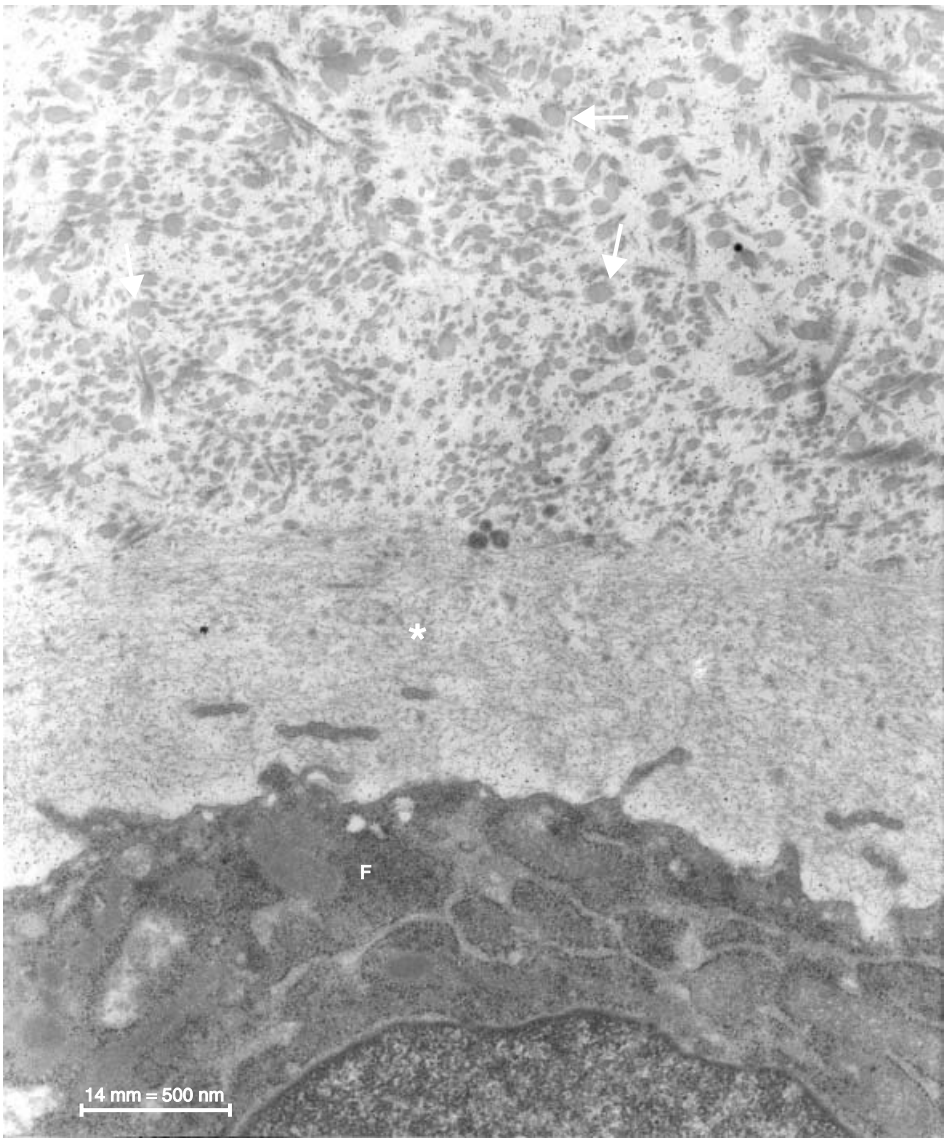

Figure 18. Transmission electron micrograph of fibrous cartilage of the human annulus fibrosus. The fibrochondrocyte, F, is surrounded by a cartilaginous matrix (*) and together they are embedded in a typical noncartilaginous fibrous connective tissue matrix containing large diameter banded collagen fibers, seen here mostly in cross section (arrows). Scale bar: 14 mm = 500 nm.

the tissue. Fibrocartilage usually develops from fibrous tissue in response to a loss of vascularity and/or to compressive forces [157]. The chondrocytes arise by metaplasia of existing fibroblasts and produce a cartilaginous matrix within the context of the preexisting fibrous matrix. However, fibrocartilage can also develop from hyaline cartilage or from condensing mesenchyme, where a fibrous tissue forms first and is followed by the appearance of chondrocytes [161].

RECENT DEVELOPMENTS

Matrilins

Cartilage matrix protein (CMP) is the first of a new family of proteins called matrilins (for review, see [162,163]). CMP is designated matrilin-1, and three other members have been identified, matrilin-2 [164], matrilin-3 [165], and matrilin 4 [166]. Only matrilin-4 has not been found in developing or mature endochondral skeleton. Starting at the amino terminus, matrilins contain a von Willebrand factor A domain, one or more EGF motifs, a second von Willebrand factor A domain (lacking in matrilin-3), and, finally, a coiled coil sequence responsible for oligomerization that results in either trimers or tetramers.

In the cartilage of developing bones, matrilin-3 and matrilin-4 generally co-distribute [167]. They are absent from the hypertrophic zone of the growth plate and from developing and mature articular cartilage [168]. Analysis of their molecular organization as recombinantly expressed proteins [169], or in tissue [167], indicates that they assemble into homotrimers of matrilin-1, homotetramers of matrilin-3, and heterotetramers comprising different combinations of

both. Matrilin-1 and matrilin-3 have been shown to assemble into collagen fibril-dependent and collagen fibril-independent filamentous networks [168,170]. Within cartilage, matrilin-2 is found in the hypertrophic zone [171,172], appears to form homotrimers [173], and can form filamentous networks [172].

At its simplest level, the matrilin system is an example of the complexity and regional specialization of cartilage extracellular matrix composition. However, because matrilin-1 has been shown to associate with type II collagen [174] and proteoglycans [175], and to show integrin-mediated effects on chondrocyte attachment and spreading [176], it is likely that matrilins contribute to the structural integrity of developing cartilage. Two different knockouts of matrilin-1 in mice showed no developmental effects [177,178], although one did show an alteration of collagen fibril formation and organization in the maturation zone of the growth plate [178]. It is possible that functional redundancy between matrilin-1 and matrilin-3 may mitigate the effects of gene inactivation. However, two different missense mutations within the von Willebrand factor A coding region of matrilin-3 have been found to be associated with autosomal dominant multiple epiphyseal dysplasia [179] (see Chapter 23, Part II, this volume). This suggests a dominant negative effect of mutant matrilin-3 molecules on the function of the matrilin-1/matrilin-3 network and an important role for matrilins in the structure of cartilage. Autoimmune reactivity to matrilin-1 is associated with relapsing polychondritis [180], and has been used to generate the disease in a mouse model [181].

Perlecan

An additional example of the functional significance of matrix macromolecules in endochondral bone formation is the heparan sulfate proteoglycan, perlecan. Perlecan is a multidomain, heparan sulfate proteoglycan, usually associated with basement membranes and other tissues, and can function as both a cell surface-attached and -unattached molecule. In addition, it has many binding activities, including the potentiation of fibroblast growth factor activity [182,183]. Perlecan protein is widely distributed in fetal cartilage templates that will be replaced by bone [184–186], in which it is expressed primarily after overt chondrocyte differentiation and appears in greater amounts in hypertrophic cartilage.

Evidence that perlecan plays an essential role in endochondral ossification has been provided by two studies of targeted perlecan gene inactivation [187,188]. In homozygous −/− mice in both cases, skeletal development was substantially perturbed, features including dwarfism and pronounced bowing of long bones. Pattern formation, mesenchymal condensation, joint formation, and chondrogenesis appeared normal, consistent with the expression of perlecan later in chondrocyte differentiation. However, the cartilage was soft, endochondral ossification was delayed, and the organization of primary and secondary ossification centers was disturbed. It is likely that these effects accounted for much of the skeletal phenotype observed. Collagen fibrils were fewer in number, and shorter, and disorganization of the growth plate was acute in that columns of cells and distinct zones were lacking and hypertrophic chondrocytes were fewer in number. Mineralization of the hypertrophic cartilage was also disorganized and was often horizontally oriented rather than being restricted to the longitudinal septa as in normal cartilage. Finally, the expression of Indian hedgehog, a regulator of chondrocyte hypertrophy, could not be detected in the growth plate.

Two ideas have been advanced for the function of perlecan that would lead to the effects of gene inactivation mentioned [182]. Perlecan may be required for the orderly process of matrix degradation during the complex and extensive tissue remodeling associated with endochondral ossification. Indeed, the expression of vertebrate collagenase is higher in the growth plate than in any other location in the developing vertebrate embryo. Evidence suggests that perlecan may protect matrix from inappropriate degradation and that its absence may lead to pervasive matrix degradation [187]. Alternatively, or in addition, perlecan may participate in growth factor function and developmental signaling, particularly with regard to FGFs and Indian hedgehog, which are central to the regulation of chondrocyte differentiation in the growth plate [188].

Mutations in the human perlecan gene, *HSPG2*, have now implicated this molecule in the function of human cartilage (see Chapter 23, Part II, this volume). Functionally null mutations have been detected in patients with the lethal autosomal recessive disorder, dyssegmental dysplasia, Silverman-Handmaker type (MIM 224410) [189]. Affected individuals have a skeletal phenotype very similar to that observed in perlecan knockout mice. Missense mutations and small truncations of perlecan result in the milder Schwartz-Jampel syndrome (MIM 255800), in which mutant perlecan is nevertheless secreted into the matrix and likely retains partial function [190].

Joint Formation

Recent evidence has shed light on the mechanism of joint formation. While some joints form at the interface of separately formed skeletal elements, more frequently they do so as a result of the subdivision of the prechondrogenic mesenchymal condensation. This is especially the case in the appendicular skeleton. Joint formation begins with the de-differentiation of a band of chondroblastic cells to form a joint interzone. Apoptosis then leads to cavitation and the physical separation of skeletal elements. A few growth and differentiation factors and developmental signaling molecules are expressed at the sites of developing joints, and their identities are now becoming apparent [191]. The first factor shown to be involved in regulating joint formation is the growth and differentiation factor, GDF5 [192,193]. Mutations in the corresponding gene result in the absence of certain joints in both mice and humans [194-196]. Paradoxically, ectopic expression of GDF5 results in chondrogenesis, not de-differentiation, apoptosis or other manifestation of joint formation. It is now apparent that the intercellular signaling molecule, Wnt-14, plays a key role in initiating joint formation [197]. Ectopic expression of Wnt-14 results in cellular changes associated with joint interzones, as well as the activation of genes normally expressed in the interzone and the suppression of genes not normally expressed there. Misexpression of Wnt-14 in developing cartilage also suppresses the formation of the nearest joints, suggesting that it may also be involved in regulating the spacing of joints.

Morphology of Bone

R. Schenk

INTRODUCTION

Bone is considered the last and most perfect achievement in the evolution of supporting tissues. As far as mechanical properties are concerned, connective tissue made the first decisive step with the elaboration of collagen fibrils, which offer a superb tensile strength but no resistance to other sorts of deformation. In cartilage, proteoglycans were extruded into the interfibrillar space. Trapped within the collagen network, their osmotic or electrostatic swelling capacity provides an intercellular matrix that can withstand compression and shear elastically. The high water content of this material allows the metabolic supply of the enclosed chondrocytes by diffusion over distances of several millimeters. The tissue could also be shaped as a skeleton and provides a unique capacity for interstitial growth.

The final step toward a solid building material was mineralization. Calcified cartilage is the first step in this direction. Calcium phosphate and hydroxyapatite are precipitated in the interfibrillar space formerly occupied by proteoglycans. This filler stiffens the cartilaginous mold, but also hampers the transport of nutrients to the cells. This was a severe limitation on the construction of massive components in the skeleton. In bone, the elaboration of cytoplasmic connections between osteocytes and the surface lining cells was the prerequisite for a further increase in mineral density, and the direct association between collagen and the inorganic phase improved the mechanical properties. In addition, the cytoplasmic net within the canaliculo-lacunar system gave access to the mineral phase, which has become the ultimate source of calcium ions in land-dwelling organisms.

STRUCTURE AND FUNCTION OF BONE CELLS

Osteoblasts and Bone Formation

Bone is formed by osteoblasts. These cells not only deposit osteoid, the organic matrix of bone, but also initiate and control its subsequent mineralization. Osteoblasts cover all active bone formation sites. At regular intervals, some osteoblasts are predetermined to become osteocytes, stop matrix extrusion on their mineral-facing side, and become buried within the calcifying matrix by adjacent cells [1]. They maintain communication with overlying osteoblasts and neighboring osteocytes via cytoplasmic processes.

Structural Organization of Osteoblasts

Fully developed osteoblasts form a monolayer upon bone-forming surfaces (Fig. 1A–C). In contrast to true epithelia, the intercellular gaps are not sealed by tight junctions. This indicates that osteoblasts do not have full control over the ion exchange between the extracellular fluid compartment and bone. They exhibit, however, a functional polarity: matrix is only extruded along the osteoblast-bone interface. Accordingly, the shape of an osteoblast determines the size of its secretory territory and reflects to some extent the local intensity of bone formation; columnar, cylindrical, or cuboidal osteoblasts achieve a higher linear rate of matrix apposition than flattened cells.

The cytoplasm of osteoblasts is highly basophilic, except for a clear juxtanuclear area representing the Golgi-negative. Electron microscopy reveals an abundant rough endoplasmic reticulum loaded with ribosomes, and a prominent Golgi complex (Fig. 1C). The secretory activity is further reflected by a great number of energy-producing mitochondria and a pronounced alkaline phosphatase reaction. Along the lateral portion of the cell membranes, gap junctions transfer information to and from neighboring osteoblasts. Numerous processes originate from the osteoid-facing surface, contained within canaliculi and connected to the lacunae of adjacent osteocytes (Fig. 2A). Again, gap junctions are described at the contact sites of the cytoplasmic processes [2]. This opens the way for the intercellular transport of small molecules, in addition to passive diffusion via the extracellular bone fluid. The transport capacity of the canaliculo-lacunar system is limited to a distance of approximately 100 μm, a critical

Von Kossa-McNeal, × 400. **B:** Lamellar bone formation on the endosteal cortical surface of the same section. Golgi-negative (arrow), osteoid seam with osteoid osteocyte (OS), × 400. **C:** Electron micrograph of a similar location to show the epithelial-like arrangement of osteoblasts in the primary spongiosa. There is abundant rough endoplasmic reticulum, and an extensive Golgi zone (arrow), × 3,700. **D:** Electron micrograph of human lamellar osteoid, × 22,000. **E:** Electron micrograph of mineralized human lamellar bone matrix. × 22,000. (C,D, and E reprinted with permission from [388].)

value for the wall thickness of osteons in compact bone, as well as for the diameter of plates or trabeculae in cancellous bone [3]. Gap junctions may also facilitate a concerted response of the interconnected cells to stimuli regulating calcium metabolism.

Structural Organization of Bone Matrix

In the current literature, only two types of bone tissue are commonly distinguished: woven bone and lamellar bone. Based upon Weidenreich's classification of 1928 [4], Pritchard [5] listed five different bone types, some of which

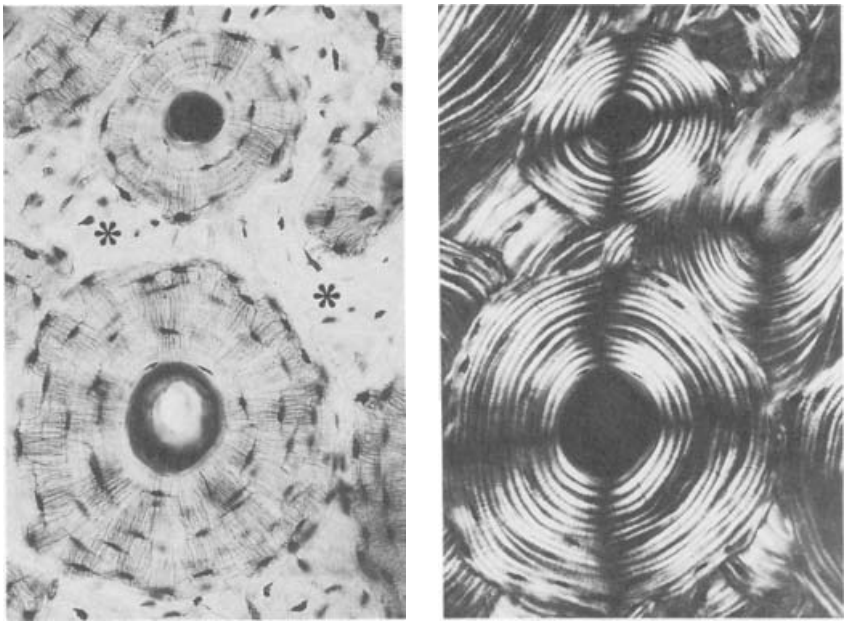

Figure 2. Transverse section through secondary osteons in adult human compact bone. **A:** A fresh, undecalcified ground section, stained with basic fuchsin, demonstrates osteocytes and their cytoplasmic processes. Most of the interstitial lamellae (*) are devitalized (or micropetrotic). × 150. **B:** Same section to show the lamellae under polarized light.

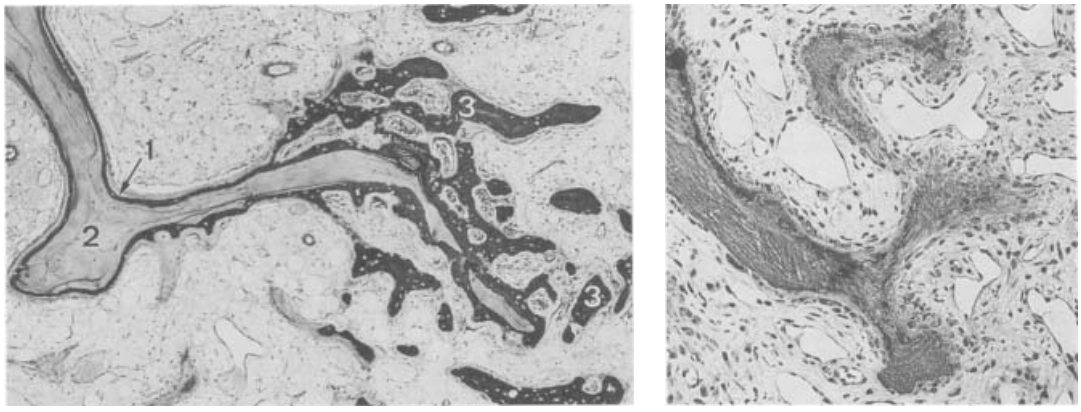

Figure 3. Activation of lamellar and woven bone formation in a 3-week-old fracture of a human femoral neck. **A:** Newly formed bone is identified by the more intense surface staining with toluidine blue. Lamellar bone (1) is strictly deposited along the surface of preformed trabeculae (2). Woven bone (3) is able to construct a scaffold of beams protruding into the intertrabecular space and possibly across the fracture gap. × 60. **B:** A microtome section stained with Goldner's trichrome clearly shows the association of osteoblasts and blood vessels in the interfragmentary granulation tissue. × 120.

occur only in lower vertebrates. For the mammalian skeleton, Pritchard restricted this number to three, namely woven bone, lamellar bone, and the mixed type. Our view, in accordance with that of the group of Marotti [1], is that the category "parallel-fibered, finely bundled bone" or simply "parallel-fibered bone," should be revived on the basis of observations made in recent experimental studies [6,7].

Woven bone. This form of bone is structurally characterized by the random orientation of its collagen fibrils, the great number of large, often irregularly shaped osteocytes, its short mineralization lag time, a diffuse uptake of fluorochromes, and often by its high mineral density (see Fig. 10C). This is due to the fact that apatite is not only deposited upon and within the collagen fibrils but equally in the interfibrillar spaces. Under polarized light, the matrix is not birefringent. The most important features, however, are its pattern and dynamics of growth: it forms rapidly growing, branching struts and plates, and is able to occupy a relatively large territory within a short space of time. Woven bone is formed predominantly in embryos and growing children, and is later

substituted by lamellar bone. In the adult, it reappears when accelerated bone formation is demanded, as in the bony callus during fracture repair (Fig. 3) and in pathological conditions with accelerated osteogenesis such as Paget disease, renal osteodystrophy, hyperparathyroidism, and fluorosis.

Parallel-fibered bone. In parallel-fibered bone, the collagen fibrils are oriented parallel to the surface, but otherwise do not follow a preferential course. Formation of parallel-fibered bone requires a preformed solid base, consisting of either woven bone, calcified cartilage, or, in the case of bone repair, preexisting lamellar bone. Parallel-fibered bone is not, or is only faintly, birefringent. Fluorochrome labels appear as relatively wide bands with poorly defined boundaries. The apposition rate is higher than in lamellar bone and amounts to 3–5 μm per day. Parallel-fibered bone enables accelerated bone deposition in both intramembranous and endochondral ossification in the growing skeleton, as well as in bone healing.

Lamellar bone. Lamellar bone is characterized by 3–5 μm-wide layers of parallel collagen fibrils. The course of the fibers changes from lamella to lamella. This pattern was first analyzed by polarized light (Fig. 2B) and later confirmed by electron microscopy. The exact delineation of the lamellae and the detailed arrangement of the fibrils, however, is still under debate [8]. Lamellar bone requires a preformed solid scaffold for its deposition, and the newly formed lamellae run strictly parallel to the underlying surface. Under such conditions, it is not surprising that the linear apposition rate for lamellar bone amounts to only about 1–2 μm per day. Fluorochrome labels appear as thin, clearly delineated bands, and the birefringence under polarized light strongly emphasizes the lamellar pattern resulting from the parallel arrangement of the collagen fibrils (Fig. 2B).

Formation and Mineralization of Bone Tissue

Bone formation always starts with the deposition of osteoid, which subsequently mineralizes. Woven bone is formed more rapidly than lamellar bone, and the interval between osteoid deposition and mineralization is short (1–3 days). The osteoid seams are small and sometimes barely visible. The mineralization of woven bone is initiated by matrix vesicles, spherical, membrane-bound bodies with a diameter of 100–200 nm. They are pinched off from cytoplasmic osteoblast processes. The role of matrix vesicles was originally described and extensively discussed with regard to cartilage calcification in the growth plate. Later on, they were also demonstrated in woven bone (for a review, see [9]). Matrix vesicles are also described in parallel-fibered bone [1]. In both instances, the first needle-like calcium phosphate deposits appear within the matrix vesicles in close contact with the inner leaflet of the membrane. This localization has been confirmed by anhydrous embedding techniques (high-pressure freezing and freeze substitution) [10,11]. After rupture of the membrane, the crystals are set free and serve as secondary nucleation centers. These morphological observations strongly support the assumption that osteoblasts directly participate in woven bone mineralization.

Lamellar bone formation is slower. The orderly deposition of the collagen fibrils restricts the linear rate of osteoid production to about 1–2 μm per day. The cause and control of the alternating fiber orientation in successive lamellae are still poorly understood. Ascenzi and Benvenuti [12] postulate a periodical rotation of osteoblasts in order to change the direction of the collagen fibrils. Others [13] assume that electrical forces accumulate with increasing thickness of a lamella and rotate incoming fibrils and attached osteoblasts when a critical level is reached. In any case, the final pattern is already set during osteoid deposition.

Lamellar bone formation requires a relatively flat surface upon which collagen fibrils can be deposited in parallel and/or concentric layers. Unlike woven bone, lamellar bone is not able to construct ridges or beams. Mineralization occurs along a clearly delineated calcification or mineralization front. It is separated from the osteoblast-bone interface by an osteoid seam (Fig. 4A). An active mineralization front exhibits some peculiar staining properties and, above all, quite a number of substances are adsorbed and permanently bound to the rapidly growing apatite crystals. This mechanism forms the basis of labeling techniques, especially with fluorochromes, allowing accurate measurements of the mineral apposition rate (Fig. 4B). The daily linear advance of 1–2 μm mentioned above was, in fact, determined at the level of the mineralization front. As long as the osteoid seams maintain a constant width, it is also true for osteoid deposition. The mean thickness of osteoid seams is about 10 μm. From this value one can also derive a mineralization lag time of roughly 10 days in between osteoid production and mineralization. The nature of the postulated maturation process, however, is not clear.

In contrast to woven bone, matrix vesicles are not, or are only rarely, seen in mineralizing lamellar osteoid, and up to now no structural element besides collagen has been reported that could take over their role. There is general agreement on some basic requirements for undisturbed mineralization [14], such as an adequate concentration of calcium and phosphate ions, the presence of a calcifiable matrix and of nucleating agents, and finally the control by regulators, i.e., promoters

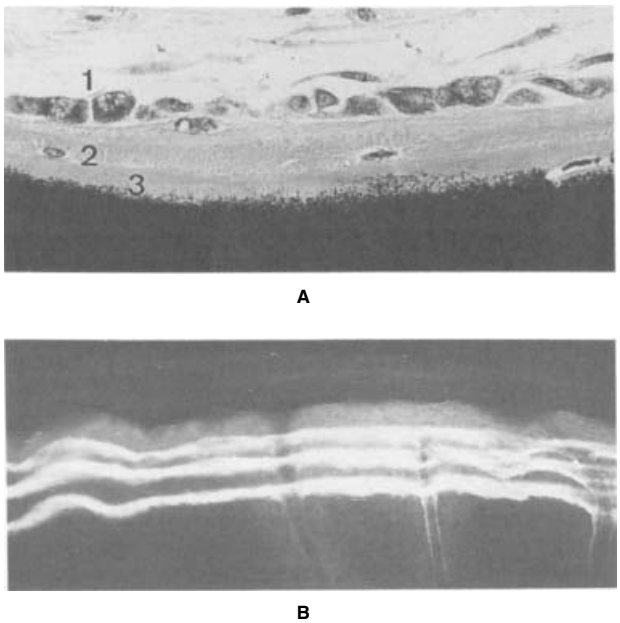

Figure 4. Lamellar bone formation. **A:** Osteoblasts (1), osteoid seam (2) including osteoid osteocytes, and calcification front (3). Human iliac crest biopsy, von Kossa-McNeal. × 400. **B:** Formation of circumferential lamellae by periosteal lamellar bone apposition in a foal. Sequential polychrome labeling at intervals of 3 and 4 weeks, corresponding to a daily mineralization rate of 2.1 μm.

and inhibitors. Collagen is a strong candidate for being a nucleator among other contenders. In lamellar bone there is, in fact, a much closer association between collagen and apatite crystals than there is in woven bone (Fig. 1D,E). The mineral deposits accentuate the typical 64-nm banding pattern of the collagen. It has been suggested that the crystals are located within the fibrils, preferentially in the hole regions resulting from the quarter-stagger arrangement of the tropocollagen molecules. Numerous *in vitro* tests have shown that native collagen with a 64-nm periodicity is capable of precipitating apatite in metastable solutions of calcium and phosphate ions [15,16]. It has been postulated that the nucleating capacity of collagen depends on its combination with osteonectin [17] or phosphoproteins [18].

A number of promoters and an even greater number of inhibitors of calcification are described in the literature (for a review, see [18]). Some inhibitors are of particular interest for the prevention of ectopic calcification (e.g., pyrophosphate, bisphosphonates) [19]. Highly aggregated proteoglycans inhibit mineralization *in vitro* and possibly do so also in cartilage [20]. There is much controversy, however, about the definition of a "calcifiable matrix" and the physiological role of nucleators such as collagen or possible candidates for such among the noncollagenous proteins, phosphoproteins and proteolipids.

The Fate of Osteoblasts — Bone Lining Cells

When bone formation ceases, osteoblasts flatten out and transform into bone lining cells (see Fig. 15C). These cells definitely belong to the osteoblastic family, but other names like inactive osteoblasts, resting osteoblasts, and surface osteocytes create unnecessary confusion. Lining cells still maintain cytoplasmic connections with osteocytes. Whether they act as a barrier for the ion exchange between bone and extracellular fluid is doubtful, as is also their potential to revert directly into osteoblasts. Lining cells may participate in the initiation of bone resorption through an active contraction that is thought to expose the bone for the attachment of osteoclasts [21]. Lining cells may also produce activating factors for the generation of osteoclasts. The exact composition of the intercellular substance underneath the lining cells is not clear, and it is not certain whether it is mineralized up to the surface [22] or coated by a layer of nonmineralized matrix [23,24]. If the latter were the case, the nonmineralized matrix would have to be removed before the osteoclasts could get access to the calcified bone [25]. For a discussion, see Vaes [26,27].

Osteocytes

Differentiation

The origin of osteocytes and the formation of the canaliculo-lacunar system has been described above. After being fully encompassed by mineralized matrix, osteocytes first go through a short osteoblastic or formative phase, and continue to deposit a thin layer of matrix upon the walls of their lacunae. At this time, the cytoplasm still contains a considerable amount of rough endoplasmic reticulum and a well-developed Golgi apparatus. Later on, these organelles disappear and mitochondria, as well as vesicles and lysosomes, prevail. These changes may indicate a transition into a resorptive phase, or, as Bélanger and Jande named it, an osteocytic osteolysis [28,29]. This concept assumed that osteocytes were capable of forming larger resorption cavities, but now it is generally agreed that osteocytes only remove minute layers of the lacunar and canalicular walls, too thin to be detected by light microscopy. Electron microscopy, however, indeed gives evidence of such alternating formative and resorptive activity [30]. This mechanism is thought to contribute to the calcium exchange between bone mineral and extracellular body fluids, and may be regulated by parathyroid hormone and calcitonin.

Fate of Osteocytes

The canalicular system and the cytoplasmic connections of the osteocytes are essential for their metabolic activity. Ultimately, this metabolism depends upon the blood vessels within the cortical canals and along the periosteal and endosteal surfaces. With undisturbed vascularization, osteocytes stay alive for years or decades. With increasing age, however, some vessels become obliterated, the corresponding domains (osteons in cortical bone) become deprived of nutrients and oxygen, and the osteocytes die and disintegrate. Such devitalized or necrotic areas are recognized by empty lacunae and, after some time, by a higher mineral density of the matrix (see Fig. 10C). Finally, the canaliculi and lacunae become obstructed and filled with mineral (micropetrosis) [31]. An accumulation of micropetrotic areas makes bone more brittle and also reduces the surface available for calcium exchange. A reasonable proportion of vital, vascularized bone tissue in the aging skeleton, however, is maintained by internal remodeling. On the other hand, such remodeling creates cement lines that may interrupt the canalicular pathway and thus produce another physiological type of micropetrotic compartment (see below, Cortical Bone Remodeling).

Osteoclasts and Bone Resorption

Structure and Function of Osteoclasts

Osteoclasts belong to a family of giant cells specialized in the breakdown of calcified matrices (bone, dentin, enamel, calcified cartilage) or of the mineral phase alone (calcium-phosphate-ceramics). They differ from other giant cells, especially foreign body giant cells, and are conventionally identified by their location in resorption foci, their light- and electron-microscopic structure, and a positive tartrate-resistant acid phosphatase (TRAP) reaction [32,33].

Osteoclasts had already been accurately described in 1873 by Kölliker [34]. Actively resorbing osteoclasts adhere to the bone surface and produce localized pits called Howship's lacunae (see Fig. 16A). They are mobile and possibly form grooves in the bone surface resembling the tracks of bark beetles. The cell diameter varies from 30 to 100 μm and the number of nuclei from 3 to 30. The cytoplasm is acidophilic and often contains vacuoles. A perpendicular striation, sometimes mistaken for a brush border, is frequently seen on the bone-facing side.

Electron microscopy has provided relevant information regarding the cytoplasmic organization of osteoclasts (Fig. 5). A detailed description of the osteoclast-bone interface has been given by Holtrop and King [35]. The marginal area of the osteoclast (clear zone, sealing part) consists of cytoplasm rich in actin-like filaments but devoid of organelles. There, the membrane adheres to the mineralized surface and seems to seal off an actual resorption chamber. In this central part, the cell surface is enlarged by numerous cytoplasmic folds forming the ruffled border. The increase in surface membrane may be related to the release of hydrogen ions for acid production. After dissolution of the mineral, the exposed collagen fibrils are digested by lysosomal and nonlysosomal enzymes (for reviews see [26,36], and Chapter 7, this volume).

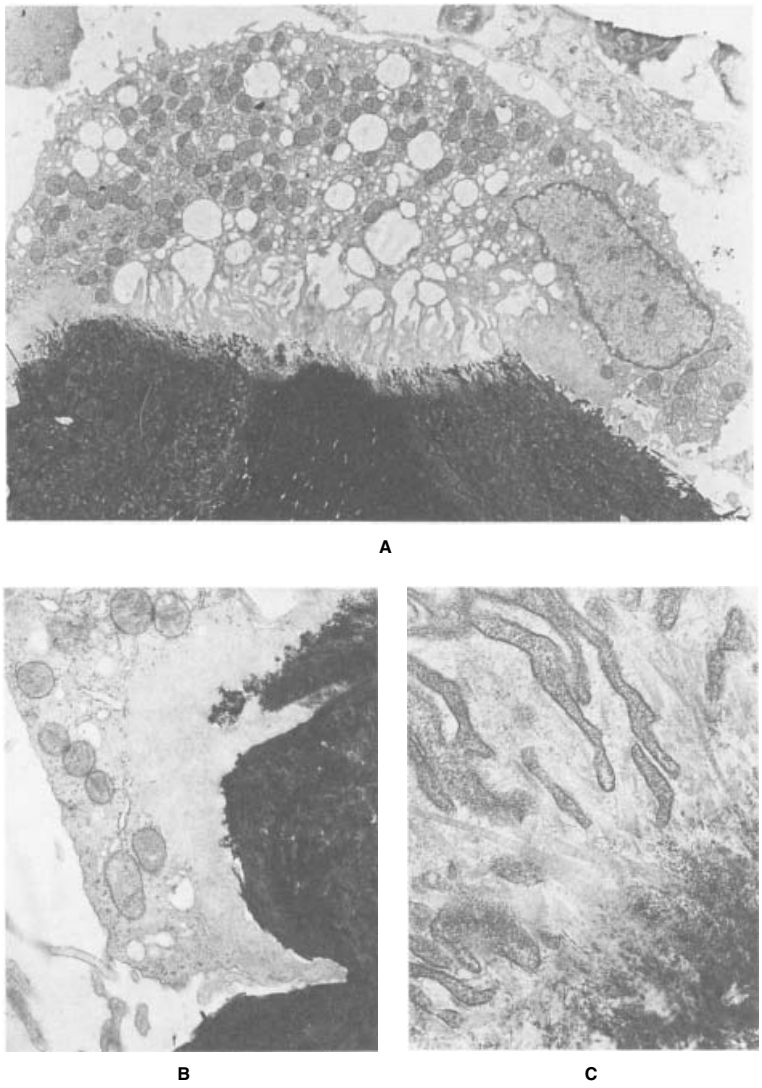

Figure 5. Osteoclastic bone resorption (reprinted with permission from [388]). **A:** Low-power electron micrograph of an osteoclast in a rat's tibial metaphysis. This section exhibits only a single nuclear profile. The cytoplasm shows numerous mitochondria, vesicles, and vacuoles. A marginal clear zone is visible surrounding the ruffled border along the osteoclast-bone interface. × 3, 050. **B:** The cell membrane of the clear zone (sealing part) is in intimate contact with the mineralized matrix. × 7, 000. **C:** A higher magnification of the ruffled border suggests that the mineral is dissolved before the collagen fibers are enzymatically digested. × 14, 000.

The cytoplasm of osteoclasts is extremely rich in mitochondria. These are the ultimate source of H^+ ions and supply the energy necessary for all other activities that enable osteoclasts to resorb a 50-μm or more thick layer of calcified bone per day. A well-developed rough endoplasmic reticulum, free ribosomes, multiple Golgi fields, and many vesicles and vacuoles give further proof of the equipment needed to fulfill this task.

Fate of Osteoclasts

The average life span and the ultimate fate of osteoclasts is still debated. They cannot be compared with regular mononuclear cells. They undergo continuous renewal by fusion with additional mononuclear precursors, and obviously can also dispose of exhausted organelles and nuclei ("nuclear shedding"). After the injection of tritiated thymidine into adult beagle dogs, the average life span of labeled nuclei in the osteoclasts was estimated to be 11 days [37]. Inactivated osteoclasts (for example, those following inhibition by bisphosphonates) may persist in the tissue for weeks or months and reach giant dimensions with high numbers of nuclei. This suggests that fusion with new precursors might continue, whereas nuclear shedding from such paralyzed cells is slowed down or arrested.

MACROSCOPIC STRUCTURE OF BONE

Long bones are subdivided into epiphysis, metaphysis, and diaphysis (Fig. 6). The epiphysis is confined by an articular surface covered with hyaline cartilage. The body of the epiphysis is formed by cancellous or spongy bone consisting of plates and trabeculae. During growth, the metaphysis and epiphysis are separated by the cartilaginous growth plate. In the adult, a discontinuous transverse bone plate

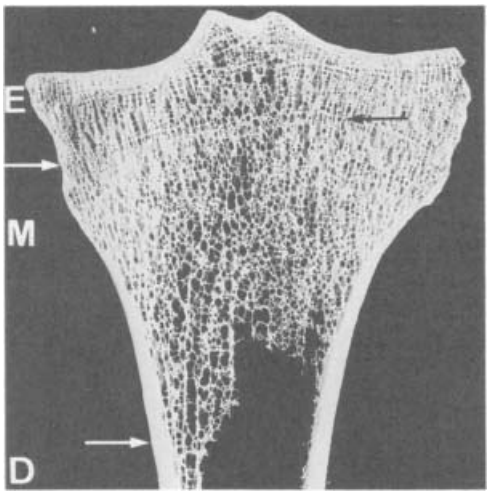

Figure 6. Frontal section through the proximal end of a human tibia to show the location and borderline of the epiphysis (E), epiphyseal line (black arrow), metaphysis (M), and diaphysis (D). White arrows mark the borderlines between the metaphysis and diaphysis, and between the metaphysis and epiphysis.

remains to indicate its original position, and may be identified radiographically as an epiphyseal line. The metaphysis is composed of cancellous bone encompassed by a compact cortical layer. The boundary between metaphysis and diaphysis is not so clearly defined. Anatomically, it corresponds to the level where the spongiosa ends and the marrow cavity begins. Age-related rarefaction of the spongiosa and corresponding expansion of the marrow cavity, however, will shorten this segment, with corresponding expansion of the diaphysis. The diaphysis, finally, has a compact wall surrounding a uniform marrow cavity.

Small bones, such as the vertebral bodies and the carpal and tarsal bones, lack the diaphysis, and the metaphyses have merged. Ribs also consist of cancellous bone surrounded by a cortical layer, grow only from the anterior costo-chondral junction, and can be considered as extremely lengthened metaphyses.

Bone is separated from adjacent tissues by three bone envelopes: the periosteum, the endosteum, and lining cells within the intracortical (endocortical) canals (the Haversian envelope). These three envelopes share two important features: osteogenic potential and abundant vascularization. This enables the envelopes to participate in modeling and remodeling activities, as well as in bone repair. The periosteum covers the outer surface of the bones, with the exception of the articular surfaces and tendon and ligament insertions. Its structure varies from delicate, loose connective tissue sheets to dense fibrous membranes. Osteoprogenitor cells are commonly located in the vicinity of blood vessels near the bone surface. The cells of the endosteum belong to the stroma of the bone marrow or are derived from resting osteoblasts, which most probably constitute the main source of the lining cells in the cortical canals.

DEVELOPMENT AND GROWTH OF BONE

Types of Ossification

Bone formation depends, among other things, on two important prerequisites: an ample blood supply and mechanical support. Osteoblasts function only in the proximity of blood vessels. Lack of oxygen seems to change the gene expression of osteoblasts toward the production of cartilage, fibrocartilage, or fibrous tissue. Bone matrix production and mineralization requires a mechanical rest, and, except in early embryonic life, bone is only deposited upon a solid base as provided by preexisting bone or calcified cartilage. These principles serve as a key for the understanding of the two modes by which bone develops. In intramembranous ossification, connective tissue serves as a mold into which bone is deposited. Endochondral ossification, the much more prevalent type, uses mineralizing cartilage as a model and solid base which is first covered with, and then substituted by, bone.

Intramembranous or Direct Ossification

In the early embryonic stage, bony trabeculae appear as condensations in the mesenchymal tissue, always in the vicinity of blood vessels. Intramembranous ossification mainly occurs in the head and results in the formation of the following bones in the neurocranium: frontal, parietal, squamous temporal, interparietal portion of the occipital bone; and in the viscerocranium: premaxilla, maxilla, palatine, nasal, lacrimal, zygomatic, tympanic bone, and the vomer.

The mandible also forms directly in the mesenchyme lateral to Meckel's cartilage. In the 10th fetal week, a secondary cartilage appears upon the future capitulum of the condylar process. This cartilage contributes to the growth of the collum by endochondral ossification and finally differentiates into articular cartilage.

The clavicle also ossifies directly in a mesenchymal condensation. Later on, secondary cartilages appear upon its medial and lateral ends. They function as endochondral ossification centers and finally transform into the articular cartilages of the sterno-clavicular and acromio-clavicular joints.

In comparison with endochondral ossification, intramembranous ossification plays only a minor role in embryonic osteogenesis. It gains, however, in importance in postnatal bone repair, in both defect filling and direct fracture healing. In these conditions, the granulation tissue that has previously organized the blood clot serves as a matrix for bony ingrowth, and, again, bone formation appears to be tightly coupled to angiogenesis

Perichondral and Endochondral Ossification

Most of the bones in the skeleton, and especially all long bones, have a cartilaginous precursor. With the onset of chondral ossification, the cartilage undergoes mineralization and is thus converted into a firm material that serves as a solid base for bone deposition (Fig. 7). Bone is formed either by apposition upon the outer surface of the calcifying model (perichondral ossification), or by substitution of the calcified cartilage in the primary or secondary ossification centers (endochondral ossification).

Primary ossification centers arise in short bones like the vertebrae, and in the midshafts of long bones. Secondary ossification centers originate in the epiphyses of long bones and expand by endochondral ossification until the cartilage is restricted to the articular surface and the growth plate. Articular cartilage and growth plate remain connected by a cartilaginous bridge that is still covered by perichondrium (groove of Ranvier). This is the only location where appositional cartilage growth endures, thereby enlarging the transverse diameter of the epiphyseal plate. During growth,

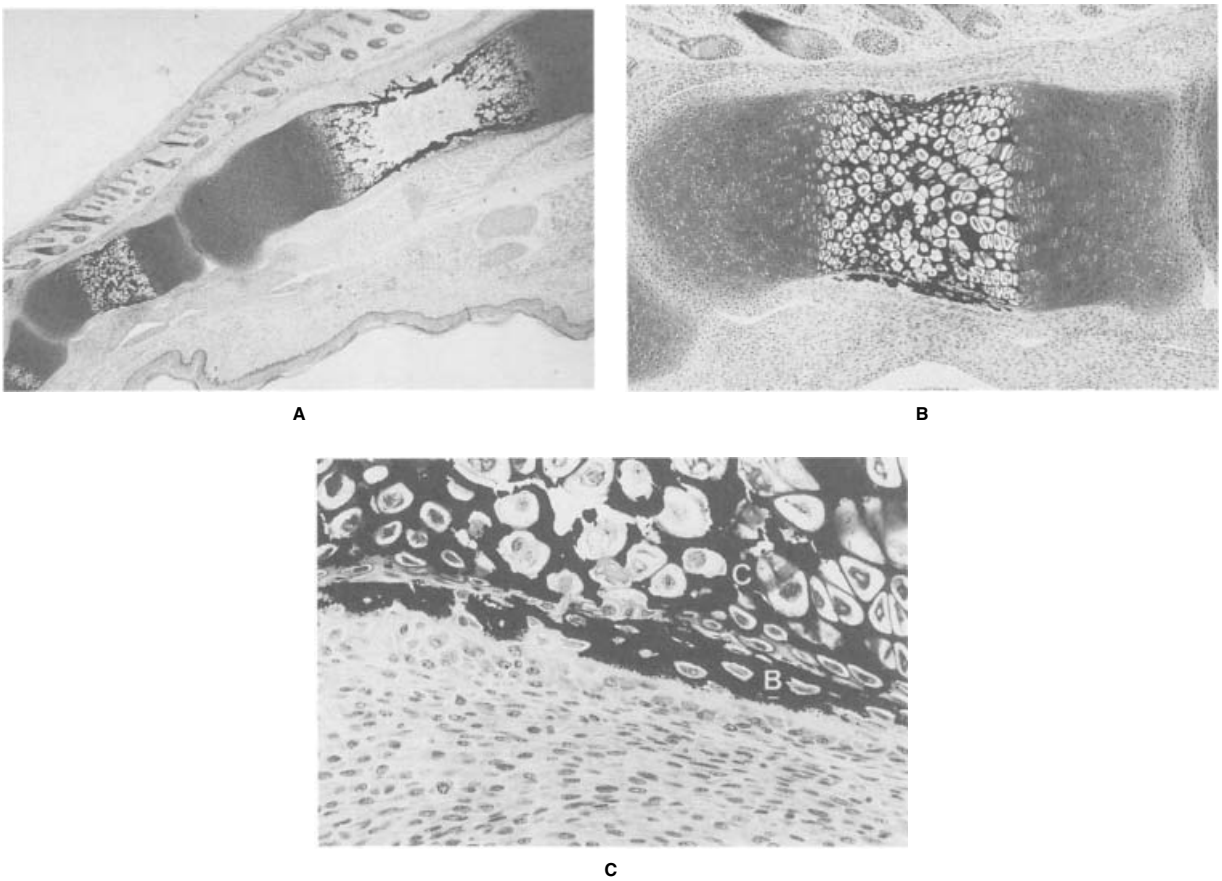

Figure 7. Perichondral ossification in the foot of a 2-day-old rat. the articular cartilage is responsible for the enlargement and precise shaping of the articular surface, whereas the growth plates function as a center for longitudinal growth.

Histological pattern of endochondral ossification. Although all sites of endochondral ossification exhibit the same basic pattern, the growth plates present the histological events in their most elaborate form. In fully developed growth plates, the chondrocytes are organized in columns that represent functional growth units. Quantitative data given in this chapter are always related to this unit [38]. In the longitudinal direction, we subdivide the growth plate into three zones, according to the prevailing function of each: 1) interstitial growth, 2) preparation for ossification, and 3) formation of the primary spongiosa (Fig. 8).

The nonmineralized part, except for the reserve zone, participates in interstitial growth, which is based on three cellular activities: proliferation, matrix production, and cell hypertrophy.

The proliferative zone comprises pools of relatively flat chondrocytes arranged in columns. Mitotic figures are found over the whole length of this part of the column. In rats, the mitotic frequency is about 1 in 48 hours [38]. All cells go through a finite number of cell divisions before they stop DNA replication at the borderline with the hypertrophic zone [39]. During the interphase the cells take part in matrix production. The matrix volume produced within 24 hours by each proliferating cell is quite constant and roughly equals the cell volume.

Cell hypertrophy is probably the most significant contribution of the chondrocytes to longitudinal growth. In rats, chondrocytes increase their volume up to 10 times in becoming hypertrophic. The formerly flat cells become spherical or ovoid, thereby increasing their longitudinal diameter by a factor of four. The elongation of the column during the process of becoming hypertrophic calls for supplementary matrix production. If hypertrophic chondrocytes are adequately preserved for electron microscopy, they appear well equipped with cytoplasmic organelles required for matrix production (rough endoplasmic reticulum, Golgi membranes), and mitochondria for production of the energy related to osmotic work. The fate of the "last chondrocyte" in the column is not clear. It disintegrates rapidly, either by apoptosis or under the attack of macrophages accompanying the invading capillaries.

Preparation for ossification essentially means the elaboration of a solid scaffold for bone deposition in the metaphysis. This is achieved by cartilage mineralization. Mineralization is confined to the longitudinal, intercolumnar septa. The

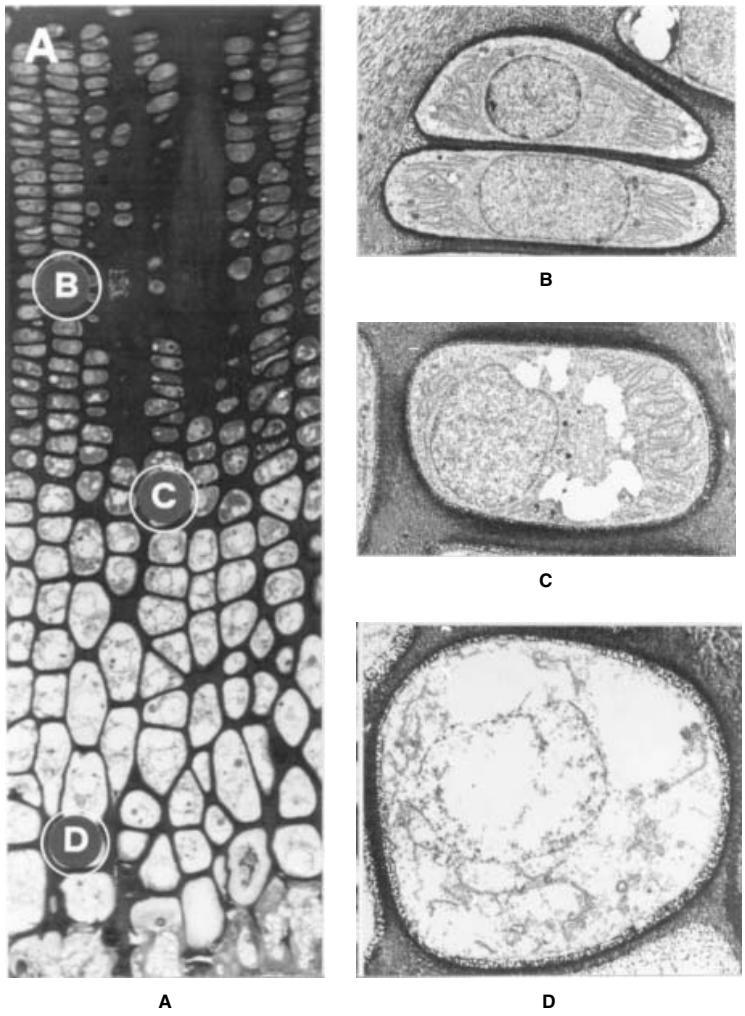

Figure 8. Light and electron microscopy of the growth plate in the proximal tibia of a 120 g Wistar rat. **A:** Thick section, toluidine blue, × 275. Fixation with ruthenium hexamine trichloride [389] preserves the proteoglycans *in situ*. The membrane remains attached to the pericellular matrix, but shrinkage causes vacuoles in the cytosol.

transverse septa separating the chondrocytes within a column remain unmineralized. Resorption of the unmineralized transverse septa by macrophages opens the way for vascular invasion. Resorption of calcified longitudinal septa by multinucleated chondroclasts reduces the number of calcified cartilage septa and widens the intertrabecular spaces [40]. In rats, about half or two thirds of the calcified cartilage septa are removed to make room for the ingrowing bone forming elements, i.e., osteoprogenitor cells and osteoblasts. The formation of the primary spongiosa results from the deposition of parallel-fibered bone upon the persisting calcified cartilage septa. The primary spongiosa in the metaphysis differs from that formed by intramembranous ossification in two respects: firstly, it is anisotropic, i.e., its trabeculae are oriented parallel to the long axis of the bone. Secondly, the trabeculae are built around a central core of calcified cartilage, instead of a core consisting of woven bone (see Fig. 9A,B).

The primary spongiosa in the metaphyses subsequently undergoes extensive remodeling and is transformed into the secondary spongiosa, which consists solely of bone, mostly of the lamellar type (see Fig. 9C). At the junction with the diaphysis, its trabeculae are finally resorbed and replaced by the marrow cavity.

In conclusion, the primary function of the growth cartilage is the continuous and well-controlled elaboration of a solid scaffold for the deposition of trabecular bone of the primary spongiosa. Growth rates vary considerably, and so do the turnover of the cells and matrix in different locations and with age. A detailed histomorphometric analysis of these relationships has been carried out in the proximal tibia of rats [85].

Development and Growth of Cortical Bone

In long bones, the final shape and structure of cortical bone is the result of four different processes: 1) perichondral ossification, 2) periosteal and endosteal bone apposition, 3) corticalization of metaphyseal cancellous bone, and 4) modeling of the external shape by the envelopes.

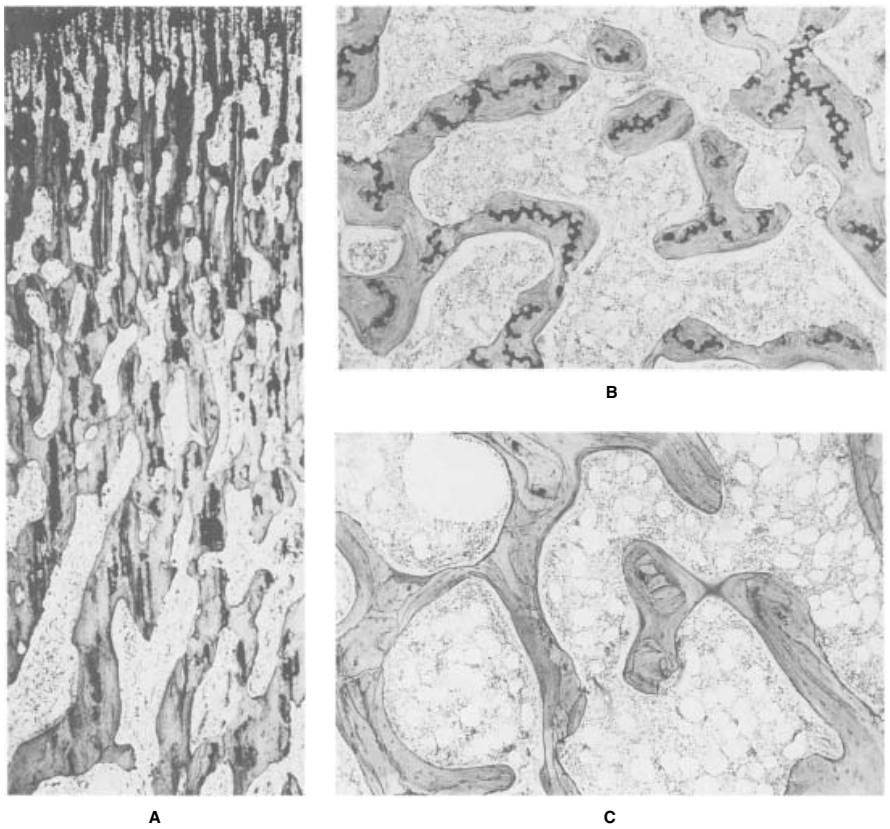

Figure 9. Cancellous bone remodeling during growth. Surface-stained ground sections reveal calcified cartilage inclusions by the heavy uptake of toluidine blue. **A:** Frontal section through the proximal metaphysis of a rabbit's tibia, × 20. There is a gradual disappearance of the calcified cartilage inclusions towards the marrow cavity. **B,C:** Transverse sections of a tibial metaphysis in a mini-pig at the level of the primary (**B**) and secondary (**C**) spongiosa. Note the numerous cement lines in the secondary trabecular profiles which indicate an intense remodeling. × 50.

Perichondral Ossification

The onset of perichondral ossification coincides with the formation of the primary ossification center in the midshaft of the cartilaginous precursor. The original perichondrium converts into a periosteum and deposits a bony cuff around the calcified cartilage that is resorbed or replaced by endochondral ossification. The initially formed woven bone is broken up by longitudinal vascular spaces, which then become narrowed by an accumulation of parallel-fibered bone. Thus, perichondral ossification strictly represents appositional bone formation, and not the substitution of cartilage by bone.

Periosteal and Endosteal Bone Apposition

Both the periosteal and endosteal envelopes contribute to the growth and shaping of bones by appositional bone formation. Lamellar bone formation results in the deposition of outer or inner circumferential lamellae. It is handicapped by the small apposition rate of 1–2 μm/day. In sites where a more rapid apposition is required, a composite of woven bone, parallel-fibered bone, and lamellar bone is deposited, resulting in the formation of primary osteons (Fig. 10). Essentially, the capacity of woven bone to form crests and ridges is activated in order to form grooves and, later on, tunnels around longitudinally oriented blood vessels. Subsequently, the tunnels are narrowed by the deposition of concentric bone layers until the primary osteons are completed. Primary osteons resemble secondary osteons, but are not confined by cement lines (see below). They are embedded within the initially formed woven bone, which can be identified in microradiographs by its higher mineral density (Fig. 10C).

Corticalization of Metaphyseal Cancellous Bone

The metaphyses of most long bones exhibit a conical shape. This shape reverses the pattern of apposition and resorption during longitudinal growth: formation prevails along the endosteal aspect of the cortex, whereas the periosteal surface is subjected to resorption (see Fig. 11A). When the metaphyseal cone advances toward the epiphysis, some peripheral trabeculae are engulfed in the cortical layer. Corticalization is accomplished by filling the intertrabecular space with parallel-fibered or lamellar bone, similar to primary osteons, and finally the compact composite is reconstructed by cortical remodeling (see Fig. 11B).

Modeling of the External Shape by the Envelopes

The midshaft of long bones grows in diameter by periosteal apposition and endosteal resorption. The cortex increases in thickness as long as apposition surpasses resorption. In the adult, both activities cease and a constant cortical diameter is preserved. In the elderly, they resume, at least to a certain extent, and endosteal resorption may exceed periosteal apposition, resulting in an increase in diameter of the marrow cavity at the expense of cortical width. This basic pattern is valid for bones with a straight diaphysis, but is subjected to manifold alterations in bones with a curved

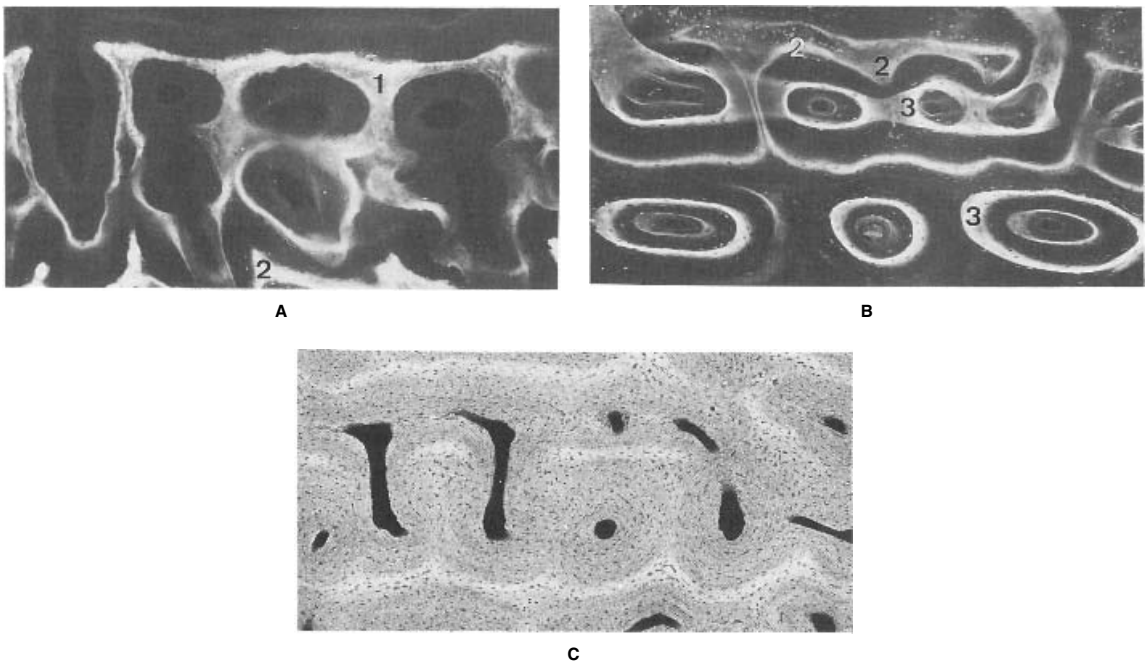

Figure 10. Formation of primary osteons during appositional growth in the periosteal envelope of an equine metacarpal bone. Three sequential polychrome labels at intervals of 3 and 4 weeks. The daily apposition amounts to 25.8 μm (compared with 2.1 μm in Fig. 4B). × 60. **A:** The woven bone initially deposited by the periosteum shows a diffuse uptake of the fluorochome label (1) given 2 weeks before sacrifice. This bone confines the walls of the future vascular canals. **B:** In a deeper layer, labels 2 and 3, given 4 and 7 weeks before sacrifice, demonstrate the concentric lamellar filling giving rise to the wall of the primary osteons. **C:** In a microradiograph, the initially formed woven bone compartment is identified by its brighter appearance, due to a higher mineral density. Its structure corresponds to the diffusely labeled woven bone in A above.

Reprinted with permission from [390]. The numbers indicate the main sites of osteoclastic resorption: (1) calcified cartilage resorption, (2) subperiosteal cortical bone resorption, (3) enlargement of the marrow cavity by resorption of the metaphyseal spongiosa. **B:** Transverse section of the metaphyseal cortex of the proximal tibia of a growing mini-pig. Surface-stained ground section, × 40. Endosteal apposition of circumferential lamellae (EA), subperiosteal resorption (PR), incorporated trabeculae of primary spongiosa (T), concentric lamellar filling of the former intertrabecular space (CF), resorption canal (R), and completed secondary osteons (O).

or more complex anatomical shape. Enlow [41] and others have carefully analyzed the principles of shape-deforming modeling in a variety of bones. Instructive examples are the conical shaping of the metaphyses and the cortical drift in the shaft of curved long bones like the femur. Lengthening at the epiphyseal ends steadily increases the bend. This must be compensated for by a shift of the cross-section in the anterior direction, as illustrated in Figure 12. To this end, the anterior cortex undergoes periosteal apposition and endosteal resorption, whereas the opposite pattern occurs in the posterior cortex.

The growing ribs also have to displace in space to reach the outer circumference of the thorax (Fig. 13). Thereby, the outer layer undergoes periosteal apposition and endosteal

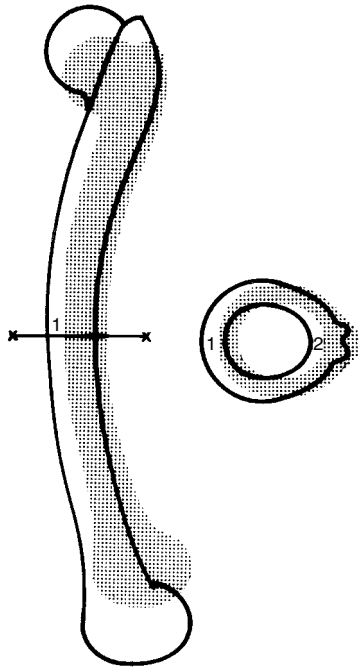

Figure 12. Cortical drift during growth and modeling of a curved long bone, e.g., the femur. Dotted area = growth stage, black outline = final stage. The scale of the cross section is three times that of the profile. (1) Zone of periosteal apposition. (2) Zone of endosteal apposition Reprinted with permission from [390].

resorption, whereas the inner cortex is subject to endosteal apposition combined with periosteal resorption.

REMODELING OF BONE

It is legitimate to make a distinction between modeling and remodeling activities in the skeleton. Modeling is a shape-modifying process, carried out by the formative and resorptive activities of the envelopes. Remodeling results in the substitution or replacement of bone moieties and thus means the renewal of material without structural change. Modeling is limited to the growing skeleton, and becomes only exceptionally operative in the adult, i.e., after the malalignment of fractures. Remodeling occurs lifelong; during growth it contributes to the maturation of bone, while in the adult it provides metabolically active bone tissue for calcium homeostasis, eliminates avascular, necrotic bone compartments, and prevents fatigue by local repair of microcracks and microfractures.

Cortical Bone Remodeling

Bone apposition by the cortical envelopes results in the formation of circumferential lamellae and primary (or appositional) osteons. Both are at least partially replaced by secondary (or replacement) osteons (Fig. 14A–E). Replacement means substitution, and this is initiated by resorption followed by formation. First, a resorption canal is formed by osteoclasts. Shortly thereafter, osteoblasts appear and start refilling this canal with concentric lamellae, until it is narrowed to the final diameter of the vascular canal of the newly formed secondary osteon or Haversian system, the bone structural unit (BSU) of the cortex. In human bone, secondary osteons reach an outer diameter of about 200–250 μm and an inner diameter of 50–80 μm. The wall thickness amounts to 70–100 μm [42] and varies somewhat with age [43]. Secondary osteons always run parallel to the long axis of the bones, but measurements of their length are impeded by frequent branching or ramifications. As a uniform cylindrical structure, they are rarely more than 2–3 mm long. In addition, they are interconnected by transverse vascular channels (Volkmann's canals) at intervals of 0.5–1 mm.

In contrast to primary osteons, secondary osteons are always delineated from the surrounding bone matrix by a cement line (Fig. 14C). Although cement lines are easily identified by their refractive properties and by various staining methods, their exact composition is not clear. Cement lines appear at sites where the bone surface stays quiescent (undergoing neither resorption nor formation) for some time. Microscopically, two types are distinguished: Resting (or arresting) lines appear when bone formation is temporarily arrested and then resumes again. Resting lines are smooth and run strictly parallel to the lamellae (Fig. 15B). Reversal lines have a crenated appearance, which indicates that bone formation was preceded by osteoclastic resorption. Cement lines surrounding secondary osteons belong to this latter type. They form the boundary between adjacent osteons or interstitial lamellae, the latter representing remnants of former osteon generations or circumferential

Figure 14. The daily osteoclastic resorption rate is calculated by measuring the distance between the tips of the labels (arrowheads) given at weekly intervals, × 120.

lamellae (Fig. 2). It is generally assumed that reversal lines are not crossed by canaliculi, and thus prevent communication between osteocytes. As a result, interstitial lamellae are often devitalized and become micropetrotic. In other locations, however, osteocytes may re-establish cytoplasmic connections with newly generated osteoblasts after resorption has ended. These connections assure the further nutrition of adjacent compartments via canaliculi across a cement line.

An important advance in our understanding of bone remodeling was the observation that bone resorption and bone formation are coupled in space and time, and occur in discrete remodeling sites or "bone multicellular units," also known as "bone metabolizing units" (BMUs) [44,45]. The sequence of resorption and formation has already been described in transverse sections. Longitudinal sections through cortical BMUs confirm this coupling. Within the tip

of a resorption canal, a group of osteoclasts is assembled in a cutter cone (Fig. 14D). This lengthens the resorption canal and, at the same time, widens it to the final diameter of the future osteon. The resorption canal is well vascularized. The vessels are accompanied by perivascular cells, possibly including osteoclast and osteoblast precursors. After osteoclasts have passed by, the wall is lined by ill-defined mononuclear cells. This portion, however, is only 100–200 μm long and represents a reversal phase of 1 or 2 days. During this phase, the cement line may be formed. Then osteoblasts appear and start depositing lamellar osteoid that will undergo mineralization 8–10 days later. Because the system advances longitudinally, the canal will assume a conical shape (closing cone). Lamellar bone formation continues until, several weeks or months later, the evolving osteon is completed.

The dynamics of the remodeling units at the cellular level have been analyzed by sequential fluorochrome labeling (Fig. 14E). A linear osteoclastic resorption rate can be measured in longitudinal sections [46,47]. In the radius and tibia of dogs, the daily longitudinal advance of the cutter cone is 50–60 μm and the average daily osteoblastic apposition rate is 1.5–2 μm [48]. In dogs, the mean outer diameter of completed new osteons is 140–170 μm and the wall thickness about 70 μm. Accordingly, the completion of a new osteon (the life span of a BMU) in a dog will take 5–6 weeks, corresponding to a length of the closing cone of 2–3 mm. In human osteons with a wall thickness of 90–100 μm and an apposition rate of only 1 μm/day, the life span of a BMU is estimated to be at least 3–4 months [49].

Cancellous Bone Remodeling

The remodeling of cancellous bone has attracted much attention in recent years because it can be studied quantitatively in biopsies. In human iliac crest cancellous bone, about 5% of the trabecular surface is covered by osteoblasts and 0.5–1% by osteoclasts. But cancellous bone exposes an enormous surface to the endosteal envelope of the bone marrow, and unbalanced resorption and formation has a profound influence on its overall density. With a diameter of roughly 200 μm, the trabeculae stay within the limits of the canaliculo-lacunar transport distance, and therefore are seldom penetrated by vascular canals. The constant remodeling results in a surprisingly complicated structure (Fig. 15B). Staining of the cement lines reveals a complex assembly of lamellar bone compartments or lamellar packets. These bone structural units must have been deposited at different times, either during growth or in a later modeling or remodeling phase.

Whereas the modeling of cancellous bone results for the most part in the functional adaptation of the framework to the mechanical load, remodeling is thought to replace discrete portions of the scaffold with new bone. This improves the quality of the tissue, with regard to both its mechanical

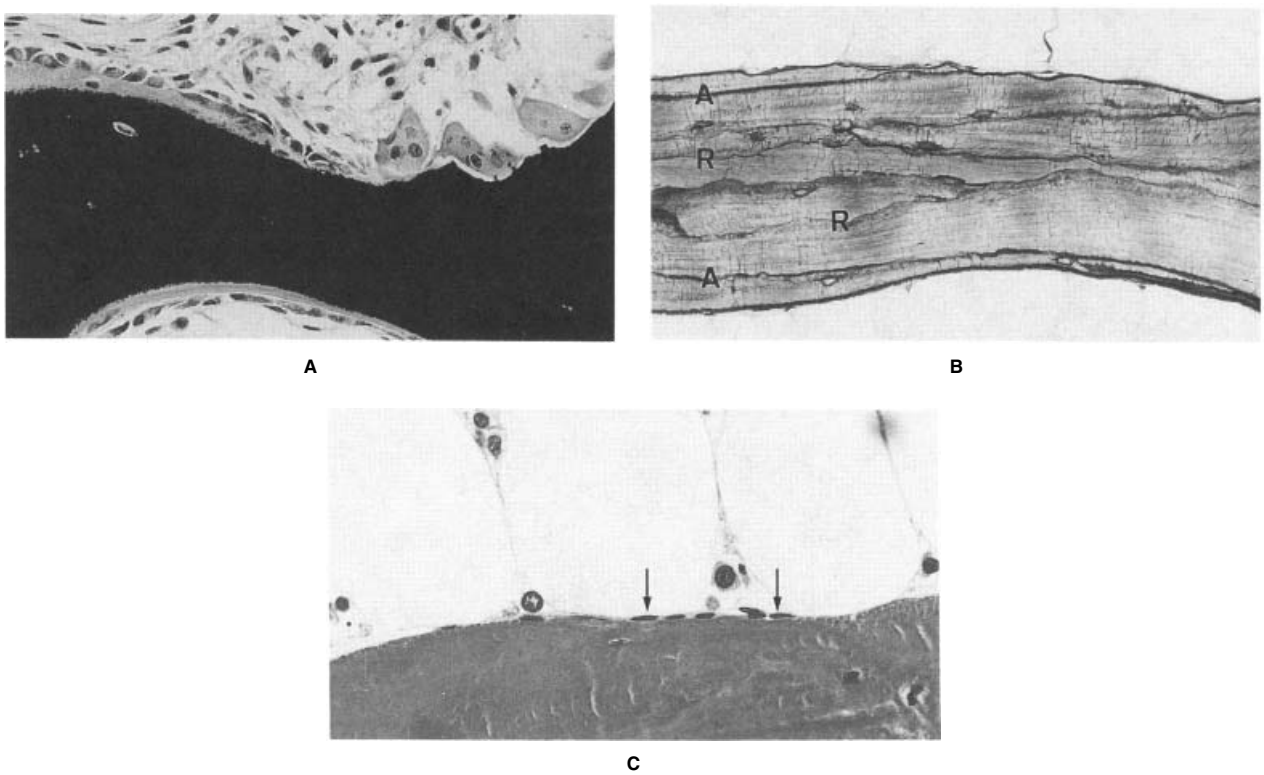

Figure 15. Surface characteristics and composition of adult human cancellous bone trabeculae. **A:** Resorption and formation on the trabecular surface in an iliac crest biopsy of a patient with increased bone turnover (renal osteodystrophy). Osteoclastic and osteoblastic activities appear to be coupled as in cortical BMUs. Von Kossa-McNeal, × 250. **B:** Surface staining of polished ground sections reveals a surprisingly complex assembly of packets, separated by cement lines. Note two smooth arresting lines (A) and multiple reversal lines (R), × 200. **C:** Inconspicuous, extremely flattened lining cells (arrows) cover the quiescent bone surface, which in this instance seems to be mineralized up to the bone-marrow interface. Goldner's trichrome stain, × 500.

properties and the availability of surface for ion exchange. Microscopically, the formation of a new packet also begins with the recruitment of osteoclasts (Fig. 16). These "dig" a cavity in the trabecular surface with a diameter of 0.5–1 mm and an average depth of 50 μm, seldom more than 70 μm. When resorption is completed, the osteoclasts are replaced by inconspicuous mononuclear cells. After a short reversal phase, osteoblasts appear, deposit new lamellae into the excavation, and possibly fill it up completely. The resulting lamellar packets represent the BSUs of the trabeculae and are analogous to secondary osteons (Fig. 16D). It is assumed that this type of cancellous bone remodeling also exhibits similar dynamics to the BMUs in cortical bone [50,51]. It is possible that resorption, followed by formation, also moves along the endosteal surface like one-half of the cutter cone and closing cone in a cortical BMU, although this is, for geometrical reasons, difficult to demonstrate in microscopic sections [52] (Fig. 15A).

Regulation of Bone Remodeling

The systemic activation of bone remodeling is attributed to the actions of growth hormone and thyroid and parathyroid hormones, whereas calcitonin and cortisone have a systemic inhibitory effect. Bisphosphonates, which are known as potent inhibitors of osteoclastic bone resorption, also reduce the overall bone remodeling rate.

Local activation is observed after mechanical lesions of bone, such as fractures, surgical manipulations, or the insertion of implants. A tremendous activation follows any temporary interruption of the blood supply. It accompanies revascularization and results in the substitution of necrotic zones by vital bone tissue.

The coupling of resorption and formation, which is so obvious from morphological considerations, poses many difficult questions as far as its regulation is concerned. The term "coupling" was first used to describe the local collaboration of osteoclasts and osteoblasts, explained by their derivation from a common osteoprogenitor cell [53]. It has to be recalled that Frost [44] defined the BMU as a basic multicellular unit and considered it as a typical example of intercellular communication. This concept initiated the search for coupling factors [54]. At present, the idea that a rather complex interaction of multiple factors is involved in the initiation and synchronization of resorptive and formative activities is favored. This sequence includes, 1) osteoclast activation, possibly mediated by lining cells, 2) factors released from the bone matrix by the resorbing osteoclasts to induce osteoblast proliferation and differentiation, and 3) factors produced by other local cells apt to stimulate all of these processes [55].

In a more comprehensive version, the term "coupling" is now not only applied to the recruitment and activation of the various cells involved but it is also suggested that their performances are balanced with respect to each other. In other words, the resorption of a certain amount of bone must be matched by the replacement of the same volume by new bone formation [50,51].

As long as resorption and formation remain coupled and balanced, cancellous bone remodeling results in substitution of bone tissue without any change in trabecular dimension

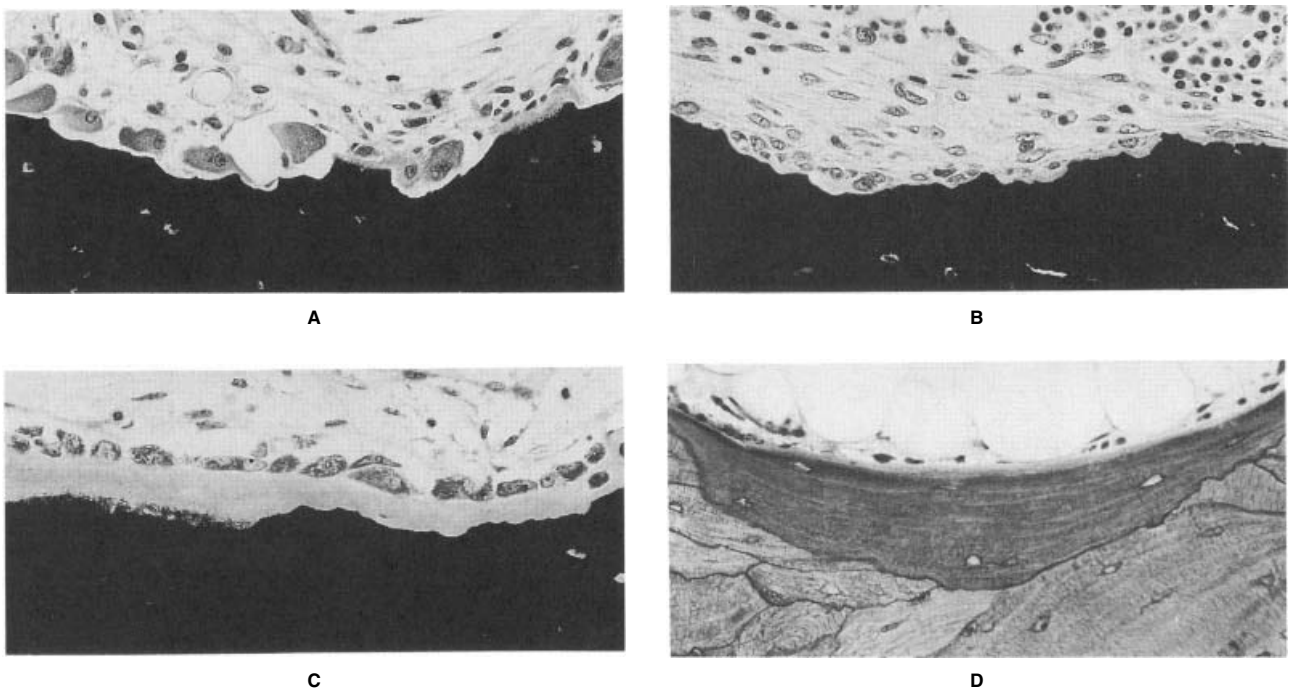

Figure 16. Stages of cancellous bone remodeling in the adult. Human iliac crest biopsies, **A**–**C**, von Kossa-McNeal, × 250; **D**, surface staining with toluidine blue, × 200. **A:** Resorptive phase: osteoclasts erode the trabecular surface. **B:** Reversal phase: Howship's lacunae, now filled with mononuclear cells of unknown origin, disclose the former osteoclastic activity. **C:** Early formative phase: Osteoblasts start filling the resorption cavity. To the right, only osteoid has yet been deposited upon the lacunar surface; to the left, a calcification front is already established. **D:** Newly formed lamellar packet, or bone structural unit (BSU), is clearly delineated by a reversal line. Note again the complexity of the adjacent trabecular structure revealed by the staining of the cement lines.

and shape. Generalized and persisting negative balance at the BMU level is, according to the current view of bone histologists, a plausible mechanism for the pathogenesis of bone loss and osteoporosis. Localized imbalance or uncoupling, however, will not only change the dimension but also the shape of the trabeculae and thus is able to modify the architecture of the spongiosa, but not the external shape of the bone. This might be an adaptive response to changes in load and physical activity, as postulated by Julius Wolff in 1892 [56] or more recently by Frost [57,58] in his concept of a "mechanostat." The functional adaptation of bone to cementless orthopedic prostheses and dental implants is another area where these structure-function relationships are convincingly confirmed.

Bone Formation

W. Hofstetter

Osteoblasts are the cells responsible for bone formation. They differentiate from mesenchymal stem cells and thus share a common origin with other mesenchymal cell lineages such as chondrocytes, adipocytes, fibroblasts, and myoblasts. Below are discussed some of the mechanisms essential for the development of the skeleton and the differentiation of cells of osteoblast lineage. Emphasis is placed on the exciting findings of the past few years, while reference is made mainly to review articles for earlier data.

BONES ARE ORGANS, BONE IS A TISSUE

The development of organs constitutes a sequence of complex processes that are all tightly regulated by a network of interacting signals. Although the results of these developmental processes are vastly different, it has become clear over time that organogenesis is controlled by members of a few gene families that have been highly conserved during evolution.

In its adult state, the skeleton comprises two main tissues, bone and cartilage, containing various cell populations, namely chondrocytes, osteoblasts, osteocytes and lining cells, and chondroclasts and osteoclasts. Among these cell populations, it is the osteoblasts that are responsible for bone formation. This task encompasses the elaboration of the components of the extracellular bone matrix and the regulation of its mineralization. The osteoblasts, however, not only produce the bone material, but are also instrumental in regulating the recruitment and/or activation of the bone resorbing cells, the osteoclasts, resulting in their having a central position in bone metabolism. The aim of this section is 1) to summarize the fundamental processes regulating the development and patterning of the skeleton; 2) to describe the development of osteoblasts from mesenchymal stem cells to the final differentiation states of either active osteoblasts, osteocytes, or resting lining cells; and 3) to discuss the role and function of various components of the bone matrix.

MORPHOGENESIS OF BONE

In recent years, many of the genes involved in the formation of bone have been identified by elucidating the molecular mechanisms underlying heritable skeletal disorders. Furthermore, as knowledge has increased, it has become evident that molecular cascades guide the formation of different organs and that the components of these cascades have been highly conserved during evolution.

Among the earliest events in the formation of the limb buds of the appendicular skeleton is the induction of structurally undifferentiated mesenchyme to transform into condensed mesenchyme. Such regions of high cell density already represent the outlines of the future skeletal elements. Subsequently, the cells in the centers of the condensations change their phenotype, differentiating into prechondrocytes. This step is accompanied by a switch from the production of a mesenchymal matrix to that of a cartilaginous matrix, as is described later in more detail. The cartilage anlage of the developing bone grows rapidly to resemble the future bone, in both size and shape. The chondrocytes in the center of the future diaphysis start to hypertrophy and the extracellular matrix becomes mineralized, while on the perichondrial surface osteogenic cells develop into osteoblasts and lay down a bone collar around the hypertrophying cartilage. Concomitantly, osteoclasts develop, which, together with blood vessels, penetrate the mineralized cartilage of the forming bone rudiment and dissolve the mineral [59,60]. Osteoblasts, following the invading osteoclasts, start to lay down bone material onto persisting residues of the mineralized cartilage septa forming the cores of the primary trabeculae, which are gradually replaced during the remodeling phase of osteogenesis (Fig. 17). By this process, which is called endochondral ossification, the major part of the skeleton is formed. In intramembranous bone formation, however, which gives rise to the bones of the skull and the clavicles, the cells of the mesenchymal condensations differentiate directly into osteoblasts that synthesize the extracellular matrix of bone. For further discussion of these processes, see the preceding part of this chapter (Chapter 1, Part II).

Some time ago, it became increasingly evident that early skeletal patterning is governed by the *Hox* genes, a family of homeobox transcription factors that was originally identified in *Drosophila melanogaster* and has been highly conserved during evolution. The gene products act as molecular switches that regulate the initiation of complete developmental programs. The roles of the individual Hox proteins have been elucidated either by investigating the molecular defects in heritable genetic disorders or by producing and analyzing gene knockout mice [61]. Using these approaches, *Hox* genes were found to act on both

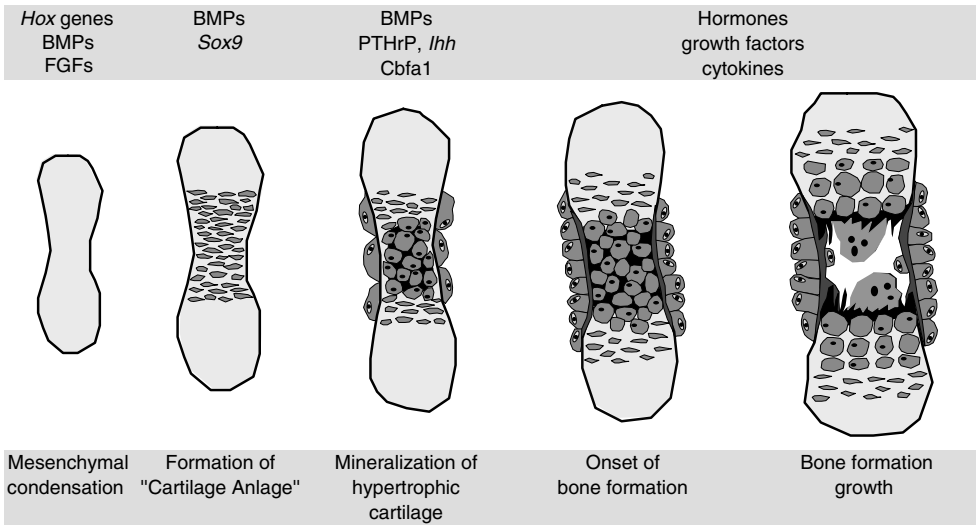

Figure 17. Schematic representation of long bone development. Specific gene products regulate each step from the mesenchymal condensation through commitment to the chondrocytic lineage, induction of the osteoblastic phenotype and the growth and development of osteoclasts.

initial mesenchymal condensation and differentiation and the later processes of proliferation and maturation of chondrocytes [62,63]. As a consequence, the inactivation or ectopic expression of *Hox* genes results in the deletion or addition of skeletal elements or in the transformation of certain elements into shapes resembling other elements [64]. For example, the misexpression of *HoxD-11* in the chicken limb bud leads to an additional phalanx in digit I with a morphology similar to that of digit II [62]. Similarly, expansions of a polyalanine stretch within the amino-terminal non-DNA binding region of *Hox-D13* have been shown to cause synpolydactyly in heterozygous individuals, characterized by the insertion of an extra digit between digits III and IV in association with variable syndactyly [64]. Such experiments have further revealed that, in mammals, *Hox* genes do not act as individual entities, but, rather, that multiple *Hox* genes function together to mediate a program by regulating common target genes. Thus, for appropriate development, the temporal, spatial, and stoichiometric expression of *Hox* genes operating within the developing tissue is critical [65].

A second class of proteins instrumental in the early events of morphogenesis of the skeleton are the bone morphogenetic proteins (BMPs), which are members of the transforming growth factor-β (TGF-β) superfamily [66]. The first BMPs were originally characterized by their capacity to induce ectopic cartilage and bone formation when implanted into experimental animals. The name, bone morphogenetic protein, however, is somewhat misleading since there is strong genetic and experimental evidence that these molecules regulate diverse biological processes such as cell proliferation, differentiation, apoptosis, and morphogenesis [67]. Several BMPs are expressed in the early mesenchymal condensations in a manner that suggests a role for these proteins in patterning of the developing bone. BMP2, BMP4, and BMP7 are all expressed in the apical ectodermal ridge of the limb buds, where they may function in regulating cell proliferation, differentiation, and/or activation [68]. In the mesenchyme of the developing limb, however, the expression patterns of these genes differ significantly from each other locally as well as temporally. The essential role of BMPs in the development of the skeletal elements was first demonstrated when the genetic defect in the murine *short ear* mutation was found to be located in the gene for BMP5 [69,70]. The phenotype of homozygous mutant mice is characterized by an alteration in the number of ribs and in additional more subtle changes in shape and size of various bone and cartilage elements. BMPs, however, are not only required for differentiation but also for the induction of apoptosis in the supernumerary cells of the interdigital web. Experimental application of BMP2 or BMP4 to developing limbs induces an acceleration of programmed cell death in mesenchymal cells [71,72], while TGF-β diverts the cells from the death program and induces the formation of ectopic cartilage or extra digits [72].

Another family of growth factors and receptors that is involved in these early processes of morphogenesis are the fibroblast growth factors (FGFs) and their receptors [73,74]. In concert with Sonic hedgehog, a member of the hedgehog family of signaling proteins [74,75], FGFs are thought to act upstream of Hox proteins and BMPs, regulating their respective expressions. Hedgehog proteins constitute a conserved family of secreted molecules that provide key signals in embryonic patterning of many organisms (for a review, see [76]).

DEVELOPMENT OF CARTILAGE

After the formation of the condensed mesenchyme, the constituent cells become committed to developing along the chondrocyte lineage. The cells in the centers of the condensations change their phenotype and hypertrophy, becoming large and round, while at the periphery a sheath of spindle-shaped cells forms the perichondrium. The central cells cease to proliferate and switch the composition of their extracellular matrix from a mesenchymal matrix that contains mainly collagens I and III to a cartilaginous matrix containing collagens II, IX, and XI and noncollagenous extracellular matrix proteins and proteoglycans such as aggrecan [77].

The chondrocytes undergo further differentiation and hypertrophy, producing a matrix that is abundant in collagen X and partially calcifies.

The molecular mechanism causing the commitment of the mesenchymal cells to the chondrocytic lineage is largely unknown as yet. Sox [Sry (testis determining factor) - type HMG (high mobility group) Box] proteins, which constitute a subfamily of DNA-binding proteins with an HMG domain, exert critical functions in a number of developmental processes, including sex determination, neurogenesis, and skeletal formation [78]. In humans, mutations in *Sox9* are associated with campomelic dysplasia (see Chapter 23, Part V, this volume), a disease characterized by skeletal malformation and XY sex reversal [79]. During morphogenesis of bone, *Sox9* is expressed in the cells of the mesenchymal condensations that develop into chondrocytes [80]. The protein is coexpressed with collagen II, binds to a specific sequence within the collagen II promoter, and induces the ectopic expression of collagen II in transgenic mice [81–83], further strengthening the notion that Sox9 contributes in a critical manner to the commitment of pluripotent mesenchymal precursors to the chondrocytic lineage. Sox9, however, does not act by itself in the regulation of the expression of chondrocyte products, but acts with other members of the gene family in the regulation of collagen II, and possibly other genes [84].

While *Sox9* contributes to the commitment of mesenchymal cells to the chondrocyte lineage, the proliferation, differentiation, and activation of chondrocyte precursors and mature chondrocytes is regulated by a diverse set of growth factors and cytokines, the nature of which is gradually being unravelled. Longitudinal growth is determined by chondrocyte proliferation, differentiation, and activity within the growth plate. Growth acceleration is achieved by cell-shape modeling, specifically by an increase in cell height, whereas cell volume, proliferation rate, and net matrix production remain largely unchanged [85]. A physiological reduction of the growth rate, on the other hand, is achieved by simultaneous reduction of cell height, volume, and proliferation rate. In growth cartilage, growth hormone has been shown to stimulate the proliferation of resting chondrocytes [86], while the mitogenic effect on proliferating chondrocytes is mediated through insulin-like growth factor 1 (IGF-1) [87]. Mutations in either growth hormone-releasing hormone [88] or IGF-1 [89] lead to reduced growth, suggesting that deficient chondrocyte proliferation leads to reduced bone size. The family of fibroblast growth factors and their receptors has also been implicated in the regulation of chondrocyte proliferation. Achondroplasia, a frequent form of osteochondrodysplasia, has been shown to be the result of a mutation in a gene of the FGF receptor family (*FGFR3*) [90] (see also Chapter 23, part IV, this volume).

Since the molecular characterization of parathyroid hormone-related peptide (PTHrP) [91], major progress has been made in defining the role of this polypeptide in development (for review see [92]). Originally, PTHrP was characterized as a tumor product causing humoral hypercalcemia of malignancy, a major contributor to morbidity and a complication in clinical treatment [93]. In contrast to IGF-1 and FGF, PTHrP does not act primarily to stimulate the proliferation of chondrocytes but rather to promote cellular development. Mice in which the gene for PTHrP has been artificially disrupted ("knockout" or "null-mutation") die shortly after birth and exhibit widespread abnormalities of endochondral bone development. These animals are characterized by the premature maturation of chondrocytes and accelerated bone formation [94]. Because the peptide and its receptor are expressed in close spatial proximity during development, it has been suggested that, in cartilage, PTHrP acts mainly as a paracrine/autocrine factor, its main effect being to delay chondrocyte differentiation during endochondral bone development [95]. The essential role of PTHrP in endochondral bone formation has been further demonstrated in $PTHrP^{-/-}$ mice carrying a PTHrP transgene targeted to chondrocytes. Targeting was achieved by placing the PTHrP transgene under the control of the collagen II promoter. The mice displayed a normal bone phenotype, while the development of other tissues, such as the mammary gland, was still impaired [96]. On the other hand, overexpression of PTHrP [97], or the expression of a constitutively active receptor [98,99], leads to chondrodysplasia due to a delay in chondrocyte differentiation and delayed mineralization. These findings indicate that PTHrP exerts a profound control on endochondral bone formation by regulating the development of chondrocytes into hypertrophic chondrocytes, and emphasize the necessity of its tightly regulated expression for normal cartilage development.

The expression of PTHrP in growth cartilage is regulated through a feedback mechanism that involves Indian hedgehog (Ihh) and its direct targets Patched (Ptc) [100] and Gli [101]. During their differentiation from proliferating to prehypertrophic to hypertrophic cells, chondrocytes transiently express PTHrP/PTH receptors, Ihh, and collagen X [102]. Simultaneously, Ptc and Gli are expressed in the perichondrium. This leads to the conclusion that PTHrP is under the control of Ihh. In this regulatory pathway, prehypertrophic chondrocytes signal through Ihh to the perichondrium. The response to Ihh in the perichondrium induces, either directly or indirectly, the synthesis of PTHrP in the articular perichondrium, blocking proliferating chondrocytes from hypertrophying [103]. This block in differentiation subsequently leads to a drop in Ihh levels, causing an interruption of the signaling cascade from the perichondrium to the periarticular cartilage, which, in turn, ceases to produce PTHrP, thus releasing the block of PTHrP on cartilage differentiation. Although proliferating chondrocytes express only low levels of PTHrP/PTH receptors, the regulation of chondrocytic differentiation is dependent on this pathway [104]. Thus, Ihh regulates the expression of PTHrP in a common feedback loop that regulates the rate of chondrocyte differentiation and thereby balances growth and ossification of long bones.

OSTEOBLASTS

Determination of the Osteoblast Lineage

Osteoblasts are the skeletal cells responsible for bone formation. They synthesize and regulate the deposition, maturation, and mineralization of the extracellular matrix. But, as described elsewhere in this chapter, osteoblasts also function in the modulation of bone resorption through both the secretion of soluble factors and the expression of surface molecules that act via cell–cell contact.

Cells of the osteoblast lineage are of mesenchymal origin and derived from mesenchymal stem cells (for a review see [105]). They include committed osteoprogenitor

cells, osteoblasts, osteocytes, and lining cells, and share a common precursor with myocytes, fibroblasts, adipocytes, and chondrocytes. A goal of recent research has been to identify molecules that are essential for the development of pluripotent precursor cells. The search has been successful, since it has identified the MyoD group of basic helix-loop-helix muscle regulatory factors as determinants of a muscle phenotype (for a review, see [106]) and the peroxisome proliferator-activated receptor γ2 (PPAR γ2) [107] as responsible for determination of an adipocyte phenotype.

The identification of transcription factors regulating the differentiation of osteoblasts has proven to be more elusive. Recently, however, evidence has been obtained demonstrating that the transcription factor Cbfa1 is essential for the development of the osteoblast phenotype. *Cbfa1* belongs to the *Runt* domain gene family and is homologous to the *D. melanogaster* pair-rule gene *runt* that plays a role in the formation of the segmented body pattern as well as in sex determination and the development of the nervous system [108]. In humans, mutations in *Cbfa1* have been shown to cause cleidocranial dysplasia, an autosomal dominant condition characterized by hypoplasia/aplasia of clavicles, patent fontanelles, supernumerary teeth, short stature, and other changes in skeletal patterning and growth [109] (see Chapter 23, Part V, this volume). Disruption of the *Cbfa1* gene in knockout mice has revealed the necessity of the transcription factor in determination of the osteoblast phenotype [110,111]. *Cbfa1*$^{-/-}$ animals died shortly after birth due to an inability to breathe. The homozygous animals had short limbs, but all organs were normal. The most striking effect caused by the lack of Cbfa1 was a total deficiency of bone. The skull was a thin layer of fibrous connective tissue, while the tibiae contained only calcified cartilage, this at an age at which bone has normally formed [112]. Mice in which only one of the *Cbfa1* alleles had been mutated showed defects that again were typical of cleidocranial dysplasia [111].

The molecular identification of Cbfa1 as a transcription factor inducing the commitment of a precursor cell to the osteoblast lineage was undertaken on the basis of previous studies that had identified putative transcription factors stimulating the expression of osteoblastic gene products [113]. Low stringency cloning and *in situ* hybridization experiments revealed that, during development, Cbfa1 is expressed in an osteoblast-specific manner. Its forced expression in nonosteoblastic cells induces the expression of osteoblast-specific genes [114], among them osteocalcin (bone Gla protein, BGP), presently the only protein known to be expressed specifically by osteoblasts [115]. Cbfa1 binds to *cis*-acting elements within the osteocalcin promoter (osteoblast-specific element, OSE) that have previously been shown to be essential for transcription of the osteocalcin gene [116,117].

Development of Osteoblasts

The development of osteoblasts, together with osteoclast formation and activation, determines the mass and shape of the bone formed. The regulation of osteoblasts takes place at several levels, namely, the proliferation of precursors, the differentiation of precursors to mature osteoblasts, the activity of mature osteoblasts, and the further development of osteoblasts to osteocytes or to inactive lining cells (Fig. 18). While many growth factors and cytokines are known to affect the proliferation and

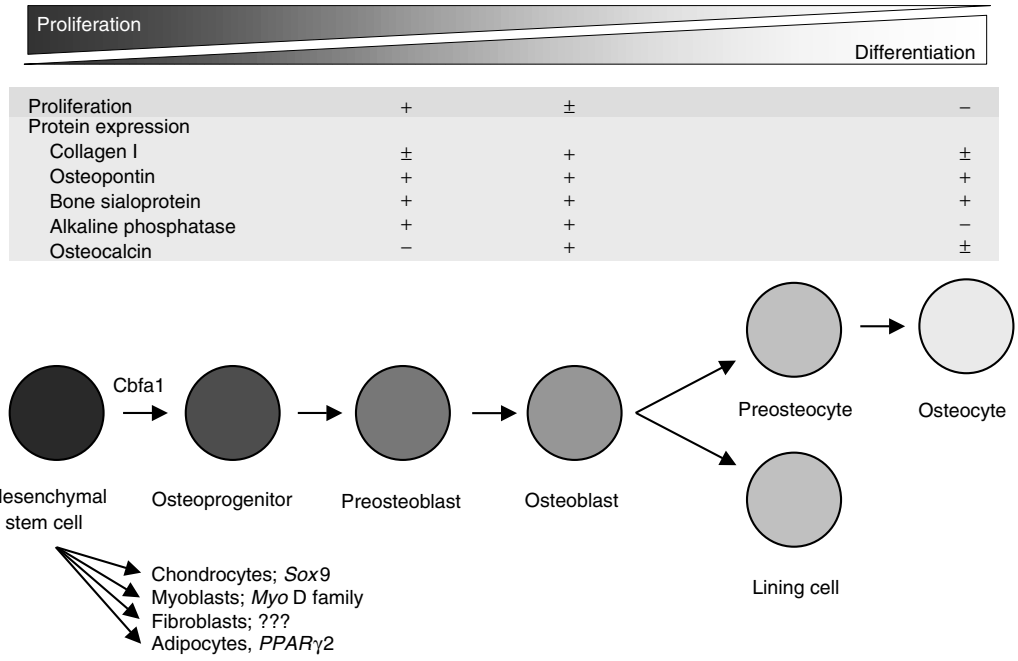

Figure 18. Development of cells of the osteoblast lineage. Osteoblasts are derived from mesenchymal stem cells. Expression of the transcription factor CbfaI commits these cells to become osteoprogenitor cells. During their development, the cells of the osteoblast lineage express specific genes, some of which are expressed during the whole differentiation pathway (like osteopontin and bone sialoprotein), whereas some of them are expressed predominantly by mature, matrix-producing osteoblasts (collagen I, osteocalcin). The ingrowth of vessels is not shown in this drawing for the sake of clarity (see also Fig. 7). Figure drawn after [118].

differentiation of the cells of the osteoblast lineage, little to nothing is known about the regulation of the further development of the osteoblasts to inactive lining cells or to osteocytes.

As noted, osteoblasts are derived from mesenchymal stem cells. During the process of differentiation, these cells pass through a number of distinct stages that can be characterized by the pattern of expression of osteoblastic marker proteins (for a review, see [118]). In the first phase, osteoblast progenitors are highly proliferative, expressing no markers specific for the lineage. With increasing maturation, the cells produce matrix proteins such as collagen I, osteopontin, and bone sialoprotein. This stage of matrix maturation is accompanied by a decrease in the potential to proliferate. Mature osteoblasts express osteocalcin and have virtually ceased proliferating. Subsequently, some of the active, matrix-synthesizing osteoblasts are induced by as yet unknown signals to arrest matrix production and are entombed as osteocytes in the bone matrix by neighboring cells. Lastly, the osteoblasts cease producing extracellular matrix and become "silent" lining cells.

The different steps in the development of osteoblasts are regulated by growth factors and cytokines. Depending on the state of the target cells, the respective factors exert differing effects. Thus, platelet-derived growth factor (PDGF), TGF-β, and the IGFs act chemotactically on osteoblast precursors. Additionally, TGF-β, PDGF, and FGFs stimulate the proliferation of their target cells [119,120]. The bone-forming capacity of TGF-β has been demonstrated in animal studies in which subperiosteal injections of the growth factor into murine calvaria induced an increase of bone apposition and a thickening of the bone layer [121,122]. The effect of TGF-β on bone, however, is even more complex because bone resorption is also modulated by this growth factor [123]. Lastly, BMP2 supports the differentiation and activation of osteoblastic cells. Animal studies have revealed that BMP2 has the capacity to induce bone in skeletal defects. When defects are filled with a collagenous carrier matrix impregnated with BMP2, osteoblasts invade the matrix and form bone within the collagen mesh, indicating the clinical potential of this growth factor [124–127]. Elucidating the actions of these cytokines and growth factors is complicated by the fact that, to a large extent, they are produced by osteoblasts themselves, enabling both autocrine and paracrine actions, and are integrated into the extracellular matrix during bone formation. As a consequence, the liberation and activation of these factors during bone resorption may be a possible mechanism for coupling the processes of bone formation and resorption.

The Functions of Osteoblastic Proteins

The composition of the extracellular matrix of bone defines its unique properties among the various extracellular matrices in the organism. Although mineral is required for resistance to pressure, it is the organic fraction, mainly the collagen fibers, that are responsible for the tensile strength and elasticity of bone. Correspondingly, mineral constitutes approximately two thirds of the dry weight of bone, while the organic portion is predominantly (approximately 90%) collagenous, the remaining 10% consisting of various noncollagenous proteins. While collagen is considered extensively elsewhere in this book (see Chapter 2), the major noncollagenous bone matrix proteins are briefly described below. Because it is not within the scope of this review to discuss the components of bone matrix in detail, and because this topic is reviewed elsewhere in this book, the present focus is on those proteins, the function of which has been studied recently using transgenic or knockout mouse models.

The noncollagenous matrix proteins, which define the specific functions of the bone matrix, can be divided roughly into four groups: proteoglycans such as decorin and biglycan [128], the RGD (arginine-glycine-aspartate)-containing proteins osteopontin (OP) [129] and bone sialoprotein (BSP) [130], glycoproteins such as osteonectin (ON) [17] and the γ-carboxyglutamic acid (Gla)-containing proteins, osteocalcin (BGP) [131], and matrix-Gla-protein [132]. Although the functions of these proteins have remained largely unknown until recently, with the establishment of knockout strains, some aspects of their biological roles in the formation and maintenance of bone have been elucidated.

Biglycan is an extracellular matrix proteoglycan that is enriched in bone. Mice deficient in biglycan appear normal at birth, but during growth they display a phenotype characterized by a reduced growth rate and decreased bone mass [133].

Osteopontin is a widely expressed protein that is also found in bone matrix. The expression of osteopontin is increased in transformed cells [134] or in response to stimuli such as myristate acetate [135]. Due to the presence of the cell attachment RGD-sequence, osteopontin has been proposed to be involved in cell adhesion as well [136]. Mice homozygous for a null mutation in the osteopontin gene develop normally during embryogenesis and reach fertility. They do, however, show alterations in wound healing, suggesting a role for osteopontin in tissue remodeling [137]. Double knockout mice for osteopontin and the RGD-binding vitronectin receptor are also viable, suggesting that other ligand/receptor pairs compensate for the two proteins [137]. Preliminary data suggest that osteopontin deficiency may affect osteoclast activity [138], because $OP^{-/-}$ mice are characterized by an increase in the number of osteoclasts that resorb bone inefficiently.

Only preliminary data have been presented relating to the phenotype of mice deficient in BSP, which suggest a decrease in the number of osteoprogenitor cells in $BSP^{-/-}$ animals, and subtle disturbances in the regulation of bone formation [139].

Osteonectin is thought to play a role in the mineralization of bone as a result of its affinity for hydroxyapatite and type I collagen [17]. Furthermore, it has been postulated to modulate the proliferation of cells of osteoblast lineage. Mice deficient in osteonectin develop normally up to the age of 6 months, at which time they develop severe eye pathology [140]. At birth, no skeletal abnormalities can be observed, but within 4 months the animals become severely osteopenic, $ON^{-/-}$ mice having 50% less bone mass than normal littermates. The numbers of osteoblasts and osteoclasts are reduced, causing a decrease in bone remodeling with a negative bone balance [141].

The role of the only bone-specific protein, osteocalcin (BGP), also proved elusive in the past. The protein is characterized by its high content of γ-carboxyglutamic acid, an amino acid that derives posttranslationally from glutamic acid by addition of a carboxyl group. The carboxylation reaction is catalyzed by the enzyme γ-carboxylase, which uses vitamin K as a cofactor. Rats treated with warfarin, an antagonist of vitamin K, show excessive mineralization at the growth plate [142], suggesting a putative role of osteocalcin in the regulation of mineralization. Somewhat contradictory data were also presented, suggesting a role for osteocalcin as a chemoattractant for osteoclasts. The protein has been described both as being required [143] and as being dispensible [144] for the dissolution of subcutaneously implanted bone particles. Since osteocalcin is not expressed during initial bone formation, it has been suggested that it may play a role in the remodeling and maturation of bone [145,146]. This hypothesis is supported by the finding that $BGP^{-/-}$ mice develop normally but show an increase in bone mass. Bone resorption, on the other hand, is not affected by the mutation. Therefore, it has been proposed, in accordance with the earlier warfarin experiments, that the main role of osteocalcin in bone metabolism consists in limiting bone growth [147].

As noted, osteoblasts pass through a series of stages before reaching maturity and laying down the bone matrix. A critical step in this complex process is the recruitment of osteoprogenitor cells to the sites of future bone formation. Extracellular matrix proteins that are known to serve in other tissues as substrates for cell attachment and to act as guides for cell migration are, therefore, of special interest. One of these proteins is heparin-binding growth-associated protein (HB-GAM), which is required for the development of neuronal tissues [148,149]. Transgenic mice that specifically overexpress HB-GAM in osteoblasts show an increase in bone mass resulting from an increase in bone formation [150]. Furthermore, HB-GAM is upregulated at the surface of damaged bone, where the recruitment and activation of new osteoblasts occurs. Potential sources of the protein are cells of osteoblast lineage, including osteocytes. The data suggest that growth factors, cytokines promoting bone formation, and even mechanical strain, might act through the production of HB-GAM to attract and activate osteoprogenitor cells and osteoblasts [150].

MINERALIZATION IN BONE AND CARTILAGE

Besides producing the organic components of the extracellular matrices of bone and cartilage, osteoblastic and chondrocytic cells control the mineralization of these matrices. For this purpose, chondrocytes and osteoblasts release matrix vesicles that induce, and subsequently serve as nuclei for, mineralization (for a review, see [151]).

Matrix vesicles are extracellular membrane vesicles that are released by budding from the surfaces of chondrocytes and osteoblasts [152]. Two pieces of evidence suggest that only specific compartments of the cell perimeter can give rise to matrix vesicles. Firstly, the protein composition of the matrix vesicles is far less complex than that of cell membranes [153]. Secondly, the release of matrix vesicles from the cells is a highly polarized process. The deposition of vesicles within the calcifying matrix is restricted to those areas in which mineralization will begin. In cartilage, matrix vesicles are localized to the calcifying longitudinal septal matrix [154], while in developing bone they are deposited within the newly formed osteoid beneath the osteoblasts [155].

At the time of their release, matrix vesicles are rich in phosphatases (among them alkaline phosphatase) and calcium-binding proteins. They do not, however, contain any mineral. The mineralization process, which is regulated and initiated by matrix vesicles, can be divided into two phases, phase one being the initiation of mineralization, which is enzymatically regulated, and phase two being the propagation of mineralization, which is a self-perpetuating process.

In both bone and cartilage, matrix vesicles are the first sites of mineralization. The first mineral crystals appear within the vesicles, often in close alignment with the membrane. This first phase of mineralization begins with the attraction of calcium into the vesicles by concentrating calcium-binding lipids and proteins [156,157] and by the action of calcium channels in the matrix vesicles [158]. The accumulation of calcium is followed by the accumulation of phosphate, which may result from the action of phosphatases within the vesicles or from membrane-localized phosphate transporters [159]. When sufficient calcium and phosphate have been accumulated within the vesicles, calcium phosphate precipitates [160]. The first precipitate consists of amorphous, noncrystalline calcium phosphate, which is subsequently converted to the less soluble hydroxyapatite [160,161].

While growing, the hydroxyapatite crystals penetrate the vesicle membrane, thereby initiating the second phase of the mineralization process. After penetration of the membrane by the growing crystals, a process that may be facilitated by the hydrolytic action of phospholipases [162,163], the hydroxyapatite becomes exposed to the extracellular fluid, in which calcium and phosphate concentrations are sufficiently high to cause spontaneous mineral proliferation. During this second phase of mineralization, the hydroxyapatite crystals, which originally formed within the matrix vesicles, serve as nuclei for crystal formation. Because crystal growth is dependent only on the concentrations of calcium and phosphate in the extracellular fluid, mechanisms that contain the progress are of major importance to avoid excessive mineralization. Cellular control of mineralization is achieved by regulating the budding of new matrix vesicles and by balancing mineralization and resorption. Molecular control, as mentioned above, may involve osteocalcin, which, in animal models, has been shown to regulate bone growth, eventually by interfering with the mineralization process [147].

THE OSTEOBLAST–OSTEOCLAST CONNECTION

As noted above, the central role in bone metabolism is assigned to osteoblasts, because cells of osteoblast lineage are thought to synthesize the components of the extracellular matrix and also to regulate, at least in part, the recruitment and activation of osteoclasts [164]. Indeed, it has been known for some time that hormones or cytokines like parathyroid hormone (PTH), interleukin-1 (IL-1), and tumor necrosis factor-α (TNF-α) indirectly exert their stimulatory effect on bone resorption through osteoblasts [165–167].

The molecules, however, that function as mediators between osteoblasts and osteoclasts have not yet been characterized [168–171]. Only recently, two molecules have been identified that are products of cells of osteoblast lineage and which, together, are sufficient to support the formation of functional osteoclasts from hematopoietic precursors. Colony-stimulating factor-1 (CSF-1), also called macrophage colony-stimulating factor (M-CSF), was originally described as essential for the proliferation, differentiation, activation, and survival of the cells of the mononuclear phagocytic system. This growth factor is expressed constitutively by mesenchymal cells *in vitro* and by activated macrophages [172]. It binds to a single class of high-affinity receptors encoded by the proto-oncogene *c-fms*. Interest in the role of CSF-1 in bone resorption was initiated by the finding that the osteopetrotic murine mutant strain *op* was characterized by a decreased number of macrophages and impaired bone resorption as a result of a virtual absence of osteoclasts. On the basis of these findings, it was suggested that osteopetrotic *op* mice were deficient in a growth factor for macrophages [173]. Subsequently, *op* mice were demonstrated to lack biologically active CSF-1 [174,175], the deficiency being the result of a point mutation within the coding region of the gene encoding the cytokine [176]. That the deficiency of CSF-1 was indeed responsible for the observed osteopetrosis was shown when injections of CSF-1 into *op/op* animals reversed the osteopetrotic phenotype [174,177]. Supporting a local effect of CSF-1 during bone development and osteoclast recruitment were the findings that osteoblasts, both *in vivo* and *in vitro*, produced the cytokine [178,179]. Furthermore, in bone, transcripts encoding c-fms can be detected by *in situ* hybridization only in osteoclasts and their precursors [180,181].

Previously, CSF-1 had been shown to be synthesized as either a rapidly secreted molecule or as a membrane-bound molecule expressed on the cell surface and released slowly through proteolytic cleavage (for a review, see [182]). The major portion of the secreted molecule is post-translationally modified by the attachment of a glycosaminoglycan side chain that may serve as an anchor for integration into the extracellular matrix [183,184]. Cells of osteoblastic lineage synthesize both the secreted and the membrane-bound molecules [179,185], suggesting that the cytokine may act either chemotactically by attracting osteoclast precursors or via cell-cell contact to induce final differentiation, support survival, and modulate the activity of osteoclasts.

Although it has been shown unequivocally that CSF-1 is synthesized by osteoblastic cells in close local and temporal relationship with bone resorption, little is known about the regulation of its expression and the respective contributions of the different molecular forms to the formation of osteoclasts. In murine osteoblastic MC3T3-E1 cells, CSF-1 expression is constitutive and can be further increased by PTH, IL-1, TNF-α, and dexamethasone [181,186–188]. *In vivo*, however, the expression of the cytokine is tightly regulated. Thus, it is dramatically induced during pregnancy by 17β-estradiol and progesterone in the uterus [189]. In bone, expression of the cytokine is affected by estrogen deficiency in stromal cells [190–192], and by this mechanism may contribute to the onset of postmenopausal osteoporosis. Even less clear than the *in vivo* regulation of CSF-1 are the biological functions of its different molecular forms. It has previously been hypothesized that the membrane-bound form is required for full biological activity [193]. Only recently, however, has evidence been obtained that the expression of this form is specifically modulated in osteoblasts and that it is highly efficient in promoting the formation of osteoclasts [194].

While CSF-1 acts on a common precursor of macrophages and osteoclasts, a second factor synthesized by osteoblasts and essential for osteoclast formation has been found to act at a later stage of osteoclast differentiation. Osteoclast differentiation factor (ODF/RANKL/TRANCE)[1] is a member of the membrane-bound tumor necrosis factor ligand family [195,196]. The recombinant soluble form of ODF, together with CSF-1, supports the formation of osteoclasts *in vitro* demonstrating that the two factors are sufficient to induce the respective developmental programs in hematopoietic precursor cells [197]. The action of ODF on osteoclast formation is counteracted by another osteoblastic product, known as osteoprotegerin (OPG) [198] or osteoclast inhibitory factor (OCIF) [199]. OPG is a member of the tumor necrosis factor receptor superfamily, is synthesized by cells of osteoblastic origin, and is expressed as a soluble protein. It binds to ODF and, in this manner, blocks its osteoclastogenic effect [199]. Knockout mice carrying a null mutation in the OPG gene are characterized by severe trabecular and cortical bone porosity and a high incidence of fractures, demonstrating the critical role of OPG in the regulation of postnatal bone mass [200]. In consequence of the important role of OPG/ODF in the regulation of the formation of osteoclasts by cells of osteoblast lineage, several studies have been performed on the regulation of the expression of these genes. OPG mRNA is upregulated in response to TNF-α and TNF-β, indicating that the factor may help counteract the bone-destroying activity of these cytokines [201]. Other data, however, indicate that the ratio of ODF:OPG is increased by osteoclastogenic hormones and cytokines such as $1,25(OH)_2D_3$, PTH, and IL-11 [202]. Thus, OPG may be synthesized by osteoblastic cells to counteract the stimulatory effects of these hormones and cytokines on bone resorption, and, by this mechanism, the extent of loss of bone mass may be reduced.

Taking all these results together, it would appear that CSF-1 may be a factor required for the formation of osteoclasts and that it constitutes a critical part of the microenvironment of hematopoietic precursor cells, while the ODF/OPG pair provides local control for the fine tuning of the resorptive response.

To elucidate further the interactions between osteoblasts and osteoclasts, and, in particular, the coupling of bone formation and bone resorption, a mouse model that can be depleted of differentiated, active osteoblasts has been established [203]. When osteoblasts are destroyed in these animals at the age of 6 weeks, the rate of bone resorption is not affected, suggesting that this process does not require the presence of mature osteoblasts. Although great care has to be taken in the interpretation of the model [204], it shows that by combining physiology, morphology, and molecular biology, many exciting discoveries may be made, leading step by step to a better understanding of the mechanisms that allow bone to work in the magnificent way it does.

[1] Abbreviations: ODF, osteoclast differentiation factor; TRANCE, tumor necrosis factor-related activation-induced cytokine; RANKL, receptor activator of c-jun N-terminal kinase and NF-κB ligand

Bone Resorption

R. Felix

Bone, like other tissues, is continuously turned over by cellular processes. The osteoblast forms the bone matrix, and the osteoclast, a multinucleated cell, resorbs it. Thus, bone mass depends on the balance between these two processes. In childhood, bone formation is more rapid than resorption, and bone mass increases; between the ages of 20 and 40 years, the two processes are equal and it remains constant; in later years, resorption is more rapid than formation, and bone mass decreases. The rate of bone resorption is determined by both the number of osteoclasts and their activity. Osteoclast numbers are consequent upon their rates of formation and disappearance, the latter occurring through apoptosis. Whereas osteoclasts have a single function, namely to resorb bone, osteoblasts have two functions, not only forming bone matrix, but also regulating its resorption. This regulatory function is performed by stimulating osteoclasts in response to hormonal and cytokine signals. Further, osteoblasts support the development of osteoclasts through the synthesis of matrix proteins and growth factors. Osteocytes, also, probably have an influence on osteoclasts, but no information about this is available as yet.

The aim of this section of the present chapter part is to provide an overview of present knowledge concerning the development of osteoclasts and their function as bone matrix resorbing cells, but it does not cover every detail. Nor is there any information relating to the signal transduction involved in the generation and activation of osteoclasts. Additional information may be obtained from reviews elsewhere [205–208].

THE DEVELOPMENT OF OSTEOCLASTS

The Hemopoietic Origin of the Osteoclast

Thirty years ago, it was thought that osteoblasts and osteoclasts originated from the same precursor cell. In elegant work, several groups have shown this to be a misconception, and demonstrated that the hemopoietic stem cell is the precursor of the osteoclast.

In a parabiotic procedure, two rats, in one of which all hematopoietic tissue and local precursors had been destroyed by irradiation, were joined via a common circulation [209]. This demonstrated that the cells that fused to form multinucleated osteoclasts in a healing fracture in the irradiated rat must have been derived from the nonirradiated rat through the circulation. Another useful model for studying the origin of osteoclasts is osteopetrosis, an inherited disorder characterized by bone sclerosis resulting from deficient osteoclastic bone resorption. In this model, both the parabiotic union of osteopetrotic mice with normal littermates and the transplantation of hemopoietic stem cell suspensions from normal to affected siblings have been shown to cure some forms of the disorder [210,211]. These experiments indicated that precursors of osteoclasts are of hemopoietic origin and present in the circulation.

In a third approach, quail-chick chimera were investigated [212,213]. The embryonic long bones of one species were grafted onto the chorioallantoic membrane of the other, and it was possible to exploit the known morphological difference between chick and quail cell nuclei to determine the origin of different types of cells present in the developing bone. It was shown that osteoclasts formed through the fusion of host mononuclear cells derived from the vasculature of the chorioallantoic membrane, whereas the origin of osteoblasts was the local donor graft.

More recently, the hemopoietic origin of osteoclasts was also demonstrated in co-culture systems *in vitro*, in which hemopoietic precursor cells were grown either with fetal bone rudiments devoid of osteoclast progenitor cells, or with stromal cells [214,215]. Through these experiments, it also became evident that the stromal/osteoblastic cells play an important role in supporting the generation of osteoclasts. Scheven succeeded in generating osteoclasts in culture from hemopoietic stem cell populations [216]. Recently, macrophage cell lines that can be induced to form osteoclast-like cells [217,218] and immortalized mouse osteoclastogenic cell lines [219,220] have been generated.

The Pathway of Osteoclast Differentiation

Osteoclast markers are important for the identification of osteoclast-like cells grown in culture and osteoclast precursors observed *in vivo* or *in vitro*. Such markers have been identified when hemopoietic precursor cells develop into osteoclast-like cells in co-cultures of bone marrow cells and osteoblasts in the presence of 1,25-$(OH)_2D_3$ [221]. Precursor cells at the state before fusion (prefusion osteoclasts) have been isolated [222,223]. Postmitotic osteoclast precursor cells are positive for nonspecific esterase (NSE) and antigens Mac-1 and Mac-2, but negative for the macrophage-specific antigen F4/80. Mac-1 and Mac-2 are rat monoclonal antibodies against mouse macrophage-associated antigens. Mac-1 recognizes C3bl. C3bl is expressed preferentially on monocyte-macrophages, granulocytes, blood monocytes, and neutral killer cells, but not thymocytes. Mac-2 reacts with

Abbreviations: BMP: bone morphogenetic protein; CSF-1: colony-stimulating factor-1; GM-CSF: granulocyte-macrophage colony-stimulating factor; IGF-1: insulin-like growth factor-1; IL-1: interleukin-1; LIF: leukemia inhibitory factor; NFκB: nuclear factor κB (a transcription factor); *oc*: osteosclerotic; ODF: osteoclast-differentiation factor (also named: OPGL: OPG ligand; RANKL: RANK ligand; TRANCE: TNF-related activation-induced cytokine); *op*: osteopetrotic; OPG: osteoprotegerin (also named: OICF: osteoclast inhibitory factor); OSM: oncostatin M; PGE_2: prostaglandin E_2; PTH: parathyroid hormone; PTHRP: PTH-related protein; RANK: receptor activator NFκB; TNF-α: tumor necrosis factor-α; TRAP: tartrate-resistant acid phosphatase.

a 32-kDa glycoprotein that is expressed in a subpopulation of mouse macrophages including peritoneal macrophages provoked by thioglycolate. Neither resident macrophages, splenic macrophages, granulocytes, thymocytes, nor most marrow cells express this antigen. The rat monoclonal antibody to F4/80 recognizes a 160-kDa glycoprotein, which is specifically expressed in mouse macrophages. During further differentiation to committed osteoclast precursors, these cells become TRAP-positive and express receptors for calcitonin. An almost simultaneous expression of TRAP and calcitonin receptors has also been observed in differentiating osteoclasts in cultured embryonic murine metatarsals [224]. During subsequent differentiation to mononuclear preosteoclasts, NSE and the Mac-1 antigen disappear, while antigen Mac-2 remains. The expression of Mac-2 antigen as a marker in preosteoclasts has also been verified *in vivo* in *op/op* mice (osteopetrotic mice deficient in CSF-1) injected with CSF-1 [225]. Mature multinucleated osteoclasts express carbonic anhydrase II, c-Src, the vacuolar proton ($V\text{-}H^+$) ATPase, the 92-kDa type IV collagenase (matrix metalloproteinase 9), the osteoclast-specific cysteine proteinase cathepsin K, integrin $\alpha_v\beta_3$, and a high number of receptors for calcitonin [223,226]. $1,25\text{-}(OH)_2D_3$ has been shown to affect positively the expression of carbonic anhydrase II and integrin $\alpha_v\beta_3$ [227-229]. These marker proteins are characteristic for osteoclasts, but are produced also by other cell types, such as macrophages. Markers highly specific to osteoclasts are the binding of calcitonin and the production of cAMP on stimulation with calcitonin. Osteoclasts are also the only cells with the capability to resorb mineralized matrix (when cultured on mineralized matrix, they excavate lacunae). Mononuclear osteoclasts which have not yet fused to multinucleated cells also resorb bone [230].

The Function of Stromal and Osteoblastic Cells in Osteoclast Generation

When Suda and colleagues succeeded in growing osteoclast-like cells expressing osteoclastic markers in bone marrow cell culture in the presence of $1,25\text{-}(OH)_2D_3$, they observed that these cells appeared to be in contact with cells positive for alkaline phosphatase [231]. This suggested that the alkaline phosphatase positive cells may support the generation of osteoclasts. Indeed, it was demonstrated that it was necessary to co-culture marrow-derived stromal cells with hemopoietic precursor cells from spleen to support the development of osteoclasts [215], and that cell-cell contact between the two cell types was required [232,233]. Several stromal and osteoblastic cell lines supporting the formation of osteoclast-like cells in co-culture have now been characterized: MC3T3-G2/PA6 [215], KS-4 [234], ts8 [235], TM8 [236], MR1.8 [223], BMS2 [237], and MS1 [238]. If such cell lines are not available, osteoblastic cells isolated from murine calvaria can be used for co-culture with hemopoietic cells [239]. The co-culture system allows the production of a high number of osteoclast-like cells that can be used for biochemical investigations [240,241].

It has proved possible to grow osteoclasts from human bone marrow cells aspirated from healthy volunteers [242]. In an initial phase of culture, the bone marrow cells are grown on plastic. This is then followed by a second phase in which the cells are plated on bone slices where they resorb bone and form pits (lacunae). In contrast to murine marrow cultures, CSF-1 has to be added during the first phase to support the generation of osteoclasts. However, just as with the murine culture, high concentrations of CSF-1 suppress the formation of osteoclasts [243]. Human osteoclasts have also been generated by culturing precursor cells obtained from peripheral blood samples in both the presence and the absence of murine stromal cells [244–246]. The mesenchymal cells support the generation of osteoclasts by producing matrix proteins (see also "Bone Formation") and growth factors.

The Role of Matrix Proteins in Osteoclast Generation

Matrix proteins such as osteopontin, vitronectin, and collagen bind to their corresponding receptors on the cell surface, the integrins. Osteoclasts express the vitronectin receptor $\alpha_v\beta_3$ [247], the collagen receptor $\alpha_2\beta_1$ [248] and the fibronectin receptor $\alpha_v\beta_1$ [249]. On binding of the respective ligand, the integrins transduce signals into the cell in the same way that hormone and growth factor receptors do, inducing proliferation and differentiation of the cell. That matrix proteins support the development of osteoclasts is demonstrated by the observation that, in fetal long bone rudiments, the tripeptide arginine-glycine-aspartic acid (RGD), which competes with matrix proteins for the vitronectin receptor, inhibits the fusion of mononuclear precursors to form multinucleated osteoclasts [250]. Osteocalcin, the most abundant noncollagenous protein of the bone matrix, has also been suggested to support the differentiation of osteoclasts [251]. However, recent data obtained from transgenic osteocalcin-deficient mice demonstrate that the absence of osteocalcin does not impair bone resorption. The extent of bone surface covered with osteoclasts and their numbers are even greater in the mutant mouse, and ovariectomy causes a rapid increase in bone resorption that ultimately leads to osteoporosis [147].

Factors Required for the Development of Osteoclasts

Colony-Stimulating Factor-1 and Osteoclast Differentiation Factor

The factors, CSF-1 and ODF, are essential for the generation of osteoclasts. Since they are synthesized by osteoblasts, their role in bone resorption is described in the previous section "Bone Formation." ODF, a new member of the TNF receptor-ligand family, has only recently been identified, and knowledge about this membrane-integrated protein is still accumulating. An important point to note here is that the hormones and cytokines that stimulate the formation of osteoclasts act indirectly through osteoblasts and induce the synthesis of ODF by them. The receptor for ODF, named RANK, is expressed on both osteoclast precursor cells and mature osteoclasts. Thus, ODF binds to RANK and induces differentiation of the precursor cells to mature osteoclasts (Fig. 19) [252,253]. Osteoprotegerin, a novel member of the TNF receptor superfamily, binds as a soluble decoy receptor to ODF and inhibits its action.

Osteopetrosis Indicates Essential Factors Required for the Generation of Osteoclasts

Mutations in genes required for the generation of osteoclasts result in low numbers of osteoclasts, or even in their absence. Consequently, bone resorption is impaired, leading to osteopetrosis. Various types of heritable defects in osteoclast generation are known in the mouse (Fig. 20). In some types, genes encoding transcription factors are mutated, in others genes encoding growth and differentiation factors.

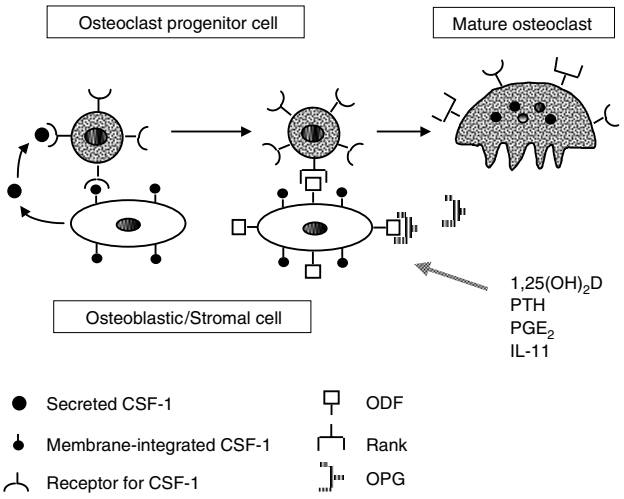

Figure 19. The roles of colony-stimulating factor-1 (CSF-1), osteoclast differentiation factor (ODF) and osteoprotegerin (OPG) in the generation of osteoclasts. CSF-1, either secreted or integrated within the membrane, and ODF, also integrated within the membrane, are the two proteins synthesized by osteoblastic/stromal cells. CSF-1 is essential for the generation of osteoclasts and ODF for their generation and activation. Secreted CSF-1 also binds partially to the extracellular matrix (not shown). Whether CSF-1 and ODF are expressed by a single osteoblastic/stromal cell or by different cells is not known. CSF-1 is constitutively synthesized, and its production is probably not much influenced by hormones and cytokines stimulating bone resorption (an exception is estrogen deficiency). In contrast, the expression of ODF seems to be strongly regulated by these hormones and cytokines. The receptors for CSF-1 and ODF are expressed on osteoclasts and their precursor cells. OPG binds ODF and prevents binding to RANK. This results in inhibition of osteoclast formation and activation. OPG is a critical regulator of postnatal bone mass. Other names for ODF are RANKL (RANK ligand), OPGL (osteoprotegerin ligand), and TRANCE (TNF-related activation-induced cytokine). Abbreviations: 1,25-dihydroxycholecalciferol ($1,25(OH)_2D$); parathyroid hormone (PTH); prostaglandin E_2 (PGE_2); interleukin-11 (IL-11).

Regarding the very early steps in the ontogeny of the osteoclast, one might expect an absence of transcription factors governing myeloid differentiation to result in osteopetrosis. Indeed, transgenic mice lacking the myeloid and B lymphoid transcription factor PU.1 (also called Spi-1 or Sfpi-1) fail to generate macrophages and osteoclasts, consequently developing sclerotic bone disease [254].

Further along the pathway of differentiation, the *op* mouse presents a defect in the osteoblastic/stromal cells, specifically, a point mutation in the coding region of the CSF-1 gene that leads to a lack of biologically active CSF-1 [176]. Injection of recombinant CSF-1 reverses the osteopetrotic phenotype, demonstrating the essential function of this cytokine in the generation of osteoclasts [174,177].

Resident macrophages and osteoclasts, both of which require CSF-1 for their early development, derive from the same precursor cell. The question arises as to which factor determines the branching of the pathway toward either macrophage or osteoclast, and the osteopetrotic *c-fos* knockout mouse provides the answer. This mouse generates macrophages but no osteoclasts [255]. This indicates that *c-fos* expressed in the hemopoietic lineage is involved in the commitment to differentiation of postmitotic osteoclast precursors towards osteoclasts.

Another type of osteopetrotic mouse unable to generate osteoclasts is the transgenic mouse lacking the transcription factors $NF\kappa B_1$ and $NF\kappa B_2$ [256,257]. The defect appears to be located within cells of the hemopoietic lineage. These mice fail to generate osteoclasts and B cells, and the function of macrophages is impaired. The role of NFκB in the formation of osteoclasts can be explained by the finding that these transcription factors are activated by ODF, resulting finally in the differentiation of osteoclasts [196]. ODF binds to its receptor RANK (receptor activator of NFκB), which is expressed by osteoclast precursor cells and induces the activation of NFκB [258,259]. NFκB is also involved in cell survival. Inhibitors of NF-κB induce apoptosis of rabbit mature osteoclasts [260]. Both ODF and IL-1 promote the survival of murine osteoclast-like cells [261,262]. Thus, the NFκB transcription factors, activated by ODF or IL-1, are probably required for the differentiation of osteoclast precursor cells and for the survival of osteoclasts. Consequently, their absence leads to osteopetrosis.

In the naturally occurring osteopetrotic microphthalmia (*mi*) mouse, the number of osteoclasts is normal, but they do not form ruffled borders. The *mi* locus encodes a member of the basic-helix-loop-helix-leucine zipper (bHLH-Zip) protein family of transcription factors [263]. Investigating osteoclast formation in cultured metatarsals/metacarpals, and in cell cultures prepared from neonatal calvaria from these mice,

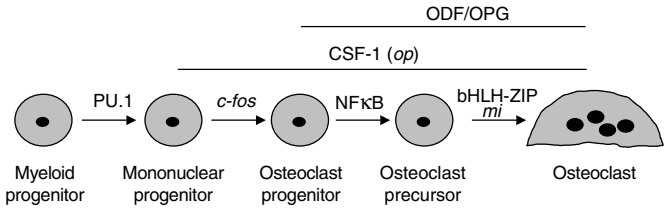

Figure 20. Osteopetrosis indicates essential factors required for the generation of osteoclasts. The expression of various genes is required for the generation of osteoclasts and, consequently, mutations of these genes result in osteopetrosis. Investigations of these inheritable defects helped to elucidate the pathway of osteoclast differentiation. PU.1 (also called Spi-1 or Sfpi-1) is a transcription factor required for the early differentiation of the myeloid precursor to the mononuclear progenitor cell. The transcription factors c-Fos, NFκB, and bHLH-Zip (basic helix-helix-loop-leucine zipper) act later in the differentiation pathway. CSF-1 (colony-stimulating factor-1) is a growth factor required for the generation of osteoclasts. An inactivating mutation in the gene encoding CSF-1 results in an osteopetrotic phenotype, as is the case in the osteopetrotic mouse strain *op*. The other factor required for the differentiation of osteoclasts is ODF (osteoclast differentiation factor). Consequently, transgenic mice deficient in ODF are osteopetrotic. Furthermore, transgenic mice overexpressing OPG (osteoprotegerin), which binds ODF and inhibits its action, are osteopetrotic.

indicated a defect in the fusion of osteoclast precursor cells [264,265].

The function of OPG as an inhibitor of bone resorption has been demonstrated in mice that overexpress OPG in the liver [198]. The high amount of OPG released into the circulation binds ODF on the surface of osteoblasts and inhibits the interaction of this ligand with its receptor, RANK, on osteoclasts and their precursor cells, resulting in impaired formation and activation of osteoclasts, and subsequent osteopetrosis.

Instead of overexpressing OPG, the ODF gene has been disrupted in mice. This results also in osteopetrosis [252].

Nonessential Factors Supporting the Formation of Osteoclasts

To generate osteoclast-like cells in bone marrow culture or in co-cultures of hemopoietic cells and osteoblastic/stromal cells, one of the following hormones has to be added: 1,25-$(OH)_2D_3$, PTH, PTHRP, or PGE_2 [231,266,267]. The action of these hormones is mediated by osteoblasts/stromal cells, since they, and not osteoclastic precursor cells, express receptors for these hormones [268,269].

PTH and PTHRP induce osteoblasts to synthesize cytokines that stimulate the generation of osteoclasts. They stimulate IL-6 production by osteogenic cells *in vitro* [270] and the expression of IL-6 and LIF *in vivo* [271]. PTH has also been shown to stimulate the expression of CSF-1 in a human osteosarcoma cell line [194]. For the formation of human osteoclasts, prostaglandin synthesis seems to be essential as indomethacin, an inhibitor of cyclooxygenase, blocks this process [272].

1,25-$(OH)_2D_3$ may also have several direct effects on osteoclast precursor cells. As already noted, it induces the expression of carbonic anhydrase in myeloid cells and of $\alpha_v\beta_3$ integrins in avian osteoclast precursors. Furthermore, it has been shown to induce fusion in macrophages [273].

PGE_2 may also act directly on osteoclast precursor cells. It antagonizes the inhibitory effect of both IL-4 and interferon γ (IFN-γ) on the osteoclastic cell-forming potential of bone marrow macrophages [274]. This may be related to the positive effect PGE_2 has on the generation of osteoclasts in co-cultures of bone marrow cells and osteoblasts. Addition of 10^{-6} M PGE_2 in combination with 1,25$(OH)_2D_3$ completely blocks the formation of any macrophages [240] (and personal observation).

Interleukin-1 and Tumor Necrosis Factor-α

TNF-α has been shown to support osteoclast formation in cultured long bone rudiments [275]. IL-1 stimulates the formation of osteoclast-like cells by a mechanism involving PGE_2 production both in mouse bone marrow cell culture and in co-cultures of osteoblasts and spleen cells since indomethacin completely blocks the effect [276]. In human cell culture, IL-1 and TNF-α also enhance osteoclast formation and bone resorption by increasing the synthesis of PGE_2 [272].

Cytokines Acting Through gp130

IL-6 is one of the cytokines that acts through the signal-transducing protein, gp130. It exerts its activity via a cell surface receptor that consists of two components, an α subunit, gp80, a ligand-binding protein (IL-6 receptor, IL-6R), and a non-ligand-binding β subunit, gp130, that is shared by other cytokines such as OSM, LIF, and IL-11 (Fig. 21) [277]. Besides the IL-6 binding α subunit associated with the membrane, a recombinant human and mouse soluble IL-6 receptor (α subunit) lacking transmembrane and cytoplasmic domains is also able to mediate the IL-6 signal through gp130 [278]. Native soluble IL-6 receptors have been detected in urine and serum from healthy subjects [279,280]. Their levels are increased in patients with multiple myeloma [281].

IL-6 stimulates the formation of osteoclasts. Thus, in cultured embryonic metatarsals/metacarpals, IL-6 has been shown to increase bone resorption by stimulating the generation of osteoclasts [270]. When IL-6 was added to co-cultures of mouse osteoblasts and bone marrow cells, it had no effect on the formation of osteoclasts in this culture system. However, simultaneous treatment with IL-6 and the soluble IL-6 receptor strikingly induced osteoclastogenesis [282], indicating that IL-6 supports the generation of osteoclasts, provided the soluble receptor is

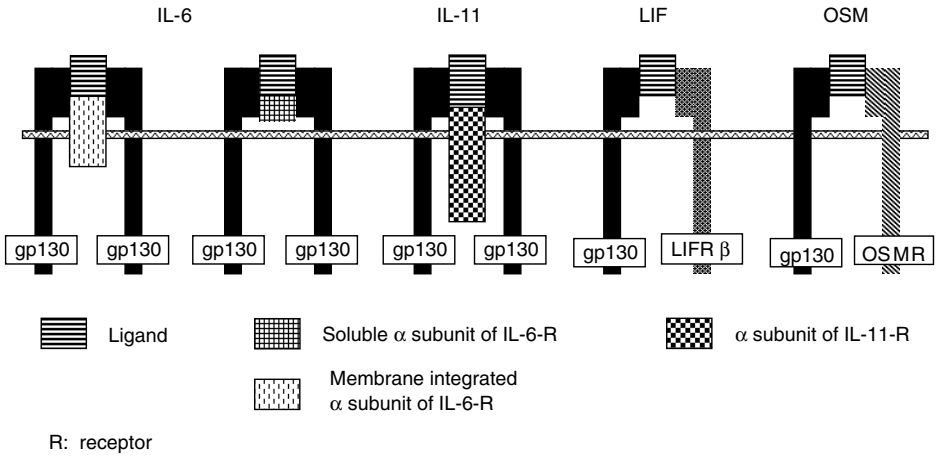

Figure 21. The receptors for interleukin-6 (IL-6), interleukin-11 (IL-11), leukemia inhibitory factor (LIF), and oncostatin M (OSM). Members of the subfamily of cytokines that include IL-6, IL-11, LIF, OSM, and ciliary neurotrophic factor (not shown) induce the assembly of related multicomponent receptors. The α subunit of the IL-6 receptor appears also in a soluble form that can bind IL-6 and assemble with, and activate, gp130. The β subunits, but not the α subunits, transduce the signal into the cell.

available. Related cytokines such as IL-11, OSM, and LIF, which also exert their function through gp130, also induced the formation of osteoclast-like cells.

The experiments above did not show whether IL-6 exerted its effect directly by binding to osteoclast precursors or indirectly by binding to osteoblasts. However, dexamethasone was subsequently found to increase the expression of IL-6 receptor mRNA in osteoblasts and, in parallel, their sensitivity toward IL-6 [283]. Finally, in co-cultures of osteoblasts and spleen cells derived from transgenic mice constitutively expressing the human membrane-anchored IL-6 receptor and from normal mice, osteoblasts were demonstrated to be the target cells for IL-6 action. Thus, IL-6 stimulated the formation of osteoclasts if the osteoblasts were taken from the transgenic mice and cultured with normal spleen cells. In contrast, it had no effect if the spleen cells were from the transgenic mice and the osteoblasts were normal [283]. These results indicate that the ability of IL-6 to induce osteoclast formation is indirect and depends on signal transduction mediated by the IL-6 receptor expressed on osteoblastic cells but not on osteoclast progenitors. The preceding data also suggest that the action of IL-6 is dependent on the concentration of the soluble IL-6 receptor and that this concentration may be affected by drugs and in certain diseases.

Whereas IL-6, as described below, may participate in the stimulation of the osteoclastogenesis that occurs after estrogen loss (see below) and in other diseases (e.g., rheumatoid arthritis, myeloma), IL-11 seems to regulate osteoclast formation under normal physiological conditions. IL-1, TNF-α, PGE_2, PTH, and 1,25-$(OH)_2D_3$ all induce the production of IL-11 in osteoblasts [284]. In accordance with these results, an anti-IL-11 neutralizing antibody was found to suppress osteoclast development in bone marrow induced by 1,25-$(OH)_2D_3$, PTH, IL-1, and TNF-α [285]. The effects of IL-11 on osteoclast development were also blocked by indomethacin, an inhibitor of prostaglandin synthesis, but did not depend on the estrogen status of the bone marrow donors.

Three different signal transduction pathways are activated by the various nonessential factors that support the generation of osteoclasts [206]. One mechanism, for PTH, IL-1, and PGE_2, is mediated by signaling involving cAMP. Whereas PTH and PGE_2 stimulate the production of cAMP directly, IL-1 acts through the induction of prostaglandin synthesis. The second mechanism, for 1,25-$(OH)_2D_3$–induced osteoclast formation, is mediated by the nuclear vitamin D receptor independently of cAMP. It is not known whether the recently described membrane-integrated vitamin D–binding receptor also plays a role in the generation of osteoclasts [286]. The third mechanism, for gp130 signaling, activated by cytokines such as IL-11, IL-6/sIL6 receptor, LIF, and OSM, is an additional important pathway for the formation of osteoclasts. However, as described above, some hormones and cytokines act through more than one signal pathway. Thus, 1,25-$(OH)_2D_3$, PTH, IL-1, and TNF-α partially stimulate the generation of osteoclasts via the activation of IL-11 production [285]. In contrast to IL-11, IL-6 is not involved in osteoclast formation induced by IL-1 and 1,25-$(OH)_2D_3$ [282], but it does partially mediate the effect of PTH.

The unifying mechanism by which the above-mentioned hormones and cytokines modify osteoblasts to support the generation of osteoclasts can now be explained [253]. As described above, most of them, if not all, induce the osteoblastic/stromal cells to synthesize ODF which is, in addition to CSF-1, essential for the formation of osteoclasts. Additionally, some of them also decrease the synthesis of the inhibitor of osteoclast formation, OPG. Extensive studies into ODF, RANK, and OPG are in progress, which will demonstrate the exact function and regulation of these three proteins.

Cytokines Inhibiting the Generation of Osteoclasts

The cytokines IL-4, IL-10, and GM-CSF suppress the generation of osteoclasts [274,287]. They act directly on the osteoclast precursor cells. The production of GM-CSF has been demonstrated in mouse bone marrow culture, and its inhibition by dexamethasone increases the generation of osteoclasts [288]. IL-10 increases the expression of CSF-1 mRNA. Since an excess of CSF-1 has been shown to inhibit osteoclast generation in favor of macrophage formation [289], it may be, at least in part, that an increased CSF-1 production is the mechanism by which IL-10 suppresses the formation of osteoclasts. IL-18 inhibits osteoclast formation by stimulating T cells to release GM-CSF, suggesting one possible means by which T cells may modulate bone resorption [290].

APOPTOSIS OF OSTEOCLASTS

The number of osteoclasts depends on the rates of both formation and apoptosis. Glucocorticoids and estrogen are known to induce apoptosis in mature osteoclasts. Glucocorticoids cause a dose-dependent decrease in bone resorption by rat osteoclasts incubated on bone slices [291]. This decrease is accompanied by a parallel loss in the number of osteoclasts due to apoptosis. Glucocorticoids seem to act directly on osteoclasts, since immunocytochemistry reveals the presence of glucocorticoid receptors in osteoclasts, and glucocorticoid-induced apoptosis can be prevented by a glucocorticoid antagonist [291]. Estrogen has also been shown to inhibit bone resorption by isolated rabbit osteoclasts by apoptosis. Its effect has been blocked completely by a pure antagonist and partially by a partial one, which suggests that the effect is mediated by the estrogen receptor [292]. The presence of mRNA for this receptor was also demonstrated in the rabbit osteoclasts. The results suggest a direct action of estrogen on osteoclasts, inducing apoptosis and consequently a decrease in bone resorption. The induction of apoptosis by estrogen has also been observed in murine osteoclasts, both *in vitro* and *in vivo* [293]. In contrast to the results obtained with rabbit osteoclasts, the effect of estrogen is mediated by transforming growth factor-β (TGF-β) in these cells. Estrogen induces the production of TGF-β by osteoblasts, and a neutralizing antibody against TGF-β abolishes apoptosis, demonstrating the role of TGF-β as a mediator in this process [293].

Apoptosis can also be induced by cytokines that stimulate the production of nitric oxide. Nitric oxide inhibits bone resorption by inducing apoptosis of osteoclast progenitors and suppressing osteoclast activity [294]. This may be a mechanism for protecting bone against aggressive bone resorption in inflammation induced by IL-1 and TNF-α. IFN-γ, synthesized by inflammatory cells, stimulates the formation of nitric oxide and inhibits bone resorption, at least partially [295].

Cytokines that prevent apoptosis are CSF-1, IL-1, and IGF-1 [296–299]. Furthermore, the recently described

ODF also supports the survival of osteoclasts [300]. One group also reported calcitonin to be a survival factor for osteoclasts [301], but this finding has not been confirmed by others, who have observed it to have only a minor effect on the survival of osteoclasts [208].

RESORPTION OF THE BONE MATRIX BY OSTEOCLASTS

The Role of the Osteoblast in Bone Resorption

Osteoblasts are the cells that regulate the bone-resorbing activity of osteoclasts. It is not osteoclasts, but osteoblasts that possess receptors for the hormones and cytokines that stimulate bone resorption, and these do so by inducing the expression of ODF by osteoblasts. ODF is a type II transmembrane protein that belongs to the new class of members of the TNF receptor family. It not only has the capacity to support the differentiation of osteoclast precursor cells (see above), but is also the factor that mediates the signal for bone resorption from osteoblasts to mature osteoclasts. Osteoclasts express the receptor RANK, which binds ODF [252,253], (see Fig. 19 and also the section "Bone Formation").

In addition to expressing ODF, osteoblasts also support osteoclastic bone resorption by removing the organic material that covers the bone surface and prevents osteoclasts from attaching to the mineral. For this purpose, osteoblasts secrete metalloproteinases and plasminogen activator and digest proteins covering the mineral surface [302–305]. Subsequently, osteoclasts attach to the now exposed mineral surface and start resorbing the bone [306]. It has also been suggested that collagen fragments released during digestion by osteoblast interstitial collagenase activate osteoclasts to resorb bone [307]. In recent years, several metalloproteinases have also been identified in osteoclasts (see below). Therefore, it seems likely that the organic material covering the bone surface is not digested by osteoblasts alone, but may be degraded by metalloproteinases of both osteoblasts and osteoclasts acting in concert [305].

Interaction of Osteoclasts with Matrix Proteins

When osteoclasts attach to bone matrix, they do so through integrin adhesion receptors. Osteoclasts express on their surface the classical vitronectin receptor $\alpha_v\beta_3$ [136], the collagen receptor $\alpha_2\beta_1$ [248], and integrin $\alpha_v\beta_1$ [249]. When osteoclasts are exposed to matrix proteins, such as osteopontin [308], sialoprotein [309], vitronectin, fibronectin, and collagen type I, but not collagen type IV or laminin [310], they become stimulated to resorb bone. Accordingly, antibodies against vitronectin receptors inhibit bone resorption *in vitro* [311]. Similarly, RGD peptides, which compete with RGD-containing matrix proteins in binding to vitronectin receptors, diminish bone resorption both *in vitro* and *in vivo* [312–314]. However, the mechanism by which molecules interact with the vitronectin receptor to inhibit bone resorption is not clear. Echistatin, an RGD-containing peptide and a strong inhibitor of bone resorption, inhibits bone resorption in mice with secondary hyperparathyroidism but, surprisingly, no histologic evidence for inactivated osteoclasts has been observed [315]. Echistatin treatment increased the area of osteoclast-covered bone surface; the osteoclasts appeared normal and the proportion of cells containing a ruffled border and a sealing zone was similar to that in controls. The peptide was localized in the basolateral membrane and the intracellular vesicles of actively resorbing osteoclasts, but not in the sealing zone. The number of osteoclasts was increased in the treated mice, which may be explained by a reduced osteoclast efficiency leading to a feedback-driven osteoclast recruitment. Antibodies against $\alpha_v\beta_3$ or RGD-containing peptides cause osteoclast retraction and detachment *in vitro*. However, much higher concentrations of echistatin are required to block osteoclast attachment than to reduce osteoclast activity. This suggests that echistatin inhibits bone resorption by a mechanism other than osteoclast detachment [312].

Searching for a drug that binds to $\alpha_v\beta_3$ integrin-binding sites and inhibits bone resorption, a synthetic chemical peptide mimetic, β-[2-[[5-[(aminoiminomethyl)amino]-1-oxopentyl]amino]-1-oxoethyl]amino-3-pyridinepropanoic acid, bistrifluoroacetate (SC56631) was synthesized. When continuously infused intravenously to ovariectomized rats, it prevented the massive bone loss that normally occurs within 6 weeks after ovariectomy [316].

Integrins play an important role not only in adhesion of osteoclasts to the bone surface, but they are also necessary for the movement of these cells upon it [317]. Since these receptors are also present on the serosal side, solubilized fragments of matrix proteins can bind at this location and activate osteoclasts.

It was demonstrated some years ago that mammalian osteoclasts can resorb mineral containing little or no matrix protein, such as that in egg and oyster shell [306,318]. This shows that matrix proteins are not required for the activation of osteoclasts; however, attachment to a solid surface is an essential step in such activation. This was demonstrated when factors inducing osteoclast polarization were examined [319]. An indication for the polarization of an osteoclast attached to a solid phase is the formation of an actin ring, which consists of closely assembled filamentous actin dots. The actin ring is similar to the sealing zone, which is formed when an osteoclast attaches to the bone surface and resorbs the matrix (see below). When osteoclasts grown in co-cultures of mouse osteoblastic cells and bone marrow cells were placed on plastic, calcified dentin, or calcium phosphate in the presence of fetal calf serum, they formed actin rings. However, when they were placed on demineralized matrix or type I collagen gels, no actin rings were formed. These results indicate that the physical properties of bone, such as its rigidity and hardness, are required to induce the polarization of osteoclasts. The mineral components may also be important in maintaining the polarized state.

The physical properties of bone may also play an important role in the interaction of the sealing zone membrane with the mineralized bone surface. The sealing zone is an organelle-free area of the osteoclast, rich in actin filaments, where the plasma membrane is closely apposed to the bone surface (Fig. 5) [320]. It is essential for bone resorption; it surrounds the ruffled border that defines the area beneath the osteoclast to be resorbed (see below). The membrane proteins of the sealing zone that interact with the bone surface have not been identified to date. $\alpha_v\beta_3$ integrins seem not to be present in the sealing zone, and some other as yet uncharacterized proteins must mediate the interaction of actin with the extracellular portion of the sealing zone. The tight seal may be formed between the plasma membrane and bone mineral and/or mineral-associated proteins that may be liberated from bone during decalcification and, therefore, may not be identified easily [321].

The Process of Bone Resorption

During the process of bone resorption, the osteoclast adheres to the bone surface at the sealing (clear) zone, the special structure that seals off the area to be resorbed. There is a very tight interaction of the plasma membrane with the mineralized matrix, the gap being less than 10 nm. This distance is narrower than any other interaction between cells and matrix [321]. The sealing zone surrounds the so-called ruffled border, an area of intense membrane folding where the process of bone resorption occurs.

Bone is composed of organic and inorganic material. About 90% of the organic material is collagen type I, the remaining 10% being noncollagenous proteins, while the inorganic material is hydroxyapatite, a calcium phosphate salt. During the resorptive process, osteoclasts fulfill the unique task of dissolving the mineral phase of bone with acid. To accomplish this highly specialized role, osteoclasts express an array of enzymes and transport systems (Fig. 22). Carbonic anhydrase II (EC 4.2.1.1) catalyzes the formation of carbonic acid (H_2CO_3) from water and carbon dioxide, which is the end product of the oxidative metabolism that occurs at a high rate in osteoclasts. Carbonic acid spontaneously dissociates to bicarbonate ions (HCO_3^-) and protons (H^+). The protons are subsequently transported through the cell membrane to the bone surface by a proton pump, a vacuolar H^+-ATPase, located in the ruffled border [322–326]. The mineral is dissolved in the acidic environment thereby created in the lacuna beneath the osteoclast. While protons are actively transported through the membrane of the ruffled border, chloride ions are translocated through a Cl^- channel, resulting in the net transport of hydrochloric acid. The bicarbonate ion produced by the dissociation of carbonic acid is eliminated from the cytoplasm via a HCO_3^-/Cl^- exchanger, which replaces the Cl^- secreted into the resorption lacuna [327]. Each of these steps is essential to the overall bone resorption process. This has been demonstrated in experiments in which bone resorption is impaired if the enzyme reactions or transport systems are blocked [326,328].

After dissolution of the mineral, the organic material is exposed and can now be digested by lysosomal enzymes and metalloproteinases secreted by the osteoclasts. Cathepsins (see Chapter 7, this volume) have been demonstrated to be present in osteoclasts and to play an important role in digesting matrix proteins [329,330]. That most abundantly expressed is cathepsin K, originally called cathepsin O [331,332], which is essential for bone resorption to occur. This has been demonstrated in experiments in which cathepsin K antisense oligodeoxynucleotides were found to inhibit the bone resorbing activity of rabbit osteoclasts cultured on dentin slices [333]. In addition, several metalloproteinases have been shown to be present in osteoclasts [334–336]. While the acid pH in the lacuna below the resorbing osteoclast favors the activity of lysosomal enzymes, it has been more difficult to find an explanation as to how the neutral metalloproteinases can participate in the digestion process in the acid environment of the lacuna. Recent data suggest that after dissolution of the mineral, the lysosomal cysteine proteinases first digest part of the organic bone matrix and finally, when the pH has increased, metalloproteinases exert their activity [330].

After having formed a lacuna, the osteoclast probably stops resorbing and migrates to a new site where it starts the process again. Metalloproteinases integrated in the plasma membrane seem to be involved in these migratory and attachment activities [336]. In developing bone, TRAP-positive mononuclear cells migrate from the periosteum into the bone, fuse to form multinucleated osteoclasts, resorb the mineralized matrix, and form the bone marrow cavity. Inhibitors of metalloproteinases prevent the migration of osteoclast precursor cells from the periosteum to the developing marrow cavity of mouse fetal metatarsals in culture, indicating the important role of these enzymes in the migration of osteoclasts and their precursors [337].

Hydrolytic digestion seems not to be the sole mechanism for breaking down bone matrix. Superoxide and other

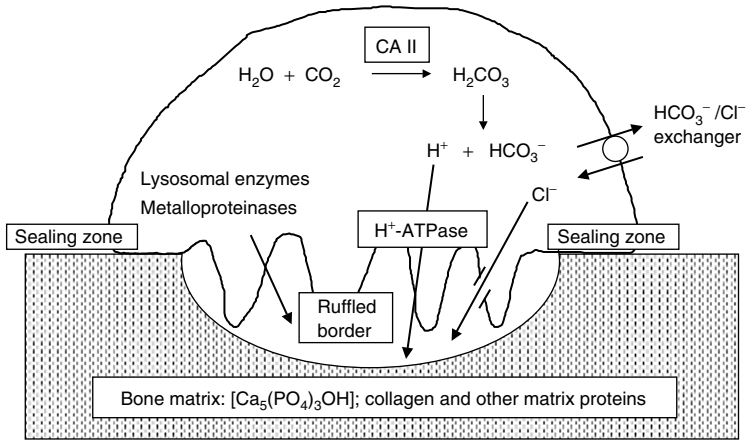

Figure 22. Enzyme reactions and transport systems involved in the bone resorption process. The area of bone below the ruffled border and surrounded by the sealing zone is resorbed and an excavation, a lacuna, is formed. Carbonic anhydrase II (CAII) catalyzes the formation of carbonic acid (H_2CO_3) from water and carbon dioxide, which dissociates into a proton (H^+) and a bicarbonate ion (HCO_3^-). The vacuolar H^+-ATPase transports the proton through the membrane of the ruffled border. Together with the proton, a Cl^--ion migrates through a chloride-channel into the lacuna, resulting in the net transport of hydrochloric acid. In the lacuna, the acid environment generated by the H^+-ATPase dissolves the mineral (hydroxyapatite: $Ca_5(PO_4)_3OH$). The bicarbonate ion produced by the dissociation of carbonic acid is eliminated from the cytoplasm via a HCO_3^-/Cl^-exchanger, replacing the chloride ion secreted into the lacuna.

reactive oxygen molecules produced by activated osteoclasts seem also to participate in the complex process of bone resorption [338]. The enzyme catalyzing the production of superoxide, NADPH-oxidase, has been demonstrated to be expressed in resorbing osteoclasts [339]. Reactive oxygen molecules and ions seem also to stimulate the generation of new osteoclasts [340]. The exact mechanism of these processes is, however, not known.

The lacuna and the ruffled border under the resorbing osteoclast are sealed off by the sealing zone. Consequently, a major question is how is the material released during resorption eliminated. It was earlier suggested that an osteoclast might move on when a certain amount of solubilized material had accumulated in the lacuna. Newer data, however, demonstrate that degraded proteins and inorganic matrix components are transcytosed in vesicles to the membrane of the osteoclast opposite the ruffled border [341,342]. This transcytosis may be more than just a disposal pathway. Bone formation stimulating factors, such as TGF-β, IGF, and BMP, which are incorporated in the matrix and released during resorption, could be translocated by this transport system to neighboring osteoblasts and, as coupling factors, induce bone formation. This may be part of the mechanism coupling bone resorption and bone formation.

Osteopetrosis Due to Mutations in Genes Required for Bone Resorption

Five types of osteopetrosis are known, three in humans and two in the mouse, in which a gene encoding a protein required for bone resorption is mutated, and results in osteopetrosis (Table 1).

The human gene for carbonic anhydrase II (EC 4.2.1.1) was identified as the site of the primary defect in the autosomal recessive syndrome of osteopetrosis with renal tubular acidosis and cerebral calcification (MIM 259730) [343] (see also Chapter 19, this volume).

Nonsense, missense, and stop codon mutations in the gene encoding cathepsin K (EC 3.4.22.38) are the cause of pycnodysostosis (MIM 265800), a rare autosomal recessive osteochondrodysplasia characterized by osteosclerosis and short stature [344]. It seems that due to these mutations, cathepsin K is not synthesized as a stable protein, or that its activity is impaired.

Craniometaphyseal dysplasia is a rare craniotubular bone dysplasia transmitted in both autosomal dominant (MIM 123000) and autosomal recessive (MIM 218400) forms. It is characterized by hyperostosis of the cranial bones and deformities of the metaphyses of the long bones. Investigation of osteoclast-like cells cultured from the bone marrow of a 3-year-old patient suggested that osteoclast dysfunction due to impaired expression of the vacuolar proton pump leads to this disease [345].

A defect in the proton pump is also seen in the osteosclerotic (*oc/oc*) mouse. Osteoclasts from this mouse fail to form ruffled border and resorption pits (lacunae) on dentin [346]. Further studies have indicated that the vacuolar proton pump is present throughout the cytoplasm but not on the apical membranes as in phenotypically normal littermates [347].

Finally, there is the *src*-deficient mouse. Targeted disruption of the *c-src* proto-oncogene has been shown to induce an osteopetrotic disorder [348]. The gene product c-Src is a tyrosine kinase that, in addition to many other functions, participates in the reorganization of the cytoskeleton. It has been identified in the ruffled border of osteoclasts of normal mice [349,350]. Osteoclasts in the *src*-deficient mouse develop normally, but fail to form a ruffled border and do not resorb bone [351]. The c-Src protein seems to play a unique role in the formation of ruffled borders and the bone resorption process that cannot be replaced by other members of the Src-kinase family.

Hormones and Cytokines Which Stimulate Bone Resorption by Acting Directly on Osteoclasts

Interleukin-1, Interleukin-6, and Interleukin-11

Osteoclasts express receptors for IL-1, IL-6, and IL-11. This has been demonstrated by identifying their mRNAs, and for IL-6 also by immunostaining the receptor protein [284,352,353]. The direct effect of IL-11 on mature osteoclasts is not known. As mentioned earlier, IL-1 is a survival factor for osteoclasts. It can also directly activate the bone resorbing activity of osteoclasts in the absence of osteoblasts/stromal cells [261]. IL-6, which is also produced by both osteoblasts and osteoclasts, has been shown to reverse the calcium-induced inhibition of the bone resorbing activity of osteoclasts and to attenuate their calcium sensing. Furthermore, high calcium concentrations enhance IL-6 and IL-6 receptor gene expression and IL-6 secretion. These results suggest that IL-6 production increases when osteoclasts become exposed to an inhibitory calcium level during resorption and that IL-6 sustains resorption, at least in part, by attenuating extracellular calcium sensing [353].

TABLE 1. Osteopetrosis Due to Mutations in Genes Involved in the Bone Resorption Process

Enzyme Reaction Affected[1]	Disease
$CO_2 + H_2O \xrightarrow[\text{anhydrase}]{\text{Carbonic}} H_2CO_3$	Human osteopetrosis with renal tubular acidosis and cerebral calcification
Hydrolysis of proteins by Cathepsin K	Pycnodysostosis: osteochondrodysplasia characterized by osteosclerosis and short stature
H^+-ATPase	Craniometaphyseal dysplasia in humans
H^+-ATPase not associated with apical membrane	Osteosclerotic mouse (*oc*)
No c-Src ⟶ no ruffled borders	Osteopetrotic *c-src* knockout mouse

[1]Mutations in genes encoding enzymes involved in the bone resorption process resulting in osteopetrosis

Insulin-like Growth Factor-1

The expression of IGF-1 receptors on osteoclasts has been demonstrated [299]. In contrast to insulin, IGF-1 stimulates the bone resorbing activity of mature osteoclasts. It also prevents apoptosis of these cells. The stimulatory effect of growth hormone seems to be partly mediated by IGF-1 [354].

Inhibition of Bone Resorption

When bone resorption is greater than bone formation, bone loss and finally bone fracture occurs. Thus, to protect bone against such damage, it seems necessary that inhibitors of bone resorption exist that counteract hormones and cytokines stimulating bone resorption. Native inhibitors (e.g., calcitonin, estrogen) are also applied as drugs in disorders with high bone resorption (e.g., postmenopausal osteoporosis). In addition to native inhibitors, there are synthetically produced drugs like the bisphosphonates, which are potent inhibitors of bone resorption.

Osteoprotegerin

OPG inhibits bone resorption by binding ODF and preventing its association with its receptor, RANK (see Fig. 19 and also previous section). Adolescent and adult mice deficient in OPG exhibit a decrease in total bone density characterized by severe trabecular and cortical bone porosity, marked thinning of the parietal bone of the skull, and a high incidence of fractures [200]. These findings demonstrate that OPG is a critical regulator of postnatal bone mass. Unexpectedly, OPG-deficient mice also exhibit medial calcification of the aorta and renal arteries, suggesting that regulation of OPG, its signaling pathway, or its ligand(s) may play a role in the long observed association between osteoporosis and vascular calcification.

Estrogen

The decrease in estrogen levels that occurs after the menopause causes bone loss through increased bone resorption and may finally result in osteoporosis. Postmenopausal osteoporosis and the effect of estrogens on bone is a major field of research [355] that will be touched on only briefly in this chapter. The main function of estrogens in bone is to regulate the number of osteoclasts and, to a lesser extent, their activity. They stimulate the cell death of osteoclasts as previously mentioned, but, probably more importantly, suppress their formation by inhibiting the synthesis of cytokines IL-1, TNF, and IL-6. The relative importance of these cytokines in mediating the effect of estrogen loss is still unclear, some proposing TNF and IL-6 as crucial factors [355,356], others, IL-1 and TNF [357,358].

Experiments with transgenic mice have demonstrated that IL-1 and TNF play an essential role in mediating the bone loss induced by estrogen deficiency. Transgenic mice unresponsive to IL-1 because of deficient expression of IL-1 type I receptor were shown to be protected against bone loss after ovariectomy (the type II receptor is a "decoy" receptor that has similar extracellular and transmembrane domains to IL-1 type I receptor but lacks critical intracellular elements that are necessary for postreceptor signaling) [359]. The results, demonstrating that IL-1 is an essential mediator of the effect of estrogen deficiency on bone, are particularly convincing because the mice displayed both normal bone mass and normal growth rates. By a similar approach, the essential role of TNF in bone loss due to estrogen deficiency was also demonstrated. Transgenic mice unresponsive to TNF due to soluble TNF-receptor overexpression, are also protected against bone loss induced by ovariectomy [360]. Although the finding that the functional blocking of either IL-1 or TNF is sufficient to prevent estrogen deficiency-induced bone loss may appear difficult to reconcile, it should be emphasized that in most biological systems IL-1 and TNF have synergistic effects.

As far as IL-6 is concerned in mediating the effect of estrogen deficiency on bone loss, it has been reported that transgenic mice deficient in IL-6 are protected from bone loss caused by estrogen depletion [361]. However, whereas these results support the essential role of IL-6, other data do not. Thus, in mice overexpressing IL-6, bone turnover was suppressed and bone resorption and the number of osteoclasts were reduced [362]. Furthermore, in contrast to the situation with TNF-binding protein, neutralizing antibody against IL-6 failed to prevent osteoclastogenesis, an increase in bone resorption, and bone loss induced by ovariectomy in mice [363].

Accordingly, IL-1 and TNF seem to be the important factors in estrogen deficiency. They stimulate the stromal cells in the bone marrow to synthesize CSF-1, IL-6, and IL-11, each of which supports the generation of osteoclasts [190]. IL-1 and TNF are thus regarded as "upstream" cytokines necessary to induce the secretion of "downstream" factors that stimulate hemopoietic osteoclast precursors.

Calcitonin

Osteoclasts express a high number of calcitonin receptors on their surface [226]. In contrast to the indirect effects of hormones that stimulate bone resorption, calcitonin binding to osteoclasts leads to a rapid cessation of osteoclast mobility and bone resorbing activity [364]. The growth of osteoclasts *in vitro* is also reduced by calcitonin given during the whole culture period [231]. When calcitonin is used therapeutically, resistance to the hormone develops rapidly. This phenomenon was originally noted in calcitonin-treated organ cultures and described as "escape" [365]. With the aim of explaining this phenomenon, T.J. Martin and colleagues in Australia have investigated extensively the regulation of osteoclast calcitonin receptor levels. Pretreatment of osteoclasts with calcitonin *in vitro* leads to down-regulation of the receptor and a reduced bone-resorbing capacity [366]. Importantly, treated osteoclasts are 100 times less sensitive to rechallenge with calcitonin. In contrast, dexamethasone increases the number of calcitonin receptors, and pretreatment with this drug lessens somewhat calcitonin-induced down-regulation of the calcitonin receptor [366]. Dexamethasone treatment results in a higher level of calcitonin receptor mRNA as a result of increased transcriptional activity [367]. Calcitonin seems to increase the rate of decay of calcitonin receptor mRNA. It was noted some years ago that calcitonin in combination with glucocorticoids protects against the development of calcitonin resistance in clinical therapy [368]. The above results found in *in vitro* studies seem to provide an explanation for this observation. Finally, when calcitonin is added to bone marrow cultures, even for short periods, developing osteoclast-like cells possess a normal capacity to resorb bone, but the number of calcitonin receptors is reduced and remains low [369,370]. The data suggest that the "escape" phenomenon may result from a prolonged calcitonin-induced loss of calcitonin responsiveness, at least in part due to reduced synthesis of calcitonin receptors and the development of osteoclasts deficient in calcitonin receptors.

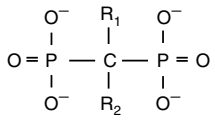

Figure 23. Structure of bisphosphonates: The structure "phosphonate–C–phosphonate" binds with high affinity to mineral. R_1 is generally H or OH and influences binding only slightly. R_2 together with the bisphosphonate structure determines the biological activity of a bisphosphonate, i.e., its potency to inhibit bone resorption.

Bisphosphonates

Bisphosphonates, synthetic compounds with a high affinity for mineral, are used in the management of patients with various disorders affecting the skeleton, including osteoporosis, metastatic bone disease, and Paget's disease of bone [371]. Their specific pharmacological properties include selective uptake at active bone sites, suppression of osteoclast-mediated bone resorption, and long-time skeletal retention.

The structure of a bisphosphonate molecule consists of a C-atom, to which two phosphonate groups and R_1 and R_2 groups are bound (Fig. 23). The structure "phosphonate-C-phosphonate" is the portion of the molecule that binds with high affinity to the mineral [372]. Because of this property, bisphosphonates accumulate in bone and mineralized cartilage, but not in other tissues. The nature of R_2, together with the bisphosphonate group, determines the potency with which bone resorption can be inhibited. When various bisphosphonates have been synthesized, R_1 has not been varied much. It is normally H or OH, and this variation does not much influence the inhibitory activity.

During bone resorption, osteoclasts take up bisphosphonates bound to the bone surface and become inactive [373]. Over the years, the mechanism of inhibition has been elucidated. It was found that bisphosphonates with R_2 containing an amino group inhibit steroid synthesis from mevalonate [374]. However, the significance of this observation was not realized until M.J. Rogers and R.G.G. Russell and their colleagues demonstrated that bisphosphonates containing nitrogen inhibit the mevalonate pathway and prevent post-transcriptional prenylation of GTP-binding proteins [375–377]. Various intracellular proteins involved in signal transduction require prenylation for attachment to the cell membrane and for activation. Inhibition of prenylation disturbs the intracellular regulation of cell function, which finally results in apoptosis [378]. Other bisphosphonates, not containing nitrogen in R_2, are incorporated into adenine nucleotides by aminoacyl-tRNA synthetase enzymes. These products cause both necrotic and apoptotic cell death [379].

Although bisphosphonates, when taken up, disturb the function of every cell, only osteoclasts are the targets of this drug. The reason for this is, as mentioned above, that bisphosphonates accumulate only in bone because of their high affinity for mineral. Any excess is rapidly secreted through the kidney. Furthermore, osteoclasts are the only cells that resorb bone and, therefore, take up bisphosphonates.

While in the mechanism described above, the osteoclast is the target of bisphosphonates, there have been *in vitro* experiments that suggest that bisphosphonates induce osteoblasts to release inhibitory activities that reduce the bone resorbing activity and the formation of osteoclasts [380–384]. The mechanism of this bisphosphonate action on osteoblasts is not known, and up to now there is no indication that bisphosphonate action is mediated *in vivo* by osteoblasts.

Extracellular Calcium

It has been suggested that an increase in local calcium concentrations in the resorption lacunae suppresses osteoclastic bone resorbing activity through an increase in intracellular calcium mediated through a specific receptor. A calcium-sensing receptor has been identified in mature osteoclasts and an increase in extracellular calcium reduces the bone resorbing activity of osteoclasts cultured on bone slices [385,386]. As mentioned above, some data also indicate that high calcium concentrations stimulate the secretion of IL-6, which reduces the calcium-induced inhibition of bone resorption by attenuation of osteoclast calcium-sensing [353]. Such an autocrine-paracrine loop may sustain osteoclastic activity in the face of an inhibitory calcium level generated during resorption.

Insulin

Insulin is known to stimulate bone formation through its effect on osteoblasts. Recently, it was demonstrated that both murine osteoclast-like cells generated *in vitro* and primary osteoclasts isolated from mouse and rat bone express the insulin receptor [387]. Insulin added to osteoclast-like cells cultured on dentin slices inhibited bone resorption. This is consistent with the well-known effect of insulin on bone formation, and together they result in net bone growth.

RECENT DEVELOPMENTS

Bone Formation

W. Hofstetter

Coupling of Bone Formation and Bone Resorption

The paradigm for the maintenance of bone mass states that bone formation and resorption are tightly coupled. In transgenic mouse strains which overexpress the Fos family members Fra-1 [392,393] and ΔFosB [394], respectively, however, an increase in bone formation occurs without a concomitant increase in bone resorption. In both cases, the mice are normal at birth, but over time an increase in bone

formation becomes evident throughout the skeleton and an osteosclerotic phenotype develops.

ΔFosB is a naturally occurring splice variant of FosB. In osteoblasts, ΔFosB is further truncated to the Δ2ΔFosB isoform, which seems to be responsible for the observed bone phenotype [394]. Thus, alternative splicing of *FosB* mRNA during the differentiation stage of osteoblasts may regulate the development and function of these cells. Proteins of the Fos family associate with members of the Jun family of proteins to form the heterodimeric transcription factor AP-1. Most interestingly, FosB and Fra-1 lack a C-terminal transactivation domain [395], suggesting that their transcriptional potential depends on their partners in the heterodimer or on transactivation factors.

In mice overexpressing ΔFosB, the osteosclerotic phenotype is accompanied by a decrease in adipogenesis [394]. Since osteoblasts and adipocytes both derive from the mesenchymal stem cell [396], it was suggested that ΔFosB supports osteogenesis at the expense of adipogenesis [394]. In *Fra1* transgenic mice, however, adipogenesis is not affected, indicating that in these animals the development of cells of the osteogenic lineage is independent of adipogenesis. This suggests a sequential action of ΔFosB and Fra-1 during osteoblast development, rather than an inverse relationship between the two cell lineages with a common bi- or multipotential precursor.

Since the phenotype in the development of adipocytes is seen only in the Δ*FosB*, but not the *Fra1* transgenic mice, a role for adipocyte-derived products in the regulation of bone mass in these animals can be excluded. Leptin is a polypeptide hormone secreted primarily by adipocytes and acts through specific receptors in the hypothalamus. Mice deficient in leptin or its receptor are obese and have a high bone mass phenotype, which is resolved by the infusion of leptin into normal or receptor-deficient mice, supporting the concept of a central regulation of bone mass through the activation of a hypothalamic relay [397].

Effect of Estrogen on Bone Cells

Estrogen deficiency exerts profound effects on the hematopoietic microenvironment, stimulating lymphocytes, amongst other cells, to express osteoclastogenic cytokines [398]. It has now been shown that osteoblastic cells require estrogen for survival, demonstrating that it also has a direct effect on bone formation [399]. This effect is not mediated at the genetic level, but involves the sequential activation of a signal transduction cascade involving Src/Shc/ERK [400,401]. It is noteworthy that estrogen as well as androgens exerts its effects through ERα and ERβ, as well as through the androgen receptor, demonstrating a striking promiscuity of the receptors in their choice of ligands [399].

Chondrocytes Regulate the Migration of Osteoclasts into Developing Bone Rudiments

Recent findings suggest that hypertrophic chondrocytes in developing long bones induce osteoclasts to invade mineralized cartilage by producing the chemotactically active vascular endothelial cell growth factor (VEGF) [402]. Blocking VEGF activity with chimeric anti-VEGF antibodies caused a suppression of blood vessel invasion, concomitant with impaired trabecular bone formation and an expansion of the zone of hypertrophic chondrocytes in experimental animals [403]. VEGF is liberated from cartilage matrix by the action of gelatinase B/matrix metalloproteinase-9 (MMP-9) [404]. Consequently, MMP-9 deficiency delays osteoclast invasion, possibly due to impaired function of VEGF [405].

The Role of Cbfa1 in the Development and Function of Skeletal Cells

Chung et al. have demonstrated that Ihh not only regulates chondrocyte development, but also defines the sites of initial bone formation. Using chimeric mice containing both wild type and $Ihh^{-/-}$ cells, induction of a bone collar was observed in the perichondrium of wild type prehypertrophic and hypertrophic chondrocytes, but not in the vicinity of $Ihh^{-/-}$ prehypertrophic and hypertrophic chondrocytes in developing long bones [406]. This data supports previous results suggesting that cartilage development and bone formation are coupled through the action of Ihh. Analysis of $Ihh^{-/-}$ mice demonstrated a failure in the development of osteoblasts in endochondral bones due to a deficiency in Cbfa1 induction in the perichondrium of bone rudiments [407]. The fact that vascular invasion is blocked in $Ihh^{-/-}$ mice provides additional evidence that this process is induced by cartilage cells producing specific growth factors. The aforementioned production of VEGF by hypertrophic chondrocytes is critical for triggering vascularization and invasion of osteoclasts into the mineralized cartilage rudiment [402]. In the absence of chondrocyte differentiation, the cells will not synthesize VEGF and, as a consequence, the mineralized cartilage will not be vascularized and resorbed.

Further study of *Cbfa1* knockout mice has revealed that not only is bone tissue not formed, but that the development of chondrocytes is impaired as well. Calcification of cartilage occurs in $Cbfa1^{-/-}$ mice in the distal limbs, where Ihh is expressed in the hypertrophic chondrocytes, but in femur and humerus, however, chondrocyte differentiation is blocked before the onset of hypertrophy and Ihh is not expressed [408]. In animal models in which Cbfa1 is constitutively overexpressed in cartilaginous tissues, accelerated endochondral calcification due to precocious chondrocyte maturation is observed [409,410]. In $Cbfa1^{-/-}$ mice, targeting Cbfa1 expression to chondrocytes restored hypertrophy and vascularization of cartilage rudiments. Although no osteoblasts develop in such animals, vessels and multinucleated, tartrate-resistant acid phosphatase (TRAP)-positive osteoclasts are found within mineralized cartilage [409], further confirming the role of chondrocytes in regulating vascularization and invasion by osteoclasts. An additional piece of evidence for the role of Cbfa transcription factors in chondrocyte development has been provided by the demonstration that expression of the metalloproteinase MMP-13, which solubilizes unmineralized cartilage upon stimulation by MMP-9, is directly affected by a cooperative function of Cbfa/Runt proteins with the transcription factor complex AP-1 [411].

Bone Resorption

R. Felix

RANK, RANKL and OPG

A standard nomenclature for new tumor necrosis factor family members involved in the regulation of bone resorption has been recommended [412]. The following names were selected from the various acronyms: RANK for the receptor, making obsolete ODAR and TNFRSF-11; RANKL for the ligand, making obsolete ODF, OPGL, TRANCE, SOFA and TNFSF-11; and OPG for the decoy receptor, making obsolete OCIF, TR-1, FDCR-1 and TNFRSF-11B.

A number of reports have described the effects of hormones and cytokines on the mRNA and protein levels of RANKL and OPG *in vitro* [413, 414], and indicate that the number of osteoclasts is regulated by the ratio of RANKL to OPG. This has been confirmed *in vitro* by the correlation that exists between bone remodelling indices in normal human cancellous bone and this ratio, although this is not the case in osteoarthritis [415].

CSF-1 has been found to stimulate the expression of RANK in c-Fms$^+$ early-stage precursor cells; IL-3 and GM-CSF are less effective [421]. The timing of RANK expression and the subsequent binding of RANKL are critical for osteoclastogenesis. Fully differentiated macrophages have lost the potential to form osteoclasts. TNF, as well as RANKL, have been shown to upregulate RANK expression in precursor cells [417].

Using reverse transcriptase–polymerase chain reaction (RT-PCR), three RANKL isoforms have been identified [418], each of which when transfected into NIH 3T3 cells is translated. Bone marrow stromal cells and the osteoblastic cell line ST2 express the originally described membrane-bound RANKL (RANKL1) and the soluble RANKL3. This would suggest that cell-cell contact is not required for the stimulation of osteoclasts and their precursor cells by osteoblasts. Lymphocytes express all three isoforms, the pattern being dependent on the type of lymphocyte. Membrane-bound RANKL seems also to be released by proteolytic cleavage, and two shedding activities distinct from the TNFα convertase have been characterized [419].

TNFα Acts on Osteoclast Formation Similarly to RANKL

TNFα can replace RANKL as a factor necessary for the differentiation of osteoclasts [420, 421], supporting their formation in two ways: in combination with RANKL, it synergistically up-regulates RANK [417] thereby stimulating osteoclastogenesis at permissive levels of RANKL [422], and it also seems to induce differentiation to mature osteoclasts in the absence of RANKL. Since the signaling pathways of RANKL and TNFα overlap, it is not surprising that both factors support osteoclastogenesis [417, 423]. However, in contrast to RANKL [424], TNF-α does not directly activate the bone resorbing activity of mature osteoclasts [420, 421]. Although osteoclast precursor cells express TNF receptors 1 (p55r) and 2 (p75r), TNFα-induced osteoclastogenesis seems mainly dependent on p55r and soluble TNFα [425]. An important role of TNF in bone resorption induced by inflammation and the possibility that it may be the main mediator of periprosthetic osteolysis is suggested [426].

RANKL-Induced Intracellular Signalling

RANKL induces the survival, formation and activation of osteoclasts by activating the transcription factor NF-κB, JNK (cJun N-terminal kinase) and p38 mitogen activated (MAP) kinase. TNFα, IL-1 and LPS (lipopolysaccharide) seem to affect osteoclasts and their precursors also via these signaling proteins [417,423,427–429]. Activation of the p38 MAP kinase, JNK and finally the transcription factor AP-1 play an important role in RANKL and TNFα-induced osteoclast differentiation from precursor cells [423,429,430]. NF-κB seems to be important for the induction of the bone resorbing activity of osteoclasts [431], but is also activated during osteoclast formation [432]. Finally, RANKL activates protein kinase B (Akt/PKB) via c-Src and PI 3-K (phosphoinositide 3-kinase) and thus supports the survival of osteoclasts, and may also activate NF-κB and affect cytoskeletal reorganization by this pathway [433,434]. In contrast to RANKL, CSF-1 required for the formation and survival of osteoclasts activates the MAP kinase p42/44-ERKs (extracellular signal-regulated kinase) [429,431].

Effect of Immune Cells

Recent data have drawn attention to the importance of lymphocytes in regulating the formation and activity of osteoclasts and their precursors. Immune response often results in tissue destruction, especially in enhanced osteoclastic bone resorption. In a T-cell dependent model of rat adjuvant arthritis characterized by severe joint inflammation, bone and cartilage destruction is induced by T-cell derived RANKL [435]. Additionally, IL-1 and TNF-α, cytokines typically produced in inflammatory conditions, increase bone marrow stromal cell production of IL-7 [436]. This factor upregulates the production of osteoclastogenic cytokines by T cells that are different from CSF-1 and RANKL, as antibodies against these latter factors do not or only partially inhibit the formation of osteoclasts [437]. Immune cells have also been demonstrated to inhibit the formation of osteoclasts. Depletion of CD4 and CD8 T lymphocytes (nonactivated cells) in mice *in vivo* enhanced the formation of osteoclasts in cultured bone marrow treated with $1,25(OH)_2D_3$ [438]. This stimulation was dependent on prostaglandin synthesis, suggesting that nonactivated lymphocytes produce factors that inhibit prostaglandin synthesis or that lymphocyte depletion affects the type of stromal cell that populates the bone marrow. Furthermore, mature B lymphocytes inhibit osteoclast formation in peripheral blood stem cell cultures, a system that generates

functional osteoclasts in the absence of stromal cells, through the production of TGF-β [439].

TGF-β Supports Osteoclast Formation

The stimulation of osteoclast formation by TGF-β in the presence of CSF-1 and RANKL has been reported [440–442]. The cytokine seems to prevent the final differentiation of macrophages to the mature cell type and hence prolongs the period during which osteoclast development is possible. Since TGF-β is incorporated in the bone matrix, its release during bone resorption may enhance the osteoclast-forming potential of precursors as they migrate towards sites of cell-bound RANKL. This migration is probably controlled by CSF-1 and TGF-β both acting chemotactically on osteoclasts [443–445]. TGF-β may stimulate osteoclasts directly, but inhibit them indirectly by inducing the production of OPG by bone marrow stromal cells [446]. The generation of osteoclasts from human peripheral blood mononuclear cells in the presence of CSF-1 and RANKL suggests an even more complicated action of TGF-β. It abrogates the suppressive effect of non-adherent lymphocytes, and its effect on osteoclastogenesis seems to be determined by the cytokine milieu of the microenvironment and the state of activation by TGF-β of the target cell [447].

Stimulators of Bone Resorption

Vascular endothelial growth factor (VEGF). In aged *op/op* mice, the numbers of osteoclasts and macrophages increase and the bone marrow cavity expands, resulting in resolution of the osteopetrosis. The mechanism of this recovery has been investigated. A single injection of recombinant human VEGF into *op/op* mice induced osteoclast recruitment similar to that induced by CSF-1, demonstrating that VEGF and CSF-1 have an overlapping function in the support of osteoclastogenesis [448]. Endogenously produced VEGF may be responsible for the age-related resolution of osteopetrosis in *op/op* mice. VEGF is also essential for osteoclast recruitment into developing long bones [449]. The receptor for VEGF (Flt-1) has been identified as a surface marker as well as a functional molecule for the monocyte-macrophage lineage in humans [450].

GM-CSF and IL-3. IL-3 and GM-CSF are also suggested to induce osteoclast formation in aged *op/op* mice. Serum concentrations of each are elevated in these animals, and their injection into both young and aged *op/op* mice expands the bone marrow cavity [451].

Fibroblast growth factor. Fibroblast growth factor (FGF) receptors 1 and 4 have been detected in isolated mouse osteoclasts. FGF-2 stimulates directly, and indirectly mediated by osteoblasts, the bone resorbing activity of rabbit and mouse osteoclasts *in vitro* [452].

Chemokines. Macrophage inflammatory protein 1-α (MIP 1-α) induces osteoclast formation from human bone marrow cells cultured in medium containing 20% horse serum [453]. This chemokine enhances PTHrP-, IL-6- and RANKL-induced osteoclast formation and appears to act directly on human osteoclast precursors and to stimulate independently of RANKL in the later stages of osteoclast differentiation [454].

ADAM8. ADAM8, a member of the ADAM (a disintegrin and metalloproteinase) family of proteinases, has been identified in a murine osteoclast precursor cell line, and found to increase both the formation of osteoclasts when present in the second half of the culture period, and the activity of osteoclasts cultured on dentine slices [455].

Prostaglandins. Prostaglandins stimulate bone resorption indirectly, activating the synthesis of RANKL by osteoblasts via a cyclic AMP-dependent mechanism. Recent data suggest that prostaglandin receptors E4 and, to a certain extent, E2, respond to prostaglandin E_2 and induce bone resorption [456–458].

Extracellular matrix proteins. Investigations into the differentiation of osteoclast precursor cells in nonadherent and adherent systems point to a two stage process, in which precursor cells are initially bipotential and capable of anchorage-independent growth, the further proliferation and differentiation of osteoclast-committed precursor cells subsequently becoming anchorage-dependent, differentiation being enforced by the activation of $\alpha_v\beta_3$ integrins [459]. Matrix proteins, including vitronectin, osteopontin and bone sialoprotein, bind to $\alpha_v\beta_3$ integrins resulting in the activation of signaling pathways, including PI 3-K, c-Src, protein tyrosine kinase 2 (PYK2), a major adhesion-dependent tyrosine kinase in osteoclasts, and Crk-associated substrate (Cas). Various results suggest that activation of these pathways plays a role in linking the adhesion of osteoclasts to the bone matrix with their cytoskeletal organization and polarization and activation for bone resorption [460]. CSF-1 induces the spreading and migration of osteoclasts, and the signals induced by either adhesion or CSF-1 have been investigated and compared [461]. While c-Src is involved in the activation of prefusion osteoclasts by matrix proteins, CSF-1-initiated signaling modulates the $\alpha_v\beta_3$ integrin-mediated cytoskeletal reorganization in these cells in the absence of c-Src. This is different from the situation in mature osteoclasts grown in culture where CSF-1-induced spreading has been found to be c-Src dependent [443,462].

Osteopontin. Osteopontin exists both as an immobilized extracellular matrix protein and as a cytokine in body fluids regulating inflammation, tissue remodeling and cell survival [463]. Studies with osteopontin-deficient animals indicate that it is required for bone resorption. In organ culture, bone resorption was impaired in osteopontin-deficient bones stimulated by PTH or RANKL, and the development of osteoclasts was also reduced [464]. Ectopic bone implantation experiments have demonstrated that osteopontin facilitates angiogenesis, the accumulation of osteoclasts, and bone resorption [465]. Further, the enhancement of osteoclastic bone resorption and the suppression of osteoblastic bone formation in response to reduced mechanical stress does not occur in bone of osteopontin-negative mice [466]. Mechanical stress itself seems to increase the expression of osteopontin since oscillatory fluid flow increased osteopontin mRNA levels in the MC3T3-E1 osteoblastic cell line [467]. Finally, osteopontin-deficient mice are resistant to ovariectomy-induced bone resorption [468].

Collagenase induced in mesenchymal cells is important in bone resorption. PTH-induced bone resorption in collagenase-resistant mutant mice is diminished, proving the importance of osteoblastic collagenase in bone resorption [469].

Microvascular endothelial cells regulate osteoclastogenesis induced by inflammatory cytokines. Vascular endothelial cells, known to be intimately associated with osteoclasts both during their formation and during the resorption of bone, have now been demonstrated to express RANKL and OPG,

and the inflammatory cytokines TNFα and IL-1, although not PTH and $1,25(OH)_2D_3$, to regulate this expression [470]. Therefore, cytokine-activated vascular endothelial cells may contribute to inflammatory bone loss via the regulated production of RANKL and OPG. The latter may also serve as an autocrine signal to inhibit blood vessel calcification. It has also been reported that osteoclast precursor cells adhere to endothelial cells that have been treated with TNFα and IL-1 [471]. This is the first step before precursor cells leave the blood, cross the endothelial cell layer and migrate to the bone surface.

Inhibitors of Bone Resorption

Osteoprotegerin. A potential therapeutic role for OPG has been suggested in diseases with enhanced bone resorption. A single adenoviral gene transfer to sham and ovariectomized mice produced a persistently high-level of OPG expression and protected ovariectomized mice from bone loss [472]. In a murine model of humoral hypercalcemia of malignancy, osteoprotegerin prevented and reversed hypercalcemia and reduced osteoclast activity [473]. Most interestingly, OPG decreased the skeletal tumor burden in a mouse model of experimental bone metastasis [474], and in a prostate tumor model, prevented the establishment of mixed osteolytic/osteoclastic tibial tumors [475]. In neither model did it have any effect on the metastatic tumor burden in soft tissue organs. Inhibitors of bone resorption thus appear promising as tools for the management of skeletal metastases, especially if they can be introduced early in cancer therapy [476]. In postmenopausal women, a single, well tolerated, subcutaneous dose of 3 mg OPG per kg body weight decreased urinary levels of collagen I N-telopeptide, a marker for bone resorption (see Appendix II, this volume), by 80% and 14%, respectively, 4 days and 6 weeks after dosing [477]. Bone-specific alkaline phosphatase, a marker for bone formation, did not change for 3 weeks after dosing. The results indicate that OPG acts primarily on osteoclasts, and suggests that OPG may be effective in the treatment of diseases with increased bone resorption such as osteoporosis.

Estrogen. Using mouse models, progress in understanding the mechanism of estrogen action has been made [478]. While it was previously assumed that the inhibition of bone resorption by estrogen was mediated by bone marrow stromal cells and macrophages, new findings indicate that it acts also on immune cells. Thus, estrogen inhibits the proliferation of TNF-producing T-cells [479]. Estrogen deficiency results in increased numbers of pre-B cells in bone marrow, as well as in the production of prostaglandin E_2 which induces the expression of RANKL on pre-B cells, leading to accelerated osteoclastogenesis [480]. It also acts directly on osteoclast precursors by down-regulating RANKL-induced JNK activation [481-483]. Estrogen seems also to exert bone-protective effects by selective modulation of IL-1 receptor levels in osteoclasts, thereby reducing their IL-1 responses and cell survival [484]. Estrogen apears to be the dominant sex steroid regulating bone resorption in normal elderly men, while both it and testosterone are important in maintaining bone formation [485].

Interferon-γ. Interferon has long been known to inhibit bone resorption, and it has now been found to interfere with the RANKL-RANK signaling pathway by inducing rapid degradation of the RANK adaptor protein, TRAF (TNF receptor-associated factor) 6, thereby inhibiting activation of the transcription factor NF-κB and JNK [486,487].

Peroxisome proliferator-activated receptor-γ and IL-4. Activation of the nuclear receptor and transcription factor PPAR-γ (peroxisome proliferator-activated receptor-γ) pathway inhibits osteoclast differentiation [488,489]. The suppression of osteoclast formation by IL-4 seems, at least partially, to occur via activation of PPAR-γ1. In addition, IL-4 abrogates osteoclastogenesis via STAT 6 (signal transducer and activator of transcription 6)-dependent inhibiton of NF-κB. In $STAT^{-/-}$ mice, IL-4 failed to block osteoclastogenesis [490].

Osteoclast inhibitory lectin. A 207 amino acid residue type II transmembrane C-type lectin expressed in osteoblasts, chondrocytes, and a variety of extracellular tissues, has been cloned, and demonstrated to inhibit the formation of osteoclasts *in vitro* [491].

Osteopetrosis

Infantile Malignant Osteopetrosis

In several patients with a diagnosis of infantile malignant autosomal recessive osteopetrosis (MIM 259700) (see also Chapter 19, this volume), mutations have been found in *TCRG1*, which encodes the osteoclast-specific 116 kDa subunit of the vacuolar proton pump [492]. Mice lacking *Atp6i*, which encodes a putative osteoclast-specific proton pump subunit of 116 kDa, are also osteopetrotic [493], and osteoclasts within these mice have lost the function of extracellular acidification, although intracellular lysosomal proton pump activity is not impaired. In the osteosclerotic (*oc/oc*) mouse, a deletion in the gene encoding the 116 kDa subunit of the vacuolar proton pump has also been found [494]. All of this demonstrates that this particular gene is necessary for osteoclast-mediated extracellular acidification, and that its mutation is a cause of malignant osteopetrosis in man.

Pycnodysostosis, Microphthalmic $Mitf^{mi/mi}$ Mutant Mice and Cathepsin K Null Mice

A phenotypic similarity between microphthalmic $Mitf^{mi/mi}$ mutant mice, cathepsin K null mice, and the human disease pycnodysostosis has been observed. Mitf is a member of a helix-loop-helix transcription factor subfamily which contains the potential dimerization partners TFE3, TEFB, and TFEC. Cathepsin K has now been identified as a transcription factor target of Mitf and TFE3 via three consensus elements in the cathepsin K promoter [495], explaining the similarities between the phenotypes caused by cathepsin K and Mitf mutations.

Glanzmann Mutation in β_3 Integrin Specifically Impairs Osteoclast Function

Mice lacking β_3 integrin are osteosclerotic because of dysfunctional osteoclasts [496]. To identify the components of the β_3 cytoplasmic domain regulating osteoclast function, six point mutations known to affect integrin β_3 signaling, have been generated. Only one, a Ser752Pro substitution, which also characterizes a form of the human bleeding disorder Glanzmann thrombasthenia (MIM 273800), failed to rescue $\beta_3^{-/-}$osteoclasts or restore ligand-activated signaling [497]. This suggests that the bone mass in patients with Glanzmann thrombasthenia may be increased.

Chapter 1, Part IV

Morphology and Chemical Composition of Connective Tissue: The Cardiovascular System

Daniela Quaglino and Ivonne Pasquali Ronchetti

Department of Biomedical Sciences — General Pathology, University of Modena and Reggio Emilia, Modena, Italy

INTRODUCTION

The cardiovascular system allows the transport of blood and lymph through the tissues. The central motor of the entire system is represented by the heart, which functions to pump blood through the vascular system to the most distal parts of the body, ensuring its return to the heart, and indirectly regulating the correct distribution of lymph from the peripheral tissues back to the vascular network [1]. After being distributed through the tissues, blood returns to the right atrium of the heart through the superior and inferior venae cavae and passes into the right ventricle from where, via the pulmonary arteries, it is pumped to the lungs (Fig. 1). Here blood is oxygenated and becomes ready to reenter the heart in the left atrium being transported by the pulmonary veins. Finally, it passes into the left ventricle, enters the aorta, and is distributed in the systemic circulation [2].

The continuous activity of the heart is assured by the presence of specialized myocardial fibers that are responsible for the maintenance of the cardiac rhythm and for the contraction of atria and ventricles without any direct role for the nervous system. In fact, innervation by the autonomic nervous system does not initiate cardiac muscle contraction, but exerts a regulatory role according to body needs. Thus, impulses are generated in the sinoatrial node and transmitted through the atrial wall to the atrioventricular node, the atrioventricular bundle, and the Purkinje fibers. The nodes and the atrioventricular bundles are small cardiac muscle cells, whereas Purkinje fibers are large modified myocardial cells allowing a faster conduction of impulses.

Cells, nutrients, growth factors, and oxygen are transported through the vascular system to all tissues in response to local and/or systemic factors; reduced oxygen level, for

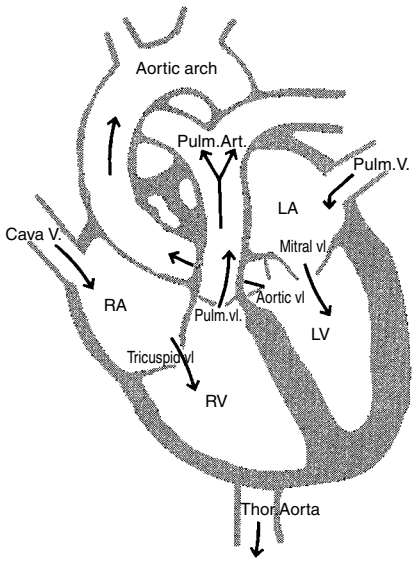

Figure 1. Drawing of the heart chambers (RA, right atrium; LA, left atrium; RV, right ventricle; LV, left ventricle) and valves (tricuspid vl., mitral vl., aortic vl., and pulmonary vl.) with main vessel insertions (aortic arch, thoracic aorta, vena cava, pulmonary artery and veins). Arrows indicate the direction of blood flow in and out of the heart.

Abbreviations used: β-MHC, β-myosin heavy chain; ACE, angiotensin I-converting enzyme; ANF, atrial natriuretic factor; ANP, atrial natriuretic peptide; bFGF, basic fibroblast growth factor, CAM, cell adhesion molecule; C-CAM, cell-cell adhesion molecule; CEA, carcinoembryonic antigen; CRP, complement regulatory proteins; CTGF, connective tissue growth factor; EGF, epidermal growth factor; ELAM-1, endothelial leukocyte adhesion molecule-1; FBN-1, fibrillin-1; GAGs, glycosaminoglycans; ICAM-1, intercellular adhesion molecule-1; IFN-γ, interferon-γ; IGF-1, insulin-like growth factor-1; IL-1, interleukin-1; LDL, low density lipoproteins; LPS, lipopolysaccharide; MAG, myelin-associated glycoprotein; MAGP, microfibril-associated glycoprotein; MAP-kinase, mitogen activated protein kinase; MEF2, myocyte enhancer factor-2; MMP-2, matrix metalloproteinase-2; NADPH, nicotinamide adenine dinucleotide phosphate; N-CAM, neural-cell adhesion molecule; NO, nitric oxide; NOS, nitric oxide synthase; PDGF, platelet-derived growth factor; PDGF-rβ, platelet derived growth factor-receptorβ; PECAM, platelet-endothelial cell adhesion molecule; PF-4, platelet factor-4; RGD, arginine-glycine-aspartate; SkA, skeletal α-actin; TGF-β, transforming growth factor-β; TIMP, tissue inhibitor of metalloproteinases; TNF-α, tumor necrosis factor-α; VCAM-1, vascular cell adhesion molecule-1; VE-cadherin, vascular endothelial-cadherin; VEGF, vascular endothelial growth factor.

Connective Tissue and Its Heritable Disorders, pages 121–144

instance, causes a relaxation of arterial smooth muscle cells and increased blood flow, whereas the secretion of norepinephrine exerts the opposite effect. Although there are many systems regulating traffic between blood vessels and the extracellular milieu, capillaries, due to their permeability, are mostly responsible for exchanges of cells and molecules to and from tissues.

STRUCTURAL ORGANIZATION

Heart

In a normal adult, the heart is about 98 mm wide, 107 mm long, and 52 mm thick; however, dimensions differ depending on thoracic conformation and exercise. Similarly, its weight depends greatly on height and development of the muscle mass and varies from about 21 g at birth to 300–350 g in adulthood, with a decrease in the ratio of heart weight to body weight from 6×10^{-3} at birth to 4.5×10^{-3} in adulthood.

The heart is covered by a thin layer of dense connective tissue called pericardium that is in close continuity with the external layer of the major vessels arising from the heart. It is a muscular organ divided into four cavities (Figs. 1 and 2): two atria and two ventricles that are organized into the following three layers:

- The epicardium represents the outer surface of the organ and is mainly comprised of mesenchymal cells and scarce collagen fibrils.
- The myocardium is the major constituent of the organ, and is composed of myocytes that are organized into a thicker layer in the ventricles compared with the atria.
- The endocardium, the inner surface of the heart, is 50–500 μm thick depending on the area, being more pronounced in the atria than the ventricula; its inner surface is covered by an endothelium that lies on the tunica propria, which is rich in elastic fibers, and it consists of smooth muscle cells, collagen fibrils, and proteoglycans. The impulse-conducting system of the heart is located in the deep region of the endocardium.

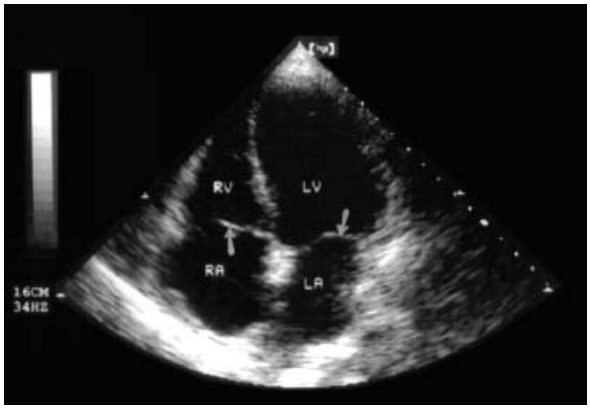

Figure 2. An apical ''4-chamber'' view from a normal adult by two-dimensional echocardiography. Leaflets of the tricuspid and mitral valves (arrows) are seen between the right atrium and ventricle (RA and RV) and between the left atrium and ventricle (LA and LV), respectively. (Figure courtesy of L.Targa, MD, Division of Cardiology, Este Hospital, Padova, Italy.)

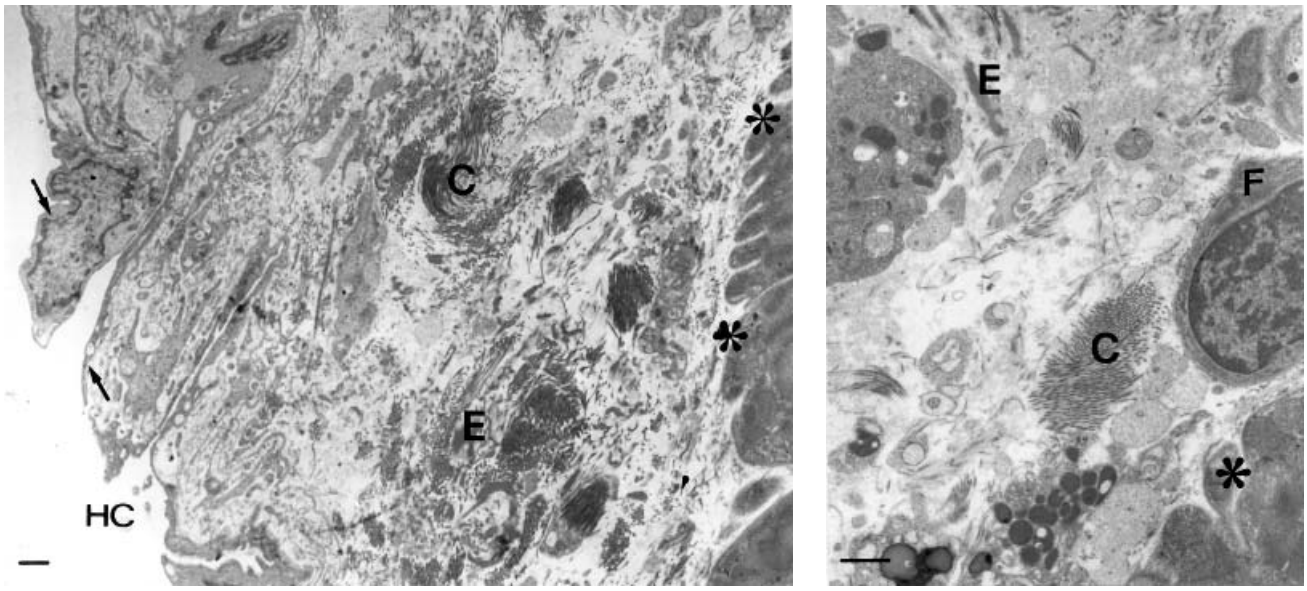
Although extracellular matrix molecules are present in the endocardial layer and in the interstitial spaces between myocytes (Fig. 3), the major sites of deposition of cardiac



a b

Figure 3. Electron micrographs showing the organization of the extracellular matrix in the endocardium **a** and myocardium **b** of an adult heart. The endocardium consists of a layer of loose connective tissue, 50–500 μm thick, separated from the heart cavity (HC) by endocardial cells (arrows) and extending to the contractile myocytes (asterisks). It is formed by collagen bundles (C) and small elastic fibers (E) scattered among hydrated proteoglycans and glycoproteins. The connective tissue within the myocardium (b) (asterisks) contains very small collagen bundles (C) and elastic fibers (E) together with scarce fibroblasts (F). Bars: 1 μm

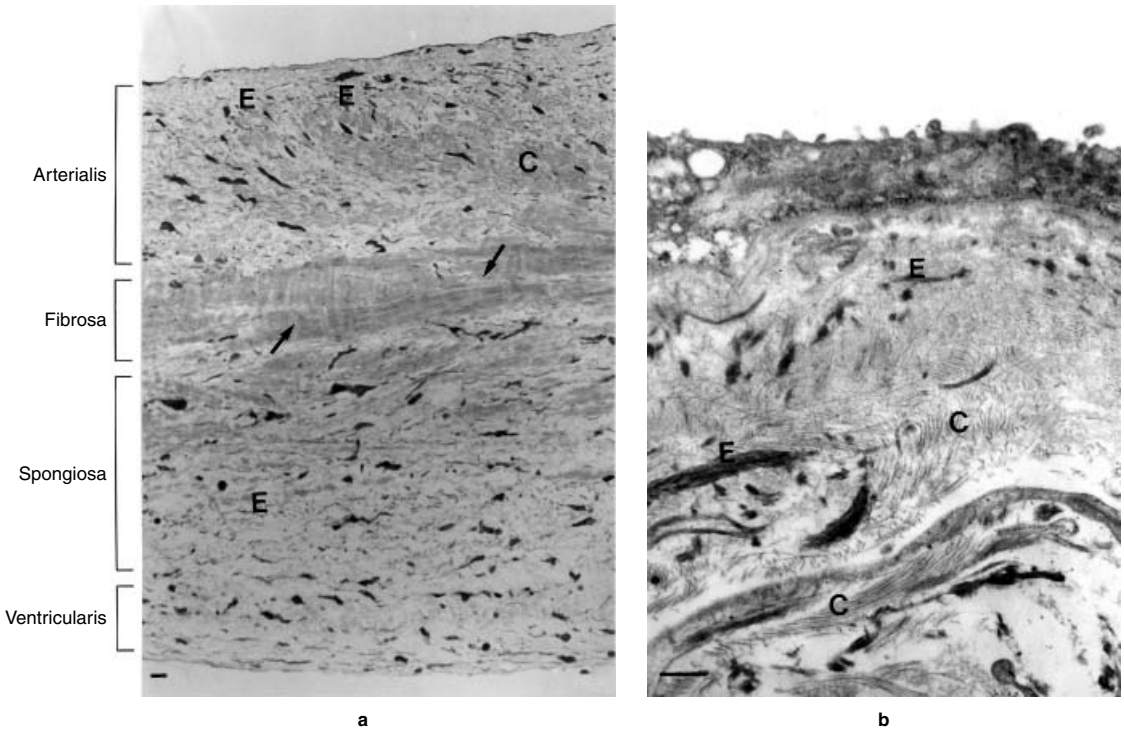


Figure 4. Light **a** and electron **b** micrographs showing a portion of the aortic valve. The different organization of the extracellular matrix can be appreciated in the different areas (arterialis, fibrosa, spongiosa, and ventricularis) of the valve wall. In particular, the free surfaces of the valve are covered by endothelial cells (a, top and bottom). The arterialis consists of loose connective tissue containing scarce cells, collagen fibrils (C) and elastic fibers (E) immersed in an hydrated matrix, as can be appreciated by electron microscopy (b). The fibrosa is characterized by compact collagen bundles (arrows), whereas the spongiosa is highly hydrated with few cells, small collagen bundles and some elastic fibers (E) that are present in the thin ventricularis. Bars: a) 10 μm; b) 1 μm.

connective tissue are at the insertions of the aorta and pulmonary artery, and continue in the atrioventricular rings, forming a network for the attachment of the valves. The cuspid valves located between the atria and the ventricles and the semilunar valves of the aorta and pulmonary artery assure the unidirectionality of blood flow. These valves are covered on both surfaces with endothelial cells, beneath which a few layers of connective tissue are present (Fig. 4). The aortic valve, for instance, is characterized by areas of different composition and function, called arterialis, fibrosa, spongiosa, and ventricularis [3]. The arterialis is comprised of small and spread collagen bundles and elastic fibers similar to those of the arterial intima. The fibrosa has a dense extracellular matrix, whereas the spongiosa has few cells immersed in a loose extracellular matrix, mainly comprised of glycosaminoglycans, especially dermatan and chondroitin sulfates. The ventricularis is a thin layer made of collagen bundles and contains more elastic fibers than other areas. The adult human aortic valve cusps comprise about 10–15% of elastin and 45–55% of collagen (dry weight ratio), mainly collagen type I, even though small amounts of collagen type III can also be measured [3].

Blood Vessels

The blood vessels represent a complex network that can be divided into several categories according to function (pulmonary and systemic circulation), structure (arteries, veins, and capillaries), or size (small, medium, and large). Generally speaking, the walls of arteries and veins are comprised of a tunica intima, tunica media, and adventitia [4] (Fig. 5 and Table 1).

The tunica intima consists of a single layer of flat and elongated endothelial cells underlined by a thin space made of loose connective tissue and limited, in human arteries, by the internal elastic lamina. Endothelial cells exhibit their long axis parallel to blood flow and are connected one to the other by tight and gap junctions in order to strictly regulate the exit of blood cells and diffusion of nutrients from the blood stream. The most efficient system allowing the transport of nutrients through endothelial cells is via pinocytotic vesicles. Endothelial cells may present Weibel-Palade bodies, rod-like cytoplasmic inclusions exhibiting an electron dense structure and containing coagulation factor VIII.

The tunica media is characterized by layers of smooth muscle cells, with their long axes concentric to the lumen, which are responsible for the production of the extracellular molecules in which they are situated. Smooth muscle cells are surrounded by a basal lamina, except where they are connected to one another by gap junctions and where they make close contacts with elastic fibers (Fig. 6). Among the cells, collagen bundles and proteoglycans can be seen; concentric elastic lamellae alternating with smooth muscle cells are present in the arteries and their number is highly variable according to the functional role of the vessel, being more numerous in the ascending aorta and decreasing proportionally to the reduction of blood pressure in the abdominal aorta. The number of lamellae in the aortic arch varies from 10 to 13 in the rat and from 40 to 70 in

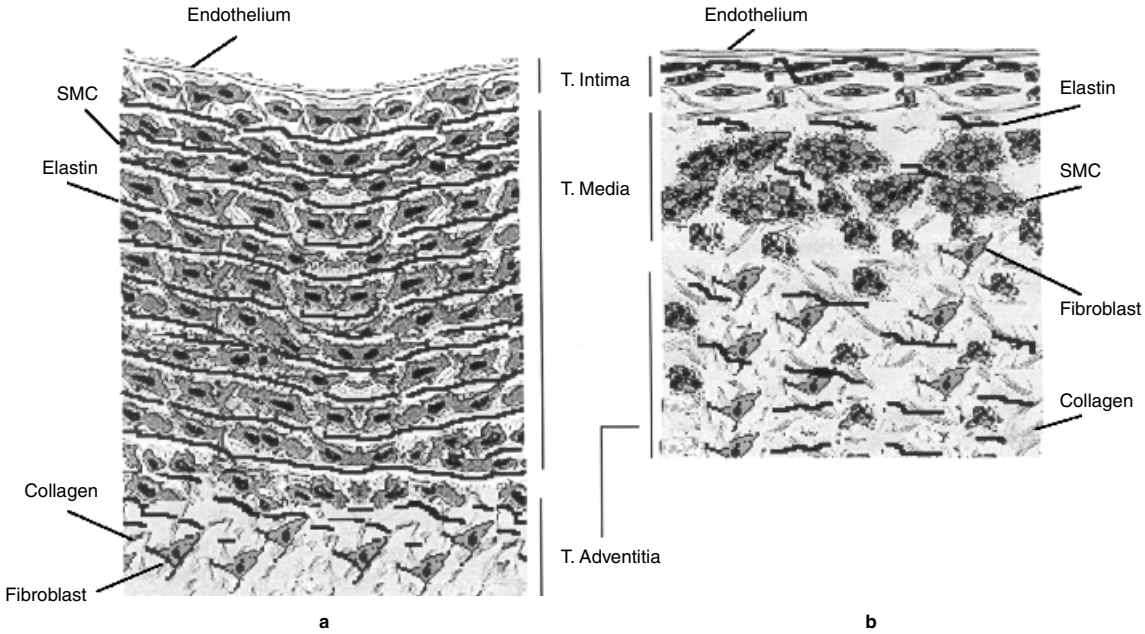

Figure 5. Schematic views of the organization of arteries **a** and veins **b**. The lumen of all vessels is covered by endothelial cells that lie on a basement membrane. The tunica intima is very thin at birth and tends to become thicker with age in arteries. Arteries and veins have different organization of the tunica media as far as thickness and composition are concerned, this being thick and mostly formed by elastin and smooth muscle cells (SMC) in arteries, and rather thin and mainly made of smooth muscle cells in veins; the external layer (tunica adventitia), on the contrary, is thicker in veins than in arteries of comparable size, and consists of collagen, fibroblasts, and smooth muscle cells.

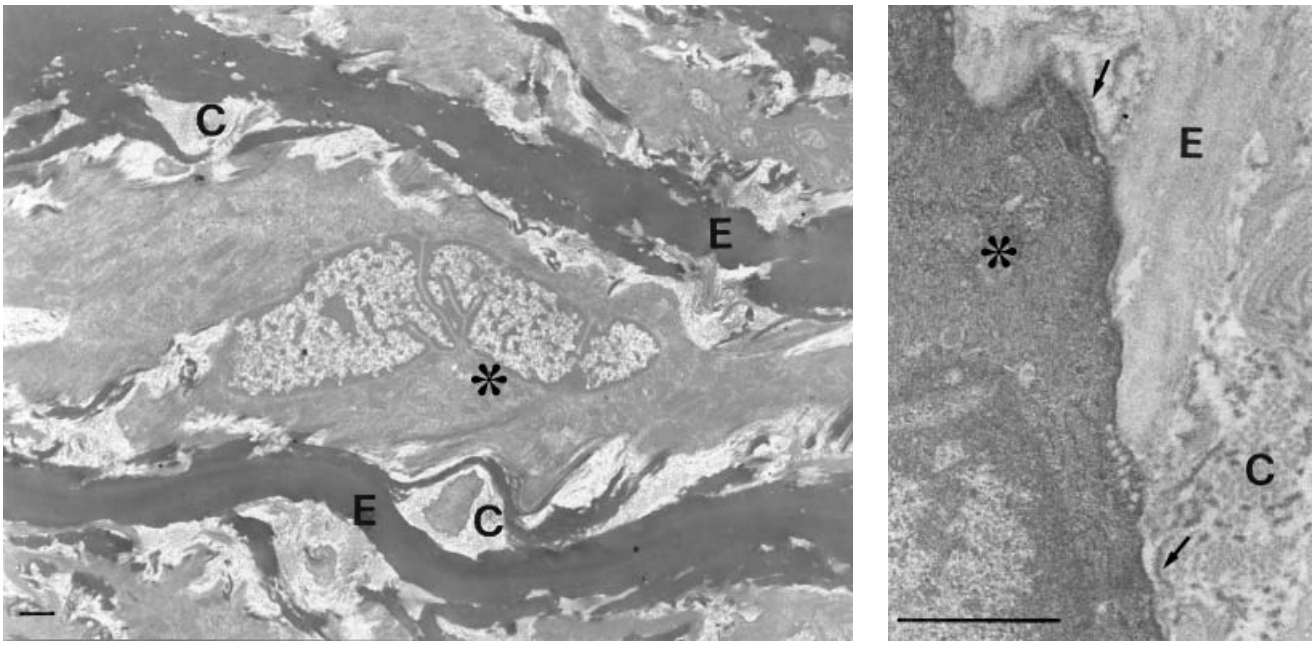

Figure 6. Electron micrographs showing a typical aortic smooth muscle cell (asterisk) in the space between elastic laminae (E) **a**. Collagen bundles can also be appreciated (C). At higher magnification **b**, it appears that the smooth muscle cell basal lamina (arrows) is interrupted in areas where the cell is in contact with the elastic fiber (E). Bars: 1 μm.

TABLE 1. Vessel Parameters in Humans

	Type	Diameter	Tunica Intima	Tunica Media	Tunica Adventitia
Arteries					
	Elastic	>1 cm	50–100 μm thick (increases with age), endothelium, basement membrane, proteoglycans, a few collagen fibrils, internal elastic lamina	1–3 mm thick, layers of smooth muscle cells, layers of elastic lamellae, small collagen bundles, proteoglycans	300–400 μm thick, fibroblasts, scarce smooth muscle cells and elastic fibers, thick collagen bundles, vasa vasorum
	Muscular	0.1–10 mm	50–100 μm thick (increases with age), endothelium, basement membrane, proteoglycans, a few collagen fibrils and smooth muscle cells, prominent internal elastic lamina	0.1–1 mm thick, layers of smooth muscle cells, scarce elastic lamellae, small collagen bundles, proteoglycans	200–400 μm thick, fibroblasts, scarce smooth muscle cells and elastic fibers, thick collagen bundles, vasa vasorum
	Arterioles	<100 μm	Thin endothelium, basement membrane, little collagen, thin elastic lamina	one to two layers of smooth muscle cells, scarce elastin, collagen, and proteoglycans	Thin, ill-defined sheets of connective tissue
	Capillaries	<10 μm	Endothelium, basement membrane	None	None
Veins					
	Postcapillaries	10–30 μm	5–20 μm thick (increases with age), endothelium, basement membrane, pericytes	None	None
	Small	0.1–1 mm	20–50 μm thick, endothelium, basement membrane, pericytes, rare smooth muscle cells, scarce collagen fibrils and proteoglycans	50–100 μm thick, smooth muscle cells (one to three layers), scarce collagen, and proteoglycans	100–200 μm thick, fibroblasts, collagen bundles, some elastic fibers
	Medium	1–10 mm	20–50 μm thick, endothelium, basement membrane, rare smooth muscle cells, scarce collagen fibrils, and proteoglycans	100–500 μm thick, smooth muscle cells (up to eight layers), scarce collagen bundles, elastic fibers and proteoglycans	200–500 μm thick, fibroblasts, scarce smooth muscle cells, collagen bundles, some elastic fibers
	Large	>1 cm	20–50 μm thick, endothelium, basement membrane, rare smooth muscle cells, scarce collagen fibrils, and proteoglycans	>0.5 mm thick, few fibroblasts, smooth muscle cells (up to 15 layers), collagen bundles, elastic fibers, proteoglycans	>0.5 mm thick, fibroblasts, smooth muscle cells, collagen bundles, some elastic fibers

man. Fenestrations occasionally present in the elastic laminae facilitate movements of cells and nutrients through the vessel wall [5].

The tunica adventitia is composed of dense connective tissue mainly comprised of collagen bundles and a few spread elastic aggregates. Fibroblasts are the most abundant cell type in this area of the vessel wall, but a few macrophages can also be seen.

Arteries

Arteries, on the basis of the major constituent of the tunica media, are classified into elastic arteries, muscular arteries, and arterioles. Their diameters and structural organization progressively change from heart to peripheral tissues (Table 1). The aorta and the pulmonary arteries are the most important elastic arteries, and are characterized by numerous elastic laminae intercalated by layers of smooth

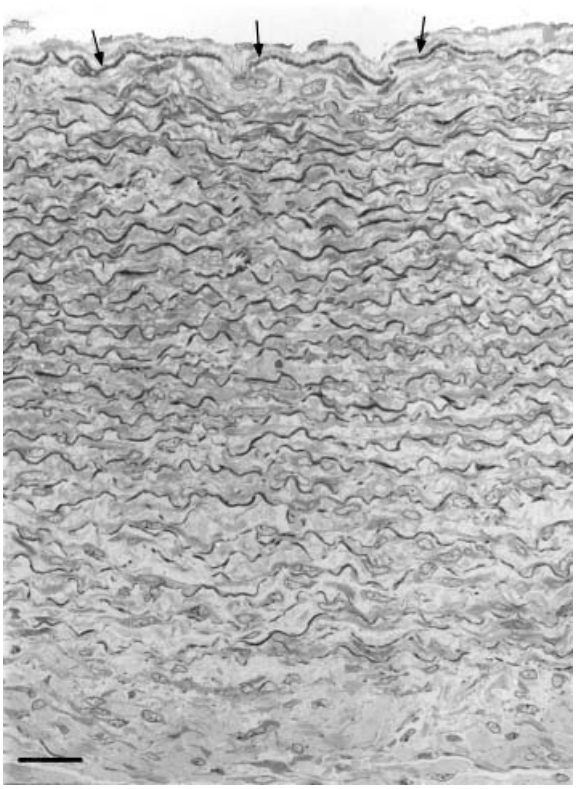

Figure 7. Light microscopy of the aorta from a newborn individual. Endothelial cells (**top**) cover a thin tunica intima that is separated from the tunica media by a still incomplete internal elastic lamina (arrows). In the tunica media, layers of elastic lamellae (waved dark lines) alternate with smooth muscle cells and collagen bundles. The organization of the adventitia (**bottom**) is less ordered and is characterized by scanty elastic fibers, fibroblasts, and collagen bundles. Semithin section stained with toluidine blue. Bar: 100 μm.

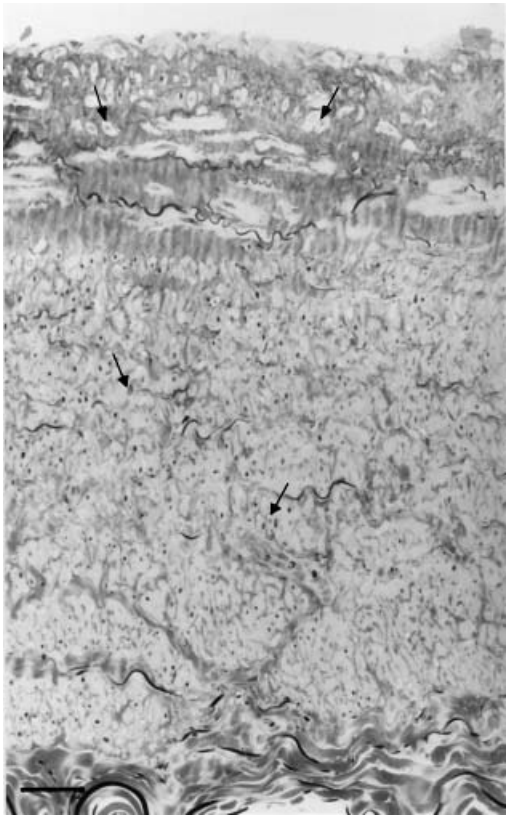

Figure 8. Light microscopy of a portion of the saphenous vein from an adult subject. Underneath the endothelium (**top**), scanty and irregular elastic fibers (waved dark lines) are immersed in a matrix containing numerous smooth muscle cells in different orientations that occupy the greatest part of the vessel wall (arrows). Part of the adventitia of the vein is shown at the bottom and is mainly formed by collagen bundles. Semithin section stained with toluidine blue. Bar: 20 μm.

muscle cells (Figs. 5 and 7). Muscular arteries are sometimes difficult to distinguish from elastic arteries, although they have more smooth muscle cells and less elastin compared with the elastic ones. In small arteries and arterioles, the number of smooth muscle layers in the tunica media is reduced to seven or eight and one or two, respectively. Moreover, the internal elastic lamina is frequently absent from arterioles.

Veins

Veins, as arteries, present a tunica intima, a tunica media, and a tunica adventitia, although these areas are less well defined and thinner than in arteries (Figs. 5 and 8); moreover, their lumens are generally wider than those of comparable arteries. In contrast to arteries, the tunica media of large veins contains also a few fibroblasts in addition to smooth muscle cells (Table 1). Veins also contain valves to allow them to convey blood against gravity. Postcapillary venules are characterized by an endothelial lining and are surrounded by pericytes enclosed by basal lamina material that is continuous with that of the endothelium.

Capillaries

Capillaries are the smallest blood vessels and are characterized by a single layer of endothelial cells resting on a basal lamina and connected to each other by specialized junctions (Fig. 9). Depending on their structure, capillaries may be distinguished into continuous, fenestrated, and discontinuous [6]. In particular, continuous capillaries, which are typical of muscle, lung, and central nervous system, are delimitated by thin and elongated endothelial cells exhibiting a cytoplasm enriched with pinocytotic vesicles, about 70nm wide, that allow transport of substances across their plasma membranes. Sometimes, associated with endothelial cells, pericytes, enclosed by a basal lamina, can be recognized (Fig. 10). Pericytes, also called Rouget cells or mural cells, exhibit some structural differences according to tissue; moreover, they seem to contribute to the regulation of vessel growth and blood flow. Interactions and exchanges between endothelial cells and pericytes occur at different levels, and a number of endothelium-related growth factors (PDGF, bFGF, EGF, CTGF) stimulate pericyte proliferation, migration and also differentiation into osteoblasts, phagocytes, or adipocytes. Moreover, gap junctions, cell adhesion molecules, and integrins can mediate transmembrane signaling within pericytes and play a role in the activation of growth factors such as TGF-β [7]. In fenestrated capillaries, which are mainly present in the endocrine glands, gallbladder and intestine, endothelial cells have a cytoplasmic membrane with fenestrations of 80–100 nm that contribute, together with a few pinocytotic

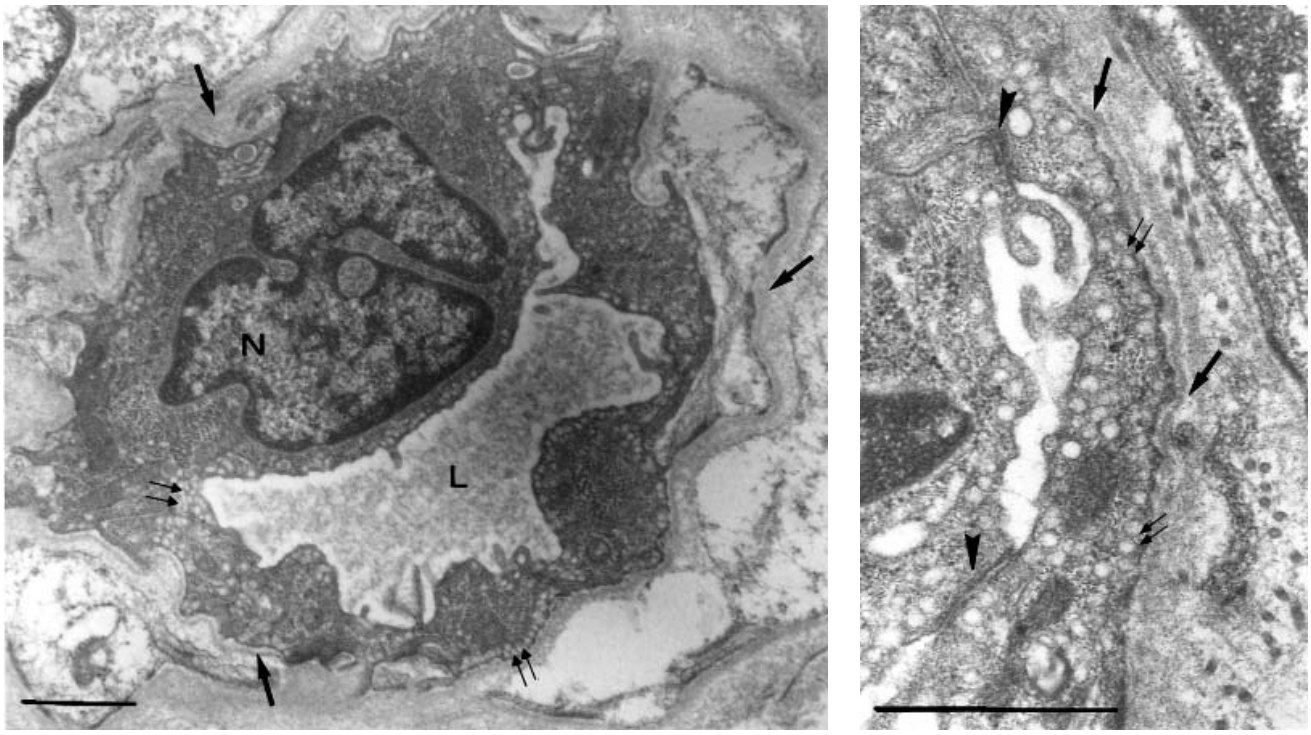

Figure 9. Electron micrographs of a dermal blood capillary comprised of a single layer of endothelial cells and surrounded by a basal lamina (single arrows). Numerous pinocytotic vesicles (double arrows) and cell junctions (arrowheads) between adjacent endothelial cells can be seen **b**. L, capillary lumen; N, endothelial cell nucleus. Bars: 1 μm.

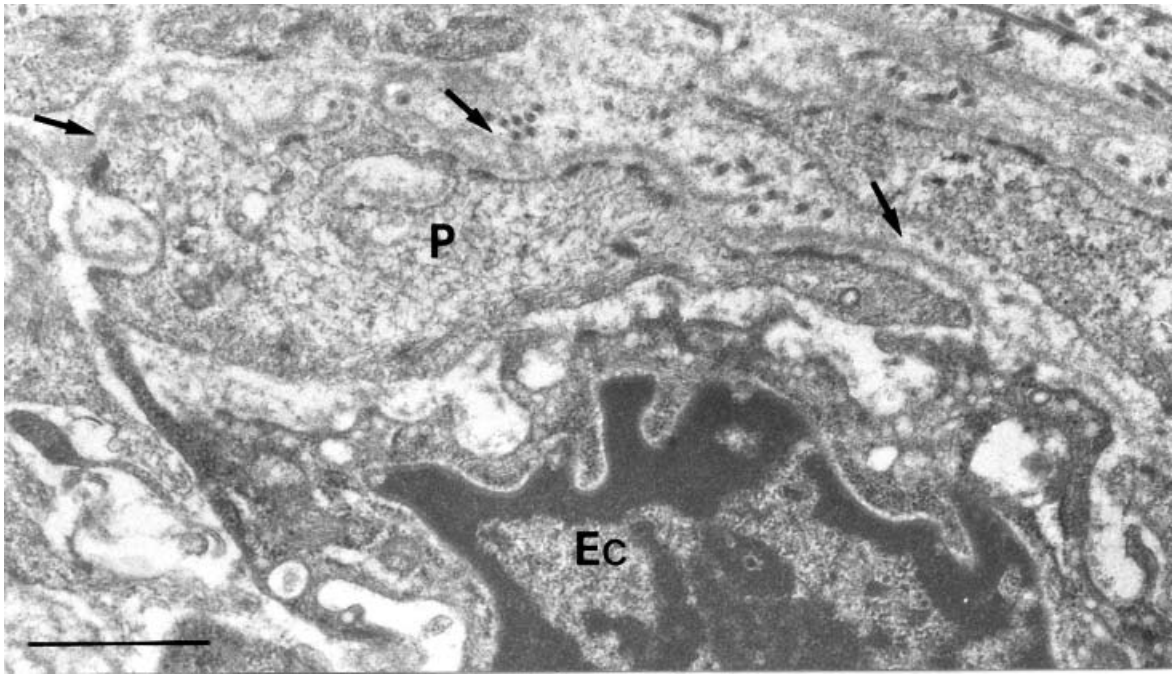

Figure 10. Electron micrograph of a pericyte (P) from a dermal blood vessel surrounded by the same basal lamina (arrows) as the endothelial cells (Ec). Bar: 1 μm.

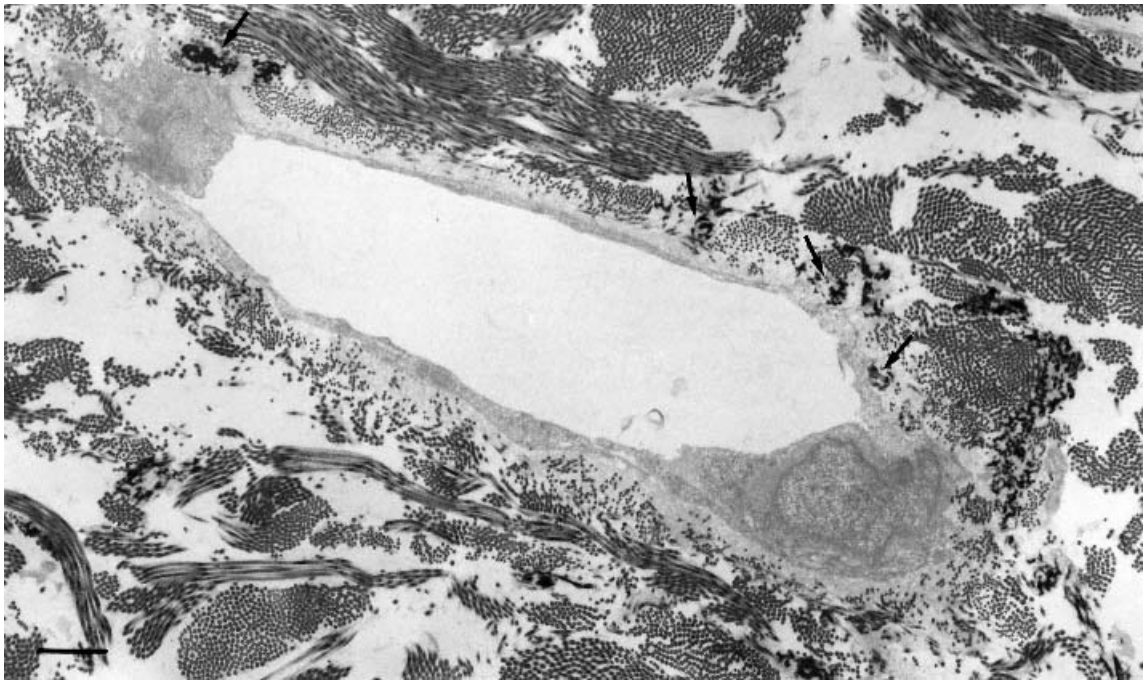

Figure 11. Electron micrograph of a dermal lymphatic vessel delimited by a single layer of endothelial cells and devoid of a continuous basal lamina. Numerous elastic fibers (arrows) can be seen at the periphery of the vessel. Bar: 1 μm.

vesicles, to molecular transport. Discontinuous capillaries, also called sinusoids, are typical of liver, spleen, and bone marrow. They are larger than the other types and characterized by the absence of a basal lamina and the presence of spaces between endothelial cells.

Lymphatic Vessels

These vessels transport fluid from the tissues back to blood vessels; they begin as blind-end tubes that form capillaries, thereafter becoming lymphatic vessels that terminate in the thoracic and right lymphatic ducts. The lumen of lymphatics is larger than that of blood vessels, is more irregular, and contains valves [8]. Due to their physiological role, lymphatic capillaries have to be highly permeable and therefore are devoid of a continuous basement membrane [9]. Moreover, unlike blood capillaries, they are almost always surrounded by a thin network of elastic fibers that may help in the propulsion of the lymph (Fig. 11). Going from the abluminal surface of these capillaries toward the extracellular matrix, oxytalan, elaunin and typical elastic fibers may be observed [10].

CELLULAR AND EXTRACELLULAR COMPONENTS

Endothelium

Endothelial cells constitute a monolayer of flat, expanded cells underlying the interior of the whole cardiovascular system (Figs. 3, 4, 5, 9, and 11) [11]. The biology as well as the pathological behavior of endothelial cells has been intensively studied, because they form the first and probably the most important barrier for the transport of nutrients to all organs [12]. Under physiological conditions, endothelial cells produce several substances involved in the regulation of vessel tone and permeability, hemostasis, immune and inflammatory reactions, fibrinolysis, and cell proliferation, such as nitric oxide, prostacyclins, bradykinin, acetylcholine, histamine, endothelin, thromboxane, adhesion molecules, tissue plasminogen activator and its inhibitor, angiotensin, von Willebrand factor, and several growth factors. Von Willebrand factor is synthesized and stored within the Weibel-Palade bodies of endothelial cells and is released when cells are damaged. It is involved in coagulation as it mediates platelet adhesion and fibrin formation and is required for factor VIII stability in the plasma. Metabolic characteristics and synthetic properties of endothelial cells as well as their products are mentioned in different sections of this chapter.

Myocytes

These cells constitute the heart tissue: they are very large with a centrally located nucleus and numerous mitochondria, are delimited by a cellular membrane called the sarcolemma, and exhibit numerous myofibrils (about 1 μm wide, 2 μm long) that represent 50% of cell volume. Their cross-striated appearance is due to the ordered arrangement of A-bands and Z-lines of contiguous myofibrils. The peculiar properties of myocytes, which contract or relax in response to changes in cell membrane potential, are a consequence of the sarcoplasmic reticulum forming a network of tubules that surround the myofibrils and are engaged in Ca^{++} release and uptake. The contractile proteins, in fact, are organized in sarcomeres and composed of myofilaments: the thicker are made of myosin and represent the A-bands, the thinner are made of actin and form the Z-lines at the ends of the sarcomeres [1]. In these areas is located a continuous coil of tropomyosin that interacts with actin and troponin in the complex that forms the contractile apparatus. In addition to these components, the sarcomeres contain other proteins

such as α-actinin, protein C, titin, and nebulin that can modulate sarcomere function [13].

Smooth Muscle Cells

Smooth muscle cells account for the major portion of the vessel wall and form concentric layers around the vessel lumen just beneath the intima. They are responsible for the homeostatic control of the organization of the vessel wall as major producers of elastin, collagens, proteoglycans, and glycoproteins [14]. Vascular smooth muscle cells *in vitro* are able to reproduce layers of cells intercalated by elastic fibers and collagen, mimicking the construction of a vessel wall. Recently, this property has been utilized to produce *in vitro* a vessel fulfilling the fundamental requirements for grafting [15]. In mature vessels, smooth muscle cells exhibit a contractile phenotype. They express mainly vimentin, as do other mesenchymal cells, but also smooth muscle cell α-actin, myosin, and desmin. In particular, desmin and vimentin are highly expressed in muscular arteries, whereas desmin is poorly represented in elastic arteries [16]. Interestingly, a few smooth muscle cells have been shown also to express cytokeratin, which is a typical marker for epithelial cells [16]. These data sustain the hypothesis that smooth muscle cells may have multiple origins; in fact, depending on vessel location, these cells originate from lateral mesoderm, cardiac neural crest, splanchnopleural mesoderm, dorsal mesocardium, and also endothelium [17]. Smooth muscle cells make contacts with each other and with elastic fibers (Fig. 6). Moreover, vessel smooth muscle cells promptly respond to endothelial injury by migrating towards the intima, proliferating and synthesizing a number of matrix molecules. These events are considered to be at the basis of intimal expansion and atherosclerotic plaque formation [18].

Fibroblasts

Fibroblasts are present in the connective tissue associated with the whole cardiovascular system (Fig. 3). In the vessel wall they are scattered among bundles of collagen fibrils and elastic fibers and are more strongly represented in the tunica adventitia (Fig. 5). Their presence is essential for the resistance of the vessel wall as they produce the collagenous extracellular matrix that confers tensile strength to the organ. No specific studies have been performed on adventitial fibroblasts; however, their presence has been considered of some importance in the production of engineered blood vessels in culture. Actually, artificial tubes of smooth muscle cells, seeded with endothelial cells on the internal lumen and coated by adventitial fibroblasts, were found to behave as good complete blood vessels [15]. Moreover, adventitial fibroblasts seem to be the major source of cell proliferation upon damage [19], and may differentiate into myofibroblasts [20,21].

Collagens

Apart from the elastic arteries, the major structural proteins of the cardiovascular system are collagens, in particular, types I and III (Figs. 3–8). In the adult human heart, collagen, measured by hydroxyproline, reaches an amount of 300–350 mg; of this, collagen type I accounts for about 85%, and type III for 10%, of the matrix produced by local mesenchymal cells. In vessels, the collagen content represents more than 30% of the total dry weight and varies along the vessel tree, being relatively more abundant in muscular arteries and in the adventitia of the vessel wall (Fig. 5). With age and in pathological conditions, collagen content may vary [22,23]; it usually increases relative to other vessel constituents as a result of reparative processes following injury [24] or hypertension [25,26]. As in other organs, the homeostatic balance between collagen synthesis and collagen degradation is regulated by several cytokines, either locally produced or transported by the blood stream.

Human heart fibroblasts have been shown to increase the production of type I collagen and TIMP mRNA in response to the addition of TGF-β, whereas collagenase secretion into the culture medium is stimulated by bFGF [27]. The presence of matrix metalloproteinases, MMP-2 in particular, in the myocardium, suggests that these enzymes may play a role in maintaining the integrity of the cardiovascular structure [28,29].

Types IV and V collagens are the major components of the basal lamina and the subendothelial space in the endocardium and beneath capillaries, acting as an antithrombotic barrier. Collagen type VI is present in the subendothelium, the media, and the adventitia. Moreover, collagen types VI, XII, and XIV are associated with laminin in different areas of the venous walls [30].

Elastin

Elastic fibers and lamellae confer extensibility and elastic recoil upon tissues, and are the major constituent of the largest arteries (see also Chapter 3, this volume). In human aorta, elastin represents about 20% of the total dry weight and its content per unit area decreases from the proximal to the distal aorta, there being a 58% decrease between the suprarenal and the infrarenal aorta [31]. Elastin synthesis is very active around birth and continues during body growth. The soluble monomeric precursor, tropoelastin, is rapidly and efficiently polymerized to mature insoluble elastin (Fig. 12a) by the copper-dependent enzyme lysyl oxidase (see also Chapter 3, this volume). Once laid down, insoluble elastin appears to turn over only very slowly, if at all [32,33]. Both *in vivo* and *in vitro,* elastin synthesis has been shown to be stimulated by TGF-β acting at both pre- and post-translational levels [34–36]. However, in spite of the clear evidence for developmental regulation of elastin production, and for altered elastin synthesis in pathological conditions, mechanisms controlling elastin production are not completely known [37,38]. Glucocorticoids have been reported to increase elastin synthesis, at least in the fetal period [39–41]. *In vitro*, elastin production is negatively influenced by lowering the pH and by increasing the concentration of sodium and potassium, whereas it is insensitive to several substances, including nonsteroidal anti-inflammatory agents, α- and β-adrenergic agonists, and histamine [42]. The degradation of elastin in vessels seems mainly to be influenced by local degrading enzymes, among which is elastase, and free radicals produced by local metabolic events, such as the radical species, nitric oxide, or by moderate inflammatory processes occurring as a consequence of lipid infiltration into the vessel wall. It has to be noted that elastin is a very hydrophobic protein that can bind unsaturated lipids rather efficiently, thus increasing its susceptibility to degradation by elastases and/or other proteolytic enzymes [43]. It is also possible that interactions with other extracellular components, such as glycosaminoglycans or proteoglycans, may modify the sensitivity of elastin to enzymatic degradation.

Glycoproteins

The glycoproteins most represented in the arterial wall are laminin, a constituent of the basal lamina of endothelial and smooth muscle cells, and fibronectin and vitronectin, which

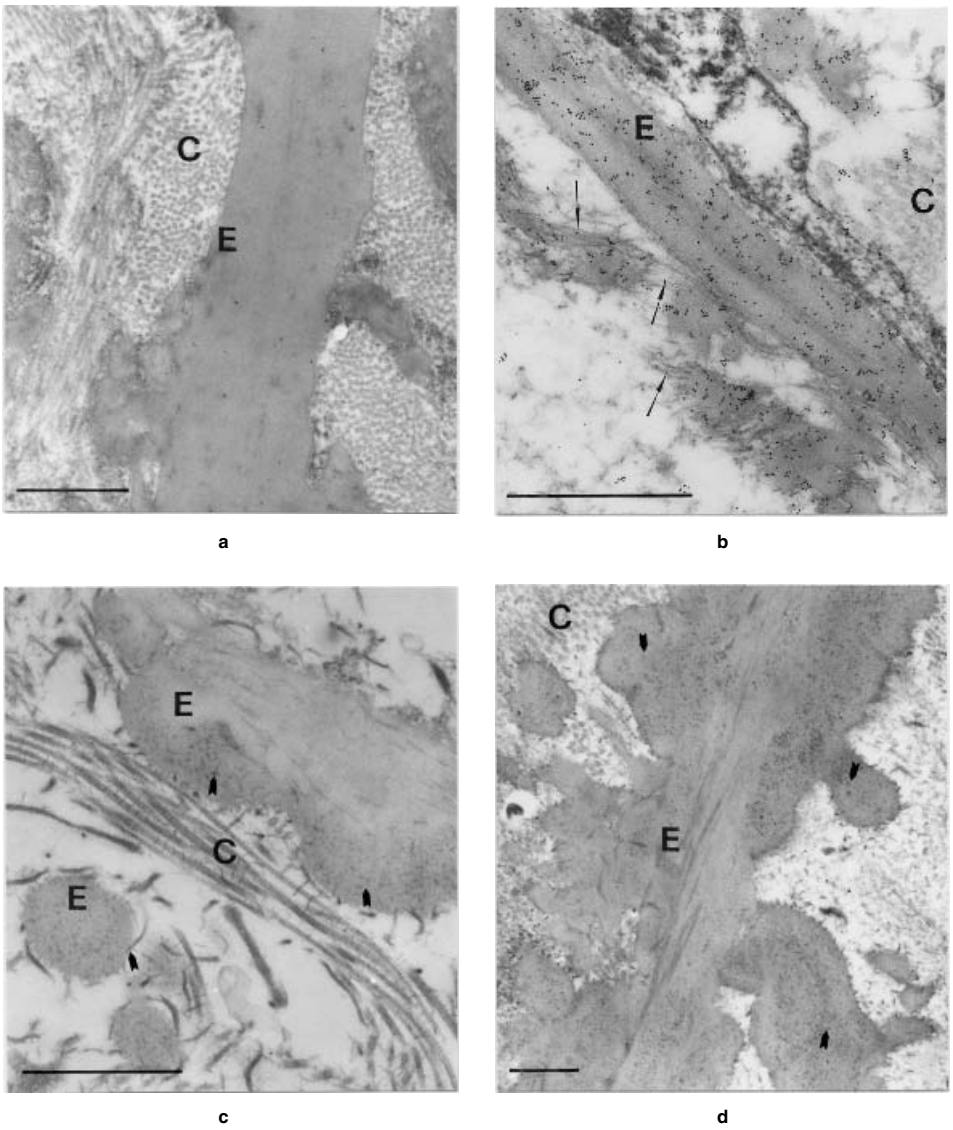

Figure 12. Electron micrographs of aortic collagen (C) and elastic fibers (E). In adult subjects (**panel a**) elastin (E) appears as lamellae of amorphous material surrounded by collagen fibrils (C). Microfibrils associated with the elastic lamellae are clearly visible in a longitudinal section from a fetal human aorta (**panel b**, arrows). Elastic fibers further contain several other molecules beside tropoelastin, such as osteopontin, that has been immunolocalized and visualized by means of gold particle-conjugated antibodies (**panel b**). Glycosaminoglycans are known to be major constituents of elastic fibers, and can readily be observed as alcian blue precipitates after the inhibition of lysyl oxidase in experimental lathyrism (**panel c**, arrowheads) as well as having been observed in a patient with Menkes disease (**panel d**, arrowheads). Bars: 1 μm.

serve to attach endothelial cells and adventitial fibroblasts to the matrix scaffold [44–46] (see also Chapter 5, this volume).

Laminin

The laminins are a family of molecules formed by the association of three from eight genetically distinct chains. Laminin 1 is the major constituent of basement membranes and plays a role in embryonic development, tissue homeostasis, and remodeling, whereas laminin 2 seems mostly to be involved in maintaining the integrity of muscle cell function [47].

Fibronectin

Fibronectin, by actively interacting with collagens and glycosaminoglycans (GAGs), is involved, for example, in the attachment and polarity of endothelial cells and in their migration during angiogenesis [45]. Its transcription is induced by serum, cAMP, epidermal growth factor (EGF), platelet-derived growth factor (PDGF), transforming growth factor (TGF)-β, and angiotensin II.

Vitronectin

Vitronectin modulates cell migration, tissue remodeling, and proteolytic degradation. Within the cardiovascular system it is mainly localized near elastic fibers, in the media, and adventitia of blood vessels [48]. Moreover, it has been suggested that vitronectin is also internalized and translocated to the subendothelial matrix by an integrin-independent mechanism that requires the presence of the

urokinase (u-PA) receptor [49]. In the subendothelial matrix, in association with fibronectin, vitronectin may play a role in platelet–vessel wall interactions [50] through Arg-Gly-Asp (RGD)-binding [51].

Osteopontin

Osteopontin, an extracellular matrix phosphoprotein that is produced in many tissues in response to inflammation and injury, is induced in both cardiac myocytes and microvascular endothelial cells by glucocorticoids and, in turn, reduces the expression of nitric oxide synthase in pretreated endothelial and cardiac cells [52]. We have recently shown that osteopontin is present in the normal arterial wall in humans, where it is associated with elastin fibers (Fig. 12b). Given the inhibitory effect of osteopontin on mineral crystal growth, we have suggested that its presence inside elastic fibers may prevent the occurrence of mineral precipitates over time [53].

Elastin-Associated Microfibrils

Elastic fibers are associated with arrays of microfibrils (Fig. 12b) that are composed of a series of proteins, including fibrillins, microfibril-associated glycoproteins (MAGP), emilin, and others (see also Chapter 3, this volume). The importance of fibrillins, in particular fibrillin 1, localized on human chromosome 15, has been recognized in the last decade by the discovery that mutations in the *FBN1* gene are the fundamental molecular defect in Marfan syndrome (see also Chapter 12, this volume). Microfibrils have been suggested to serve as a scaffold for elastin fibrillogenesis [54] and therefore may play a regulatory role during development. In developing aorta, for instance, fibrillins, in particular fibrillin 2, and tropoelastin are up-regulated simultaneously during elastogenesis, whereas MAGP mRNA levels remain constant. The peak of elastin and fibrillin gene expression in the human aorta is reached within the first year of life, following which there is an age-dependent progressive decline [55]. These data suggest that microfibril composition may change according to structural and/or physiological needs [56] and support the hypothesis that microfibrils have also anchoring functions, running from the surfaces of elastic fibers to plaque sites on smooth muscle cell plasma membranes [57].

Proteoglycans and Glycosaminoglycans

Proteoglycans, particularly those containing chondroitin sulfates, are present in great amount in the cardiac jelly and cardiac extracellular matrix during development and their relative content declines with age. The proportion of proteoglycans in adult aorta is relatively low (0.5–1% of the dry weight); however, their extended structure is sufficient to completely fill the aqueous spaces of the tissue and to allow multiple contacts with cells and other extracellular matrix constituents.

The vessel wall contains several proteoglycan species that are differently distributed from the intima to the adventitia, and that may function as structural elements of the extracellular matrix or modulators of cell adhesion or biohumoral processes [58]. Heparin, for example, may inhibit smooth muscle cell proliferation and migration. Moreover, it may negatively influence intimal thickening and elastin and collagen production, whereas, on the contrary, it seems to stimulate the synthesis of proteoglycan subclasses [59]. Very little is known about the structural role of proteoglycans within the vessel wall. By the use of cytochemical markers, proteoglycans have been shown to form a three-dimensional scaffold connecting all vessel constituents, to be more abundant in the intima, and to be strictly associated with elastin, especially when lysyl oxidase activity is chemically (lathyrism) (Fig. 12c) [60] or genetically (Menkes disease) (Fig. 12d) [61] inhibited. The biological role of these molecules may depend on both their protein and carbohydrate moieties. For example, thrombomodulin, a protein exposed on the endothelial surface, contains a chondroitin sulfate chain that enhances the affinity of thrombomodulin for thrombin, thus preventing coagulation [62]. The amount, as well as the nature and distribution of proteoglycans, has been widely studied in relation to their possible role in degenerative processes of the arterial wall, such as atherosclerosis [63]. Arterial proteoglycans have been shown to interact with circulating low density lipoproteins (LDL), inducing structural rearrangements of both the lipid and the protein moieties of the lipoproteins. This would lead to increased uptake of modified LDL by macrophages and arterial smooth muscle cells, the accumulation of lipids within cells [64], and increased smooth muscle cell proliferation [65]. However, recently, proteoglycans, and in particular heparan sulfate-containing proteoglycans, have been suggested to have a protective effect against the peroxidation of LDL. Peroxidated LDL would favor macrophage uptake and thrombotic events affecting both endothelial cells and platelets [66]. Other physiological roles of heparin-containing proteoglycans appear to be in the control of the release of growth factors affecting neighboring cells [67,68] and modulation of smooth muscle cell proliferation and migration [59].

CELL–CELL AND CELL–MATRIX INTERACTIONS

Given its role in the transport and controlled release of oxygen and nutrients to all parts of the body, the correct functioning of the cardiovascular system is strictly dependent on its structural organization, which, in turn, relies on cell–cell interactions on the endothelial side and cell–matrix interactions in the remaining vessel wall (Table 2). In the heart, cell–cell interactions are essential for stimulus transmission through the organ. Gap junctions, for example, play a crucial role in the synchronized contraction of the heart [69]. Their functional unit, the connexon, is composed of six identical transmembrane protein subunits, called connexins, which form a channel that mediates electrical and chemical coupling between cells. This channel is a dynamic structure that undergoes reversible conformational changes allowing its closure in response to changes within the cell [70]. Furthermore, contraction of both interacting and single myocytes may be modulated by N-cadherin, a cell-surface Ca^{2+}-dependent adhesion molecule, found in intercalated disks and extrajunctional sites of the myocardium. In addition, it has been hypothesized that N-cadherin may also promote the myofibril formation necessary for functional activity of the myocardium [71].

Different types of endothelial cell interactions have been described. Tight, gap, adherens junctions, desmosomes, and syndesmos are variously represented in the vessel tree in relation to the requirement for permeability control, coordination of cell migration and replication during angiogenesis, and injury repair [72,73]. In particular, tight junctions are mainly comprised of a transmembrane protein called occludin, which is directly or indirectly associated with cytoskeletal proteins. Adherens junctions appear in different shapes and sizes and contain the transmembrane glycoprotein

TABLE 2. Adhesion Molecules

Family	Names	Structure	Function
Cadherins	B-cadherin E-cadherin M-cadherin N-cadherin P-cadherin R-cadherin T-cadherin VE-cadherin	Polypeptides of 750 aa with an extracellular, a transmembrane and a small highly conserved cytoplasmic domain that interacts with proteins related to the 'armadillo' family (β-catenin, plakoglobin, and p120)	Cell–cell adhesion proteins developmentally regulated. Are involved in morphogenetic processes, embryogenesis, tumor invasion and metastasis, vascular remodeling
Integrins	$\alpha_1\beta_1$; $\alpha_2\beta_1$; $\alpha_5\beta_1$ $\alpha_6\beta_4$; $\alpha_7\beta_1$; $\alpha_4\beta_7$ $\alpha_X\beta_1$; $\alpha_L\beta_2$; $\alpha_M\beta_2$ $\alpha_{IIb}\beta_3$; $\alpha_V\beta_3$; and others	Glycoproteins comprised of two noncovalently associated subunits: α_n(150–200 kDa) and β_n (90–110 kDa) differently combined	Cell–cell and cell–matrix adhesion molecules. Involved in embryogenesis, platelet aggregation, inflammation, immune functions, wound repair, metastasis, angiogenesis
Ig superfamily	CD2; CD4; CD8; CD22; CD58; C-CAM; N-CAM; ICAM-1,-2; PECAM-1; CEA, MAG; contactin; and others	Proteins of 70–110 aa organized in two parallel beta sheets; the primary structure is highly variable, whereas the tertiary is quite constant	Cell–cell adhesion molecules. Involved in development and regulation of the immune system, contribute to the assembly of vascular structures
Selectins	E-selectin (ELAM-1) L-selectin P-selectin	Characterized by three different domains: a calcium-dependent lectin domain at the N-terminal; an EGF-like domain and several CRP repeats	Cell–cell adhesion molecules. Involved in the regulation of inflammatory and immunological events at the vessel wall, mainly promoting leukocyte extravasation

CAM, cell adhesion molecule; ICAM, intercellular adhesion molecule; PECAM, platelet and endothelial cell adhesion molecule; CEA, carcino-embryonic antigen; MAG, myelin-associated glycoprotein; ELAM, endothelial leukocyte adhesion molecule.

E-cadherin. The cytoplasmic portion of E-cadherin forms complexes with α-, β-, and γ-catenin and plakoglobin, which, together with other proteins such as vinculin, constitute a plaque at which actin microfilaments insert. Desmosomes are membrane domains traversed by the two types of desmosomal cadherins, the desmogleins and the desmocollins, the cytoplasmic tails of which contribute to the formation of a dense plaque containing plakoglobin and desmoplakin. Lymphatic endothelia exhibit junctions of variable size and shape called complexi adhaerentes, among which, syndesmos allow connections between the retothelial cells of lymph node sinuses. Syndesmos are almost negative for vinculin and α-actinin, and have a desmoplakin- and plakoglobin-rich plaque, the specific transmembrane proteins of which include the endothelial cadherin-5 (also called VE-cadherin). In contrast to desmosomes, the syndesmos are negative for the known desmosomal cadherins and also for E- and M-cadherin [74,75]. It has been hypothesized that adherens junctions and VE-cadherins, in particular, play a major role in vascular remodeling by controlling and limiting endothelial cell migration and growth [73].

Usually, the number of specialized endothelial junctions is greater in large vessels than in capillaries and postcapillary venules and, moreover, their presence and functioning are regulated by constitutive as well as local factors. In the brain microvasculature, for example, endothelial cells have unique metabolic and permeability properties induced by astroglial cell-released factors [76]. Furthermore, endothelial cells serve as a nonthrombogenic, selectively permeable boundary between the blood stream and the extravascular space. On the luminal side, endothelial cells present a series of ligands and receptors for cells and molecules circulating in the blood stream, namely CAM proteins, members of the immunoglobulin and selectin gene families [77,78], and heparan sulfate proteoglycans [79,80]. The expression of these receptors is finely regulated as they participate in bidirectional transmembrane signal transduction, lipid metabolism [81], and microvessel involvement in the inflammatory process in response to bacterial endotoxins [lipopolysaccharides (LPS)] through the up-regulation of interleukin (IL)-1 and tumor necrosis factor (TNF)-α [82]. Endothelial adhesion receptors clearly play an important role also in hemostasis and thrombosis as well as in cancer metastasis [83]. Leukocyte and LDL adhesion to the endothelium, for example, is mediated by several adhesion molecules, namely vascular cell adhesion molecule (VCAM)-1, ICAM-1, and ELAM-1, that in turn may activate the transcription factor NF-κB, a proinflammatory molecule able to up-regulate the gene expression of cytokines and cell-adhesion molecules [84].

On the basement membrane side, endothelial cells interact mainly with laminin, collagen type IV, and heparan sulfate proteoglycans through specific integrins (Table 2). These are heterodimeric membrane proteins mediating cell attachment to the extracellular matrix [85]. Following the binding of the integrin to its ligand in the matrix, the cytoplasmic domain of the β-chain interacts with talin, which, in turn, binds to vinculin, which is associated with α-actinin and is thus linked to an actin filament. Integrin-mediated

cell–matrix interactions control the formation of the matrix itself as well as the expression of the number and nature of integrin receptors on the cell membrane [86]. Resting endothelial cells and smooth muscle cells of the vessel wall express integrins α1β1, α5β1, α6β1, and αvβ3, which are receptors for collagens, fibronectin, laminin, and vitronectin, respectively [83]. The use of transgenic or "knockout" mice involving genes for adhesion or matrix molecules is revealing that integrins as well as cell–matrix interactions are of paramount importance in the development and maintenance of integrity of several organs, among which is the cardiovascular system [87,88].

Cell–matrix interactions seem also to regulate the phenotype of vessel smooth muscle cells; in fact, adhesion to laminin, through integrins α3β1 and α2β1, permits the persistence of the contractile nonproliferative phenotype, whereas adhesion to fibronectin through integrin α5β1 leads to *ras* activation and cell proliferation [89].

Vascular cells, as well as monocytes, neutrophils, and lymphocytes, express a multifunctional 67-kDa protein that differs structurally and functionally from other matrix adhesion molecules and is known as an elastin receptor, functioning as a chaperone that facilitates the secretion of tropoelastin and the assembly of elastic fibers. Similarly to the transmembrane selectins, the 67-kDa protein has lectin-like properties, but unlike integrins and cadherins, it is not a transmembrane molecule, although it can be immobilized on the cell surface by association with two other membrane-anchored proteins, mediating cell–matrix interaction in a calcium-independent manner and recognizing the secondary structure of matrix macromolecules. It has been hypothesized that the 67-kDa protein may play a role in the interactions between vascular smooth muscle cells, leukocytes and several components of extracellular matrix in physiologic as well as pathologic conditions [90].

STRUCTURAL CHANGES

Developmental Changes

The cardiovascular system develops quite early during embryogenesis [91]. The heart is already present as a tube in the human embryo at 19 days of gestational age, when cellular aggregates increase their mass and form a lumen, thus creating the first vascular network through the process of vasculogenesis. At the stage of 21–22 days, the vascular system is bilaterally symmetrical and the heart is organized into three different layers: an inner layer, also called cardiac jelly, poorly structured and devoid of cells; a middle layer comprised of numerous cells, some of which start to exhibit the contractile properties typical of the myocardium; and an outer layer that takes the form of a monolayer of mesenchymal cells. Cardiac septation is almost completed by the 27th day of embryonal age. One of the most well-known mammalian cardiogenic transcription factors is MEF2, which binds to regulatory DNA sequences in both early cardiogenic precursor cells and differentiated cardiomyocytes [92]. During the third and fourth weeks, venous and coronary vessels are formed from epicardial vascular buds. When the vascular tubes associate with pericytes, growth of blood vessels proceeds by angiogenesis, a phenomenon characterized by the disruption of basement membranes, and the migration and proliferation of endothelial cells to form new vessels. Thickening of the tunica media and adventitia of the vessel wall due to collagen deposition and the formation of the elastic laminae occur between the fourth month and birth, and continue during the first year of life [93,94]. The role of cell adhesion molecules in cardiovascular system development has been widely investigated. In particular, β1- and β3-containing integrins seem to play a major role, since impairment of binding to β1 integrins can block lumen formation of the dorsal aorta in chick embryos [95]; it has been suggested that these integrins are crucial for later development, whereas they do not seem to influence angioblast differentiation [96]. By contrast, VCAM-1 or α4 integrin mutant embryos reveal, beside placental abnormalities, loss of the epicardium and lack of subepicardial vascular development [96]. Furthermore, connexins seem to be critical for heart contraction, since alterations in connexin 43 cause blockage of the right ventricular outflow and consequent perinatal mortality [97]. During fetal and early postnatal life, the heart increases in mass through an increase in the number of myocytes. However, after birth, cardiac myocytes lose their ability to divide and, during life, the response to work overload is assured only by cellular size increase. The mechanisms involved in the terminal differentiation of myocytes are still under investigation.

Several growth factors are also involved in the induction of lateral plate mesoderm and subsequent cardiac organogenesis. Among these, TGF-β superfamily factors have been shown to display spatial and temporal expression suggestive of cardiac muscle induction, septation and valve formation [98–100]. TGF-β factors have been shown to stimulate cardiac differentiation of axolotl mesoderm explants [101] and to induce the expression of sarcomeric proteins, such as myosin heavy chain, titin, α-actinin, and troponin I, in splanchnic mesodermal cells *in vitro*. Moreover, antibodies to TGF-β or antisense oligonucleotides against TGF-βs have been demonstrated to inhibit the induction of valve-forming mesenchyme in the endocardial cushions [102]. However, the complex role of TGF-β family growth factors has not yet been completely elucidated. Interestingly, it has been demonstrated that mice deficient in TGF-β1 develop a normal cardiovascular system accompanied by an inflammatory cardiomyopathy [103]. Moreover, TGF-β1 seems to have either stimulatory or inhibitory effects on cardiac gene expression that differ depending on the target gene, being more active in up-regulating the array of fetal cardiac genes characteristic of myocardial hypertrophy, such as those for smooth muscle α-actin, SkA, β-myosin heavy chain (MHC), and atrial natriuretic factor (ANF) [104]. Furthermore, TGF-βs, in particular TGF-β1, are very much involved in the production of the extracellular matrix; however, very little is known about such involvement in the early stages of cardiovascular development [105], where the relationships between cells and between cells and matrix are fundamental in cell migration, cavitation, and modeling of the tubular organization of vessels, in the organization of the vessel wall, and, later, in the maintenance of the nonadhesive properties of blood cells in respect of endothelial cells [106,107]. It has been shown that fibrillar fibronectin and collagen type I are necessary for normal endothelial–mesenchymal interactions during early development and that alteration in the organization of both fibronectin and collagen type I by retinoic acid leads to transposition of the great arteries in a mouse model [108]. The role of connective tissue molecules (namely collagens, glycoproteins, glycosaminoglycans, and proteoglycans) during myocardial development is still under investigation. It has been demonstrated that myocardial growth proceeds from the epicardium toward the endocardium, with progressive

structural organization in strata. The interstitium grows in parallel with the myocardial growth, beginning with a thin network surrounding each fiber and progressively becoming more dense. Collagen fibers first appear at the epicardial level, especially around coronary vessels [109]. During heart development, vitronectin is present before endocardial cushion cell migration and remains until prevalvular structure formation [110].

Postnatal Changes

From birth and throughout life, the cardiovascular system undergoes continuous remodeling. Major changes occur at birth due to the transition from fetal to newborn circulation and consist of 1) closure of the foramen ovale as a result of increased blood flow and augmented left atrial pressure that becomes greater than that in the right atrium; 2) closure by collagen deposition of the ductus venosus sustained by an increase in the systemic vascular resistance; 3) closure of the ductus arteriosus, first by smooth muscle cell contraction and later by collagen deposition, related to high oxygen tension; and 4) dilatation of pulmonary vessels after separation of the pulmonary and systemic circulations [1].

During body growth, the vessel tree must increase its spread and ramifications through a series of controlled mitotic and apoptotic events [111], and by controlled matrix synthesis and degradation through a balance between the following three factors: the presence of growth factors, the regulation of receptors, and the control of growth inhibitors. These last include PF-4, thrombospondin-1, angiostatin, TGF-β, interleukins, and tissue inhibitors of metalloproteinases (TIMPs).

Age-Related Changes

In adults, the cardiovascular system has to overcome a series of mechanical, nutritional, and hormonal stresses that lead to a continuous rearrangement of its structural organization. Apart from cardiac myocytes, fibroblasts, as well as smooth muscle cells and endothelial cells, are capable of proliferation in the presence of growth factors, such as insulin-like growth factor (IGF)-1, basic fibroblast growth factor (bFGF), PDGF, and EGF, at least in part through activation of the p21-Ras/MAP kinase pathway [112,113]. TGF-β is also implicated in the hypertrophic growth of cardiac muscle cells upon mechanical load, where its release can be induced by the initial production of angiotensin II [114]. The pleiotropic functions of TGF-β isoforms have also been shown in the development of cardiovascular pathologies, such as hypertension, arterial restenosis, and infarct, in which these growth factors interact with others (IL-1, NO) in modulating cell growth and differentiation and matrix deposition [115].

With age, the heart, and in particular the left ventricle (Fig. 13), progressively increases in volume and weight, despite a numerical reduction of myocytes. The increased size of the aging heart, mainly as a consequence of peripheral vascular stiffening, is due to collagen deposition, increased myocyte size and the augmentation of adipose tissue especially in the subendocardial region [116,117]. These phenomena are more evident in men than in women. Moreover, there is an increased deposition of lipofuscin among myofibrils and of amyloid in the interstitial spaces in more than 50% of individuals over 70 years [118,119]. In the rat, collagen has been demonstrated to accumulate from the age of 3 months, the amount being doubled in 2-year-old animals [120]. Fibrosis is generally dispersed within the myocardium, although small areas of dense collagen bundles may be noted in the subendocardial and subepicardial areas [121].

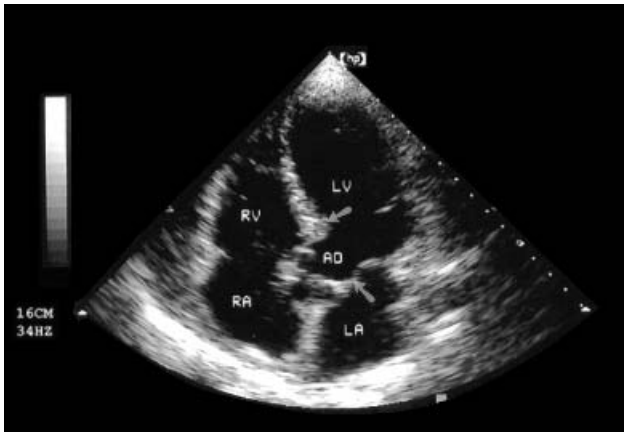

Figure 13. An apical ''4 chamber with aorta'' (AO) view of the heart by two-dimensional echocardiography of a 70-year-old asymptomatic subject. The thickness of the wall separating the right from the left ventricle and of the mitral valve leaflets is suggestive of a mild septal hypertrophy of the left ventricle (LV) and fibrosis of the valve (arrows). Compare Figure 2. LA, left atrium; RA, right atrium; RV, right ventricle (Figure courtesy of L.Targa, MD, Division of Cardiology, Este Hospital, Padova, Italy.)

Changes occur also in the morphological characteristics of the valves, such as fibrosis and degenerative calcification, which affect their function. Interestingly, whereas the relative content of elastin is independent of age, the amount of collagen decreases progressively, even though it becomes more cross-linked, and therefore less insoluble [3]. Furthermore, lipids, as well as amyloid, may also accumulate within valves and a fibroelastic hyperplasia may frequently be observed, especially at the insertion of mitral leaflets, the aortic cusp, and the anulus [122]. Aging is also associated with dramatic changes in the vascular system, i.e., vessel dilatation, vessel wall thickening, and reorganization of the cellular and extracellular compartments (Fig. 14) [123].

Several factors, including genetic and/or environmental components, contribute in human beings to the age-associated cardiovascular modifications [124]. It is therefore quite difficult to separate changes due to aging from those due to pathologic events and/or complications, such as hypertension and atherosclerosis [84,125]. We performed studies of vascular connective tissue components in the rat, in which it is much easier to investigate the role of the aging process itself (Fig. 14) [126,127], and how exogenous factors, such as diet, may influence these phenomena [128].

We have shown that the interactions between cellular and extracellular compartments as well as the relative proportions of collagen and elastin play a key role in conditioning the morphological and functional properties of the arterial wall. With time, endothelial cells become progressively more elongated, have reduced contacts, and form a more fragile barrier at the lumen surface. The subendothelial space consists of a coat of proteoglycans that changes quantitatively and qualitatively, thus contributing to alterations in the permeability and metabolism of the intima. *In vitro* studies, for instance, revealed that the concentrations of hyaluronic acid and chondroitin sulfate increase with time,

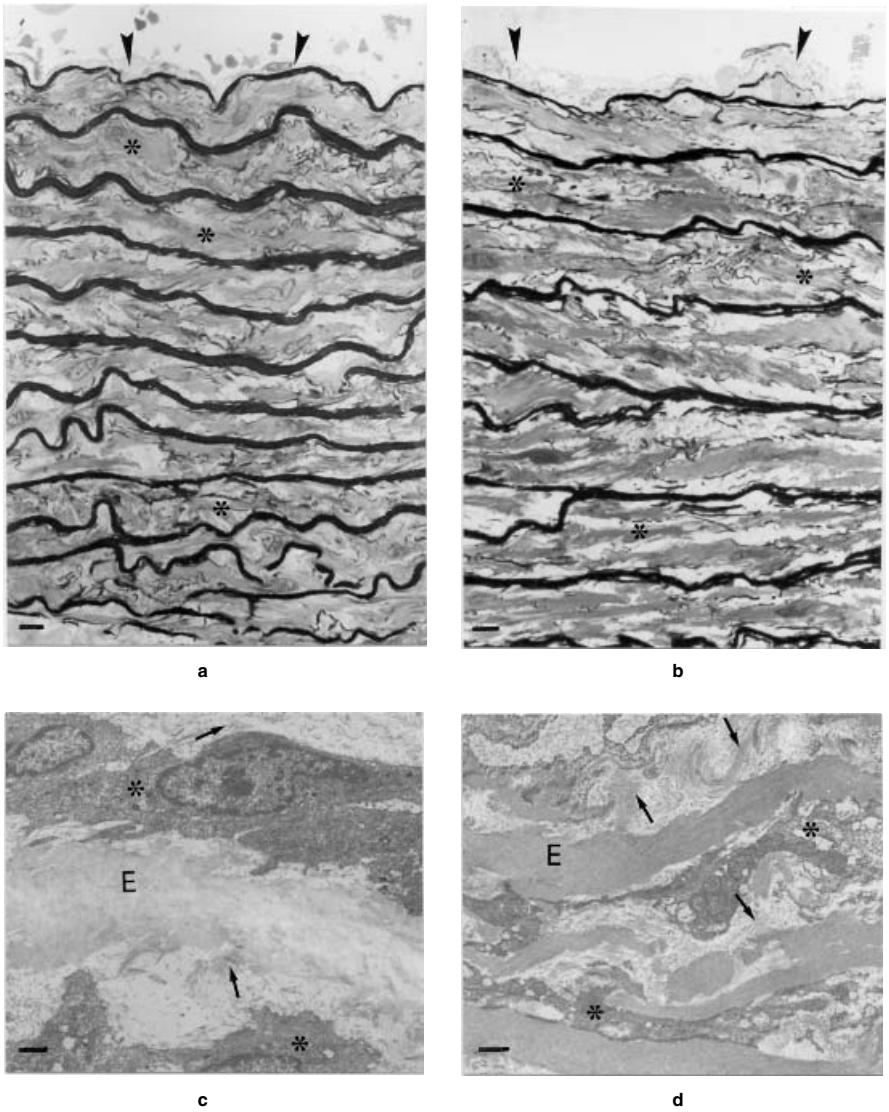

Figure 14. Light (**a, b**) and electron (**c, d**) micrographs of aorta from rats of 5 (**a, c**) and 29 (**b, d**) months of age. With time, there is an increase in the subendothelial space (arrowheads), elastic lamellae become less ordered (compare **a** and **b**; dark waved lines), and collagen increases in the extracellular matrix (compare **c** and **d**; arrows) contributing to the distortion of smooth muscle cells (asterisks) between elastic lamellae (E). Bars: **a, b**: 10 μm; **c, d**: 1 μm.

whereas that of heparan sulfate decreases. Ultrastructural studies have demonstrated that, with age, smooth muscle cells undergo several modifications with respect to shape, nucleus to cytoplasm ratio, abundance of cytoplasmic organelles, such as Golgi, endoplasmic reticulum, and mitochondria, and thickening of basal lamina [126,129]. Morphometric data indicate that the total number of smooth muscle cells is quite similar in young and old rats. On the contrary, with age, there is an increase of collagen volume density in the arterial wall due to the persistence of collagen type I synthesis, continuing lysyl oxidase activity [127] and the nonenzymatic glycosylation of amino-groups (Maillard reaction) [130,131] in collagen and other molecules, such as vitronectin. These changes may contribute to decreased adhesion and spreading of endothelial cells on matrix molecules and impaired endothelial function [132].

Vascular elastin metabolism has been shown to be age-related: elastin synthesis and deposition are particularly efficient in aortas of newborn and very young rats, then dramatically decrease [127], even though in some circumstances, as after surgical intimal injury or in the presence of atherosclerosis or hypertension, at least some smooth muscle cells seem to be able to produce large amounts of elastin together with other matrix proteins [133]. An increase, with age, of minor constituents of the cardiovascular extracellular matrix, such as fibronectin, has been shown by several authors [134,135]. Because fibronectin exhibits high affinity for LDL [136], this has been strongly related to some cardiovascular risk factors with age.

Even though the importance of growth factors in extracellular matrix regulation has been widely demonstrated in different experimental models, during development and

in pathologic conditions [137,138], little data is available regarding their role in the aging of the cardiovascular system. Cytokines, such as TGF-β, are able to stimulate matrix deposition also in systems aged *in vitro* [139]; moreover, vascular endothelial growth factor (VEGF) may significantly delay senescence of endothelial cells [140]. Interestingly, an age-related increase of PDGF-rβ and TGF-β1 expression has been observed in the rat aorta, whereas a decrease was noted in the heart [141]. The physiological role of these differences is not obvious.

INFLUENCE OF EXOGENOUS AND ENDOGENOUS FACTORS

Mechanical Loading

Mechanical stresses influence the structural and functional properties of cells at the molecular and genetic levels. In an *in vitro* model, static stretching has been demonstrated to stimulate tropoelastin synthesis by porcine aortic smooth muscle cells [142], sustaining the hypothesis that matrix secretion is regulated in response to hemodynamic forces. Collagen and elastin synthesis increase after elevation of intraluminal tension, but are inversely regulated along the aorta, elastin deposition diminishing proportionally from the arch toward the abdominal portion, whereas collagen secretion behaves oppositely [143,144]. Cell surface proteins and extracellular matrix are linked by transmembrane proteins to the cytoskeleton, and mechanical deformations can be converted to electrophysiological and biochemical responses. The vascular wall is continuously exposed to mechanical forces and reacts both acutely, by relaxation/contraction of smooth muscle cells, and chronically by the reorganization of the cellular and extracellular components. Endothelial cells respond to pressure and shear stresses with changes in ionic conductance [145], adenylate and guanylate cyclase activity (mediated by NO), inositol-triphosphate generation [146], and, within hours, with activation of genes for growth factors, endothelin and regulators of fibrinolysis. These events require the integrity of the cell membrane, cell–cell and cell–matrix interactions, and the cytoskeletal network [147,148]. At least some of these effects seem to be mediated by PDGF-B, as a stress response element has been found in its promoter region [149]. Mechanical loading also induces specific gene expression in cardiac myocytes leading to cell hypertrophy [150] and in vessel smooth muscle cells leading to the expression of muscle-specific myosin isoforms [151]. Also in these cells, mechanical stimulation is mediated by the extracellular matrix through cell–matrix interactions [152]. Chronic overload, such as hypertension, stimulates smooth muscle cells to produce large amounts of extracellular matrix, especially collagen, leading to a progressive fibrosis of the vessel wall.

Nitric Oxide

Nitric oxide is a free-radical gas produced by a family of enzymes (NOS) that catalyse the conversion of L-arginine to L-citrulline in the presence of oxygen and reduced NADPH. The enzymes are present in various organs and tissues, especially the nervous system, and have been immunolocalized to several areas of the heart and within endothelial cells. Both cardiac and endothelial NOS mRNAs increase *in vitro* upon the addition of IL-1β, TNF-α, or IFN-γ, and decrease in the presence of dexamethasone or TGF-β [153]. *In vivo*, NO production is induced by chronic exercise in dogs [154]; *in vitro*, NOS expression is induced by cyclic strain, shear stress [155], and a low concentration of oxidized LDL [156], whereas it is depressed by hypoxia, TNF-α, and high concentrations of LDL. Released from the endothelial cells, NO diffuses in a few seconds to smooth muscle cells, where it acts as a relaxant by binding to the heme iron at the active site of guanylate cyclase, thus generating cGMP. Thus, NO, formerly called endothelium-derived relaxing factor (EDRF) [157], is a powerful vasorelaxant, and is considered the major physiological regulator of basal blood vessel tone. Interestingly, basal release of NO may vary considerably among vessel types and diameters, being secreted more abundantly in smaller rather than larger arteries and veins, but its production may be increased in large arteries undergoing mechanical stress due to intense blood flow [158]. Moreover, NO has pleiotropic functions, and may act as a scavenger for superoxide anion in inflammatory reactions, and as an inhibitor of platelet aggregation, smooth muscle cell proliferation, and adhesion molecule expression [159,160].

Hypoxia

Chronic ischemia is an important factor in the process of angiogenesis. There is *in vivo* evidence that myocardial ischemia results in collateral development and the opening of preexisting vessels [161], and that chronic intrauterine hypoxia is associated with retinal neovascularization of the fetus. *In vitro*, endothelial cells cultured under hypoxic conditions show increased DNA synthesis and proliferation [162,163], very likely by up-regulation of the expression of VEGF [164]. Hypoxia, among a variety of other factors (thrombin, TGF-β, IL-1, angiotensin II, epinephrine), induces also the transcription, synthesis, and secretion of endothelin-1, a 21-amino acid peptide produced by endothelial cells, which acts as a transient vasoconstrictor by binding to specific receptors on smooth muscle cells. Endothelin secretion is regulated by cGMP- and cAMP-dependent mechanisms which are, in turn, activated by NO levels [165].

Low oxygen levels may also stimulate the secretion of adenosine, which is one of the most powerful vasodilators and one of the major regulators of coronary perfusion. Adenosine acts on the surface of vascular smooth muscle cells, activating specific receptors that block the entry of Ca^{++} into cells, causing vasodilatation; moreover, adenosine diminishes the atrioventricular conduction and myocardial contractility induced by adrenergic compounds [166].

Nutrients and Hormones

Among nutrients, the vascular system is particularly sensitive to copper, vitamin C, and vitamin A deficiencies. Copper is essential for the production of the active form of lysyl oxidase, the enzyme that catalyzes the first step towards the formation of stable intermolecular crosslinks in both collagen and elastin [167,168] (see also Chapters 2 and 3, this volume). Vitamin C is a cofactor of lysyl and prolyl hydroxylases, enzymes necessary in the biosynthesis of collagen molecules prior to their secretion, and increases collagen type I mRNA levels [169,170]. In contrast, vitamin C decreases elastin production by negatively influencing elastin mRNA stability and elastin gene expression [171]. Vitamin A deficiency during embryogenesis induces myocardial defects, suggestive of a role for the retinoid signaling pathway in cardiac gene regulation [172].

Homocysteine exerts a negative influence on endothelial cells, affecting their interactions with platelets and increasing thrombomodulin expression. Atherosclerosis is one of the major complications in patients with alterations in

homocysteine metabolism [173] (see also Chapter 13, this volume).

Nitrite ions, constituents of cigarette smoke, and meat preservatives, have been shown to react with insoluble elastin, inducing remarkable structural alterations, and could be responsible for some of the chronic vascular elastin damage associated with cigarette smoking [174].

Angiotensin I-converting enzyme (ACE) is a cell membrane peptidase constitutively present on vascular endothelial cells and inducible on smooth muscle cells and adventitial fibroblasts [175]. The product of the reaction is angiotensin II, a potent vasoconstrictor. ACE expression is stimulated *in vitro* by glucocorticoid hormones and bFGF; *in vivo*, a high level of ACE expression is mostly associated with renovascular or general hypertension. In humans, there is a considerable degree of ACE gene polymorphism. Although no conclusive evidence has been obtained for an association between high ACE levels, coronary artery disease, cardiac hypertrophy, and vascular wall thickening, the treatment of hypertension with ACE inhibitors has been proven to be highly beneficial in humans [176,177].

Among others, renin, aldosterone, norepinephrine and atrial natriuretic peptide (ANP) are known to regulate cardiovascular system homeostasis. Plasma ANPs, in particular, increase during rat growth and do not seem to change with age, whereas tissue immunoreactive ANPs are significantly increased in old animals [178]. Secretion of a series of hormones is altered in aged animals, thus contributing to the impairment of the senescent cardiovascular system [179].

RECENT DEVELOPMENTS

Response to Mechanical Stimulus

Additional information has been reported in relation to the modulation of connective tissue metabolism within the cardiovascular system in response to mechanical stimuli. The myocardium responds to mechanical stresses as a result of changes in blood pressure or volume by increasing both contractile and extracellular matrix protein synthesis [180].

Contractile Cells

Within seconds to minutes of onset, the unidirectional loading of myocytes stimulates signaling molecules. There is activation of membrane-associated phospholipases, an increase in inositol triphosphate, diacylglycerol, and arachidonic acid metabolites, stimulation of protein kinase C activity, and intracellular calcium release. Activated MAP-kinases then translocate to the nucleus and phosphorylate nuclear factors such as c-fos and c-jun, which form a heterodimer that binds to AP-1 sites in a number of gene promoters including those for matrix metalloproteinases and interleukins, as well as *COL1A1*, the gene for the α1(I) chain of collagen I [180].

Fibroblasts

Among the proteins and factors synthesized and released by cardiac fibroblasts are endothelin-1, TNF-α, and angiotensin II [181–183]. Cardiac fibroblasts *in vitro* have been shown not to respond to stretching by activating the Erk and Jnk signaling pathways when spread on collagen I, whereas they do show activation of both factors, or of Jnk alone, in response to stretching when cultured on fibronectin and on laminin or vitronectin, respectively. As there is increased expression of fibronectin, laminin, and vitronectin in pathologic conditions such as hypertension or ischemic injury, it may be that in the presence of such matrix glycoproteins, cardiac fibroblasts express Erk and Jnk, leading to increased collagen production [184].

Endothelial Cells

Endothelial cells transmit information regarding changes in shear, pressure, and tensile stresses to underlying cells by producing vasoactive substances and growth factors, such as PDGF-B, the promoter for which includes a shear stress response element [185]. A stretch response element involving the transcription factor Egr-1, and possibly Sp-1, has also been demonstrated in the promoter of the gene for PGDF-A [186]. Interestingly, the synthesis and release of PDGF-A chain in response to cyclic load can be blocked by RGD peptides, suggesting a crucial role for integrins in mechanical signal transduction [180].

Smooth Muscle Cells

Smooth muscle cells, which are relatively resistant to the antimitogenic effect of heparin, have been shown still to exhibit heparin-dependent inhibition of Erk activation and may develop c-fos-independent pathways for proliferation. Protein kinase C-dependent signaling through the Erk family of MAP-kinases activating c-fos transcription is selectively inhibited by heparin. Moreover, upstream of Erk, heparin decreases also the phosphorylation of Raf-1 in response to PDGF, without affecting PDGF receptor phosphorylation [187].

Integrins

There is growing evidence for the role of integrins as mechanosensors for both cardiac fibroblasts [180] and vascular smooth muscle cells [188]. Integrin-mediated cell adhesion and spreading lead to intracellular signalling and regulation of cell function similar to that observed in response to mechanical load, namely an increased focal adhesion kinase and phosphorylation and activation of a cascade of second messenger events. In particular, integrins α5β1 and αvβ3 are essential for the load-induced stimulation of procollagen synthesis and for the replicative response of aortic smooth muscle cells to mechanical load. Cells grown on fibronectin respond more dramatically, in terms of replication, than cells grown on collagen, laminin, or elastin, and the RGD peptides, the major extracellular binding domain of many integrins, partially inhibit the load-induced response.

It has been demonstrated that, in ventricular myocytes, voltage-dependent calcium channels are regulated in a cytoplasmic compartment close to the cell membrane and to the ryanodine-release channels of the sarcoplasmic reticulum, allowing a tight spatial control of the Ca^{2+}-induced Ca^{2+} release mechanisms [189]. Integrin β1-deficient cardiomyocytes display defective myofibrillogenesis and an absence of the typical electrical properties of ventricular-, atrial-, and nodal-like cells [190]. Therefore, integrins appear to play an important role during cardiac development and in the regulation of heart function.

Besides integrins known to link cell adhesion to intracellular signaling pathways, thereby determining whether a cell will survive, proliferate, or differentiate in response to soluble factors [191], several other proteins have been implicated in cell adhesion, migration, and proliferation, among which is galectin-1, a small β-galactoside-binding lectin, particularly abundant in cardiac smooth muscle. Galectin-1 has been shown to enhance DNA synthesis and to affect the adhesion

of smooth muscle cells *in vitro* by interacting with α1β1 integrin, laminin, and fibronectin [192].

Remodeling

Changes in the characteristics of newly deposited collagens may lead to alterations in the functional properties of the cardiovascular system. Li et al. have shown that an increase in the amount of collagen I and/or its enhanced cross-linking increase myocardial stiffness, whereas an increased amount of collagen III may facilitate myocardial compliance [193]. MMPs may facilitate the production of matrikines, peptides arising from the degradation of matrix components, and the tripeptide Gly-His-Lys, derived from the degradation of several matrix proteins, including α2(I), α2(V), and α2(IX) collagen chains, osteonectin, thrombospondin-1 and the fibrin α chain, actively stimulates new connective tissue formation [193].

Increased MMP activity may thus result in fibrillar collagen degradation, extracellular matrix synthesis and remodeling, and progressive structural changes in the cardiovascular system leading, for example, to ventricular dilatation. The interplay of MMPs, TIMPs, and their regulators, determines the progression of fibrotic processes in the heart. The level of extracellular MMP inducer (EMMPRIN) protein is very high in failing human hearts. Since mechanical stretch has been shown to induce neutral transmembrane MMPs in isolated cardiac fibroblasts, it has been suggested that EMMPRIN could be modulated *in vivo* by changes in the hemodynamic load [193].

With age, the structural architecture and composition of the extracellular matrix progressively and irreversibly change as a result of the fragmentation and loss of elastin, and the accumulation of GAGs, fibronectin, and collagen, accompanied by increased elastase and MMP activity, all of which contribute to a shift from an elastic to a stiff/fibrotic vessel. Both fibronectin and TGF-β expression are regulated by angiotensin II, and prolonged administration of ACE inhibitors is able to reduce some of these changes [194]. Advanced glycation end-products (AGEs), the products of irreversible, nonenzymatic glycation and oxidation of proteins and lipids, also exert an effect on vascular cells, indirectly, by cross-linking extracellular matrix proteins, thereby increasing vascular stiffness, and directly, by inducing pro-oxidant stress through cell surface receptors such as that for AGEs, RAGE, that is markedly increased in atherosclerotic lesions and after vessel injury [194].

The late events of angiogenesis, in which matrix degradation is associated with the proliferation of endothelial cells that migrate into the perivascular stroma, forming capillary buds and then tubes with a patent lumen, have been described by Deroanne et al. in an *in vitro* model of tubulogenesis [195]. The addition of native collagen to the matrigel substrate, leading to increased stiffness of the support, inhibits endothelial cells from forming tubes [195].

Stem Cells

The potential use and future applications of stem cells are currently under intensive investigation [196]. Not only hematopoietic stem cells [197,198], but also adult liver-derived stem cells [199], have been shown to respond to the microenvironment of the adult heart, *in vivo*, and to differentiate into mature cardiac myocytes. It has been shown that $Flk1^+$ cells derived from embryonic stem cells, and devoid of markers for endothelial cells or mural cells (smooth muscle cells and pericytes), can be stimulated to differentiate *in vitro* into endothelial cells under the influence of VEGF, and into smooth muscle cells under the influence of PDGF-BB [200].

Chapter 1, Part V

Morphology and Chemical Composition of Connective Tissue: The Eye

Richard Mayne

Department of Cell Biology, The University of Alabama at Birmingham, Birmingham, Alabama 35294

INTRODUCTION

The human eye contains a wide diversity of connective tissues that function in a coordinated manner both during the development of the eye and to ensure successful vision. It might, therefore, be anticipated that genetic diseases involving connective tissues generally throughout the body would also have profound effects on the eye and seriously impair vision. However, for reasons that are not entirely clear, this has rarely proved to be the case except for such notable examples as Marfan syndrome, which involves the zonular apparatus, often leading to ectopia lentis [1], or Stickler syndrome which features vitreous collapse due to mutations in either the type II or type XI collagen chains [2] (see also Chapters 12 and 23, Part II, respectively, this volume). In contrast, some genetic diseases of connective tissue specifically affect the eye. For example, various corneal dystrophies are now known to involve mutations in the product of the *BIGH3* gene, kerato-epithelin [3] (see Chapter 26, this volume).

In this limited chapter, it is not possible to provide a detailed morphological description of all of the connective tissues of the eye, and interested readers should consult a recent and highly readable textbook for details [e.g., 4]. Instead, this chapter specifically describes the connective tissue macromolecules present in each tissue of the eye together with some functional information and an indication of their potential involvement in genetic disease. A recent textbook [e.g., 5] should be consulted for more general information on the wide variety of genetic diseases that involve primarily the eye. Figure 1 shows the morphology of the human eye together with the location of the various connective tissues that will be discussed.

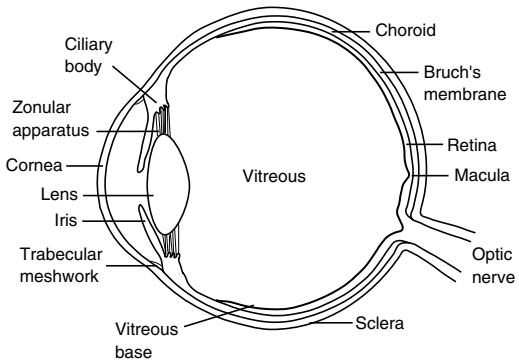

Figure 1. Diagram of the structure of the human eye.

CORNEA

The function of the cornea is to allow the clear passage of light. As such, the stroma contains highly ordered arrays of collagen fibrils of a constant small diameter that are associated with a number of small leucine-rich-repeat (LRR) proteoglycans [6]. In addition, the cornea also possesses an epithelial and an endothelial cellular layer, both of which are associated with highly specialized connective tissues known respectively as Bowman's layer and Descemet's layer (Fig. 2).

Stroma

For many years, the chicken cornea has provided a suitable model for studying both the morphology [7] and biochemical

organization of the corneal stroma [8]. The latter review [8] emphasizes the structure of the primary stroma (which does not arise in development of the mammalian eye) and should be consulted for details of the potential mechanisms in birds by which the primary stroma swells and is replaced by the secondary stroma.

In this chapter, the structure and biochemical composition of the mammalian corneal stroma is reviewed in detail. Morphological observations illustrated in Figure 3 show that the collagen fibrils are of constant diameter and spacing and are organized into interweaving sheets as shown in Figure 4 [9]. Lateral associations between the collagen fibrils are also apparent from quick-freeze deep-etch electron microscopy (Fig. 5) [10]. How this highly ordered arrangement is initially achieved and subsequently maintained by the keratocytes remains unclear.

Collagen

The major collagen type of the adult mammalian cornea is type I but it is also reported that type V may constitute as much as 20% of the total collagen [11–14]. Mammals also differ from birds in exhibiting the presence of type III collagen in the corneal stroma [15,16]. The cornea contains the highest proportion of type V collagen of any tissue of the body and it is thought that this is directly related to the very tight control that must exist on fibril diameter within the stroma [8]. There is some evidence that supports this conclusion from experiments in which the synthesis of type V collagen during corneal development was selectively reduced, resulting in the formation of wider fibrils [17]. In addition, a transgenic mouse with a targeted deletion of a key exon of the α2(V) chain displayed a disruption in the organization of corneal collagen fibrils [18]. Remarkably, these results contrast with Ehlers-Danlos syndrome (EDS) I and EDS II patients who possess mutations in the α1(V) and α2(V) chains yet do not present with noticeably impaired vision (see Chapter 9, this volume). As described in Chapter 2, Part I, this volume, type V collagen is thought to be located such that its noncollagenous amino terminus projects from the surface of the fibril [19]. Both type XII and type XIV collagens are additionally present in the corneal stroma in appreciable amounts and often at discrete locations both in the chicken [20,21] and in mammals [22,23]. Their function there is unknown. Microfibrils of type VI collagen are also present throughout the corneal stroma [24–28], but this tissue and the eye in general appear unaffected in patients suffering from Bethlem myopathy (MIM 158810) (see Chapters 2, Part I, and 26, this volume). Another collagen of the corneal stroma is type XIII, which is an unusual collagen since it contains a transmembrane sequence, and does not form fibrils (see Chapter 2 Part I this volume). It is located in the posterior two thirds of the human cornea where it may play a role in cell–matrix or cell–cell interactions [29].

Proteoglycans

At least four small LRR proteoglycans have been isolated from the corneal stroma [30–32]. These are decorin, lumican, keratocan, and osteoglycin, the latter more recently having been renamed mimecan [33–35] (see Chapter 4, this volume). The organization of these LRR proteins between the surfaces of the collagen fibrils and the interfibrillar matrix is not precisely known, nor is the contribution of the chondroitin sulfate or keratan sulfate chains of each LRR proteoglycan to the staining patterns observed with cupromeronic blue [36]. Renewed interest in the function of these proteoglycans in the cornea originates from the recent knockout of lumican, in which disorganized collagen fibrils of the cornea led to a cloudy appearance [37]. It was also recently demonstrated that mutations in keratocan are responsible for at least one form of corneal dystrophy called

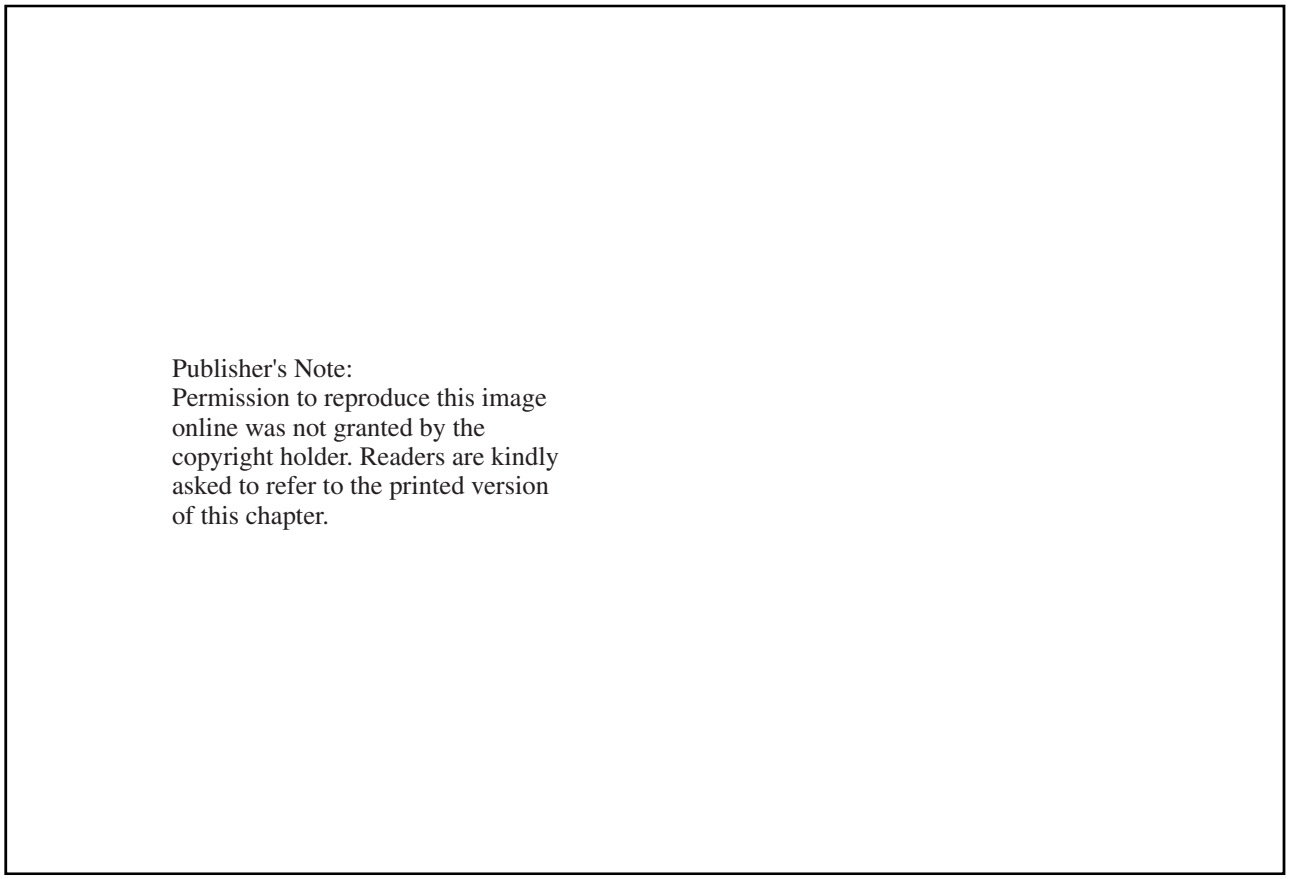

Figure 4. **A**. Scanning electron micrograph of the human corneal stroma (paracentral region). Note a small lamella (arrow) crossing through a larger lamella (arrowhead). **B**. Model for the proposed three dimensional arrangement of lamellae composed of collagen fibrils within the cornea. Figures kindly provided by Dr. Wolfgang Radner, and published previously [9] (with permission of the publishers).

cornea plana 2 (MIM 217300) [38]. However, a knockout of decorin did not appear to affect the cornea sufficiently to cause it to become opaque [39].

Epithelial Basement Membrane

This is a thin, discontinuous, basement membrane that separates the corneal epithelium from Bowman's layer. It appears to be a typical basement membrane and in both mouse and human contains type IV collagen, laminin, nidogen/entactin, and heparan sulfate proteoglycan [40–45]. It is connected to the epithelial cells by hemidesmosomes containing such structural proteins as α6β4 integrin, laminin 5, and type VII and type XVII collagen [46–50].

Bowman's Layer

This layer is a separate structure from the basement membrane of the epithelial cells. Bowman's layer in the human cornea contains collagen fibrils of types I, III, and V, together with microfibrils of type VI collagen but not type IV collagen [51,52]. By electron microscopy, the collagen fibrils are randomly organized in the form of a feltwork and are of slightly narrower diameter than those of the corneal stroma [53].

Descemet's Layer

Much of what is known concerning the structure of this tissue is derived from electron micrographs initially produced by Jakus, in which hexagonal arrays of fibrils were observed stacked on top of each other [54]. The consensus now is that these arrays are type VIII collagen arranged in an antiparallel manner [55,56] (see Fig. 6). However, it appears likely that other as yet unidentified components are also present that stabilize the arrays. Type IV collagen is certainly present and, for rabbit corneal endothelial cells in culture, type VIII and type IV collagen are the major secreted collagens [57].

SCLERA

Recently, the structure and composition of the sclera has been examined in considerable detail in an attempt to understand its role in establishing successful focusing on the retina during eye development (emmetropia) [58,59]. However, less is known concerning the different extracellular matrix macromolecules present within the sclera when compared to the cornea.

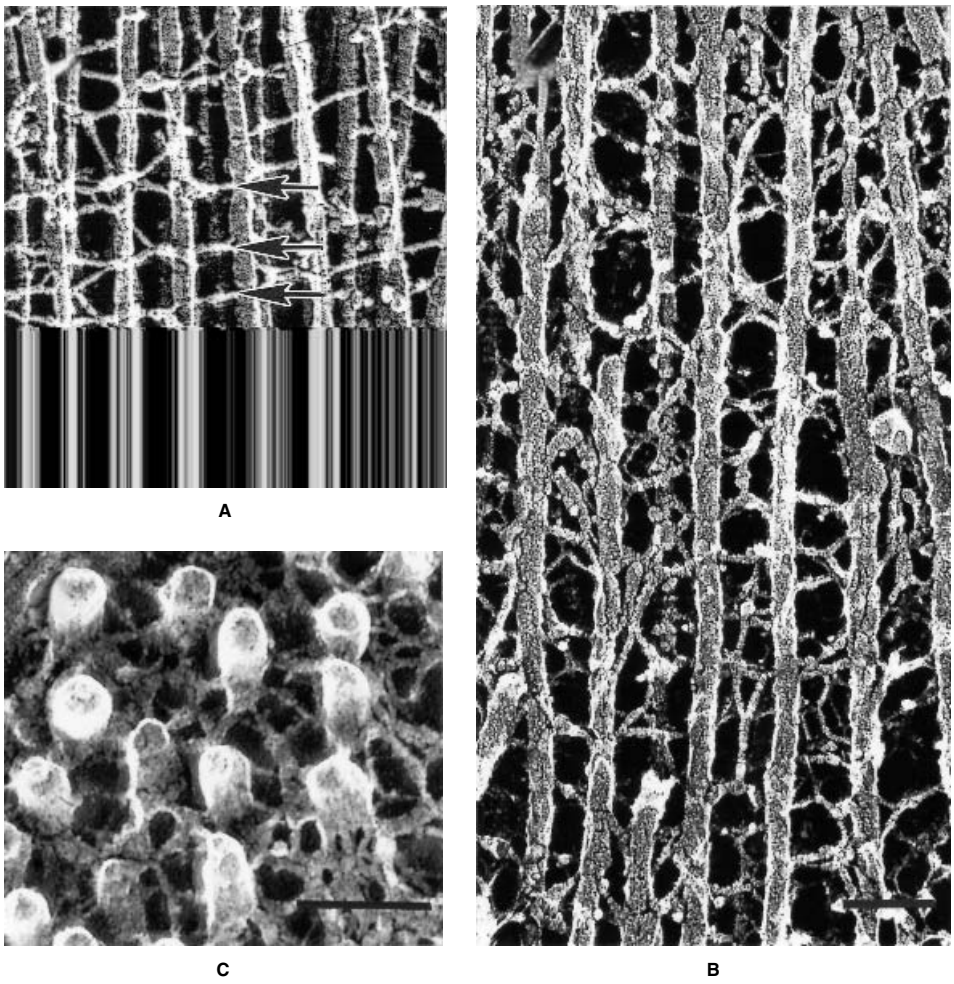

Figure 5. Structure of embryonic chicken corneal stroma as demonstrated by quick-freeze, deep etching at 10 days (panels **A** and **C**) and 15 days (panel **B**). (Bars = 100 nm). Note cross-linking struts between the collagen fibrils often decorated with a small globule (arrows). Figures kindly provided by Dr. Michel Hirsch and Professor Gilles Renard and published previously [10] (with permission of the publishers).

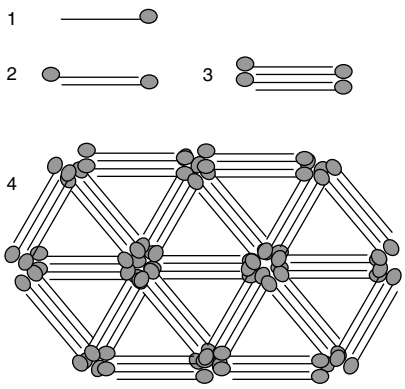

Figure 6. Diagram to show the proposed organization of type VIII collagen molecules to form the hexagonal arrays observed in Descemet's layer. Assembly is thought to occur by antiparallel associations of monomer (1), dimer (2) and tetramer (3) with final formation of an hexagonal array (4). Each monomer consists of a collagen triple helix (shown as a rod) with a globular domain at the carboxyl terminus.

Collagen

The fibrils are much larger in diameter when compared with those in the cornea. In addition, they are not so highly organized and increase in diameter towards the outer surface. Type I collagen is the major collagen of the sclera with smaller amounts of type III collagen and a little type V collagen [51]. It appears that the scleral fibrils are affected in some forms of osteogenesis imperfecta, often being thinner, and the sclera also appearing markedly blue in color (see Chapter 8, this volume).

Proteoglycans

The three major proteoglycans of the sclera are decorin, biglycan and aggrecan [59–62]. The smaller proteoglycans appear largely associated with the collagen fibrils as observed using cuprolinic blue at the critical electrolyte concentration [63,64].

TRABECULAR MESHWORK

It is thought that an accumulation of extracellular matrix within the trabecular meshwork may prevent aqueous outflow, leading to eventual glaucoma. Type VI

collagen is prominent in morphological observations of the trabecular meshwork [65], and often appears as "wide spacing collagen" with a typical banding pattern [66,67]. Other studies have localized collagen types I, II, III, and V to the human trabecular meshwork [68]

LENS CAPSULE

During development, the lens largely consists of epithelial cells which transform to lens fiber cells, elongate, and accumulate large amounts of crystallins [69]. The major extracellular matrix component of the lens is the capsule, which is located on the outer surface of the epithelial cells and contains many typical basement membrane components. The lens capsule is a good source of basement membrane material and played an important role in the initial identification of type IV collagen [70]. In addition to α1(IV) and α2(IV) chains, the presence of α3(IV), α4(IV), and α5(IV) chains has been identified in the lens capsule using highly specific antibodies [71]. These observations are particularly relevant to the etiology of Alport syndrome in which the lens and sometimes Bruch's membrane can be affected (see Chapter 25, this volume) [72]. During the development of the lens, extracellular matrix molecules and their ligands may, however, play critical roles. Thus, mice with a targeted deletion of SPARC (osteonectin, see Chapter 5, this volume) develop cataracts as the major phenotypic response [73–76] and it is considered that SPARC may play a critical role in directing the continuing development of the lens epithelial cells [77]. Developing lens fiber cells synthesize integrin α6β1 [78,79], although the ligand for this integrin has not yet been identified. N-cadherin has also recently been proposed to play a key role in the development of the lens cells [80].

ZONULAR APPARATUS

This tissue forms the suspensory ligament of the lens and consists largely of microfibrils assembled from fibrillin1 [81–83]. Similar microfibrils are found throughout the body and appear to be required for the deposition of elastin. Of particular importance is the failure of these filaments in the zonular apparatus resulting in ectopia lentis as observed in Marfan syndrome (see Chapter 12, this volume).

VITREOUS

The vitreous consists of a very dilute meshwork of collagen fibrils between which are extensive arrays of long hyaluronan molecules [81,84]. The collagens consist largely of type II collagen with smaller amounts of type IX collagen and type V/XI collagen, the latter molecule being assembled from α1(XI) and α2(V) chains [85]. Clinically, collapse of the vitreous can occur because of mutations in either the α1(II) or α1(XI) chains [2] and these results have recently led to the reclassification of Stickler syndrome into 4 subclasses (see Chapter 23, Part II, this volume). The major noncollagenous connective tissue protein of the vitreous is a LRR glycoprotein called opticin, which is found associated with the collagen fibrils [86,87]. Another novel protein of the vitreous is called VIT1, which likely becomes associated with the collagen fibrils during early development and is synthesized by the lens [88]. The large proteoglycan, versican, is also found in the vitreous [89] and may originate from the retina [90]. During the aging process, collapse or liquefaction of the vitreous often occurs with rapid separation of the vitreous from the inner limiting membrane (ILM) of the retina [84]. This can cause a retinal detachment and may also potentially lead to the development of a macular hole [91]. Nothing is known at present of the molecular mechanism by which the vitreous is relatively weakly attached to the ILM or why this attachment fails with increasing age. At the vitreous base attachment is much stronger and again the molecular mechanism is unknown.

RETINA

Several structures in the retina have connective tissue components that are involved in connective tissue disease. These include the ILM and Bruch's membrane, between which is located the retina. Several proteoglycans are present in the retina. The interphotoreceptor matrix contains two novel proteoglycans called either IPM 150 and IPM 200 or SPACR (sialoprotein associated with cones and rods) and SPACRCAN (chondroitin sulfate proteoglycan expressed exclusively by photoreceptors and pinealocytes) [92–95] whereas the large proteoglycan, versican (see Chapter 4 this volume), appears to be located throughout the retina [90]. In addition, decorin [96], neurocan [97], and phosphacan [98] are all expressed in the developing retina. An unusual collagen called type XIII (see Chapter 2, Part I, this volume), is located in the neural retina where it is expressed in the ganglion cell layer [29]. It is speculated that this collagen may be involved in cell–cell contacts within the retina and may contribute to the integrity of this tissue.

Usherin is an important connective tissue macromolecule of the retina. Mutations in the usherin gene are responsible for Usher syndrome type IIa (MIM 276901) which, in the eye, is characterized by progressive retinitis pigmentosa [99–101]. Molecular cloning of usherin shows that it contains laminin-like epidermal growth factor (EGF) domains and also fibronectin type III domains [100,101]. Retinitis pigmentosa is also caused by mutations in a human homologue of *Drosophila crumbs* called *CRB1* (MIM 604210) which is located at the RP12 locus on chromosome 1q31-q32.1 [102]. This is also an extracellular protein that contains EGF-like domains, laminin A-chain G-like domains and a C-type lectin domain [102].

Inner Limiting Membrane

This forms a typical basement membrane on the inner surface of the retina and contains all of the usual constituents of basement membranes, including laminin, type IV collagen (largely α3, α4, and α5 chains, with smaller amounts of α1 and α2 [103,104]), nidogen and agrin. Interestingly, in birds it appears that the ILM is not assembled by retinal tissue, but is derived from the vitreous, where it accumulates on specific receptors located on the retinal surface [105]. These results have not so far been confirmed for mammals in which, unlike the chicken, the retina is thicker and in some species, including man, extensively vascularized. This work is very relevant to recently developed methodology for the repair of macular holes in which, after initial removal of the vitreous, the ILM is peeled from the surface of the retina [106]. If the ILM originates from the vitreous this may explain why it does not reform after peeling and why it can be peeled so easily, especially in older individuals.

Bruch's Membrane

This is a complex connective tissue with basement membrane-like elements located between the retina and

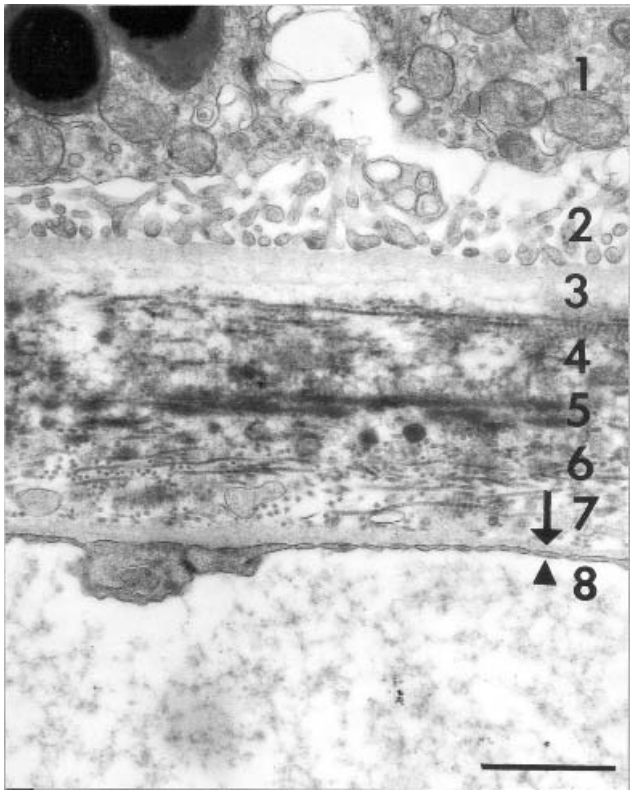

Figure 7. Bruch's membrane from the retina of an 87-year-old female. 1. RPE (retinal pigmented epithelial) cell, 2. basal location of extensive infolding of the plasmalemma of the RPE cell, 3. inner basement membrane. 4. inner collagen layer, 5. elastin layer, 6. outer collagen layer, 7. outer basement membrane, 8. choroidal capillary endothelial cell (note pores). (Bar = 1 μm). Electron micrograph kindly provided by Christine Curcio, Ph.D.

the choroid (Fig. 7) which serves as a support element for the retinal pigmented epithelium and also acts as a filtration barrier for nutrients and metabolites passing between the photoreceptors and the choriocapillaris. It shows marked changes with aging as material accumulates within Bruch's membrane that can eventually predispose the retina to age-related macular degeneration (AMD) [107]. There are five layers that can be distinguished (see Fig. 7); the innermost basement membrane associated with the retinal pigmented epithelial cells, the inner collagen zone, an elastic zone, an outer collagen zone, and an outer basement membrane associated with the endothelial cells of the choriocapillaris. The collagen fibrils consist of types I, III, and V collagen that are interwoven and appear to pass through the elastic layer [108]. Type IV collagen, laminin, and heparan sulfate are present in both basement membranes, while small proteoglycans are associated with the collagen fibrils. It is thought that Bruch's membrane is permeable to metabolites of the photoreceptor cells which are being continuously passed from the retinal pigmented epithelial cells to the choroid. With aging, drusen are observed that are poorly characterized deposits between the retinal pigmented epithelium (RPE)—basal lamina and Bruch's membrane. Interestingly, vitronectin has recently been identified as one component of drusen, but it is not known if it is derived from the retina or plasma [109], although gene expression for vitronectin occurs in the adult human retina [110]. Accumulations of long-spacing collagen commonly occur in Bruch's membrane with aging and recent results suggest that these may consist of lateral aggregates of type VI collagen [111]. Of particular interest is the recognition that the accumulation of deposits in Bruch's membrane in Sorsby fundus dystrophy (MIM 136900) is related to mutations in *TIMP3* [112–118] (see Chapter 7, this volume). Another observation of interest is the identification of a novel extracellular matrix protein called EFEMP1 (epidermal growth factor fibrillin-like extracellular matrix protein-1) in which a single mutation has been found for both the Malattia Leventinese and Doyne honeycomb (MIM 126600) forms of retinal dystrophy [119]. *EFEMP1* was previously cloned and shares sequences common to both fibulins and fibrillins [120] and presumably forms an important structural component of Bruch's membrane.

Pseudoxanthoma elasticum (PXE) (MIM 177850; 264800) (see Chapter 11, this volume) is a genetic disease in which all elastic structures of the body, including Bruch's membrane, are affected. Initially, it was considered that elastin or elastin-associated genes were likely to be involved. However, the condition arises from mutations in a gene called *MRP6*, which is a member of the ABC transporter gene family [121–123].

Interphotoreceptor Matrix

This represents the extracellular matrix that occupies the apical surface of the retinal pigmented epithelium and the external limiting membrane of the neural retina. Two novel chondroitin sulfate-containing proteoglycans have been identified in this structure, called IPM 150 and IPM 200 [92,93] or SPACR (sialoprotein associated with cones and rods) and SPACRCAN (chondroitin sulfate proteoglycan expressed exclusively by photoreceptors and pinealocytes) [94,95]. In addition, hyaluronan is present in the interphotoreceptor matrix [124] and interacts with SPACR [94] and SPACRCAN [95].

CONNECTIVE TISSUE MACROMOLECULES IN THE DEVELOPMENT OF THE EYE

In the rare autosomal recessive disorder called Knobloch syndrome, characterized by occipital encephalocele (MIM 267750) (see also Chapter 26, this volume), there is a failure of early eye development that results in severe myopia, and vitreoretinal degeneration often resulting in retinal detachment, as well as changes in macular structure [125]. In one form of the syndrome, a mutation has been identified in the gene for collagen XVIII, *COL18A1*, which was also found to be expressed in the adult human retina [125]. These results suggest a key role for collagen XVIII in early eye development. The powerful inhibitor of angiogenesis called endostatin is potentially derived from the carboxyl terminus of collagen XVIII by proteinase activity [126–128]. It is possible that endostatin plays a key role in the degeneration of the hyaloid artery present in the primary vitreous and this is supported by analysis of transgenic mice with a targeted deletion of the α1(XVIII) gene (B.R. Olsen, personal communication). Interestingly, in the adult chicken eye, collagen XVIII is a major constituent of the inner limiting membrane where it appears to be derived from the vitreous [129]. Thrombospondin-1 may also play a key role in controlling angiogenesis in the eye. It is synthesized by human retinal epithelial cells [130], is present in the vitreous

and aqueous humor [131], and can give rise to peptides that inhibit retinal angiogenesis [132]. However, other factors such as pigment epithelium derived factor (PEDF) are also likely to be important in controlling angiogenesis in the mammalian eye [133].

RECENT DEVELOPMENTS

Cornea

Macular Corneal Dystrophy I and II (MCDCI and MCDC2; MIM 217800)

Although it was long speculated that MCDC1 and MCDC2 arose from a defect in glycosaminoglycan metabolism [134], this has now been confirmed by the discovery of mutations in a novel carbohydrate sulfotransferase gene (*CHST6*; MIM 605294) which shows considerable specificity for the cornea [135]. The levels and activity of CHST6 enzyme in macular corneal dystrophy-affected cornea can easily account for the low- or nonsulfated keratan sulfate chains commonly seen in patients [136–138]. Similar mutations in *CHST6* have also been found in MCDC patients from the Icelandic population, showing that mutations in the *CHST6* gene commonly occur in diverse populations [139].

Vitreous

Further studies have now determined the structural organization of the human and mouse opticin genes [140]. In addition, *in situ* localization of opticin expression in the mouse shows that the molecule is largely synthesized by the nonpigmented posterior ciliary epithelium [140].

Retina

Interphotoreceptor Matrix

SPACR and SPACRCAN. The role of these molecules in the structure and development of the interphotoreceptor matrix has now been studied in detail [141–143]. In the present model, hyaluronan is considered to be the primary scaffold of the interphotoreceptor matrix, with SPACR and SPACRCAN interacting directly with it [144].

Retinitis Pigmentosa

Usher syndrome type IIa (USH2A; MIM 276901). Further patients with the clinical symptoms of USH2A have been examined for mutations in usherin [145–149]. Although many different mutations have been found, a single mutation (2299delG) commonly occurs among many different races and clearly represents a frequent cause of the disease. It appears that this mutation represents between 16% to 44% of all mutations detected to date in various populations [149].

Crumbs Homologue 1 (CRB1; MIM 600105). It has been shown that mutations in the *CRB1* gene, in addition, cause Leber congenital amaurosis (LCA) in a small proportion of patients [150,151].

Congenital Stationary Night Blindness, Type 1 (CSNB1; MIM 310500). Mutations in a novel small leucine-rich proteoglycan called nyctalopin (NYX; MIM 300278) have been demonstrated in X-linked complete CSNB [152,153].

Bruch's Membrane

Malattia Leventinese and Doyne Honeycomb Forms of Retinal Dystrophy

Further investigations have been made into the mutations in *EFEMP1* (epidermal growth factor fibulin-like extracellular matrix protein) which are associated with premature, autosomal dominant drusen [154,155]. A single mutation, Arg345Trp accounts for all the mutations in EFEMP1 so far detected [155]. Interestingly, EFEMP1 is identical to a protein called fibulin-3 [156]. In addition, a second gene, *EFEMP2*, has been identified [157], the product of which is fibulin-4 [156,158]. This is a potential candidate gene for several retinopathies.

Pseudoxanthoma Elasticum (PXE)

The gene involved in PXE was originally called *MRP6*, but more recently the abbreviation *ABCC6* has been used extensively. Further mutations in *ABCC6* have been described [159–161], and a general review of the disease has been published which describes the morphological changes observed in the eye [162].

ACKNOWLEDGMENTS

Pauline Mayne and Jeanne Holloway are thanked for their assistance in the preparation of this manuscript. Original electron micrographs were kindly provided by Dr. Wolfgang Radner, University of Vienna; Dr. Michel Hirsch and Professor Gilles Renard, Université Pierre et Marie Curie, Paris; Dr. David Birk, Thomas Jefferson University, Philadelphia; and Dr. Christine Curcio, University of Alabama at Birmingham. Drs. Christine Curcio, David Birk, Paul Bishop, and David Whikehart are also thanked for their critical reading of the manuscript.

Chapter 2, Part I

The Collagen Family: Structure, Assembly, and Organization in the Extracellular Matrix

Cay M. Kielty and Michael E. Grant

Wellcome Trust Centre for Cell-Matrix Research, School of Biological Sciences, University of Manchester, Oxford Road, Manchester M13 9PT, United Kingdom

INTRODUCTION

The evolution of multicellular organisms was associated with the emergence of a framework in which cells could survive in a controlled environment where cell contact was retained and cell specialization could occur. This fundamental requirement was met by the formation of a network of intercellular connecting elements that not only permitted the inflow and outflow of materials essential for life but also provided protection from external physical stress on the organism. Thus it was that the connective tissues evolved to provide the strength and shape required by higher animals, and the simple basis on which these tissues are designed has been maintained throughout much of evolution. Two main elements fulfill the needs of the structures now described as the extracellular matrix of connective tissues, namely, the insoluble fibers that resist tensile forces and the interfibrillar polymers that inflate the fibrous network, thereby providing resistance to compressive forces but also allowing diffusion of small molecules in and out of the tissue. The proteinaceous fibers are normally composed of collagen, although elastin too can provide a significant portion of the insoluble fibers in elastic tissues, and the soluble interfibrillar carbohydrate-protein complexes occur primarily as proteoglycans, although the glycosaminoglycan hyaluronan can be an important constituent in tissues such as cartilage, vitreous, and skin. Also contributing to the stability of the matrix are the noncollagenous adhesive glycoproteins such as fibronectin, laminin, tenascin, and entactin, which provide a potential bridge between the matrix and the cells embedded within it. Tissue matrices comprising collagens, elastic fibers, glycoproteins, and proteoglycans form diverse composite structures that determine organ histoarchitecture and provide cells with a mechanical scaffold for adhesion and migration. Indeed, almost all aspects of cell function are influenced, often profoundly, by the surrounding matrix, and the dynamic interplay between cells and matrix regulates tissue remodeling during growth, differentiation, morphogenesis, and wound healing, and in pathological states such as arthritis, fibrosis, atherosclerosis, and tumorigenesis.

New methodologies developed between 1940 and 1970 established the detailed chemical structures of the major constituents of the matrix. Proteoglycans (previously described as mucopolysaccharides) and collagen were shown to be the predominant components of the extracellular matrix, and noncollagenous glycoproteins (originally referred to as mucoproteins), which were initially considered to be impurities or insignificant constituents possibly of cellular or plasma origin, were subsequently shown to have a fundamental role in the matrix. Matrix–matrix interactions between modular motifs within extracellular matrix (ECM) molecules drive fibril or lamina formation and are integral to connective tissue structure and function. The relative proportions of the collagenous and proteoglycan components were generally viewed as the key determinants of the mechanical properties needed by a tissue to fulfill its biological function. Thus, a tissue such as tendon, which needs to be resistant to extension, comprises primarily tough collagen fibers, whereas a tissue like cartilage must be resistant to compression and, therefore, needs to comprise approximately 50% proteoglycan. Other tissues must be rigid and resistant to deformation, and bone achieves its function by combining calcium salts with the collagen fibers, but in tissues such as aorta and lung, where elastic recoil is a crucial feature of tissue function, the collagen fibers are accompanied by elastic fibers containing the protein elastin.

This essentially simple view of connective tissue is still valid today, although over the last 30 years it has become apparent that these important tissues that provide the framework or scaffolding of higher animals are far more complex than previously realized. The basic building blocks — collagens, proteoglycans, and glycoproteins — are now each recognized to occur as large families of matrix macromolecules, with many representatives occurring in one tissue. For example, cartilage is known to contain at least five different collagen types, several proteoglycans, and an ill-defined number of matrix glycoproteins. Similarly, bone is known to contain at least three collagen types, two or three proteoglycans, and several noncollagenous glycoproteins. Some of these components represent very minor constituents of the extracellular matrix and their roles remain unknown, but their importance to tissue integrity

Connective Tissue and Its Heritable Disorders, pages 159–221

is likely to be critical, as is well illustrated by the specific absence of functional type VII collagen, quantitatively a very minor component of skin, in patients with the severe recessive dystrophic type of epidermolysis bullosa ([1–3] and Chapter 15, this volume). In this chapter, we discuss the current understanding of the family of matrix macromolecules that are classified as collagens. Wherever possible, reference will be made to reviews and recent papers at the expense of original observations, for it is intended that the reader be provided with a way into the relevant literature rather than an exhaustive survey of the bibliography.

TABLE 1. The Family of Genetically Distinct Collagen Types

Collagen Type	Chains	Molecular Assembly	Supramolecular Structure	$M_r \times 10^{-3}$/ α chain	Examples of tissue location
I	$[\alpha1(I)]_2\alpha2(I)$	Monomers staggered by 67 nm	Large-diameter, 67-nm banded fibrils	95	Bone, cornea, dermis, tendon
I trimer	$[\alpha1(I)]_3$		67-nm banded fibrils		Tumors, dermis
II	$[\alpha1(II)]_3$	Monomers staggered by 67 nm	67-nm banded fibrils	95	Cartilage, vitreous
III	$[\alpha1(III)]_3$	Monomers staggered by 67 nm	Small-diameter, 67-nm banded fibrils	95	Dermis, aorta, uterus, intestine
IV	$[\alpha1(IV)]_2\alpha2(IV)$; also α3(IV), α4(IV), α5(IV), α6(IV)	Association of 4N- and 2C-termini	Nonfibrillar meshwork	170–180	Basement membranes
V	$[\alpha1(V)]_2\alpha2(V)$ $[\alpha1(V)\alpha2(V)\alpha3(V)]$ $[\alpha1(V)]_3$	Monomers staggered by 67 nm	9-nm diameter banded fibrils	120–145	Placental tissue, bone, dermis, cornea
VI	[α1(VI) α2(VI) α3(VI)]	Association into tetramers that aggregate end to end	5–10-nm diameter beaded microfibrils, 100-nm periodicity	α1 (VI) 140 α2 (VI) 140 α3 (VI) 340	Uterus, dermis, cornea, cartilage
VII	$[\alpha1(VII)]_3$	Lateral aggregation of antiparallel dimers	Anchoring fibrils	170	Skin, amniotic membrane, mucosal epithelium
VIII	$[\alpha1(VIII)]_2\alpha2(VIII)$	?	Nonfibrillar, hexagonal lattice?	61	Descemet's membrane, endothelial cells
IX	[α1(IX) α2(IX) α3(IX)]	Covalently cross-linked to surface of type II collagen fibrils	FACIT[1]; nonfibrillar	68–115	Cartilage, vitreous
X	$[\alpha1(X)]_3$	?	Nonfibrillar, hexagonal lattice?	59	Calcifying cartilage
XI	[α1(XI)α2(XI)α3(XI)]	Monomers staggered by 67 nm	Fine fibrils similar to those of type V collagen	110–145	Cartilage, intervertebral disc
XII	$[\alpha1(XII)]_3$	Probably associates with surface of collagen fibrils	FACIT; nonfibrillar	220,340	Dermis, tendon, cartilage
XIII	α1(XIII)	?	Membrane-intercalated	62–67	Endothelial cells, epidermis
XIV	$[\alpha1(XIV)]_3$	?	FACIT; nonfibrillar	220	Dermis, tendon, cartilage
XV	α1(XV)	?	MULTIPLEXIN[2]; nonfibrillar	125	Placenta, kidney, heart, ovary, testis
XVI	α1(XVI)	?	FACIT; nonfibrillar	150–160	Heart, kidney, smooth muscle
XVII	$[\alpha1(XVII)]_3$	?	Membrane-intercalated	180	Hemidesmosomes of specialized epithelia
XVIII	α1(XVIII)	?	MULTIPLEXIN; nonfibrillar	200	Kidney, liver, lung
XIX	α1(XIX)	?	FACIT; nonfibrillar	Unknown	Fibroblast cell lines

[1] FACIT collagens are fibril-associated collagens with interrupted triple helices.

[2] MULTIPLEXIN collagens have multiple triple helical domains and interruptions.

The Collagen Family of Proteins

Collagens are the most abundant proteins in the animal kingdom, and are even found in the earliest forms of metazoan life [4,5]. The term "collagen" has been in the English language since at least 1865, and its derivation from the Greek word γξλλξζνξ for "glue" is reflected in its early definition in the *Oxford Dictionary* (1893 edition) as "that constituent of connective tissue which yields gelatin on boiling." The economic importance of collagen has been recognized for thousands of years, for collagen is the main constituent of skin, the raw material of leather, and gelatin, which have long been commercially important commodities. Indeed, much of our current knowledge of collagen structure derives from important work conducted by chemists in the leather and gelatin industries. Subsequently, interest in the biochemistry of collagen focused on the unusual properties of this protein and its involvement in many of the chronic diseases of humans, e.g., atherosclerosis, liver fibrosis, and rheumatoid arthritis, where the excessive deposition of connective tissue elements compromises tissue structure and function. Latterly, the application of the techniques of gene cloning to the study of collagen genes and their involvement in inherited diseases such as osteogenesis imperfecta (see Chapter 8, this volume) and the Ehlers-Danlos syndrome (see Chapter 9, this volume) has provided new insight into normal collagen synthesis, structure, and function.

Modern research on collagen at the molecular level began in the 1950s, with the application of rapidly developing physicochemical techniques, e.g., X-ray crystallography and electron microscopy. The triple-helical arrangement of collagen was recognized using helix diffraction theory [6,7], and models of supercoiled triple-helical arrays were subsequently developed [8–10]. Using collagen-like peptides, high-resolution crystal structure determinations of triple-helices have been achieved [11–13], which confirm the triple-helical model obtained from fiber diffraction. Further advances in protein separation techniques (see introductory chapter by Piez, this volume) led to the discovery, in 1969, that cartilage collagen (type II) was genetically distinct from the well-studied fibrous collagen (type I) of skin, bone, and tendon — and so provided the first evidence for the existence of a family of collagenous proteins associated with the connective tissues of vertebrates [14]. Shortly after this, another unique collagen (designated type III) was detected in skin [15].

Studies over the last two and a half decades have now led to the identification of approximately 33 different collagenous polypeptides believed to be encoded by a minimum of 33 different gene sequences [4,5,16–20]. These polypeptides occur in the extracellular matrix in at least 19 different collagen types (designated I to XIX, see Table 1 and Recent Developments), and further unique collagenous polypeptides will undoubtedly be identified following completion of elucidation of the human genome sequence. The collagenous triple-helix conformation has also been found as a domain in an increasing number of secreted proteins, including host defense proteins such as complement component Clq and serum mannan-binding lectin [21–32] (see Table 2). The collagenous sequences in these proteins clearly contribute to their distinctive structures and functions, but the fact that they have no known structural role in the extracellular matrix precludes their classification as collagens.

Classification of Collagen Types

Early definitions of collagen were conditioned by our knowledge being restricted to the major fibrous collagen

TABLE 2. Non-Extracellular Matrix Molecules with Homologies to Collagen Types VIII and X

Molecule	Homologous regions	Molecular organization	Tissue distribution	Biological role
Collectin subgroup of C-type animal lectins				
Mannan-binding lectin (MBL)	Collagen-like domain, carbohydrate recognition domain (CRD), homologous to NC1	Triple-helical homotrimers, oligomeric (serpiform, 6 helices)	Liver, serum	Lectins, host defense factors involved in complement activation
Surfactant protein-A (SP-A)	Collagen-like domain, CRD homologous to NC1	Triple-helical homotrimers, oligomeric (serpiform, 6 helices)	Lung, gut	Mediator in lung, innate immune defense
Surfactant protein-D (SP-D)	Collagen-like domain, CRD homogolous to NC1	Triple-helical homotrimers, oligomeric (cruciform, 4 helices)	Lung, gut	Mediator in lung, innate immune defense
Conglutinin	Collagen-like domain, CRD homologous to NC1	Triple-helical homotrimers, oligomeric (cruciform, 4 helices)	Liver, serum	Lectin, conglutination, inhibits haemagglutination by influenza A virus
Collectin 43 (CL-43)	Collagen-like domain, CRD homologous to NC1	Triple-helical homotrimers ? Non-oligomeric	Serum	Role in innate immune defense against microorganisms
CL-L1	Collagen-like domain, CRD homologous to NC1	Triple-helical homotrimers ? Oligomers	Liver, placenta	Unknown (binds mannan weakly).

(*continued overleaf*)

TABLE 2. (*continued*)

Molecule	Homologous regions	Molecular organization	Tissue distribution	Biological role
Complement and related factors				
C1q	Collagen-like domain, NC1-like sequence	Heterotrimeric triple-helical, oligomeric	Serum	Complement component, recognition of microbes, antibody-antigen complexes
C1q-related factor (CRF)	Collagen-like domain, NC1-like sequence	Triple-helical homotrimers, ?Oligomeric	Brain	?Role in motor function
Ficolins (L- and M-forms)	Collagen-like domain, CRD homologous to NC1	Triple-helical ?Homotrimers ?Oligomeric	Liver, plasma, monocytes	Binds sugars, enhances bacterial phagocytosis.
Metabolic molecules				
Adipocyte complement-related protein of 30 kDa (ACRP30)	Collagen-like domain,NC1-like sequence	Homotrimeric, triple-helical, oligomeric	Fat cells	Energy homeostasis, obesity
Hib27	Collagen-like domain, NC1-like sequence	?Homotrimeric triple-helical, oligomeric	?? (Chipmunk)	Energy homeostasis, hibernation
Acetylcholinesterase (AchE)	Collagen-like domain	?Homotrimeric triple-helical	Neuromuscular junction	Hydrolyses released acetylcholine, controls duration of receptor activation
Cytokines and related molecules				
Tumor necrosis factor (TNF)-α	Gly, Pro-rich sequences, NC1-like sequence	?Homotrimeric triple-helical	Widespread	Roles in immunity, energy homeostasis
Tumor necrosis factor (TNF)-β	Gly, Pro-rich sequences, NC1-like sequence	?Homotrimeric triple-helical	Widespread	Roles in immunity, energy homeostasis
CD40L	NC1-like sequence		Widespread	Roles in immunity, energy homeostasis
FAS ligand (FASL)	NC1-like sequence	?Trimeric	Widespread	Membrane-bound, energy homeostasis, apoptosis in immune system
Ectodysplasin	Collagen-like domain, NC1-like sequence	Trimeric	Epithelia	Membrane bound, role in cell adhesion, epithelial- mesenchymal interactions
Elastic fiber-associated molecules				
Emilin-1	NC1, short collagenous sequence	Homotrimeric triple helical	Elastic tissues	Elastic fibre formation
Emilin-2	NC1, short collagenous sequence	?Homotrimeric triple helical	??	??

found in skin, bone, and tendon (i.e., type I collagen). Accordingly, such definitions were based on type I collagen in terms of its histological properties, electron microscopic features, chemical composition, physical properties including X-ray diffraction pattern, and behavior toward enzymes. As knowledge of the structure of the new collagens has accumulated, it has become increasingly difficult to provide a satisfactory general definition other than to state that such proteins comprise three polypeptides that fold to form triple-helical domains (determined by the high glycine and imino acid contents in specific repeating triplets of Gly–X–Y, where X is often proline and Y is often hydroxyproline), which assemble into supramolecular aggregates in the extracellular space [33]. Clues to the evolution of the different collagen types are revealed in the detailed analysis of collagen gene structure (see this Chapter, Part II), but, in functional terms, it appears that the various collagens have developed to provide a

variety of structures (fibers, microfibrils, microfilaments, and meshworks) necessary to adapt connective tissue to its numerous physiological and mechanical functions in the body.

As the number of collagen types defined in the literature has increased, attempts have been made to discuss them in terms of groups or classes. The collagen numbering system (roman numerals for each collagen type and arabic numerals for individual α chains) to some extent reflects the relative abundance of the various collagens, in that generally the more abundant collagens were identified earliest. Thus, in terms of the whole body collagens, types I, II, and III are quantitatively the most important and probably account for over 70% of the total [34]. These fibril-forming collagens were originally referred to as the interstitial collagens on the basis of their widespread distribution and structural roles within the connective tissues supporting the major organs of the body. However, this terminology is no longer favored, in as much as several other less abundant collagens (both fibril-forming and with different macromolecular arrangements) have similar tissue distributions. Early classifications often referred to major and minor collagens on the basis of their quantitative abundance in connective tissues. However, quantification is fraught with difficulties, and a major collagen in one tissue may be a minor component in another (e.g., the ubiquitous microfibrillar type VI collagen is a major collagenous component of skin but a relatively minor element of cartilage). Moreover, such a simple classification says little about the structure/function relationships of the collagen types that derive from their primary amino acid sequences.

Current classifications are based largely on primary structure, and collagenous molecules can be grouped into three categories on the basis of the respective sizes of their collagenous triple helices [35,36] (Fig. 1). Group 1 molecules are characterized by an uninterrupted helical domain of approximately 300 nm. These collagens are synthesized as procollagens comprised of three proα chains that undergo processing to α chains and subsequently assemble into collagen fibrils and fibers. Collagens in Group 1 (i.e., types I, II, III, V, and XI) exhibit several common structural features that reflect the highly conserved exon-intron structure of the genes for many of the chains involved (see this Chapter, Part II). Group 2 comprises collagen types IV and VII, whose component polypeptides are distinguished by their large M_r (>160,000) and especially by their extended triple helices (>350 nm), and whose primary structures are characterized by imperfections in the Gly–X–Y triplet sequence. These imperfections are a particular feature of type IV collagen, in which the helical domain contains more than 20 short stretches of non-helix-forming amino acids. In contrast, Group 3 comprises short-chain collagens. In this review, this grouping has been subdivided into Group 3A, which comprises short-chain collagens with continuous triple-helical domains (type VI, VIII, and X collagens), and Group 3B, which includes collagens with interrupted helical domains such as the fibril-associated collagens with interrupted triple helices (FACIT collagens) types IX, XII, XIV, XVI, and XIX, the transmembrane collagens XIII and XVII, and the MULTIPLEXIN collagens (multiple triple-helix domains and interruptions) types XV and XVIII. In Group 3B, the individual polypeptides vary in size from 623 to 3063 residues as a consequence of large nonhelical domains at the termini of some of the α chains.

This type of grouping of collagenous molecules, based largely on size and physicochemical properties, is not totally satisfactory because it provides no clues as to the biological roles of individual collagens. An alternative approach would be to classify the collagens according to particular structural features that might be related to their physiological function; e.g., the possession of intrahelical sites susceptible to cleavage by different vertebrate collagenases (as in collagen types I, II, III, IV, VII, VIII, and X) might indicate an involvement in matrix turnover and tissue (re)modeling. Further classifications based on gene structure seem likely to emerge as evidence for alternative splicing of some of the collagen genes indicates that individual collagen types may themselves represent a family or group of related collagenous structures in the extracellular matrix (e.g., type VI collagen).

Homology between the gene and protein structures of the different collagens can provide evidence of evolutionary relationships and functional activities. Thus, types IX, XII, XIV, XVI, and XIX collagens exhibit fascinating similarities in their interrupted triple-helical structures; based on structure/function considerations, the grouping or subclass of FACIT collagens, containing these types, has arisen [16,37,38]. Similarly, the remarkable homology of collagen types VIII and X suggests that they probably have similar roles in the tissues in which they are located [16,37,39].

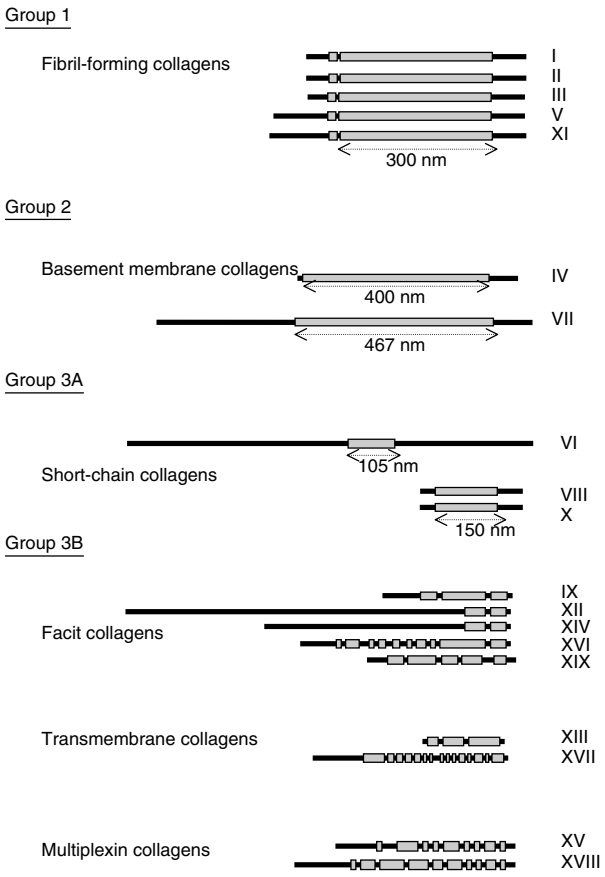

Figure 1. Schematic representation of the domain structures and relative dimensions of the different molecules of the classified collagen family (types I–XIX; groups 1–3). Triple-helical domains are represented by shaded bars and non-helical sequences as solid lines. Lengths of triple-helical domains (nm) are indicated by arrows.

In this chapter, it has been considered appropriate to discuss the biochemistry of the collagen types in relation to their known structure, organization, and function in the extracellular matrix. Where individual collagens fall into well-defined subclasses, they are discussed together. A detailed description of the structure, assembly, and supramolecular aggregation of collagen type I is presented below, for it provides the prototype against which background has developed our appreciation of the other fibrillar collagens and the nonfibrillar "minor" collagens.

COLLAGEN TYPE I: THE CLASSICAL FIBROUS COLLAGEN

Collagen is probably the most abundant protein in the human body and, while the classical fibrous collagens (types I, II, and III) occur in the greatest amounts, type I collagen is, quantitatively, by far the most important. Accordingly, it is not surprising that much of our current understanding of the structure, synthesis, and assembly of collagens is derived from studies on this collagen, which provides the major mechanical strength of tissues such as skin, tendon, bone, dentine, cornea, and sclera.

Fibrous collagen is classified as a quasi-crystal, or crystalloid, because of its highly symmetrical insoluble structure built up of essentially identical subunits. Gross visual examination of a tissue such as tendon demonstrates that type I collagen (accounting for approximately 90–95% of the dry weight of the tissue) is present as large, highly orientated fibers. More detailed examination under the electron microscope, after appropriate fixation and staining, reveals the fibers to comprise bundles of smaller, identical, and parallel microfilaments having a characteristic pattern of cross-striations or bands (Fig. 2). There is, as yet, no common nomenclature for collagen fibers and fibrils. For the sake of clarity, we refer to the structures that can be seen with the naked eye as "fibers" and the smallest structures visible by light microscopy as "fibrils."

Although not all collagen types are organized into classical cross-striated fibrillar structures, the major fibrillar collagen types form distinctive long, unbranched, banded fibrils. Low-angle X-ray diffraction studies have revealed a characteristic

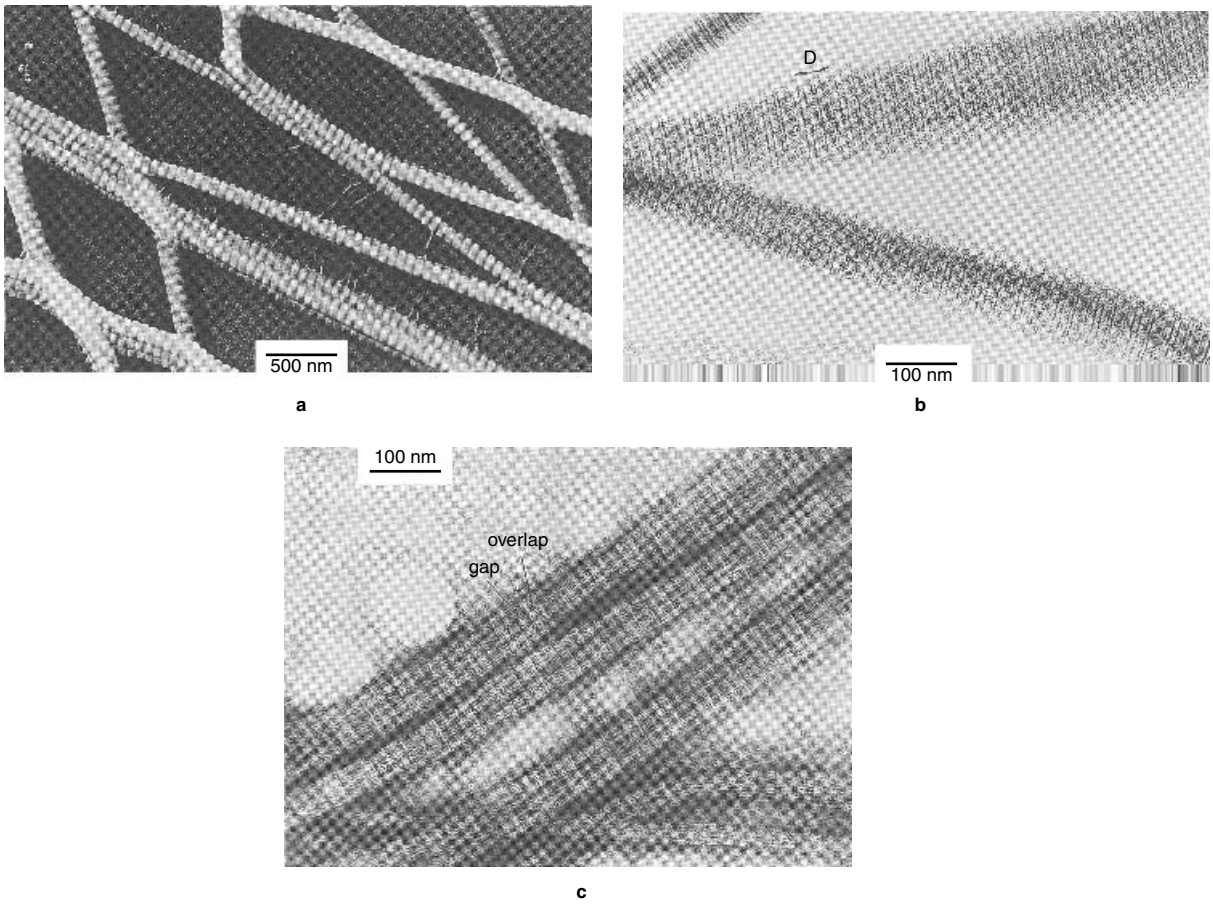

Figure 2. The appearance of collagen fibrils in the electron microscope. In (**a**), fibrils (extracted from human Achilles tendon) have been unidirectionally shadowed with gold-palladium. The D-periodic banding is strikingly revealed, but only low-resolution surface contours, accentuated by the shadowing, are detectable. In (**b**), fibrils have been positively stained by exposure to aqueous solutions of phosphotungstic acid (PTA, 1%, pH 3.4) and uranyl acetate (UA, 1%, pH 4.2). In (**c**), fibrils have been negatively stained with phosphotungstic acid (1%, pH 7.0), which reveals the characteristic alternation of dark (stain-penetrable) and light (stain-excluding) zones, the so-called "gap "and "overlap "zones. In (**b**) and (**c**), the fibrils are of type I collagen from calf skin, initially solubilized in citric acid solution and then reconstituted into fibrils. (Reprinted from ref. 53 with permission from Pergamon Press.)

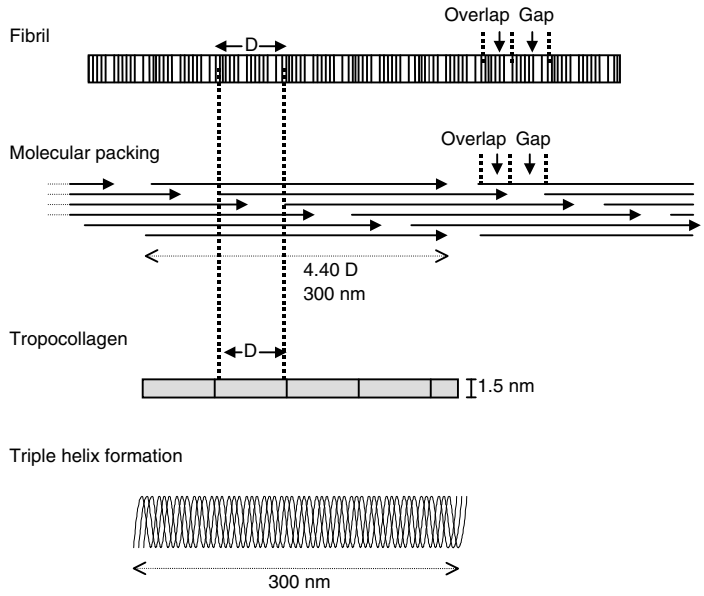

Figure 3. Schematic diagram illustrating in two dimensions the relationship between collagen chains and assembled fibrils. The right-handed triple-helical molecule of 4.4D periods in length that constitutes tropocollagen is made up of three individual collagen chains (two α1(I) chains and one α2(I) chain), each coiled in a left-handed helix. The staggered arrangement of tropocollagen molecules in the fibril gives rise to one overlap zone and one gap zone per D period. Note: 0.15D (10.4 nm) represents one turn of the superhelix.

periodicity (D) close to 67 nm in the native hydrated state [40], although dehydration and shrinkage during conventional sample preparation for electron microscopy results in lower values of around 64 nm. These fibrillar structures are accounted for by the specific parallel and mutually staggered alignment of the basic molecular units of collagen — the collagen fibril monomers (frequently described as "tropocollagen") — which is directed by the sequence of the interactive hydrophobic and charged residues distributed along the triple helix to provide the maximum electrostatic and hydrophobic interaction of the neighboring molecules. A variety of physicochemical studies, including direct visualization of the individual molecules by rotary shadowing techniques in the electron microscope, have demonstrated the rodlike nature of the collagen fibril monomer. These molecules of type I collagen have a length of slightly less than 300 nm and a diameter of about 1.4 nm. The rod is neither rigid nor randomly flexible, but appears to possess an intermediate level of semiflexibility that probably varies along its length. The individual molecules consist of three polypeptide chains (designated α chains) that are coiled into a unique type of semirigid helical structure (Fig. 3). In type I collagen, the helical molecule is a heterotrimer comprising two identical α1(I) chains and one α2(I) chain. The α1(I) and α2(I) chains are very similar, but their primary sequences, coded for by separate genes, are sufficiently different for the chains to be separable by ion-exchange chromatography and SDS-polyacrylamide gel electrophoresis. The α chains each contain just over 1,000 amino acids and have molecular weights of approximately 95,000.

The three-dimensional structure of the collagen triple helix was originally established by X-ray diffraction techniques [6–10,40–43], and more recently confirmed by crystallographic studies on small peptide models [11–13]. The occurrence of glycine as every third residue throughout 95% of the α chains and the presence of large amounts of proline and hydroxyproline (together accounting for approximately 22% of the amino acid residues) allow each polypeptide to be arranged in a stretched polyproline helix, the mobility of which is restricted by the pyrrolidine rings. This helical structure of collagen differs from the α helix characteristic of many globular proteins in that the axial distance between one amino acid and the next is 0.286 nm instead of the axial distance of 0.15 nm found in the α helix. The overall helical symmetry is left-handed, with 10 residues in three turns and a pitch of approximately 3 nm, and the three helical chains are further coiled about a central axis to form a right-handed helix (Fig. 4) with a repeat distance of approximately 10 nm [44].

The high content of glycine in fibrillar collagens (33% of all amino acid residues and therefore approximately 333 amino acids per α chain) and its occurrence as every third residue gives rise to a polymer of tripeptide units with the formula $(Gly{-}X{-}Y)_n$. The helical conformation of the individual α chains arises largely as a result of steric repulsion between the proline (approximately 120 residues per α chain in the X position) and 4-hydroxyproline residues (approximately 100 residues per α chain in the Y position). These residues also have a stabilizing effect on this conformation, as the five-membered rings of the imino acids are rigid and limit rotation about the peptide N–C bond. Collagen stability appears further to rely on inductive effects that favor the requisite *trans* conformation of the hydroxyproline peptide bond since $(GlyFlpPro)_{10}$ (where Flp is an electronegative 4(*R*)-fluoroproline residue that does not form hydrogen bonds) is more thermally stable than $(GlyProHyp)_{10}$ [45]. Glycine is the smallest possible amino acid and, as such, the only one that can pack tightly at the center of the triple-stranded collagen fibril monomer. It will immediately be appreciated that any mutation occurring within the sequences coding for the triple-helical domains of the α chains is likely

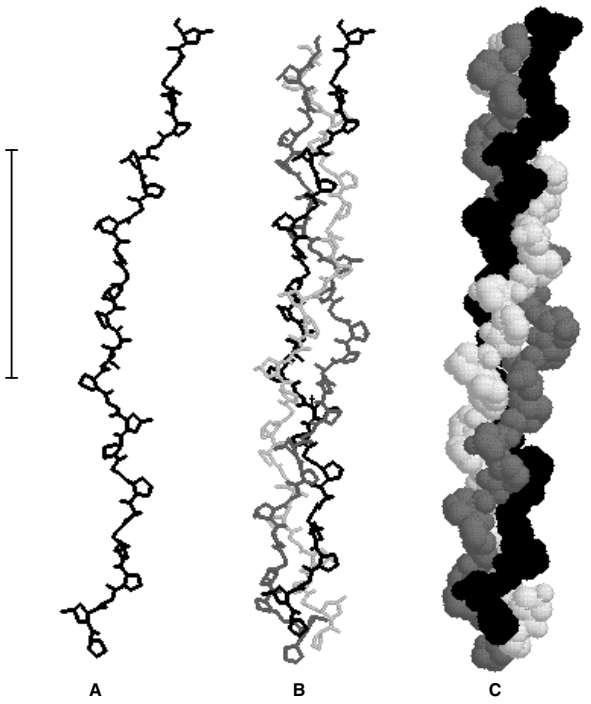

Figure 4. Three-dimensional representation of the conformation of the collagen triple helix. The repeating sequence shown is Gly–Pro–Hyp. **A**: Conformation of a single strand of the collagen helix illustrating the left-handed stretched polyproline helix with 10 residues (indicated by bar) in three turns and a pitch of approximately 3 nm. **B**: Skeletal model of the triple-stranded collagen helix in which the three helical polypeptides are coiled about a central axis to form a right-handed triple helix. **C**: Space-filling model of the assembled triple helix. Chains are shaded to demonstrate the right-handed symmetry along the longitudinal axis of the helix.

to have dramatic consequences, especially if substitution of a glycine residue occurs with consequent disruption of the helical conformation. Indeed, a glycine substitution at any site along the collagen helix of a fibril-forming collagen is the cause of a variety of diseases of bone, cartilage, and blood vessels [46,47] (see also Chapters 8, 9, 15, 23, and 25, this volume).

A major stabilizing force within collagen molecules is hydrogen bonding, and the trimerization of chains is favored by close packing and hydrogen bonding between the three chains. There is only one NH–O=C bond per Gly–X–Y triplet, involving the residue in position X. The glycine provides the HN-group for hydrogen bonding to this O=C group, and the remaining two backbone C=O groups in each triplet and any backbone NH groups of X and Y residues are not involved in peptide hydrogen bonding. The side chains of amino acids in the remaining X and Y positions protrude from the chain and this arrangement allows a variety of amino acid residues (acidic, basic, hydrophobic, etc.) to be accommodated in the molecule. These side chains have relatively minor effects on triple helix stability, but are highly exposed to the surrounding milieu and available for intermolecular interactions. The presence of an appropriate number of 4-hydroxyproline residues in the Y position is, in contrast, a crucial determinant of the stability of the triple helix under physiological conditions. Indeed, the transition temperature (thermal denaturation temperature, melting temperature, T_m) of triple helices formed *in vitro* by nonhydroxylated collagen is notably below 37°C [48]. It has long been thought that this extra stability arises from hydrogen bonds mediated by a network of bridging water molecules. Indeed, high-resolution crystal structures of triple-helical peptides show that a highly ordered hydration network satisfies hydrogen bonding with all remaining backbone peptide groups, and confirm that hydroxyproline plays a pivotal role in this network [12,13]. Nucleation of the triple helix has been studied using Gly–X–Y peptides, and folding rates have been shown to be strongly sequence dependent [49]. Gly–Pro–Hyp triplets promote rapid folding, but single amino acid substitutions in the Y positions affect the nucleation rate.

In the fibrillar collagens, the triple-helical conformation occurs throughout 95% of the length of the rodlike monomer. Thus, of the 1,057 residues in the α1(I) chain of human collagen, 1,014 occur in the repeating Gly–X–Y triplets essential for triple-helical packing. The N-terminal 17 residues and the C-terminal 26 residues (referred to as telopeptides) do not have glycine as every third residue and exist in a less regular conformation. N-terminal and C-terminal extrahelical peptides occur at the ends of the 1,039-residue-long α2(I) chain but are shorter.

The telopeptides are susceptible to proteolytic attack, whereas the intact triple-helical domain is generally resistant to most proteolytic enzymes. However, when heated above physiological temperatures, it undergoes a helix-to-coil transition and, once melted, becomes susceptible to degradative enzymes. As discussed later, the majority of covalent cross-links stabilizing the fibrillar collagens involve the telopeptides and, consequently, pepsin treatment of insoluble cross-linked fibers tends to release the triple-helical domain, which can be recovered in its native conformation. Specific collagenases of bacterial and animal origin act directly on the collagen triple helix, but whereas bacterial collagenases yield many small peptides, the animal collagenases (matrix metalloproteinases MMP-1, MMP-8, MMP-13) are specific for only one or two sequences within the triple helix and yield large, defined proteolytic fragments [50] (see also Chapter 7, this volume).

The Collagen Fibril and Its Self-Assembly

Similar fibrils and microfibrils of collagen type I are seen in different connective tissues, although their organization and arrangement are subject to considerable tissue-specific variation. Thus, in tendon, all the fibrillar units are arranged in large parallel bundles (Fig. 5a), whereas in skin, where type I collagen accounts for 80–90% of the collagenous proteins, the fibrils form a coarse network partially oriented in the plane of the skin (Fig. 5c). Further variations include the orthogonally arranged and precisely packed fibrils in corneal stroma, which form the basis of tissue transparency (Fig. 5b), and concentric circles of collagen fibrils in cortical bone. In tendon, the average diameter of the fibrils varies between 50 and 500 nm, while in skin it is between 40 and 100 nm, but in the cornea, which also has a high type I collagen content, the collagen fibrils have a uniform diameter of approximately 25 nm. Fibril formation is an entropy-driven process controlled to a large extent by the amino acid sequence of the collagen and, in particular, by the distribution of polar and hydrophobic residues. However, the fact that collagen I can be organized in these different macromolecular

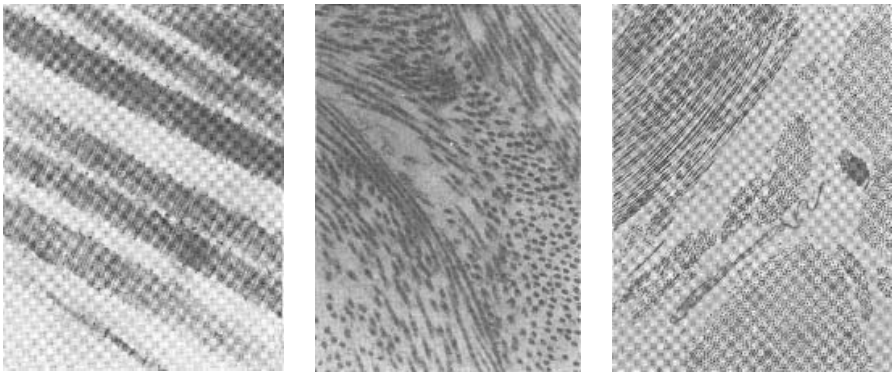

Figure 5. Electron micrographs of sections through arrays of collagen fibril bundles from different type I collagen-containing tissues, demonstrating the diversity of the fibril dimensions and arrangements that exist. structures indicates the involvement of additional tissue-specific regulatory elements.

The collagen fibrils provide long-range structures extending over tens of microns and their assembly requires that billions of collagen molecule subunits assemble to make a structure that is both space-filling and mechanical over these long distances. The mechanisms by which these long cylindrical aggregates form are not fully understood and remain a focus of investigation, hypothesis, and controversy [51–55]. Stringent control over lateral growth of the cylindrical fibers *in vivo* is obvious from assessments of the sharp diameter distributions exhibited by collagen fibrils in a wide range of developing connective tissues. How this control is exerted and how the fibrils extend in length and their diameters grow *in vivo* are ill defined. However, the discovery that fibrils will spontaneously self-assemble from solutions of extracted collagen when the pH, temperature, and ionic strength are adjusted to physiological values led to the idea that this process provided an explanation of fibril formation *in vivo*. The reconstituted fibrils exhibit a classical cross-striated banding pattern in the electron microscope, demonstrating conclusively that the aggregation of collagen molecules into axially ordered fibrillar structures is basically a self-assembly process where the information for association is contained within the assembling molecules themselves [55]. However, the process of fibrillogenesis *in vivo* is far more complex, involving tissue-specific factors influencing lateral and axial growth, fibril diameters, and interfibrillar spacings, and these factors are clearly crucial in determining the precise supramolecular architecture of the collagen fibrils in the different tissues. Part of the complexity of the process can be revealed by investigating the highly irregular fibrils that occur in some genetic disorders of collagen, notably dermatosparaxis in cattle and certain variants of Ehlers-Danlos syndrome in humans (see Chapter 9, this volume).

Nonetheless, the concept of self-assembly remains important, for there has to be a recognition phenomenon to promote aggregation and alignment of the collagen fibril monomers. Detailed analysis of the interactions involved became possible when the full details of the primary structures of the α1(I) and α2(I) chains became available from sequencing at both protein and cDNA levels. The fact that the collagen molecule is essentially a one-dimensional molecule with its near-constant axial separation between amino acid residues throughout over 95% of its tertiary structure permitted a direct correlation of structural data obtained by electron microscopy with chemical sequence data. Thus, it has been recognized for over 30 years that the cross-striated periodic structure of the native collagen fibril is a consequence of the assembly of molecules in a parallel array, but mutually staggered (i.e., axially displaced with respect to one another) by approximately one-quarter of their length — often referred to as the "quarter-staggered array." The periodicity of the cross-striations in the fibril is explained by the fact that each collagen fibril monomer, or tropocollagen unit, has five highly charged regions 67 nm apart, detectable under appropriate conditions as stained bands. This repeat period (the D-period) is confirmed by low-angle X-ray diffraction of rat tail tendon fibrils, and the overall length of a collagen fibril monomer is 4.4 D units (when D = 234 amino acids, the length of one cross-striation period of 67 nm). Within a collagen fibril, the molecules are staggered by multiples of the common distance D. Figure 6 illustrates in two dimensions 1D and 4D staggered contacts, but in a three-dimensional fibril, 0D, 2D, and 3D staggers will also be present between adjoining molecules. As the ratio of molecular length to D-stagger is nonintegral, as noted above, each D-period can be seen to be divided into an overlap zone that includes the N- and C-termini of molecules and a gap zone that does not. Thus, for every five molecular segments in an overlap, there are only four in a gap zone, and the different protein density in these zones is reflected in the negative staining patterns observed in the electron microscope.

Procollagen, the Soluble Precursor

The well-recognized phenomenon of tropocollagen self-assembly under physiological conditions prompted the question of how fibril monomers are prevented from forming insoluble fibrils prior to secretion. The answer came with the discovery in 1970 of the synthesis by fibroblasts of the precursor, procollagen, which is soluble under physiological conditions [56,57]. The term "procollagen" has often been used rather liberally to refer to the soluble precursors of all the different collagen types that have been identified since the initial discovery of procollagen type I. However, today the description of a molecule as a procollagen tends to be restricted to the fibrillar collagens, where a precursor-to-product relationship is well defined and a

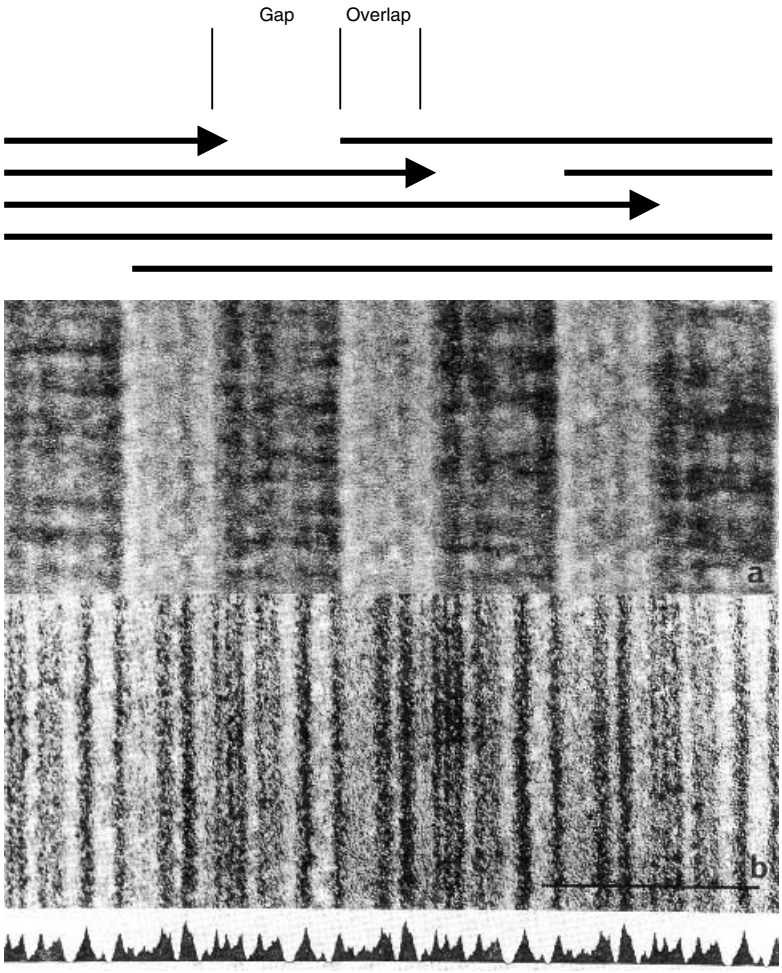

Figure 6. Matching of (**a**) the negative staining pattern with (**b**) the positive staining pattern of a reconstituted fibril of calf skin collagen. The positive stain was phosphotungstic acid (1%, pH 3.4) and uranyl acetate (1%, pH 4.2) both in aqueous solution. The negative stain was uranyl acetate (1%, pH 7.0). The broad stain-penetrable / stain-excluding zoning seen in (**a**), arising from the ''gap/overlap'' staggering of molecules in a fibril, is the most conspicuous feature of the negative staining pattern. Superimposed on this broad staining are finer dark staining bands that appear to align with the staining bands of the positive staining pattern below. The smoothed distribution of charged residues in the fibril, represented at the bottom of the picture, can be aligned with the staining patterns of the fibril, since the charge-rich (−ve and +ve) regions preferentially take up staining ions along the collagen molecule. The bar indicates one D period. (Micrographs courtesy of Dr J. A. Chapman.)

specific physiological cleavage of the procollagen to the collagen fibril monomer (tropocollagen) is known to occur.

The precursor polypeptides of the major fibrillar collagens (types I, II, and III) all have molecular masses about 50% larger than their corresponding α chains, owing to the presence of peptide extensions (propeptides) at both N- and C-termini [58]. Thus, the molecular weights of these complete proα chains are approximately 150,000. In early studies on collagen synthesis, the extension peptides were lost because the susceptibility of procollagen to proteolytic degradation during isolation was not appreciated. However, careful studies, particularly on type I procollagen, established the existence of propeptides at both the N-terminus and the C-terminus (Fig. 7A). cDNA analyses for human procollagen proα1(I) and proα2(I) chains have established that the N-propeptides contain 139 and 57 amino acids, respectively, and the corresponding C-propeptides comprise 246 and 247 residues. The structures of these propeptides were quickly shown to differ from that of the triple-helical domain and to be more typical of globular proteins. Of particular interest was the observation that cysteine and tryptophan residues, which are not present in collagen types I and II, were both present in the precursor molecules. The specific location of these amino acids in the extension peptides proved useful in the development of early assays of the proteinases effecting the extracellular conversion of procollagen into collagen. However, attention focused primarily on the role of the cysteine residues and their potential for forming intra- and interchain disulfide links, and specifically on the role of this type of cross-link in the intracellular assembly of the triple helical precursor (see below).

Studies conducted with matrix-free cells (i.e., those isolated from tissues by collagenase/trypsin digestion and then incubated in a cell suspension) from a variety of embryonic chick tissues permitted a detailed study of helix assembly, disulfide-bonding of precursor polypeptides, and procollagen secretion [59]. Such studies (see below) identified a role for the carboxyl propeptides in helix

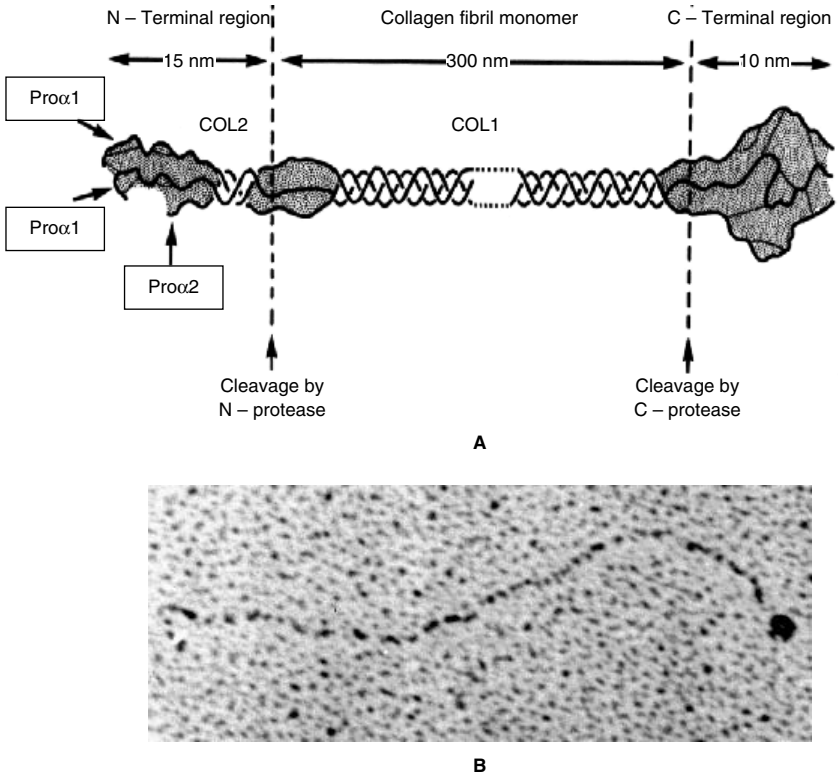

Figure 7. The structure of a type I procollagen molecule. **A**: Diagrammatic representation of procollagen I showing the relative dimensions of the rod-like triple-helical domain and the largely globular N- and C-terminal propeptides contributed by two proα1(I) chains and one proα2(I) chain. Intramolecular disulphide bridges are present in both N- and C-propeptides, but stabilizing intermolecular disulphide bonds are present in the C-propeptide only. **B**: The major structural features of type I procollagen are revealed in rotary shadowing images. The length of the rodlike triple helix is 300 nm. The C-terminal propeptide is observed as a distinct globular domain, while at the other end of the molecule is the characteristic ''hook ''arrangement of the N-propeptide that arises as a consequence of the short helical sequence it contains.

assembly. The presence of the globular extensions on the procollagens also confers solubility under physiological conditions and prevents aggregation and fibril assembly occurring intracellularly. It therefore follows that controlled cleavage of the propeptides is likely to be a prerequisite for collagen fibril formation in the extracellular space. Much research has focused on the processing of procollagen by specific procollagen proteinases [60] and a brief discussion of the relevance of the self-assembly processes of collagen fibril formation to events *in vivo* is presented below. The removal of the large globular domain at the carboxyl-terminus is apparently a necessary step in fibril assembly. This extension is clearly visible in rotary shadowed preparations of type I procollagen (Fig. 7B), and biochemical studies have shown that it is further distinguished by its content of sugar residues occurring at a single Asn–X–Ser/Thr carbohydrate attachment site in both the proα1(I) and proα2(I) chains [61]. The N-terminal extension of procollagen I can also be visualized in the electron microscope, but it appears more like a small, flexible hook than as a globular domain.

Detailed studies of the structure of the N-propeptide of type I procollagen were made possible by the abundance of pN-collagen in cattle suffering from dermatosparaxis — a heritable condition in animals, in which failure to cleave off the N-propeptide but in which there is normal removal of the C-propeptide gives rise to an accumulation, especially in the skin, of collagen molecules retaining the N-terminal extensions [62–65] (and Chapter 9, this volume). Intensive study of the N-terminal propeptides of this material showed that cysteine residues are confined to pNα1(I) chains and are involved in intrachain disulphide bonds in the very N-terminal region (approximately 100 residues) of the propeptide. Adjacent to this region of the molecule is a short helical segment rich in Gly, Pro, and Hyp (the NC2 domain), which is separated from the main body of the collagen helix by a further nonhelical segment, the amino telopeptide [66] (Fig. 7). The N-terminal propeptide of the pNα2(I) chain is shorter than that of the pNα1(I) chain, as it lacks the very N-terminal globular domain. Confirmation of this organization of the propeptides of procollagen I has come from cDNA sequence analysis of the respective genes. However, much remains to be elucidated about the detailed three-dimensional structures of these extensions, and their physiological roles associated with the assembly and processing of procollagen molecules continue to be investigated. Recently, the secondary structure of type I collagen N-telopeptide, as demonstrated by Fourier transform infrared spectroscopy and molecular modeling, has been reported. At 30°C, the structure is β sheet with β turns, and is stabilized by hydrogen bonds [67].

The subsequent fate of the propeptides is also of great interest for a role in feedback control of collagen synthesis has been suggested, and the deposition of the cleaved propeptides in the matrix cannot be excluded [68]. Detection

TABLE 3. Collagen Post-translational Processing Enzymes

Enzyme	Event Catalyzed	Substrate Requirement
A. Intracellular		
Signal peptidase	Cleavage of signal peptide of pre-proαchains	Wide range of newly synthesized proteins
Prolyl 4-hydroxylase	4-hydroxylation of proline	−X−Pro−Gly−
Prolyl 3-hydroxylase	3-hydroxylation of proline	−Pro−4Hyp−Gly−
Lysyl hydroxylase	Hydroxylation of lysine	−X−Lys−Gly−
Hydroxylysyl galactosyl-transferase	O-Glycosylation of hydroxylysine	UDP-galactose; hydroxylysine in peptide linkage
Hydroxylysyl glucosyl-transferase	O-Glycosylation of galactosyl hydroxylysine	UDP-glucose Galactosyl-hydroxylysine in peptide linkage
Protein disulphide isomerase	Native disulphide bond formation by thiol:disulphide interchange	Newly synthesized polypeptide chains
Prolyl-peptidyl *cis/trans* isomerase	Interconversion of *cis* and *trans* isomers of the peptide backbone around the planar imide bond in−X−Pro−sequences	Newly synthesized polypeptide chains
B. Extracellular		
Procollagen N-proteinase	Removal of N-propeptides	Types I and II procollagens
Procollagen C-proteinase	Removal of C-propeptides	Types I, II and III procollagens
Lysyl oxidase	Cross-link formation	D-periodic arrangement of molecules in fibril; telopeptidyl lysyl and hydroxylysyl residues

of the propeptides in the serum and urine offers a means of monitoring collagen synthesis and degradation [69,70]. The value of such clinical assays is clearly apparent with respect to the measurement of increased levels of pNα1(I) peptide in metabolic bone and cartilage diseases [71] and diseases associated with fibrosis [72], α1(II) N-propeptide associated with altered cartilage metabolism [73], α1(III) N-propeptide following severe rejection after cardiac transplantation [74], α1(III) N-propeptide and collagen IV fragments in hepatic fibrosis and abdominal aortic aneurysm [75,76], hydroxylysine glycosides and pyridinium cross-links [77], and C-telopeptide in multiple myeloma [78]. Type I collagen C-telopeptide breakdown products have also been used as markers of menopause and osteoporosis [79] (see also Appendix, Extracellular Collagen Metabolites in Body Fluids; this volume).

Biosynthesis and Assembly of Procollagen I

The biosynthesis of the collagen molecule is a complex, multistage process that begins with the transcription of the individual collagen genes and culminates in the maturation of the fibrous collagen component of the extracellular matrix [58,80,81]. This biosynthetic process is characterized by a number of complex co- and post-translational modifications, many of which are unique to collagens and collagenous sequences. Intracellular modifications of the newly synthesized polypeptide chains result in the formation of triple-helical procollagen molecules, and extracellular processing converts these into collagens and incorporates them into stable, cross-linked fibrils (Fig. 8). At least 10 different enzymes have been implicated in the post-translational processing of the collagen molecule (Table 3). The biosynthesis of type I collagen can be regarded as a useful model exemplifying many of the common features of collagen biosynthesis, although it will be noted that nonfibrillar collagens exhibit deviations from this general scheme, particularly in their macromolecular assembly.

Pre-Procollagen mRNA Translation

Translation of the mRNAs encoding the pre-proα(I) chains begins on free ribosomes with the synthesis of homologous and highly hydrophobic N-terminal signal peptide extensions of 22–26 amino acid residues, similar to those in most other secreted proteins [82]. The signal peptides are essential for the efficient and selective targeting of nascent protein chains to the endoplasmic reticulum. These sequences interact first with an intermediate cytoplasmic signal recognition particle (SRP)

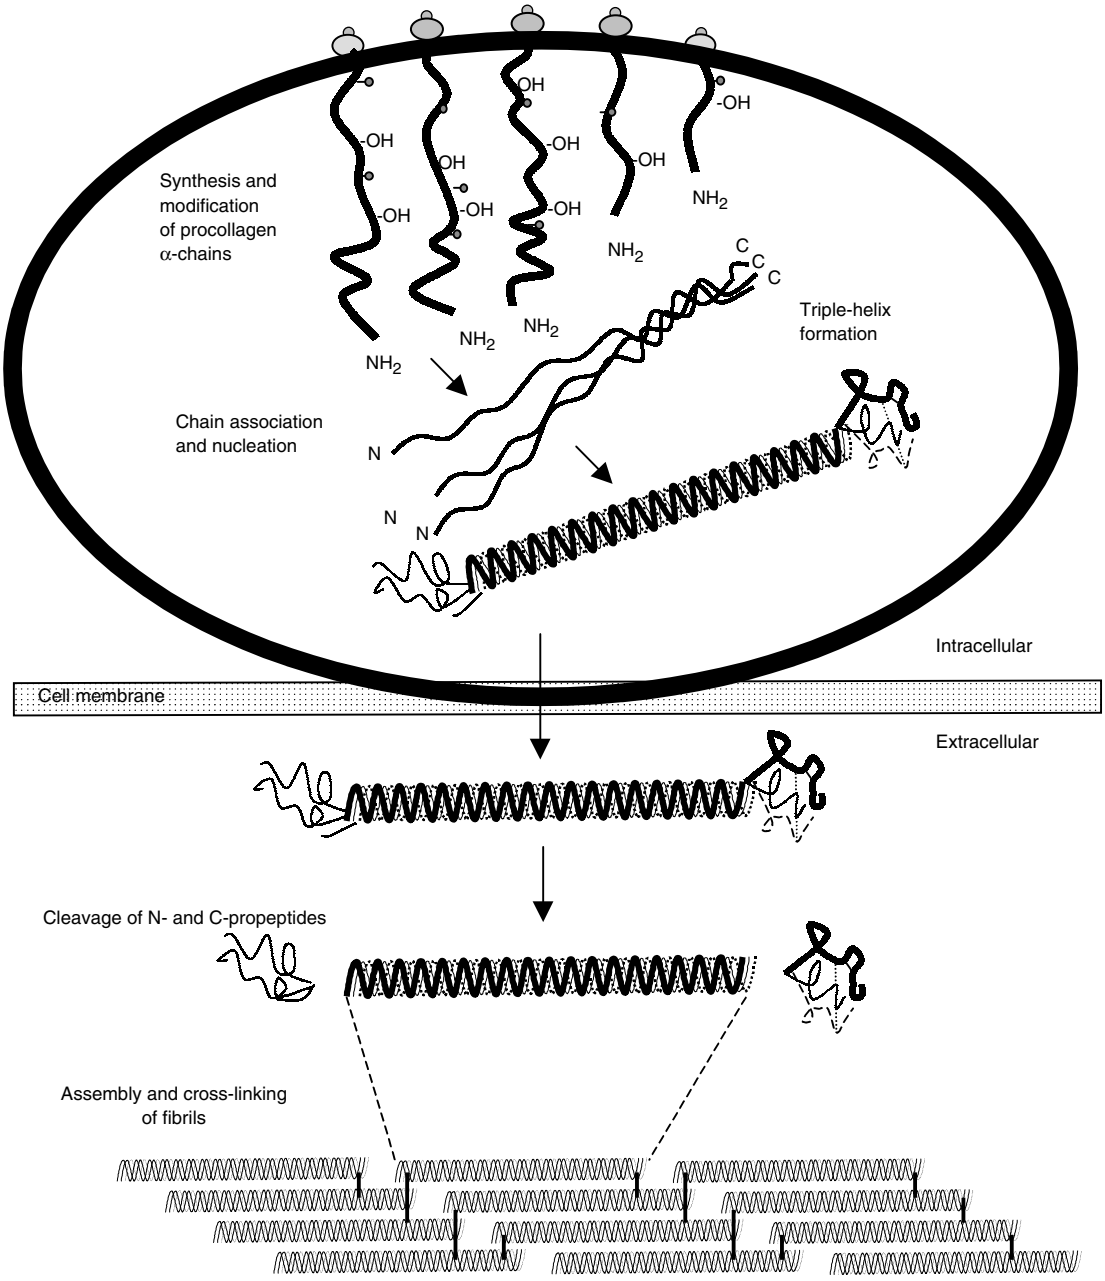

Figure 8. Schematic representation of the intracellular and extracellular steps involved in the synthesis, processing, and assembly of type I collagen molecules into fibrils. The individual collagen polypeptide chains are synthesized on the ribosomes of the rough endoplasmic reticulum and secreted into the lumen, where they undergo complex enzymic modifications prior to chain association and triple helix formation. The newly formed procollagen molecules are then secreted via secretory vacuoles originating from the Golgi apparatus, and once in the extracellular space undergo further modification by specific proteinases which cleave off the N- and C-propeptides. The tropocollagen molecules thus formed may participate in fibril formation by aligning in a characteristic staggered array that is subsequently stabilized by the formation of covalent cross-links. —OH represents prolyl and lysyl hydroxylation. —○ represents hydroxylysyl glycosylation.

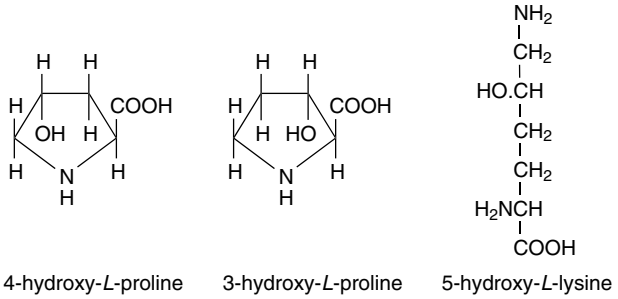
to produce an SRP/polypeptide complex able to associate either with a proteinaceous receptor component or directly with membrane lipids of the endoplasmic reticulum [83]. The signal sequences also play a central, although poorly understood, role in the translocation of the pre-proα collagen chains across the endoplasmic reticulum. During or shortly after translocation, a recognition event occurs between the signal sequence and the signal peptidase on the luminal side of the endoplasmic reticulum membrane, which culminates in the cleavage of the signal peptide to give pre-proα chains. The signal peptidase involved in this reaction exhibits a wide substrate specificity, and is able to cleave the signal peptide from a number of unrelated newly synthesized proteins within the same cell [84].

Intracellular Post-Translational Modifications

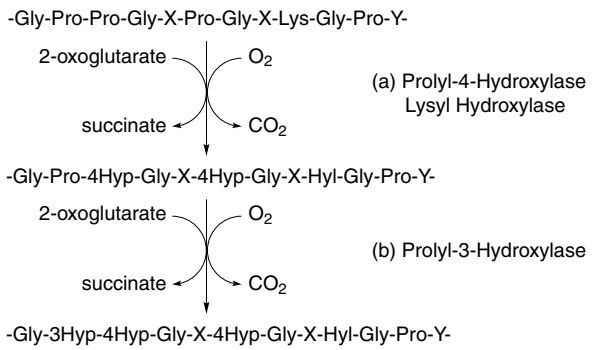
Intracellular modifications of the newly synthesized polypeptide chains result in the formation of procollagen molecules containing an array of hydroxyproline and hydroxylysine residues, which derive not from insertion into the polypeptide chains by translation of specific codons but which arise entirely as a consequence of collagen-specific intracellular enzymic modifications within the cisternae of the rough endoplasmic reticulum. The principal modifications are the hydroxylation of prolyl and lysyl residues and the glycosylation of hydroxylysyl residues, and these are brought about by the actions of three hydroxylases and two glycosyl transferases. Most of these events occur as cotranslational modifications while the nascent polypeptide chains are growing on the ribosomes, but the reactions are continued as posttranslational modifications until triple-helix formation of the proα(I) chains occurs, which prevents any further processing.

Hydroxylation of prolyl and lysyl residues. The hydroxylation of prolyl and lysyl residues in peptide linkage is catalyzed by three separate glycoprotein members of the 2-oxoglutarate dioxygenase family of enzymes, *viz.* prolyl 4-hydroxylase, prolyl 3-hydroxylase, and lysyl hydroxylase, to yield the hydroxy amino acids shown below.



All three enzymes require a nonhelical substrate and the minimum substrate requirements of these enzymes are the triplets X–Pro–Gly, Pro–4Hyp–Gly, and X–Lys–Gly, respectively. Prolyl 4-hydroxylase and lysyl hydroxylase are influenced by adjacent amino acids and by peptide chain length. All three hydroxylases are inactive when presented with a triple-helical substrate, and therefore the required modifications must be completed before triple-helix formation of the newly synthesized proα chains occurs [59,85–91].

The reaction mechanisms of all three hydroxylase enzymes are similar and each requires as cosubstrates Fe^{2+}, 2-oxoglutarate, molecular O_2, and ascorbate.



The 2-oxoglutarate is stoichiometrically decarboxylated during hydroxylation, with one atom of the O_2 molecule being incorporated into succinate and the other into the hydroxyl group formed on the proline or lysine residue. Ascorbate is also a specific requirement for the collagen hydroxylases, although it is not consumed stoichiometrically, and the hydroxylation reaction may even proceed for a few cycles in its absence. The main biological function of ascorbate in the collagen hydroxylase reaction *in vivo* may well be to act as an alternative oxygen acceptor in uncoupled decarboxylation cycles (decarboxylation of 2-oxoglutarate without subsequent hydroxylation of a proline or lysine residue) [90]. The iron chelator, α,α′-bipyridyl, is a potent inhibitor of these hydroxylase reactions, and it is frequently employed *in vitro* for the synthesis of nonhydroxylated collagen (sometimes called protocollagen), which may be used as a substrate in the assays for prolyl 4-hydroxylase and lysyl hydroxylase [86].

Prolyl 4-hydroxylase. The enzyme prolyl 4-hydroxylase (proline, 2-oxoglutarate 4-dioxygenase, EC 1.14.11.2) catalyzes the formation of 4-hydroxyproline in collagen by the hydroxylation of proline residues in X–Pro–Gly sequences [86–89,91]. These 4-hydroxyprolyl residues are essential for the folding and stabilization of the newly synthesized procollagen polypeptide chains into triple-helical molecules at physiological temperature, a crucial function which renders prolyl 4-hydroxylase a target for pharmacological modulation as a potential means of controlling fibrotic diseases characterized by uncontrolled overproduction of collagen [72]. The active prolyl 4-hydroxylase in vertebrates is a tetramer ($\alpha_2\beta_2$) of M_r 240,000 and consists of two different types of subunits (α subunits, M_r 64,000 and β subunits, M_r 60,000). It has two catalytic sites, one per pair of dissimilar subunits.

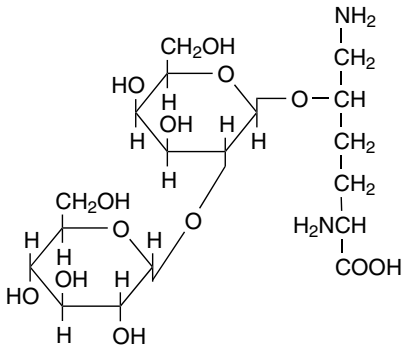
A number of inactivators and substrate analogs of prolyl hydroxylase have now been identified [89], and binding studies using several of these have demonstrated that the peptide- and 2-oxoglutarate-binding sites are located on the α subunit, whereas the ascorbate-binding sites may be built up of both α and β subunits. Thus, the principal contribution to the catalytic sites is from the α subunits, but some parts of the large catalytic sites may be cooperatively built up of both the α and β subunits. The avian and mammalian α subunit sequences revealed by cDNA analyses are highly conserved [88]. Two highly homologous isoforms, α(I) and α(II), have now been identified and both are expressed in various human tissues [92,93]. The α subunit of prolyl 4-hydroxylase from *Drosophila* has been cloned, and the corresponding enzyme tetramer characterized [94]. The β subunit has proved to be a highly unusual multifunctional polypeptide involved in two entirely different enzymic reactions. The human β subunit has been shown to be the same protein as the enzyme protein disulfide isomerase (PDI) [95–100], which catalyzes disulfide bond formation in the *in vitro* biosynthesis of collagens and other secretory and cell surface proteins, and acts as a molecular chaperone during the assembly of procollagen [96,98,101–104]. It also serves as a subunit in the microsomal triacylglycerol transfer protein [105]. Recently, it has become apparent that PDI is the archetype of a family of sequence-related PDI-like proteins [106–108].

Prolyl 3-hydroxylase. The enzyme prolyl 3-hydroxylase (procollagen proline, 2-oxoglutarate 3-dioxygenase, EC

1.14.11.7) exhibits very specific substrate sequence restraints, catalyzing the hydroxylation of prolyl residues only at the X position of X–Y–Gly triplets, and then only when the Y position is occupied by a 4-hydroxyprolyl residue [109]. It is known that prolyl 3-hydroxylase requires the same specific cofactors as are involved in prolyl 4-hydroxylation, and on this basis related reaction mechanisms are postulated [85]. Few structural details of this enzyme have so far emerged, although it is known to be a glycoprotein of M_r 160,000 [109,110]. The function of the major product of the reaction, 3-hydroxyproline, is unknown and its relative abundance varies markedly in the different collagens — the individual chains of type I collagen each contain a single residue, whereas the 3-hydroxyproline content of type IV collagen can be as high as 20 residues per 1,000 amino acids [110].

Lysyl hydroxylase. The enzyme lysyl hydroxylase (procollagen lysine, 2-oxoglutarate 5-dioxygenase, PLOD1, EC 1.14.11.4) catalyzes the hydroxylation of lysyl residues in X–Lys–Gly triplet sequences by a mechanism similar to that described for prolyl 4-hydroxylase [85,111]. The hydroxyl groups of the hydroxylysyl residues have two important functions: they act as attachment sites for carbohydrate residues (either galactose or glucosyl-galactose) and they play a crucial role in the formation of intra- and intermolecular collagen cross-links. In view of the functional significance of these residues, there is surprising variation in the hydroxylysine content of the α chains of the different collagen types (5 to 70 residues per 1,000 amino acids) [85,86,89]. The importance of hydroxylysine in collagen cross-link formation may be inferred from the inherited connective tissue disorder, Ehlers-Danlos syndrome type VI, in which lysyl hydroxylase deficiency results in impaired cross-link formation and consequent susceptibility to mechanical disruption of tissues [112–114] (see also Chapter 9, this volume). The active enzyme in vertebrates is a glycoprotein containing asparagine-linked carbohydrate moieties which are essential for enzymic activity [115]. It exists, probably, as a dimer (M_r 190,000) comprising two monomers (M_r 85,000) that may differ in their carbohydrate content. Elucidation of the cDNA sequence for chick lysyl hydroxylase revealed a polypeptide of 710 amino acids with a 20-residue signal sequence, but, surprisingly, only low homology with the catalytically important α subunit of prolyl 4-hydroxylase with which it shares certain enzymic properties with respect to cofactor and substrate specificities [116]. Other human lysyl hydroxylase isoforms have recently been identified [117,118]. The absence of X–Lys–Gly triplets within the telopeptides, the tissue specificity of Ehlers-Danlos syndrome type VI, and reports that highly purified lysyl hydroxylase fails to hydroxylate telopeptidyl lysyl residues all suggest the involvement of at least one other enzyme. Evidence has been obtained for a bone-specific telopeptide lysyl hydroxylase that directs hydroxylation of lysyl residues specifically in the nonhelical regions [119].

Glycosylation of procollagen chains. Vertebrate collagen molecules contain the monosaccharide galactose and the disaccharide glucosyl-galactose, which utilizes an unusual α1 → 2-O-glycosidic linkage. These glycosides are associated in covalent linkage with hydroxylysine residues within the triple-helical domains [120]. The structure of 2-O-α-D-glycopyranosyl-O-β-D-galactopyranosylhydroxylysine is shown below.



The extent of this glycosylation is very variable, both between collagen types and within the same collagen in different tissues and at different ages [121–123]. The biological role of the collagen-specific carbohydrate units remains unclear, although they may have some role in fibril organization. Indeed, it has been suggested that the inverse relationship that exists between carbohydrate content and collagen fibril diameter could reflect steric hindrance to the formation of highly ordered fibrils by these bulky groups [121]. However, this is only one of a number of possible factors likely to participate in determining fibril diameter.

The glycosylation of hydroxylysine residues within the triple helix requires the activity of two enzymes of the rough endoplasmic reticulum, hydroxylysyl-galactosyltransferase (UDP galactose: 5-hydroxylysine-collagen galactosyltransferase, EC 2.4.1.50) and galactosyl-hydroxylysyl-glucosyltransferase (UDP glucose: 5-hydroxylysine-collagen glucosyltransferase, EC 2.4.1.66), which transfer galactose to some of the hydroxylysines and glucose to some of the galactosyl-hydroxylysine residues, respectively [121–123]. The carbohydrate is donated in both reactions by the appropriate UDP-glycoside, and both enzymes require a bivalent cation (preferably Mn^{2+}) for activity. A free ε-amino group in the substrate hydroxylysyl residue and a nonhelical polypeptide conformation are absolute requirements for both transferases, and the reactions are further influenced by chain length (longer peptides are more effective substrates) [121,124,125]. Hydroxylysyl-galactosyl transferase can bind at least two manganese ions per molecule of active enzyme. Its molecular weight is less certain, with values of between 50,000 and 450,000 reported for impure preparations. In contrast, the molecular size of the glucosyl transferase is well defined (M_r 72,000–78,000), and it exists as a single polypeptide chain.

The propeptides of procollagen (only the C-terminal propeptide in type I procollagen but both N- and C-propeptides in procollagen II) contain asparagine-linked oligosaccharide units that are not found in the collagenous domain. These N-linked carbohydrate units are synthesized on carrier lipids and then transferred as a whole via a lipid oligosaccharide carrier protein intermediate to asparagine residues in Asn–X–Thr(Ser) sequences in the nascent proαI(I) and proα2(I) chains [126,127]. These glycosylation reactions take place within the rough endoplasmic reticulum but the function of these asparaginyl-linked oligosaccharide units of procollagen are unknown.

Helix Formation and Secretion

The assembly of the type I procollagen molecule is a complex helical folding process initiated by association of

the three C-terminal propeptides and presumed to proceed through a series of events involving chain alignment, nucleation, and propagation. Among the more poorly understood aspects of this assembly process are the mechanisms of the selection process, the locus of the initial chain registration event, and the effect of the post-translational modifications on helix assembly. The propeptides begin to fold into their appropriate secondary and tertiary structures soon after synthesis and these conformations are likely to be intimately involved in determining the association of the three polypeptide chains. As the polypeptide chains are translocated across the endoplasmic reticulum membrane, intrachain disulfide bonds are formed within the amino and carboxyl terminal propeptides, and hydroxylation of proline and lysine residues occurs within the collagenous domains. Chains then associate via their C-propeptides to form homo- or heterotrimeric molecules. This allows the triple helical domain to form a nucleation point at its carboxyl terminal end, ensuring correct alignment of the chains. The triple helix then folds in a carboxyl to amino terminal direction, with the N-propeptides finally associating and, in some cases, forming interchain disulfide bonds. The formation of the triple helix precludes further enzyme-linked post-translational modification, and, once folded, the procollagen is readily secreted into the extracellular space.

It has been proposed that the chain selection event is associated with the attachment of the cytosol-initiated signal peptide sequences of each chain to the endoplasmic reticulum surface, such that the appropriate nascent proα chains (two proα1(I) chains and one proα2(I) chain in the case of type I procollagen) might be inserted into the endoplasmic reticulum at a common entry site [128]. This recognition process may involve membrane surface component(s) of unknown identity [129]. Chain association and alignment takes place only as the chains near full elongation, such that folding may proceed in the C- to N-terminal direction, a process that may be facilitated by the organization of the attachment of the ribosomes on the rough endoplasmic reticulum [130]. This association of proα chains almost certainly is initiated by noncovalent interactions between the C-terminal propeptides.

Several sequences in α1(III) that are crucial for recognition and trimerization have recently been defined. By exchanging the C-propeptides of proα1(III) and proα2(I) chains, a discontinuous sequence of 15 amino acids in proα1(III) was identified that directs procollagen self-association [131–133]. The last ten amino acids of the proα2(I) carboxyl terminal region were shown to be important for the assembly of stable type I collagen [134,135]. A study of disproportionate micromelia (*Dmm*) in mice, caused by a three nucleotide deletion in the C-propeptide coding region of *Col2a1*, results in decreased assembly and folding of type II collagen molecules and their retention in the endoplasmic reticulum [136]. An important initial force for association is the entropy-driven association of strategic surface aromatic and hydrophilic residues within the C-terminal regions [137]. The association of C-termini is then stabilized by disulphide bond formation catalyzed by the enzyme PDI (EC 5.3.4.1), which is located within the lumen of the endoplasmic reticulum [135,138]. PDI also acts as a molecular chaperone during the assembly of procollagen [96]. Helix formation may be interrupted by the random occurrence of *cis* peptide bonds which are converted to the *trans* configuration by a separate cytosolic (and potentially rate-limiting) enzyme, prolyl-peptidyl *cis-trans* isomerase (PPI) [139–141].

It is generally believed that folding of the triple-helical domain occurs by nucleation and propagation. The existence of a stable nucleation site was first postulated some years ago when it was discovered that there was a short stretch of between 3 and 10 Gly–Pro–Hyp triplets (known from thermal stability experiments to form one of the most stable triple helices) at the very C-terminus of the collagenous domain of type I procollagen α chains. This concept has now been generally accepted with the identification of similar features in all collagens for which the sequence is known. The sequence Gly–Pro–Arg has been shown to be of similar stability to Gly–Pro–Hyp. Variations in a central guest triplet within the framework $[Gly–Pro–Hyp]_3–Gly–Xaa–Yaa–[Gly–Pro–Hyp]_4$ have highlighted the sequence dependence of the folding of collagen-like peptides, with half-times for refolding varying from 6 to 100 minutes [142]. Such information on the relative propensities of different tripeptide sequences to promote nucleation of the triple helix in peptides will aid in identification of nucleation sites in collagen sequences.

Stable triple-helix formation is dependent not only on the presence of glycine as every third residue, but also requires 4-hydroxyproline in the Y position of a high proportion of Gly–X–Y triplets (at least 100 of the 1,000 amino acids of the helical domain of each chain), and assembled proα chains that do not contain the appropriate number of hydroxyproline residues accumulate in the lumen of the endoplasmic reticulum. Some insights into the process of triple-helix formation have been provided by analysis of naturally occurring mutant collagens in inherited connective tissue diseases such as osteogenesis imperfecta and Ehlers-Danlos syndrome ([47,143–145], and Chapters 8 and 9, this volume). For example, a mutation involving the substitution of a glycine residue by another amino acid has drastic consequences for triple-helical assembly and stability. The rate of triple-helix formation is retarded, allowing post-translational enzymes the opportunity to overmodify the collagenous domain [145a]. The relationship of these biochemical modifications to the clinical phenotype, however, is not well understood.

The mechanism of procollagen secretion is also poorly understood, but it is known that procollagen follows the classical secretion route for extracellular proteins, passing through the Golgi complex *en route* to the extracellular space [59]. The normal rate of procollagen secretion is apparently dependent upon the triple-helical conformation, for if triple-helix formation is prevented by inhibiting prolyl hydroxylase (by the use of α,α′-bipyridyl or by limiting the availability of the cofactors Fe^{2+} or O_2) then the nonhelical proα chains first accumulate within the cisternae of the rough endoplasmic reticulum and are then secreted at a slower rate [59,146,147].

Extracellular Processing and Fibril Formation

The factors that control fibril assembly and lateral growth, and which account for the widely differing fibril diameters, are not well understood. Although the aggregation of collagen molecules into axially ordered fibrillar structures is basically a self-assembly process, factors extrinsic to these molecules must also be implicated in determining the sharp diameter distributions of collagen fibers *in vivo*. Fibril formation involves the specific enzymic cleavage of the procollagen N- and C-terminal propeptides in the extracellular space, and the enzymes involved must therefore play a key role in this ordered aggregation. Consequently, the study of factors involved in regulating their activity has been

an area of intense interest. It should be noted, however, that such processing is essentially a characteristic of the fibrillar collagens and is not a universal prerequisite for the assembly of all collagen types.

The cleavage of the N- and C-terminal propeptides from the procollagen I molecule at specific peptide bond cleavage sites is achieved by two specific neutral metalloproteinases, procollagen N-proteinase (EC 3.4.24.14) and procollagen C-proteinase (E.C 3.4.24.19), both of which require Ca^{2+} for activity and are members of the zinc-binding metalloproteinase superfamily [16]. These enzymes are therefore inhibited by metal chelators but not by inhibitors of serine or cysteine proteinases. The procollagen proteinases initially proved difficult to purify [148–153], but the primary structures of both enzymes have now been determined [154,155].

Purified type I procollagen N-proteinase (M_r 500,000) cleaves the N-terminal propeptides of types I and II procollagens between a proline and a glutamine residue, only if the proteins are in a native conformation, and not if they are partially unfolded so that the N-telopeptides are no longer in a hairpin conformation. It resolves into four polypeptide components on SDS-polyacrylamide gel electrophoresis, the two larger of which exhibit "N-proteinase" activity. The full-length cDNA for bovine N-proteinase encodes 1,205 residues (equivalent to a polypeptide of $M_r \sim 140,000$). An active human N-proteinase of M_r 70,000 has recently been characterized, which may have arisen by alternative splicing of a larger gene [155]. A separate enzyme is involved in the processing of the N-propeptide of type III procollagen [150], and this N-propeptidase has been purified from fetal aortic smooth muscle cell cultures and human placenta [151,152].

Type I procollagen C-proteinase was first isolated as a $M_r \sim 70,000$ enzyme from the medium of cultured fibroblasts and from organ cultures of chick embryo tendons [148,153,154]. This enzyme cleaves native and denatured C-terminal propeptides of both the proα1(I) and proα2(I) procollagen chains at an Ala–Asp bond, those of the α1(III) procollagen chain at a Gly–Asp bond, and those of type I procollagen homotrimer and type III procollagen, all at identical rates. The C-proteinase can also specifically cleave precursors of lysyl oxidase and laminin 5. A possible mechanism of stimulation of C-proteinase activity by a copurifying enhancer protein (M_r 55,000) has been described [153]. Analysis of cDNA for procollagen C-proteinase [154] revealed open reading frames for three proteins — an M_r 70,000 polypeptide identical to bone morphogenetic protein-1 (BMP-1), a similar protein with an additional histidine-rich sequence, and a polypeptide of $M_r \sim 100,000$ which has a high degree of similarity to the protein encoded by the *Drosophila* gene *tolloid*, and is thus referred to as mammalian tolloid (mTld). BMP-1/procollagen C-proteinase may also play an essential role in development in addition to its role in the processing of procollagens.

It has been shown that human mast cell chymase, but not tryptase, can cleave the proα1(I) collagen carboxyl terminus in the propeptide region at Leu-1248–Ser-1249, to create a novel C-telopeptide 20 amino acids longer than that generated by procollagen C-proteinase [156]. Turbidometric fibril formation assays demonstrated *de novo* formation of chymase-generated collagen fibrils that had characteristic lag, growth, and plateau phases. Thus, mast cell chymase may play a role in regulating collagen fibrillogenesis in fibrosis.

The precise role of the N- and C-terminal propeptides in controlling fibril formation, diameter, and general morphology is far from resolved, and even the sequence of events leading to their controlled cleavage is less straightforward than originally thought. For example, the classical pulse-chase experiments that demonstrate a precursor-to-product relationship indicative of a predominant processing sequence, primary precursor→pC-collagen→collagen, fail to explain either the presence or the proportions of pN-collagen[1] and pC-collagen[2] in extracted collagen fibrils. It has been possible to study the role of procollagen I processing *in vitro* using highly purified N- and C-terminal procollagen proteinases in an elegant, cell-free assay system [157–159] in which mixtures of type I procollagen and pC-collagen (prepared by digestion of type I procollagen with N-proteinase) are used as a substrate for C-proteinase and the fibrils formed examined ultrastructurally. These experiments demonstrate that persistence of the N-propeptide causes distortion of the morphology of the fibrils from cylindrical to fluted and sheetlike structures. A study of dermatosparactic calf skin collagen fibrils has confirmed that the persistence of the N-propeptide distorts fibril shape but does not inhibit the binding of gap-associated macromolecules (e.g., decorin) [64]. However, immunoelectron microscopic analyses of normal fibrils have demonstrated the presence of both pN-collagen and pC-collagen on fibril surfaces [160,161]. These studies have also demonstrated the coexistence of type I and type III collagens within individual fibrils, and it now appears that heterotypic fibrils containing molecules of type III collagen and possibly type V collagen, in addition to type I collagen molecules may, in fact, predominate *in vivo* [162,163]. The presence of the N-propeptide of type III procollagen, in particular, at the surface of collagen fibrils has led to the suggestion of a fibril diameter-limiting role for this peptide. Although pC-collagen can be persuaded to assemble *in vitro* into flat sheets by manipulating the kinetics of the system [159,164], the bulky C-propeptide probably precludes a major physiological role for this as an incorporated intermediate of fibril formation *in vivo*. The key role of telopeptides in collagen fibrillogenesis is now being elucidated [165].

Linear and Lateral Fibril Growth

The formation of very long and near-uniform diameter collagen fibrils is fundamental to the assembly of the extracellular matrix of animals. However, the mechanisms by which linear and lateral growth are regulated are incompletely understood. Regulated tip growth provides an attractive explanation for how cells are able to synthesize long fibrils during extracellular matrix formation. *In vitro* collagen fibrillogenesis following procollagen cleavage by purified proteinases results in fibrils that initially have a near paraboloidal pointed tip and a blunt end, and growth is exclusively from the pointed tip with the N-terminus closest to the fibril tip end [53]. Subsequently, a new N-terminal pointed growth tip appears in the other direction. Examination of developing chick embryonic metatarsal tendon fibrils by scanning transmission electron microscopy (STEM) mass mapping revealed that these physiological fibrils had smoothly tapering C- and N-terminal tips leading to an abrupt stop in lateral growth and a local plateau in

[1] pN-Collagen: Intermediate in the conversion of procollagen to collagen, which contains the N-propeptide but not the C-propeptide.

[2] pC-Collagen: Intermediate in the conversion of procollagen to collagen, which contains the C-propeptide but not the N-propeptide.

diameter [166]. The distance from the end of the fibril to the abrupt stop occurred at multiples of 5 D-periods, showing that D-periods at the ends of fibrils are not equivalent sites for accretion, that diameter regulation depends on surface structural features which repeat every 5 D, and that coarseness of the fibril tip is independent of fibril length.

Collagen fibrils from developing tendons have been shown to grow through deposition of early fibril segments that subsequently fuse [167,168]. The growth of these fibril segments and their intercalation into fibrils results in linear and lateral growth during matrix development and is an important determinant of tissue architecture, stability, and mechanical attributes. Fibril growth has also been found to be associated with a significant decrease in fibril-associated decorin [169,170], a member of the small leucine-rich proteoglycan (SLRP) family, supporting an earlier proposal [171] that fusion of fibrils occurs in tendon with possible regulation by a surface coat of decorin.

The role of decorin and other SLRPs (fibromodulin, lumican) in regulating fibril fusion has recently been confirmed in genetically manipulated mice models. Mice harboring a targeted disruption of the decorin gene are viable but have fragile skin with markedly reduced tensile strength; collagen fibers in skin and tendon appear coarser with irregular fiber outlines [172]. STEM mass mapping shows abrupt increases and decreases in mass along their axes. These data indicate uncontrolled lateral fusion of collagen fibrils in the decorin-deficient mice, provide a partial explanation for the reduced tensile strength of the skin, and demonstrate a fundamental role for decorin in regulating collagen fibril formation *in vivo*. Mice homozygous for a null mutation in lumican display skin laxity and fragility resembling that in certain types of Ehlers-Danlos syndrome, and the mice also develop corneal opacification [173]. The underlying defect is deregulated growth of collagen fibrils with numerous abnormally thick collagen fibrils in skin and cornea. Other studies have demonstrated that fibromodulin-type I collagen interactions are also crucial for regulating fibrillogenesis [174,175]. The relative contribution of each SLRP to regulated fibrillogenesis in different tissues remains to be determined.

Thrombospondin-2 also appears to be involved in collagen fibrillogenesis, because thrombospondin-2–null mice exhibit abnormal collagen fiber patterns in skin, abnormally large fibrils with irregular contours, and fragile skin with reduced tensile strength [176]. Thrombospondin-2 may function as a collagen fibril-associated molecule that regulates fibril diameter, and/or the disordered fibrillogenesis may reflect altered cell surface properties within extracellular assembly crypts formed by fibroblast cell surface folding. Cartilage oligomeric matrix protein (COMP), which is homologous to the thrombospondins, has been shown to participate in a high affinity zinc-dependent interaction with triple helical cartilage collagen type II, and may influence the organization of cartilage collagen fibrils [177].

Molecular Packing of Fibrils

Collagen fibrils are approximately cylindrical, with diameters in the range10–1000 nm, but the packing arrangement of monomers in fibrils is not well defined [178–181]. The lateral packing of monomers in fibrils is currently being investigated using electron microscopy and X-ray diffraction approaches. Monomers may be laterally packed on a triclinic unit cell lattice, in the form of microfibrils comprising monomers coiled into a rope-like pentameric structure [180]. Collagen molecules contain kinks between the gap and overlap regions that make the molecules tilted by about 5° relative to the fibril axis. The initial stages in fibril assembly are thought to involve the formation of structures that correspond to pentameric microfibrils. *In vitro* assembly systems have demonstrated that fibrils probably grow from pointed tips; a proposed mechanism for increase in diameter is by adding microfibrils or individual molecules to form microfibrils. The left-handed Gly–Pro–Pro helix is stabilized by a right-handed triple-helical conformation, and this in turn may be stabilized by a left-handed microfibril structure that may form cross-links to maintain the integrity of the fibrils [180].

Studies of the relative strengths of hydrophobic and electrostatic interactions in fibrillogenesis of acid soluble collagen molecules show that hydrophobic interactions, but not electrostatic interactions, maximize D-periodic banding [182]. The process of self-assembly of type I collagen monomers into fibrils also appears to depend on the interactions of specific binding sites in different regions of the monomer. Synthetic peptides with sequences found in the telopeptides were found to inhibit self-assembly of purified type I collagen in an *in vitro* system [183]. A strong interaction between the α2(I) N-telopeptide in the overlap zone and residues 781–794 of the α1(I) chains was identified, which would place the molecules in a quarter D stagger; this binding event could thus initiate assembly of a pentameric microfibril. Molecular modeling of the binding sites demonstrated favorable hydrophobic and electrostatic interactions between the α2(I) telopeptide and the α1(I) chains.

The importance of glycosylation to fibrillogenesis has been demonstrated in a study of human recombinant type II collagen expressed using an insect system, in which low and high levels of hydroxylysine and its glycosylated form resulted in marked differences in fibrillogenesis *in vitro* [184]. Marked differences in fibril formation were found between the collagen preparations with low hydroxylysine and high hydroxylysine, respectively, in that the maximal turbidity of the former was reached within 5 minutes under the standard assay conditions, whereas the absorbance of the latter increased until about 600 minutes. The morphology of the fibrils was also different, in that the high hydroxylysine collagen formed thin fibrils with essentially no interfibrillar interaction or aggregation, whereas the low hydroxylysine collagen formed thick fibrils on a background of thin ones.

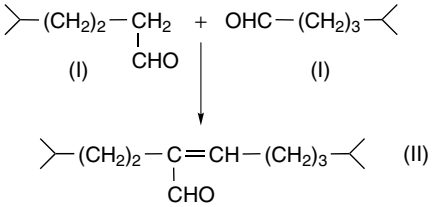
Cross-Linking and Fibril Stabilization

The spontaneous aggregation of processed collagen molecules into fibrils with a characteristic D-periodicity is followed almost immediately by the formation of covalent cross-links within and between the collagen molecules. These cross-links, which are formed from specific lysyl and hydroxylysyl residues, are essential in providing the tensile strength and mechanical stability of the collagen fibrils which their structural roles demand [185]. The only step in the cross-linking process that is known to be under direct control is the initial oxidative deamination of specific lysine or hydroxylysine residues in the nonhelical telopeptide regions. Thus, lysyl and hydroxylysyl aldehydes are generated by lysyl oxidase (protein lysine 6-oxidase, EC 1.4.3.13) [186,187], and an assortment of di-, tri-, and tetrafunctional cross-linking amino acids can form spontaneously by the intra- and intermolecular reactions of these lys/hyl aldehydes within the newly formed collagen polymers. It is noteworthy that disulfide bonding cannot play a part in the stabilization of

collagen I (or II) fibers because of the absence of cysteine residues, but a significant role for disulfide bonding in the stability of other collagen aggregates (e.g., collagens IV, VI, and IX) is well defined (see below).

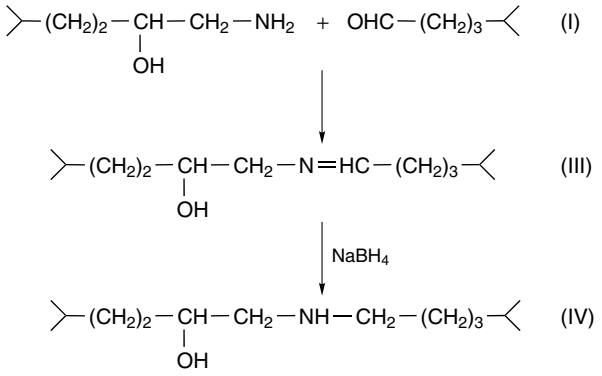
Lysyl oxidase-initiated cross-linking. Much of our early knowledge of collagen cross-links and the role of lysyl oxidase derived from studies of the tetrafunctional cross-links in elastin [36,188,189] (see also Chapter 3, this volume). In particular, the elucidation of the structure of the desmosine cross-links and the demonstration that they were derived from lysine residues provided the initial evidence for a unique mechanism for the stabilization of fibrous proteins of the extracellular matrix. However, marked differences exist between elastin and collagen in terms of their primary structures, their lysine-containing sequences involved in cross-linking, and the nature of the cross-links formed [190,191]. The catalytic activity of lysyl oxidase is dependent on strict steric requirements (in the case of collagen, the quarter-stagger arrangement of molecules in the fibril) and on the sequence of amino acids surrounding the "target" lysyl/hydroxylysyl residues [186,187,192,193]. The enzyme has been purified from several avian and mammalian sources, and its primary structure has been elucidated [192]. It is a copper-dependent amine oxidase requiring molecular oxygen and a novel aromatic carbonyl compound recently identified as lysyltyrosine quinone [194,195]. Lysyl oxidase is synthesized as a preproprotein, secreted as an M_r 50,000 N-glycosylated proenzyme, and then proteolytically cleaved to the M_r 32,000 catalytically active, mature enzyme. New lysyl oxidase-like genes have also been identified and cloned, indicating the existence of a multigene family [196–199]. Lysyl oxidase may have important roles to play in cellular homeostasis in addition to the oxidation of peptidyl lysine in the extracellular matrix [187,200]. Lysyl oxidase binds to the fibril surface and cannot penetrate to its inner domains [201], implying that the oxidation of lysyl groups must occur at an early stage of fibrillogenesis and/or that cross-links are continuously manufactured at the surface of growing fibrils.

The nature of the lysyl oxidase-derived collagen cross-links has been extensively reviewed [191,202–206]. Two related pathways can be distinguished for the fibrillar collagens, one based on lysine aldehydes, the other on hydroxylysine aldehydes. The lysine aldehyde pathway occurs primarily in adult skin, cornea, and sclera, whereas the hydroxylysine aldehyde pathway predominates in bone, cartilage, ligament, most tendons, embryonic skin, and most major internal connective tissues of the body. The first step in both pathways is the oxidative deamination of the ε-amino group in telopeptidyl lysine and hydroxylysine residues to form their corresponding aldehydes, often referred to by their trivial names as allysine and hydroxyallysine. In the lysine aldehyde pathway, two allysines (I) may condense to form the aldol condensation product (ACP) (II).

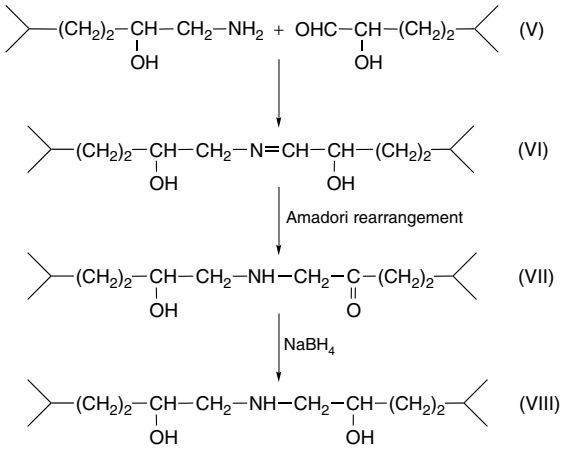


This structure was the first collagen cross-link to be identified as an intramolecular bond forming a dimer, or collagen β component, between α1(I) and α2(I) chains [207]. Its physiological significance is still not certain since it is the intermolecular, and not the intramolecular, cross-links that confer stability and strength on collagen fibers.

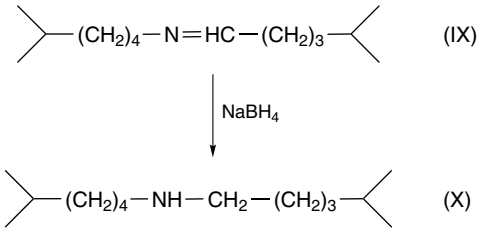
Much importance has been assigned to the aldimine (Schiff base) cross-links formed when allysine in the telopeptides reacts with lysine or hydroxylysine residues in adjacent helices to provide covalent cross-links between collagen molecules. These aldimine cross-links are acid-labile and their detection has depended on their prior reduction with $NaBH_4$ (sodium borohydride), which permits their recovery from acid hydrolyzates of collagen and their characterization by chromatographic techniques. In this way, the reduced cross-link hydroxylysinonorleucine (HLNL) (IV), derived originally from allysine and hydroxylysine, has been demonstrated as the reduction product of the aldimine cross-link, dehydro-hydroxylysinonorleucine (III).



In tissues such as bone, cartilage, and tendon, where hydroxyallysine rather than allysine residues are involved in cross-linking, the second, hydroxylysine aldehyde-derived pathway becomes important. Here, hydroxyallysine (V) can condense with a hydroxylysine residue to form the reducible cross-link dehydro-hydroxylysinohydroxynorleucine (VI) which can undergo an Amadori rearrangement *in vivo* to form hydroxylysino-5-oxo-norleucine (VII), which is resistant to heat, dilute acid, and also penicillamine (see below), and which on reduction yields hydroxylysinonorleucine (VIII).



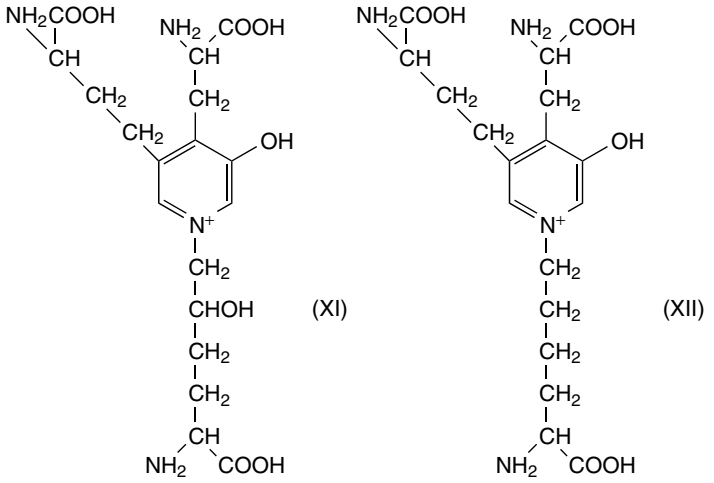
Both of these aldimine cross-links (III and VII) can occur as galactosyl or glucosylgalactosyl derivatives, demonstrating that O-glycosylation of Hyl residues does not preclude their involvement in cross-linking. A third reducible component occurs in small amounts, especially in skin, and derives from the condensation of lysine and allysine to form the dehydro-lysinonorleucine (IX), which on reduction *in vitro* is recovered as lysinonorleucine (X).



Quantification of the absolute concentration of the individual cross-links in collagens is not well documented and is complicated by the knowledge that in most tissues, with the possible exception of bone and dentine, the number of reducible cross-links decreases with age. Thus, the reducible cross-links are said to mature as they are modified to become stable, nonreducible cross-links, the nature and number of which remain to be fully defined. In the case of the hydroxylysine aldehyde pathway, however, the major mature cross-links appear to be based on trivalent 3-hydroxypyridinium residues. Two chemical forms of the cross-link have now been identified, hydroxylysyl-pyridinoline (XI), derived from 3 Hyl residues, and lysyl-pyridinoline (XII), derived from 2 Hyl and 1 Lys. These two cross-links are naturally fluorescent and can be assayed directly in tissue hydrolysates.

The highest concentrations of hydroxylysyl-pyridinoline are found in the nucleus pulposus of human intervertebral disk and in human articular cartilage [204,208], and measurement of this cross-link in body fluids has been proposed as a potential marker for the catabolism of cartilage collagens in pathological conditions such as joint and metabolic bone disease [209–211] (see also Risteli and Risteli, Appendix, this volume). Aberrant cross-link formation due to decreased activity of lysyl oxidase can occur both in inherited connective tissue diseases such as Menkes disease and the occipital horn syndrome (see Chapter 14, this volume), and in acquired disorders such as nutritional copper deficiency and lathyrism in animals [212]. The latter is a defect in collagen metabolism associated with the ingestion by animals of β-aminopropionitrile (βAPN) (derived from the sweet pea *Lathyrus odoratus*), which is a potent and irreversible inhibitor of lysyl oxidase and prevents cross-linking of newly synthesized collagen molecules into insoluble fibers. D-penicillamine is also an inhibitor of cross-linking that is able to interact with and block the newly formed lysine aldehydes and, at higher doses, inhibits lysyl oxidase activity by chelating copper. Inhibitors of cross-link formation have been used to treat fibrotic disorders such as scleroderma, and can successfully prevent excessive accumulation of collagen. Such treatment is not without risk, however, for prolonged use of βAPN, for example, may not only induce a lathyritic condition but may also interfere with elastogenesis, by inhibiting cross-linking of elastin monomers [212].

Nonenzymic glycosylation of collagen and sugar-derived cross-links. The nonenzymic glycosylation (glycation) of extracellular proteins has been of interest ever since the detection of glycosylated hemoglobin molecules in patients with diabetes mellitus [206,213]. The prolonged association of collagens with reducing sugars produces glycation end products that are implicated as factors in aging and diabetic complications. Indeed, glycation is a major cause of dysfunction of collagenous tissues in old age, and the process is accelerated in diabetic subjects due to the higher levels of glucose [206,214–216]. Glycation can affect a number of properties of collagen including its biomechanical functioning and its ability to form precise supramolecular aggregates, and result in an alteration in its charge profile and interaction with cells, and, in addition, glycated collagen can act as an oxidizing agent. The most damaging effects, however, are caused by glucose-mediated intermolecular cross-links which decrease flexibility and permeability, and reduce turnover. In virtually all extracellular proteins it is possible for a sugar group (frequently glucose) to react nonenzymically with the free ε-amino group of a lysine (or hydroxylysine) residue. This form of glycation (the Maillard reaction) involves the chemical reaction of a sugar aldehyde or ketone with a free amino group to form a Schiff base, which may undergo a rearrangement to form a fairly stable ketoamine (the Amadori product) [214]. These



structures may go on to form advanced glycation end-products (AGEs) by condensing to form imidazole-based Maillard products. Alternatively, they can be degraded into reactive α-dicarbonyl groups that react with other free amino groups to form cross-linked, pyrrole-based, pigmented, and fluorescent adducts. The occurrence and accumulation of these groups on stable low-turnover macromolecules such as collagen has received considerable attention [206]. The possibility that these cross-links could influence the resistance of collagen to being broken down or remodeled cannot be excluded and, accordingly, the contribution of nonenzymic glycosylation to normal aging and to events associated with hyperglycemia and collagen involvement in diabetic microangiopathy is under investigation [206,215,216].

ISOLATION AND CHARACTERIZATION OF COLLAGEN TYPES

The recognition of many genetically distinct collagen types was achieved initially through classical protein separation techniques [217]. The screening of cDNA libraries with individual collagen cDNA probes has now led to the identification of new collagen types (*viz.* types XII–XIX) as a consequence of the cross-hybridization of related collagen probes at low stringency. In this latter approach, the identification of amino acid sequences derived from cDNA sequences has permitted the synthesis of appropriate oligopeptides which, in turn, have been used to generate antibodies which recognize the new collagens in tissues and in cells in culture. Both classical protein separation techniques and cDNA cross-hybridization procedures rely on the distinctive features of the collagenous molecules and their respective DNA coding sequences. The application of rotary shadowing techniques to collagenous molecules has provided a visualization of the shape of individual collagen molecules [218] (Fig. 9) and, consequently, an insight into their macromolecular structure/function *in vivo*.

The key feature of collagenous macromolecules is that they perform a structural role in the extracellular matrix, where the fibrils and networks which the individual types form are stabilized by covalent cross-links. Consequently, it is virtually impossible to extract the intact subunits of these structures from mature tissues and, for this reason, the majority of work on the isolation of collagen types has been done on young animals or fetal tissues [219]. In such tissues, the biosynthetic rate is high and approximately 5–10% of the total collagens can be solubilized in dilute salt solutions and/or dilute acid solutions. By rendering animals lathyritic it is possible to increase this yield, particularly of the Group 1 collagens stabilized by lysyl oxidase-dependent cross-linking. Lathyrogens have also been found useful in increasing the solubility of collagens in two transplantable tumors — an EHS (Engelbroth-Holm-Swarm) sarcoma used in the isolation of type IV collagen [220] and a rat chondrosarcoma used in the isolation of type IX collagen [221] — and in bone for the isolation of type V collagen [222]. However, in the case of many of the minor collagens that contain substantial noncollagenous domains, it is not clear to what extent the stability of their aggregates is dependent on lysyl-derived cross-links. Indeed, in most of these collagens, disulfide bonding may predominate, and in the heavily disulfide-bonded type VI collagen aggregates, for example, no lysyl cross-links have been identified. Here it has been found appropriate to use chaotropic agents such as guanidinium chloride and urea in the presence of reducing agents to effect the solubilization of collagen VI from tissues [223–225].

Other strategies for the isolation of intact native soluble collagens and their precursors include the use of appropriate cell culture systems that permit the recovery of intact collagens from the culture medium. Care is always required to avoid proteolysis, especially of the nonhelical domains, by the inclusion of proteinase inhibitors at all stages of protein isolation and fractionation. A range of procedures, including salt fractionation followed by various chromatographic, electrophoretic, and/or immunoprecipitation procedures, is normally used to identify and characterize the collagen types. Although the yield of material from cell cultures is very limited, there are a number of advantages to the cell culture system in conjunction with radiolabeling techniques, not least among which are the ready supply of labeled precursors for the analysis of processing phenomena and the possibilities for manipulating collagen gene expression by extrinsic factors. However, for the most part, interest in collagen types relates to their occurrence in normal and diseased tissues, and consequently it has been important to develop techniques to solubilize collagens from tissues in order to quantify the proportions of types present. To this end, the most widely used approach is pepsin digestion at pH 1–2 of tissues at 4° to 15°C, which relies on the resistance of the collagen triple helix to enzymic degradation below its denaturation temperature, but the susceptibility of virtually all other proteins to digestion. The collagen triple helix is unique in being both resistant to pepsin and soluble at acid pH, so that the end product of digestion is a mixture of solubilized collagen types. This procedure rarely proceeds to complete solubilization, for, with increasing age of the tissue, the fibrillar collagens become more resistant to pepsin as a result of increased stabilization of the cross-links. In addition, it will be appreciated that those collagens (such as FACIT and MULTIPLEXIN) with interrupted helices will give rise to multiple triple-helical digestion products when pepsin cleaves the noncollagenous domains. Consequently, a complex mixture of pepsin-derived peptides can arise from the digestion of tissues such as placenta, skin, or cartilage, and salt fractionation procedures of the type shown in Figure 10 are adopted to separate the collagen types. The identification of the collagen types is initially achieved through their characteristic mobilities on SDS-polyacrylamide gel electrophoresis. Further characterization can be achieved by peptide mapping of the individual chains following cyanogen bromide (CNBr) digestion [226] or by immunoblotting with chain- or type-specific antiserum. Type VI collagen is resistant to degradation by bacterial collagenase, and it has been possible to extract microfibrils from elastic and non-elastic tissues using a combination of bacterial collagenase and size fractionation approaches [227].

Recombinant approaches to generating collagen molecules and domains have generally overtaken tissue purifications as the method of choice for generating molecules for structure: function analyses [228–235]. In these studies, it has often been necessary to coexpress the collagen genes with recombinant prolyl 4-hydroxylase to ensure stable triple helix formation [231,233].

FIBRIL-FORMING COLLAGENS

Self-assembly (assembly of the triple helix through to fibrils) is central to collagen biochemistry, but the process of assembling the characteristic fibril organization of each tissue is clearly influenced by the various cell types responsible for the biosynthesis and maintenance of each particular

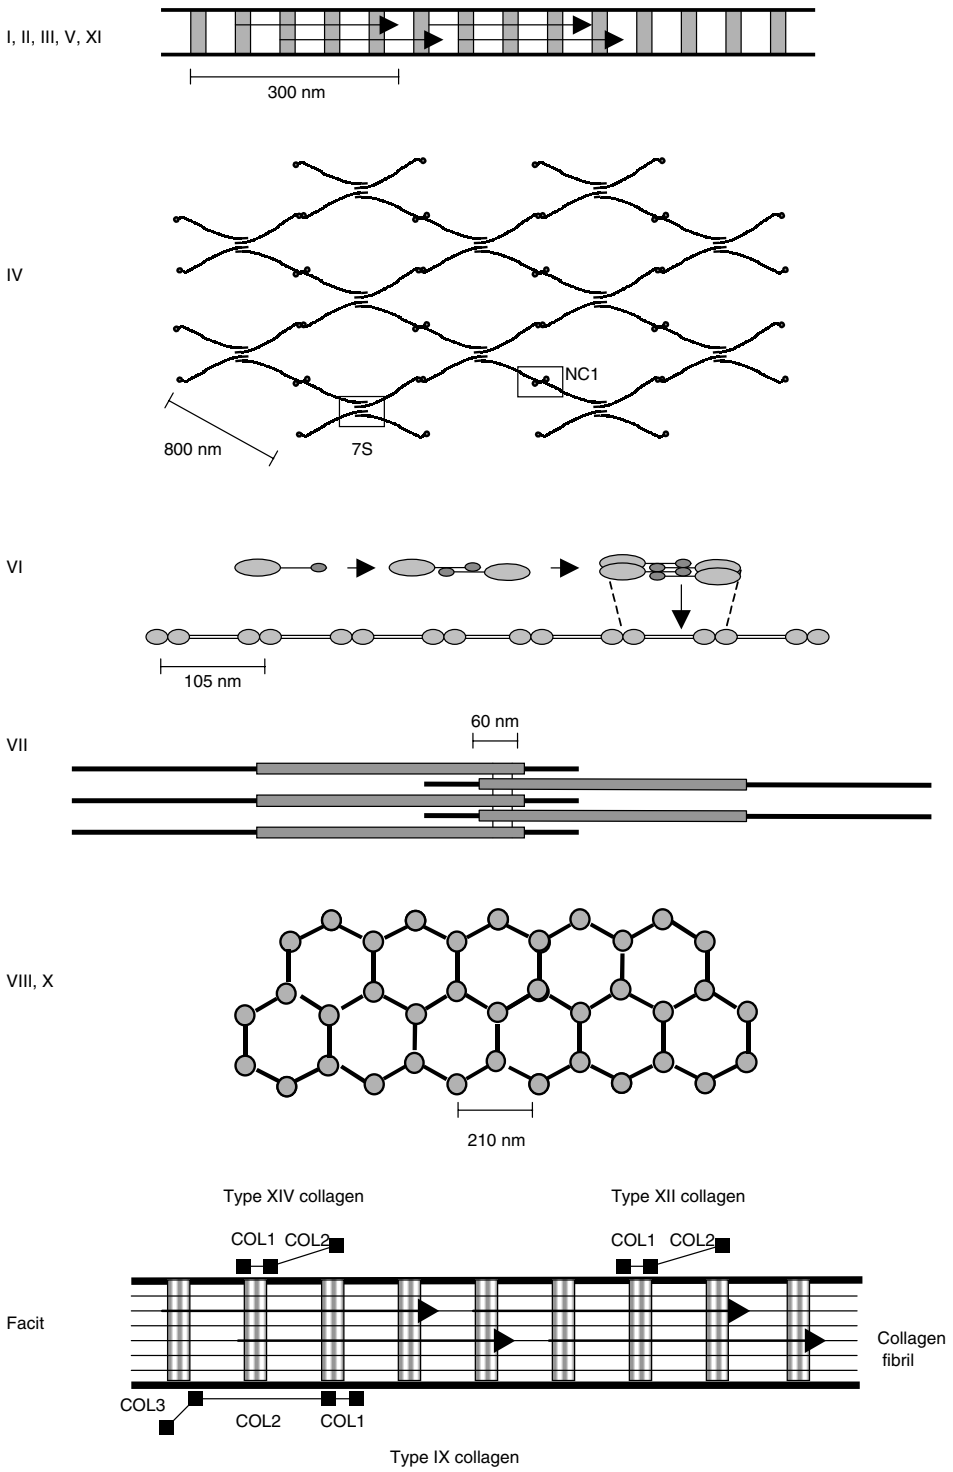


Figure 9. Diagrammatic representation of the molecular morphology of the macromolecular organization of the fibrillar and nonfibrillar collagens. Collagens I, II, III, V, and XI form fibrils as a consequence of the staggered alignment of molecules. Type IV collagen forms a flexible open network through N- and C-terminal and helical interactions, and this is the basic structural framework of basement membranes. Thin microfibrils of type VI collagen represent the end-product of a complex pathway of assembly, whereby monomers associate to form dimers, which, in turn, come together to form tetramers able to associate end to end. Type VII collagen anchoring fibrils are created as a result of monomers overlapping at their C-termini to form centrosymmetric dimers capable of aligning in limited parallel arrays. Triple-helical domains are shown as shaded bars, and non collagenous domains as lines. The closely related types VIII and X collagens form open hexagonal arrays. The FACIT collagens (fibril-associated collagens with interrupted triple helices) (types IX, XII, XIV) do not form defined assemblies on their own but instead are thought to associate with the surface of fibrils. Type IX collagen molecules are cross-linked to the outermost fibrillar collagen molecules of type II collagen fibrils.

matrix. Although virtually nothing is known of how fibroblasts, chondroblasts, and osteoblasts generate the fine architectural arrangements found in skin, cartilage, and bone, it seems likely that the packing, orientation, and organization may involve a complex interplay between cells, external forces, and the macromolecules (both collagenous and noncollagenous) of the extracellular matrix. It would appear that the cells are capable of producing discrete compartments in the adjacent extracellular space where assembly of discrete fibril bundles can take place prior to incorporation into the growing fibril [54,167,168]. Physicochemical studies demonstrating the influence of proteoglycans on collagen fibril self-assembly *in vitro* and histochemical demonstration of the close association of proteoglycans and fibronectin with collagen fibers *in vivo* provide evidence for macromolecular interactions as determinants of tissue architecture [172–175]. However, the situation is much more complex than initially thought, for at least five collagen types (I, II, III, V, and XI) are now recognized to form fibrils in the extracellular matrix (Fig. 11). Indeed, most individual fibers are very likely to be comprised of more than one of these collagen types and there is evidence to suggest that other minor collagens are also associated with these major fiber-forming collagens.

Collagen Types I, II, and III

Piez and co-workers in the 1960s demonstrated that denatured collagen molecules could be separated by carboxymethyl-cellulose chromatography into two components (see Introduction to this volume by Piez), and thus provided the description of the commonest form of collagen (now designated type I) as a heterotrimer comprising two α1 chains and one α2 chain [236]. The nonidentity of these two chains was further demonstrated after characterization of their CNBr cleavage profiles, which reflect both the abundance and position of the methionine residues contained within each polypeptide [237]. Knowledge of the CNBr-derived peptide patterns of the α1 and α2 chains was the key to the discovery of collagen type II by Miller and Matukas [14], who generated a distinct CNBr-derived peptide map for collagen extracted from lathyritic chick cartilage. This genetically distinct collagen was designated type II, and is now known to be the major collagenous component of hyaline cartilage and vitreous humor. The type II collagen molecule is a homotrimer consisting of three identical α1(II) chains, and therefore has a molecular conformation of $[\alpha1(II)]_3$ in its native triple-helical state. Subsequently, a further collagen was identified after pepsin treatment of fetal calf skin, which released the triple-helical domain of an α-chain distinct both in its chromatographic behavior on CM-cellulose and in its CNBr-derived peptide map [15]. This type III collagen was found to be of composition $[\alpha1(III)]_3$ and it has a widespread distribution, accompanying type I collagen in many connective tissues and being the principal collagenous component of the thin, so-called "reticulin" fibers present in the loose collagenous networks of highly differentiated organs such as the liver, lung, or lymphoid tissues.

Amino acid analysis reveals differences between these collagen types, a particularly notable feature being the higher content of hydroxylysine and hydroxylysine-glycosides in type II collagen; type III collagen is distinguished by its increased level of 4-hydroxyproline and the occurrence of cysteine (involved in disulfide bonds) within the triple helix. Amino acid sequence data indicate a close homology among these collagen types and explain the different CNBr-derived peptide maps on the basis of the distribution of methionine residues in the individual α chains [226]. Comparison of collagen types I, II, and III by electron microscopy of segment long spacing (SLS) crystallites also indicates a close homology [238–240]. This latter technique, in which ordered aggregates of collagen molecules are achieved at low pH in the presence of polyanions such as ATP, results in the individual molecules aligning themselves in parallel array with their ends in register rather than in the staggered array of the native fibril. These structures give a laterally extended picture of a single collagen molecule and allow the different collagen types to be compared, their staining patterns reflecting the charge distribution along the molecule.

The advent of recombinant DNA technology facilitated the determination of the complete amino acid sequences of collagen types I, II, and III, and descriptions of their gene structures provided an insight into the evolutionary relationship between these and other collagen types (Fig. 11) (see this Chapter, Part II). It has become clear that they are all translated from mRNAs coding for pre-proα chains with similar, but not identical, N- and C-terminal extensions. Thus, collagen types I, II, and III are synthesized as procollagens, which are then processed to fibril monomers in which more than 97% of each of the molecules consists of a continuous triple-helical domain along which the main information for an ordered parallel and D-staggered self-assembly is located. The formation of the continuous helical structure, the length of which varies between 1,014 residues in the α1(I) chain and 1,023 residues in the α1(III) chain, is dependent on the uninterrupted tripeptide sequence Gly–X–Y [16]. The rigidity or flexibility of distinct areas along the molecule is a reflection of the varying amounts of Pro and Hyp, in that the three types of tripeptide containing imino acids contribute to helix stability in the following order: Gly–Pro–Hyp > Gly–Pro–Y > Gly–X–Hyp [239]. Thus, at the C-terminal end of the triple-helical domain of the α1(I) and α2(I) chains is a very stable fivefold repeat of the triplet, Gly–Pro–Hyp, which probably seals the helix as it folds from the C-terminus following alignment of the three proα chains of type I procollagen during intracellular assembly. In contrast, the single vertebrate collagenase cleavage site within these fibril-forming collagens is a much more relaxed and flexible structure with a relatively low content of imino acids [241] (see also Chapter 7, this volume).

The C-propeptides of all the proα chains are strongly homologous [16], as might be expected on the basis of their similar function in helix assembly. Noteworthy differences occur between the N-propeptides, however, except for the highly conserved signal peptide sequences. Figure 7 illustrates the domain organization of type I procollagen, in which the proα1(I) N-propeptide contains a globular region of 66 residues stabilized by five intrachain disulfide bonds adjacent to a helical sequence of 48 residues, whereas in the proα2(I) N-propeptide the globular domain is absent. The N-propeptide of the proα1(III) chain is similar to that of the proα1(I) chain in having a 68-residue globular domain and a short triple helix of 39 residues, whereas in that of the proα1(II) chain the globular domain is missing and the helical region is 82 amino acids (i.e., 26 tripeptides plus a short interruption) long. There is also evidence for alternatively spliced variants of the type II collagen N-propeptide [16].

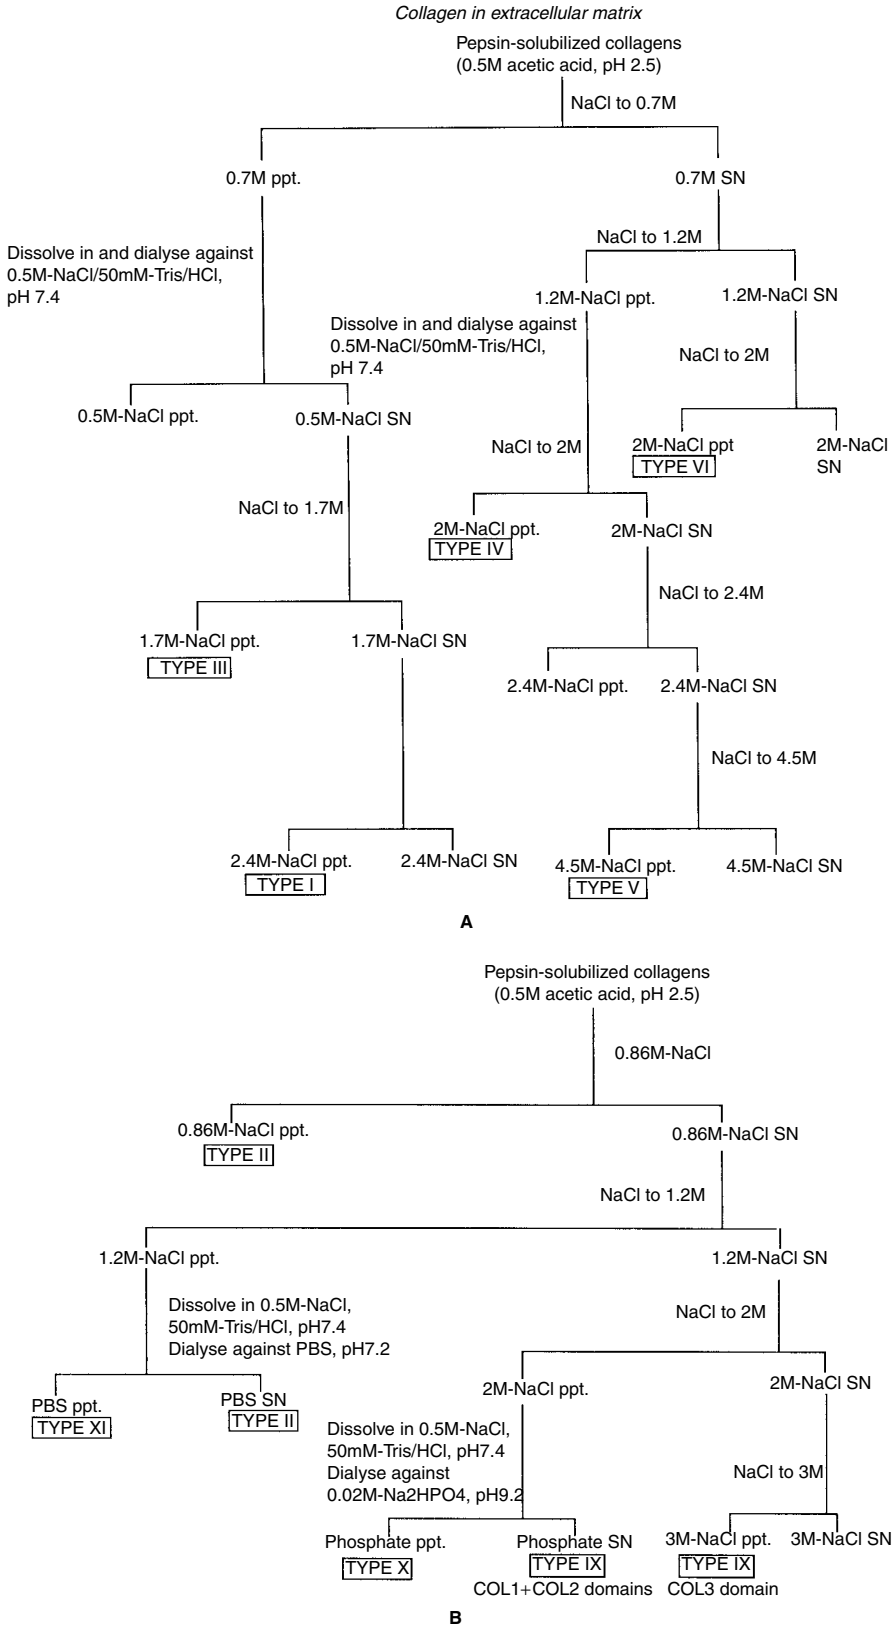

Figure 10. Fractionation procedures for the isolation of pepsin-derived tissue collagens. **A**: Flow sheet outlining the fractionation protocol for the purification of the various collagen types present in extracts of noncartilaginous tissues such as skin or tendon. **B**: Flow sheet outlining the fractionation protocol for the purification of the various collagen types present in extracts of cartilage.

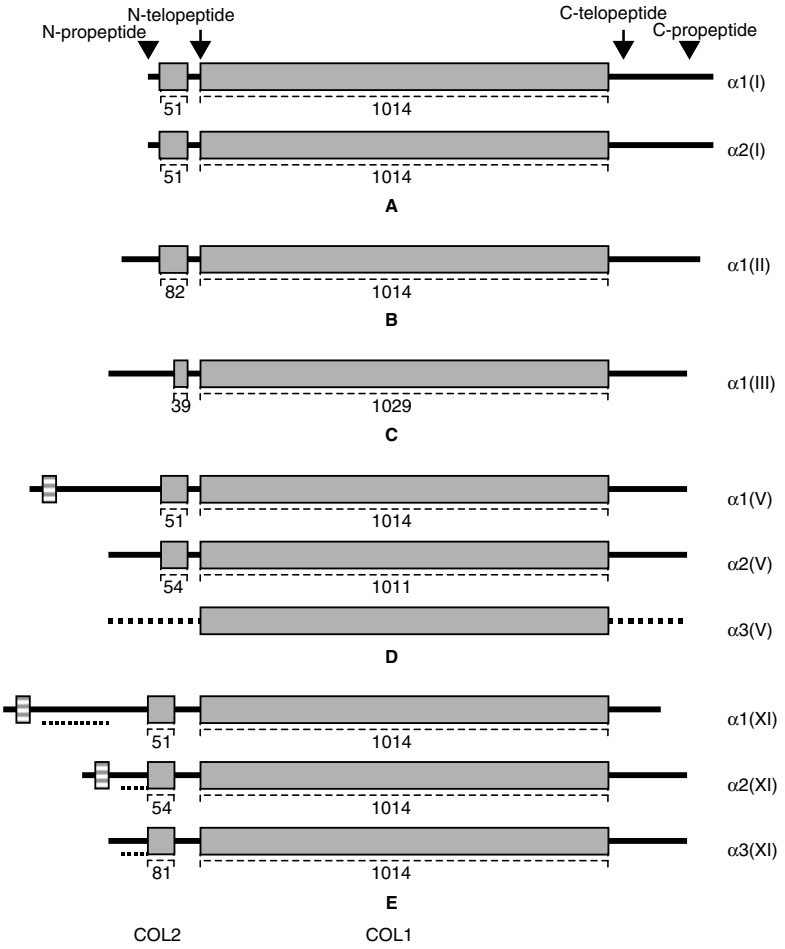

Figure 11. Molecular organization of the fibrillar collagens. Line diagrams illustrating the dimensions and domain structures of the α chains of triple-helical and non-collagenous regions of the fibrillar collagens. (**A**) Type I collagen, (**B**) type II collagen, (**C**) type III collagen, (**D**) type V collagen, (**E**) type XI collagen. Triple-helical domains (COL1 and COL2) are shown as dark shaded bars, and noncollagenous domains as lines. PARP (proline-and arginine-rich protein) domains that occur in the amino-terminal noncollagenous sequences of types V and XI collagen α chains are shown as vertical rectangles (▯) within the individual chains. The numbers of amino acid residues comprising each domain are indicated beneath the individual chains. Sequences outside the central triple helical domain of α3 (V), indicated by interrupted solid lines, are not yet known.

The removal of the N- and C-propeptides is a prerequisite for fibril formation, and cleavage of the N-propeptide from type III procollagen requires a specific N-proteinase distinct from that capable of processing procollagens I and II [150–152]. The flexible junction regions that connect the N- and C-propeptides to the main triple helix of all these α chains contain not only the cleavage sites for the specific proteinases but also nonhelical cross-link sites [242]. The rates of processing of the propeptides and the sequences in which they are removed from the procollagen are known to vary from tissue to tissue and may be a determinant of fibril size. It is fairly clear, however, that procollagen III is preferentially cleaved at the C-terminus, for a substantial proportion of the type III molecules incorporated into fibrillar elements appear to retain their N-propeptide sequences [160,161]. Such observations have led to the proposal that the N-propeptide specifically prevents the formation of thick collagen type III fibrils, and thereby offers an explanation for the occurrence of the relatively small (reticulin-like) fibrils seen particularly in elastic tissues.

No clear explanations can be offered in regard to the requirements of particular tissues and their contents of the fibril-forming collagens. Nevertheless, several generalizations seem to hold: fibrils enriched in type I collagen are often large, in terms of their cross-sectional diameter and length, are often packed in parallel bundles, and afford physical strength to tissues likely to experience extensive forces; type II collagen forms narrow fibrils and is the major collagen of cartilaginous tissues and vitreous humor; and type III fibrils are thinner and especially prevalent (up to 30% of total tissue collagen) in tissues exhibiting a degree of elasticity, e.g., skin, aorta, gut, and lung. Immunoelectronmicroscopy has demonstrated the close association of thick type I and thin type III collagen fibrils in tissues [241a], and there is chemical evidence that different collagens can be present in the same fibril [242]. Where type III collagen levels are reduced, as in patients with Ehlers-Danlos syndrome (EDS) type IV (see Chapter 9, this

volume), the tendency of the aorta or gut to rupture provides clear, if indirect, evidence of type III collagen having an important role in tissue elasticity and integrity [113].

Collagen Type I Homotrimer

Although type I collagen generally occurs as the heterotrimer $[\alpha1(I)]_2\alpha2(I)$, there is good evidence for the existence of low levels (no more than 0.5% of the fibrillar collagens) of a type I homotrimer $[\alpha1(I)]_3$ in both cells [243] and tissues [244,245]. The α chains of the type I homotrimer are the same gene products as the α1 chains of type I collagen, but in α1(I) trimer the 3-hydroxyproline content is elevated and the hydroxylation of lysyl residues is more extensive. The potential role of these hydroxylysine residues in stabilizing intermolecular collagen cross-links has led to speculation that α1(I) trimer might contribute to the stability and tensile strength of various connective tissues [245].

Early tissue analyses failed to demonstrate any major differences between fibers comprised of predominantly type I homotrimer and those of the heterotrimeric form, although the former are slightly thinner. In contrast, homotrimeric type I fibers generated *in vitro* appear not only to be thicker than corresponding heterotrimeric type I fibers, but also to differ in the kinetics of fibril formation, in that they are formed at a significantly slower rate [16]. This observation attests, perhaps, to a primary role for α2(I) chains in driving fibril formation. Further evidence for the importance of the α2(I) chain is derived from observations on a patient with a severe form (type III) of osteogenesis imperfecta [246,247]. Although fibroblasts derived from this patient synthesized proα2(I) chains, they were not incorporated into heterotrimers, and only α1(I) homotrimers were assembled. A naturally occurring mouse model (*oim*) with osteogenesis imperfecta with a mutation that also results in nonfunctional proα2(I) chains has presented a unique opportunity to explore changes in mouse tail tendon collagen fibril organization in homozygous and heterozygous mice [248]. The total absence of α2(I) chains results in type I collagen homotrimer formation, and is associated with a decrease in the order of axial packing and a loss of crystalline lateral packing. Thus, the presence of α2(I) appears to be crucial in long-range axial order in type I collagen–containing tissues [249].

Collagen Types V and XI

The genetically distinct collagen types V and XI are relatively minor components of the extracellular matrix but they share a close structural relationship with the major fibrillar collagens (types I–III) and form a distinct subset of fibril-forming collagens with functions ancillary to those of the major tissue collagens (Fig. 11) [250]. Types V and XI collagens are immunologically masked within fibrils and require partial fibril disruption for immunological detection, leading to the idea that they form a core within the major collagen fibrils (I, II and III). They can be further distinguished from the major fibrillar collagens by the complex processing they undergo, which yields monomers retaining a portion of the N-terminal globular domains [226,250–263]. These features suggest that they participate in the regulation of collagen fibril diameters. Type V collagen is a widespread component of virtually all noncartilaginous tissues (including bone, tendon, cornea, skin, blood vessels) which contain type I and types I/III collagen fibers. Type XI collagen is expressed mainly in cartilaginous tissues but is also expressed by nonchondrogenic tissues, particularly during embryonic development, and in these tissues heterotypic triple helical molecules comprising types V and XI collagen α-chains occur. Thus, these two collagens can be considered a single collagen type that is sometimes referred to as type V/XI collagen [250].

The molecular structure and assembly of type V/XI collagen shows many parallels with the major fibrillar collagens. The intact molecules are characterized by a single, continuous triple helix with N- and C-terminal nonhelical sequences, and visualization by rotary shadowing after pepsin digestion reveals rodlike molecules of approximately 300 nm, comparable in size to those of collagens I, II, and III. They can, however, be distinguished from the major collagens in thermal stability experiments that demonstrate the presence of unfolding intermediates in their triple helix to coil transitions [255]. SLS aggregates of collagen V/XI confirm the length of its helix, and demonstrate a cross-striation pattern similar to those of the major fibrillar collagens. Type V/XI collagens are synthesized as procollagens, with collagenous domain structures equivalent to those of the major fibrillar collagen precursors. cDNA-derived sequences have confirmed the homology and classification of these two collagens as fibril-forming species [16,256–258], although the N-terminal propeptides are longer than those of collagens I, II, and III, and the short helical regions therein have interruptions. The N-terminal propeptide of α1(XI) is, in fact, the longest N-propeptide described for a fibrillar collagen, with an extended and, in part, highly acidic globular region (Fig. 11). The size of the human proα1(V) chain (predicted M_r 183,415; apparent M_r 220,000–240,000) is significantly greater than that of both the proα2(V) chains (M_r 150,000–170,000) and other procollagen chains, as a consequence of a larger N-terminal propeptide of M_r 70,000–85,000. In contrast, sequences of the C-terminal propeptides of the precursors of collagen types V and XI derived from cDNA clones show very close homology in terms of residue number and organization with the C-propeptides of proα1(I), proα2(I), proα1(II), and proα1(III) chains; it is concluded that these propeptides are involved in directing triple-helix formation in a manner analogous to that in collagens I–III. Monomer assembly proceeds via disulphide-bonded precursors, although the processed chains have no interchain disulphide bonds.

Type V collagen was initially described as AB collagen following its isolation and identification in pepsin digests of chorionic amniotic membranes [257]. Ultrastructural analysis of such tissue reveals that aggregates of collagen V are frequently concentrated in pericellular zones, in close association with the basal lamina, and in association with larger fibrous elements throughout the interstitium [250]. Type V collagen is synthesized in both homotrimeric and heterotrimeric procollagen forms. The major form comprises two proα1(V) chains and one proα2(V) chain, but in some tissues (e.g., uterus and placenta) a second form comprising proα1(V), proα2(V), and proα3(V) chains is present. A homotrimer of proα1(V) chains has been observed in cell culture and the fully processed homotrimer has been identified in tissues. It has recently been shown that the carboxyl terminal propeptide of proα1(V) homotrimers is cleaved by the subtilisin-like prohormone convertase furin, while procollagen C-proteinase (BMP-1) actually cleaves the N-propeptide [259]. In addition, the proα1(XI) and proα2(XI) chains can substitute for the proα1(V) and proα2(V) chains, respectively, forming cross-type heterotrimers [250]. The procollagen forms are processed extracellularly at the C-terminus by procollagen C-proteinase. The

N-terminal domain of proα2(V) is apparently not processed, and in heterotrimers, therefore, a globular domain persists at the N-terminus that could sterically inhibit the accretion of collagen molecules. However, partial or complete processing occurs at the N-terminal end of the proα1(V) chain depending on whether it forms heterotrimers or homotrimers. The cleavage of N-terminal propeptides is particularly slow, which has a bearing on the function of type V collagen in influencing fibrillogenesis. In a recombinant study, stable homotrimeric $[\alpha1(V)]_3$ assemblies formed that were processed at the C-terminus; some of these molecules also underwent N-terminal trimming into a form corresponding to the main triple helix plus the major part of the N-terminal noncollagenous domain [234].

Differential processing of type V collagen isoforms could fine-tune fibril diameter modulation. *In vitro* studies have demonstrated that highly purified collagen V will form fine fibrils with or without a 67-nm D-periodic banding pattern [264]. It is not clear whether collagen V exists *in vivo* as independent fine fibrils, but it is often seen in intimate association with type I collagen fibrils and controls the diameter of type I collagen fibrils as a copolymerized constituent. The type V collagen molecules are staggered by 4D (D = 67 nm) and are primarily cross-linked to each other by head-to-tail bonds involving the N-telopeptides and the C-terminus of the helix. The α1(I) C-telopeptide is also cross-linked laterally to the N-terminus of the α1(V) helix. Native type V collagen resists mammalian collagenase but is cleaved by 92-kDa gelatinase (MMP-9) at two sites, one near the N-terminus and the other in the triple helix [265]. Mutations in the *COL5A1* and *COL5A2* genes have been linked to EDS types I and II, which are characterized by joint hypermobility, fragile skin, atrophic scars, and general abnormality in the architecture of the major collagen fibrils [266,267] (see also Chapter 9, this volume). Reduction of the amount of α1(V) using a dominant negative strategy in transgenic mice has confirmed the role of type V collagen in regulating fibril diameter; affected mice had altered fibrillogenesis resulting in assembly of large diameter fibrils with a broad size distribution and loss of corneal-specific fibril morphology [260]. Mice homozygous for mutations in the *COL5A2* gene produced structurally abnormal type V collagen and disorganized type I collagen fibrils, and had a high rate of perinatal mortality due to spinal deformities and both skin and ocular (especially corneal) abnormalities.

The term "type XI collagen" is used to describe the cartilage-specific chains originally designated lα, 2α, and 3α, or κ collagen, which were first isolated from pepsin digests of human hyaline cartilage [16,18,20,261]. This collagen can account for 8–10% of the collagens in most cartilages, has been localized to the territorial matrix where fine fibrils predominate, and forms heterotypic fibrils with types II and IX collagens. Type XI collagen is synthesized as a heterotrimeric procollagen comprising three distinct chains, proα1(XI), proα2(XI), and proα3(XI), although alternative assemblies with proα1(V) and proα2(V) may occur [250]. The proα3(XI) chain appears to be identical in sequence to the alternatively spliced form of the proα1(II) chain lacking the region coded for by exon 2, but its triple helical domain has more hydroxylysyl glycosides than the α1(II) chain. The proα1(XI) chain is also cleaved by procollagen N-proteinase and mammalian collagenase, indicating differences between these two chains either in amino acid sequence or enzyme accessibility. The procollagen forms are processed extracellularly at the C-terminus. Complex alternative splicing occurs in the mRNAs encoding a variable region between the PARP (proline and arginine-rich protein) and the large collagenous region (COL2) domains of both proα1(XI) and proα2(XI) chains (see Fig. 11). Differently spliced forms of α1(XI) undergo uniform N-terminal processing [267a], partial processing of the proα2(XI) chain occurs at the N-terminus, and the proα3(XI) chain is not processed further.

The bulk of the type XI collagen triple-helix is copolymerized in the interior of type II collagen-containing fibrils [250]. However, the portion of N-propeptide that remains (see above) after processing projects from the fibril surface, and is available for specific interactions with other extracellular matrix components, depending on the alternatively spliced forms present. Type XI collagen molecules are staggered by 4D (D = 67 nm) and are primarily cross-linked to each other by head-to-tail bonds involving the N-telopeptides [16]. The α1(II) C-telopeptide is also linked to the N-terminus of the α1(XI) helix. Mutations in the *COL11A1* and *COL11A2* genes have been linked to Stickler syndrome, Kniest dysplasia, and Marshall syndrome, characterized by numerous skeletal deformities [268–270] (see also Chapter 23, Part II, this volume); mutations in the *COL11A1* gene also cause ocular abnormalities [47,145]. *Cho/cho* mice homozygous for a mutation in the *Col11a1* gene that causes autosomal recessive chondrodysplasia are functionally equivalent to homozygous knock-outs for *Col11a1* [262]. These mice die at birth with numerous skeletal defects: a shortened snout, cleft palate, protruding tongue, short limbs with widened metaphyses and a shortened spine; growth plate chondrocytes are also highly disorganized.

Types V and XI collagens are implicated in regulating the diameter of types I and II collagen fibrils, respectively, a function presumably arising out of their characteristically slow N-terminal propeptide processing. Type XI collagen may participate in collagen–proteoglycan interactions and type V collagen has been shown to interact *in vitro* with a number of extracellular macromolecules including thrombospondin, heparin, heparan sulfate, and biglycan [263].

BASEMENT MEMBRANE COLLAGENS

Type IV Collagen

Basement membranes are widely distributed, sheet-like structures that underly almost all epithelia and endothelia in the body and surround many cell types, including smooth and skeletal muscle cells, Schwann cells, and adipocytes. They require molecular continuity extending over long distances, mechanical stability to resist high shearing forces or hydrostatic pressures, flexibility to allow tissue movement, and the ability to self-seal to allow the passage of immune cells. These properties are imparted mainly by type IV collagen, a large, distinctive form of collagen found only in basement membranes and which constitutes their major insoluble scaffold. Type IV collagen was originally described by Kefalides in 1971 [271,272], although the occurrence of a collagen in basement membranes had been indicated by X-ray studies of intact basement membranes some 20 years earlier [273]. Later, hydroxyproline and then hydroxylysine were detected in amino acid hydrolyzates of whole basement membranes, and the use of proteases to release the triple-helical collagen from glomerular basement membrane and anterior lens capsule led to the identification of collagen chains distinct from those of the fibrillar collagens I, II, and III [274,275].

The type IV collagen family is now known to comprise six genes, the translation products of which associate to form distinct type IV collagen molecules [16] (Fig. 12)(see also Chapter 25, this volume). The presence of distinct type IV collagen molecules, together with many additional components including the laminins and heparan sulfate proteoglycans, highlights basement membrane complexity and the considerable variation that can exist between basement membranes of the body in terms of molecular composition, organization, and function. It has proved difficult to investigate the chemistry of specialized basement membrane extracellular matrices, for they are essentially insoluble and not readily separated from underlying connective tissues. Accordingly, much of our knowledge of the chemistry and composition of basement membranes is derived from those that can be prepared in high purity and reasonable yield, i.e., lens capsule, glomerular basement membrane, seminiferous tubule basement membrane, and the extraembryonic membranes such as rodent Reichert's membrane [272,276–278]. A particularly useful source of type IV collagen is the transplantable EHS mouse tumor, which elaborates a basement membrane-like matrix that can be prepared in large amounts [279,280]. This material has been valuable in identifying the characteristics of basement membrane collagen type IV, as well as those of other basement membrane components [281–284].

Type IV collagen was the first collagen to be identified lacking the capacity to undergo a regular lateral aggregation of molecules into fibrillar structures [276,285]. It does not even form well-ordered SLS crystallites, but rotary shadowing has revealed the intact monomers to be approximately 390 nm long with a large globular domain at the carboxyl terminus (NC1 domain), an extended collagenous domain of approximately 350 nm, and a short noncollagenous amino-terminal domain. A series of kinks occur within the triple-helical domain, which arise as a result of numerous (>20) short imperfections in the Gly–X–Y repeat sequence. These noncollagenous sequences confer a high degree of flexibility on the individual monomers and, therefore, on their assembled aggregates. Newly assembled type IV collagen monomers do not undergo processing before incorporation into the matrix. Details of the macromolecular assembly of type IV collagen into a filamentous network were established largely as a result of detailed enzyme digestion experiments and rotary shadowing analyses of aggregation phenomena *in vitro*. Bacterial collagenase digestion experiments on EHS tumor and other basement membrane-containing tissues identified a stable resistant fragment that turned out to be a basic structural unit of type IV collagen, the tetrameric 7S domain, which comprises parallel and antiparallel overlapping 30 nm-long amino-terminal helical and nonhelical segments from four collagen IV molecules. Acid extractions of these tissues yielded dimers of two 330 nm-long triple-helices connected to each other by

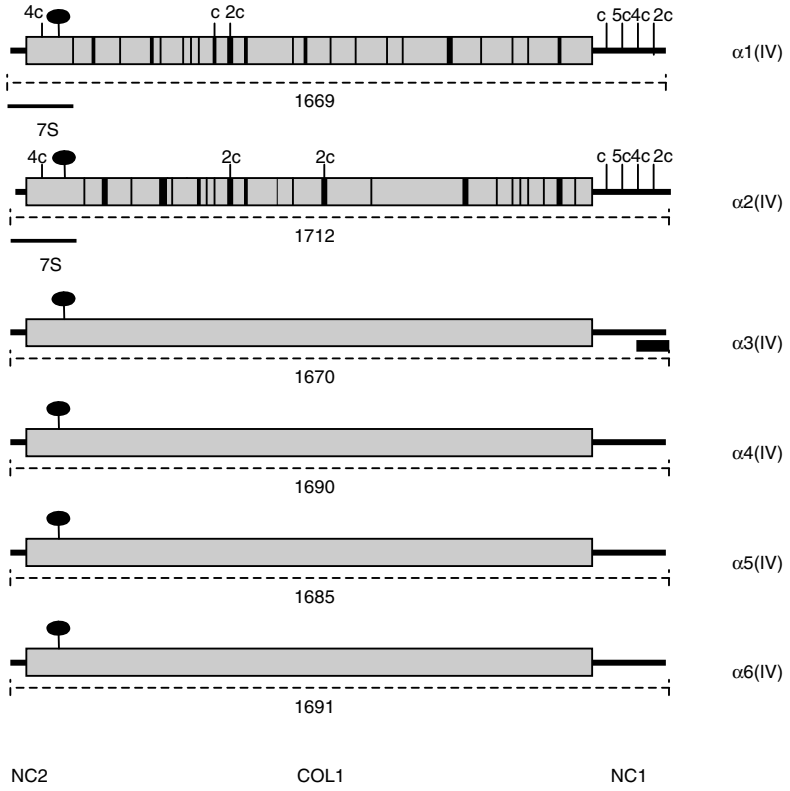

Figure 12. Molecular organization of basement membrane type IV collagen. Line diagrams illustrating the dimensions and domain structures of the collagenous and noncollagenous regions of the α1(IV) –α6(IV) chains of type IV collagen. Imperfections within the triple-helical regions are indicated by vertical lines and solid vertical bars: these endow flexibility on the triple-helical domains of the assembled molecules. The 7S region (—), alternatively spliced sequences (▬), positions of cysteine residues (c) and N-linked carbohydrate attachment sites (🍍), are marked. The numbers of amino acid residues comprising each chain are indicated below the individual chains.

multiple disulfide interactions in the NC1 domains after cleavage of the 7S domain, and pepsin digestion of type IV collagen resulted in the destruction of the NC1 domains and concomitant release of a large tetrameric fragment in which the molecules were held together by their amino-terminal ends. The identification of these interactions at both amino and carboxyl termini led to the proposal of there being an open network structure in which four molecules are bound to one another by their amino-terminal 7S domains and at their opposite ends by the joining of their carboxyl terminal NC1 domains, with each strand running between 7S domains being 800 nm long and a single triple helix thick (Fig. 9) [286–288]. Stabilization of this alignment takes place through the formation of reducible and nonreducible intermolecular cross-links. This arrangement may be repeated over many microns and is compatible with the formation of polymers of infinite size and with the mechanical properties and amorphous appearance of basement membranes. These predictions were confirmed *in vitro* by reconstituting polygonal networks from type IV collagen dimers [289,290]. However, the distances between NC1 domains were irregular, indicating a much tighter network with extensive lateral associations between central segments of the triple helix. Such laterally associated networks have also been visualized in the basement membranes of amnion and the EHS tumor, and are predicted from X-ray diffraction of lens capsule [272]. The molecular basis for this lateral association is unclear, but appears to involve low-affinity binding, with the carboxyl terminal globular domain possibly having an important role. A degree of interfilament superhelical twisting along many of the type IV collagen strands of EHS and amniotic networks has been implicated in stabilizing the laterally associated network [290–292]. The final collagen IV networks are stabilized by disulfide and/or lysine aldehyde-derived cross-links between their interacting NC1 and 7S domains and are highly insoluble. Thus, during tissue remodeling, type IV collagen must be cleaved, initially by matrix metalloproteinases, to accommodate structural changes [50] (see also Chapter 7, this volume).

Biochemical, immunohistological, and molecular biological data have shown that the most abundant form of type IV collagen molecules exists as heterotrimers with the major molecular formula $[\alpha1(IV)]_2\alpha2(IV)$ [16]. The genes encoding α1(IV) and α2(IV) chains are in a head-to-tail arrangement on chromosome 13, with common bidirectional promoters and transcription start sites separated by only 130 bp. The complete primary structures of the α1(IV) and α2(IV) chains elucidated from man and mouse display a highly conserved carboxyl terminal NC1 globular domain (229 and 228 residues, respectively) that consists of two homologous parts (C4 modules) each stabilized by three disulphide bonds and containing a high proportion of hydrophobic residues (Fig. 12). Their characteristic interrupted triple-helical domains are also of similar lengths (1,398 and 1,427 residues, excluding non-triple helical interruptions, respectively). The reducible and nonreducible intermolecular cross-links located within the 7S domain render this portion of the molecule so stable that it can easily be isolated as a bacterial collagenase-resistant fragment [293]. The NC1 domains of type IV collagen α chains are thought to play a key role in their alignment and in chain selection and the initiation of triple-helix formation in the rough endoplasmic reticulum, in a manner analogous to the C-propeptides of the fibrillar collagens with which they share limited homology. Recombinant expression studies have shown that neither α1(IV) nor α2(IV) is able to form homotrimers, and that trimer formation requires the presence of both α chains. A major focus of current research is to determine the molecular basis of specific α chain NC1 associations during trimerization [294,295].

The identification of four additional type IV collagen α chains has greatly increased the molecular complexity of basement membrane chemistry (Fig. 12) [16]. The α3(IV), α4(IV), α5(IV), and α6(IV) chains have collagenous sequences of 1396, 1415, 1415, and 1404 residues and carboxyl terminal noncollagenous (NC1) domains of 232, 229, 229, and 241 residues, respectively. As with the α1(IV) and α2(IV) genes, those encoding α3(IV) and α4(IV) chains on chromosome 2 and those on the X chromosome encoding α5(IV) and α6(IV) chains are each arranged in a head-to-tail manner and are functionally related and coordinately regulated (see also this Chapter, Part II). Their unique tissue-specific expression patterns are illustrated in immunolocalization studies using α1(IV) to α6(IV) chain-specific monoclonal antibodies [295–298] (see also Chapter 25, this volume). In kidney, all basement membranes in glomeruli and tubules stain for α1(IV) and α2(IV), whereas the α3(IV) and α4(IV) chains are confined to the glomerular basement membrane and some parts of the tubules. In stark contrast, the expression patterns of the α5(IV) and α6(IV) chains are different in the glomerulus — α6(IV) is not present in the glomerular basement membrane but occurs within the basement membranes of Bowman's capsules and some distal tubules, whereas α5(IV) is densely positive in the glomerular basement membrane where its distribution parallels that of α3(IV) and α4(IV) [295,296]. Smooth muscle cells in the urinary bladder and uterus are surrounded by basement membranes containing α1, α2, α5, and α6 type IV chains, and these four chains are also present around smooth muscle cells in the muscular layer of the fundus of the stomach, whereas those in the antrum and distal side of the gastrointestinal tract express only α1(IV) and α2(IV). In the vasculature, most smooth muscle cells are positive for α1(IV) and α2(IV), but α5(IV) and α6(IV) are also expressed in the aorta and some arteries where blood pressure changes significantly. In skin, which lacks α3(IV) and α4(IV), α1(IV) and α2(IV) are present in all epidermal basement membranes and capillary basement membranes, while α5(IV) and α6(IV) colocalize only in the epidermal basement membranes [298]. The temporal and spatial expression of the α1, α2, α5, and α6 type IV chains have also been demonstrated during the formation of the basal lamina in an *in vitro* skin model [298]. These localization studies suggest that type IV collagen molecules comprising not only α1(IV)/α2(IV) but also α3(IV)/α4(IV)/α5(IV) and α5(IV)/α6(IV) may occur.

Kidney has been a particular focus for investigating the role of type IV collagen in basement membranes due to the pathologies associated with its specialized basement membranes (see Chapter 25, this volume). The primary lesion in one such disease, the Goodpasture syndrome (a rare form of glomerular nephritis) has been localized immunologically to the α3(IV) NC1 domain [47,145,299]. Ultrastructural changes in the glomerular basement membrane started to be recognized in cases of hereditary Alport syndrome in the late 1960s. The pathogenesis of this X-linked progressive nephritis associated with hearing loss and characterized by the splitting of the glomerular basement membrane is caused by mutations in the α5(IV) gene resulting in an absence of functional α5(IV) chains [145,275]. Linkage to

chromosome Xq22-26, the locus for the genes encoding α5(IV) and α6(IV) was established in 1990, and, to date, more than 200 different mutations have been reported in the *COL4A5* gene. Moreover, deletions at the 5′ end of *COL4A6* extending to the neighboring *COL4A5* gene have been reported to cause diffuse leiomyomatosis associated with Alport syndrome, and it has been speculated that α5(IV) and/or α6(IV)-containing basement membranes that enclose smooth muscle cells of the aorta and other tubular organs might have some particular function related to mechanical stress or tensile strength during their characteristic contractile activity [300]. Several kindreds with autosomal forms of Alport syndrome have mutations in *COL4A3* and *COL4A4* genes.

Disease and structural studies have shed light on the molecular composition of type IV collagen molecules. In cases of X-linked Alport syndrome, α3(IV), α4(IV), and α5(IV) chains are virtually undetectable in the glomerular basement membrane, indicating that all three probably associate in this tissue to form a triple helical molecule. Moreover, in mouse models of Alport syndrome in which α3(IV) is lacking, there is absence also of α4(IV) and α5(IV). When pseudolysin digestions were used to excise truncated triple-helical molecules from glomerular basement membrane, two distinct assemblies were isolated, one at 4°C which comprised α1(IV) and α2(IV) chains, and the other at 25°C which contained mainly α3(IV), α4(IV), and α5(IV) chains with a few α1(IV) and α2(IV) chains [295]. The 25°C assemblies appeared as a network containing loops and supercoiled triple helices and were stabilized by disulfide cross-links between the α3(IV), α4(IV), and α5(IV) chains. Several lines of evidence suggest that heterotrimeric molecules composed of α5(IV) and α6(IV) chains also exist [275]: α5(IV) and α6(IV) chains are codistributed in basement membranes of the Bowman's capsule and some kidney tubules, and in epidermal basement membranes; in typical Alport cases in which mutations in *COL4A5* cause a lack of the α5 chains, the α6 chain is also missing from dermal basement membranes; primary sequence comparisons suggest that the α5(IV) and α6(IV)-containing molecules could have the molecular formula $[\alpha5(IV)]_2\alpha6(IV)$; loss of both α5(IV) and α6(IV) chains has been demonstrated in basal cell carcinomas, invasive prostate carcinomas, and diffuse leiomyomatosis associated with Alport syndrome [300].

As the major structural scaffold of all basement membranes, the insoluble type IV collagen network not only accommodates and interacts with many other noncollagenous and collagenous basement membrane molecules, but also directly supports cell adhesion [16,277,301]. Human mesangial cells bind avidly via α1β1 and α2β1 integrins to type IV collagen $[\alpha1(IV)]_2\alpha2(IV)$ through the major triple-helical domain and the NC1 domain, and a major, specific site ~100 nm from the amino-terminus of α1(IV) has been identified that mediates α2 integrin binding. The other molecules that make a major contribution to the repertoire of functions ascribed to basement membranes include laminin, entactin (nidogen), heparan sulfate proteoglycan, types XV, XVIII, and XIX collagens, BM-40 (SPARC), fibulins, and dystroglycan. For example, laminin, a large and abundant noncollagenous basement membrane glycoprotein (see Chapter 5, this volume), can form a noncovalent quasi-hexagonal network and has the capacity to bind to type IV collagen, heparan sulfate proteoglycans, and entactin, to create an integrated structure enmeshed within the basement membrane [276]. Entactin occurs in intimate association with laminin, and helps to integrate laminin stably in the basement membrane matrix. The laminin-entactin complex contributes to the cell-binding activity of basement membranes. Heparan sulfate proteoglycans, in contrast, provide polyanionic sites that serve as selective charge barriers that make the matrix impermeable to proteins. The roles of BM-40 and the many minor basement membrane components remain largely obscure. A clear understanding of how all these molecules interact should reveal the molecular basis of basement membrane processes such as tissue differentiation, angiogenesis, and metastasis.

Type VII Collagen and Anchoring Fibrils

Type VII collagen is one of the largest of the known mammalian collagens and constitutes a distinct fibril-forming collagen subset with a number of unique structural features that set it apart from the classical fibril-forming collagens (Fig. 13) [16,302]. Whereas type VII collagen exhibits a restricted tissue distribution and can be classified as a minor collagen, it is the major component of the anchoring fibrils, specialized extracellular structures found underlying the basement membrane of numerous external tissues such as skin, oral mucosa, and cervix, the function of which is to anchor the basement membrane to the stroma [303–305]. This collagen was first observed as a minor component of pepsin-solubilized type V collagen preparations of chorioamnion, and was subsequently identified as a triple-helical molecule comprising apparently identical α chains and with an extended helical domain almost 1.5 times the length of the type I collagen helix [306]. Native, pepsin-digested type VII collagen monomers appear rod-like by rotary shadowing, with a length of 467 nm, but the major isolated form of the molecule is a dimer of 785 nm, in which the two monomers are associated with an overlap of 60 nm (Fig. 9). The dimers then associate laterally to produce "segment long spacing (SLS)-like" structures that insert into the basement membrane via the large NC1 domains. SLS crystallites prepared from type VII collagen dimers reveal a distinctive centrosymmetrically banded aggregate with a unique cross-striation pattern [307].

Type VII collagen resembles the fibrillar collagens in that it is synthesized and secreted as a procollagen, with a broadly similar domain structure [16,302,308]. There the similarities end, however, for this procollagen species is not only significantly larger than the corresponding fibrillar procollagens, with a molecular mass of about 1×10^6 (3× 2,944 amino acids), but it also has numerous fine structural differences and, via a novel assembly pathway, forms a strikingly different fibrillar structure. Type VII collagen is synthesized and secreted as a homotrimeric molecule with the molecular formula $[\alpha1(VII)]_3$. Secreted type VII procollagen monomers aggregate extracellularly into antiparallel assemblies of two monomers that overlap each other at the amino-terminus by 60 nm [306,307,309]. These form centrosymmetric aggregates that are thought to be stabilized by intermolecular disulphide bonds within the overlap, and with the large amino-terminal NC1 domain extending outward from both ends. This aggregation is probably specified by the carboxyl terminal NC2 domain prior to its removal by proteolytic cleavage [311]. This model for the macromolecular assembly of type VII collagen predicts that these dimers associate laterally in a nonstaggered array to form a tightly packed, fibrous SLS-like structure, in which the NC1 domains are embedded at one end in type IV collagen and laminin-5 in the lamina densa and at the

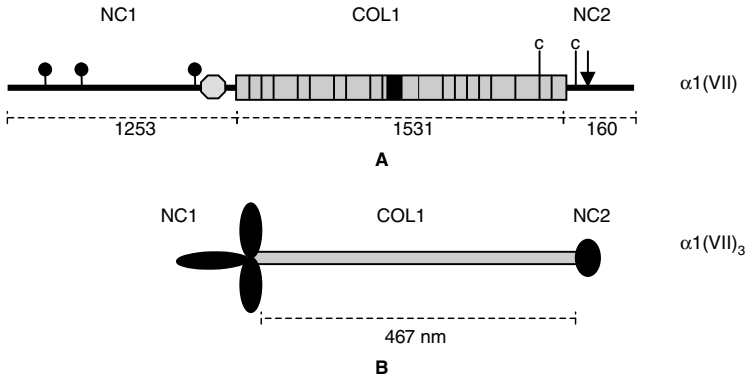

Figure 13. Molecular organization of type VII collagen. **A.** Line diagram illustrating the dimensions and domain structures of the collagenous and non-collagenous regions of the α1(VII) chain of type VII collagen. The triple-helical domain is represented as a dark shaded bar, with approximate positions of the deduced interruptions of, and imperfections within, the triple-helical region indicated by vertical lines and solid vertical bars, and non-collagenous domains shown as horizontal lines. The A-domain that occurs within the NC1 domain is indicated (●), together with the positions of cysteine residues (c) and N-linked carbohydrate attachment sites (Y). The numbers of amino acid residues comprising each domain are indicated beneath the chains. **B**. other end in anchoring plaques containing type IV collagen within the stroma, with the triple-helical zone extending between them. These structures are further stabilized through the formation of transglutaminase-2-mediated cross-links, with both triple-helical and noncollagenous domains serving as substrates for tissue transglutaminase-2 [312]. Such anchoring fibrils have been identified in human skin by immunogold labeling, although some adopt a U-shaped structure in which both ends are inserted into the lamina densa [311]. Anchoring fibrils thus exist as an extensive scaffolding, capable not only of providing support to the stromal matrix elements but also of reinforcing the attachment of epithelial cells to the subjacent stroma. Such a role for type VII collagen is supported by the clinical manifestations of severe recessive dystrophic epidermolysis bullosa, in which the principal lesions are blisters caused by separation of the dermal stroma from the epithelium immediately below the basement membranes in response to normal mechanical friction, and which is characterized by a lack of ultrastructurally identifiable anchoring fibrils [1–3,145,313] (see also Chapter 15, this volume).

The α1(VII) chain comprises a central collagenous region flanked by non-collagenous terminal sequences (Fig.13) [16,308]. The small C-terminal NC2[3] domain (M_r 100 kDa, 160 amino acids) is nonhelical and in rotary shadowing images appears as a small globule. It is cysteine-rich and contains a Kunitz proteinase inhibitor-type repeat similar to that found in the α3(VI) chain of type VI collagen. The processing of type VII collagen is thought to contribute to correct association and folding of the polypeptide subunits [311]. The putative cleavage site is within amino acids 2814–2843 in the proximal NC2 domain. This 29 amino acid stretch contains a consensus sequence for procollagen C-proteinase [314], and this enzyme may therefore cleave the C-propeptide of procollagen VII. This cleavage site falls within the sequence that brackets the junction of the COL1 and NC2 domains; this region also contains the two cysteine residues that stabilize the pro-α1(VII) antiparallel dimers. The central triple-helical domain (1531 amino acids) contains 19 nonhelical discontinuities (Gly–X–Y imperfections, or insertions) with the major disruption (39 amino acids in length) occupying a central position, and also possesses cleavage sites for vertebrate interstitial and type IV collagenases [50] (Fig. 13) (see also Chapter 7, this volume).

The amino-terminal NC1 domain of type VII procollagen contains a very large and unusual sequence of M_r 450 kDa (1237 amino acids), which consists of submodules with homology to known adhesive proteins, including a partial von Willebrand factor type A domain, nine consecutive fibronectin type II repeats, a complete von Willebrand factor type A domain, and a cysteine/proline-rich domain [16]. Because these modules reside at the ends of the assembled anchoring fibrils and are thought to interact with basement membrane structures, their adhesive properties probably play a critical role in providing integrity to the lamina densa/papillary dermis interaction. This NC1 domain has been visualized as a three-armed structure linked by interchain disulfide bonds within the junctional region, and it provides potential targets for interactions with other extracellular matrix molecules including type IV collagen, the recently identified GDA-J/F3 antigen (a small 45–50 kDa globular protein), and possibly fibrillar collagens [16,315]. Type VII collagen also interacts with fibronectin via a unique subdomain within the collagenous triple helix [316], and with laminin 5 via the NC2 domain [317,318]. The deduced primary structure of human α1(VII) contains four RGD (Arg–Gly–Asp) sequences that may mediate interactions with cells.

Recent studies on the recessive dystrophic forms of epidermolysa bullosa (EB) have disclosed several mutations in the type VII collagen gene that have been highly instructive toward understanding the structure-function relationships of the various type VII collagen

[3]Historically, nonhelical, noncollagenous (NC) domains have been numbered from the carboxyl-terminal domain [16]. In the cases of collagen VII and collagen XIII, the NC1 domain is now accepted to be the amino-terminal noncollagenous region and numbering is from the amino-terminal domain.

domains [1–3,47,145,313,319,320] (see also Chapter 15, this volume). Many of the mutations consist of premature termination codons that predict the synthesis of truncated α1(VII) polypeptides. In the homozygous state these mutations result in the absence of anchoring fibrils, thus explaining the fragility of skin. A compound heterozygote for two premature termination codons indicated that the polypeptide segment between the upstream and downstream termination codons (von Willebrand factor A domain and cysteine/proline-rich region), is a critical region for fibril assembly. The intact triple-helical conformation is required for the function of type VII collagen, because substitutions in the Gly–X–Y repeat structure result in dominant dystrophic EB. However, recent data demonstrate that type VII collagen is a remarkable exception among collagens in that not all glycine substitutions within the triple helix exert dominant-negative effects [3]. Thus, the biological consequences of these substitutions seem to depend on their position within the triple helix. The NC1 domain is one of the most highly conserved sequences in the molecule, yet mutations here cause a relatively mild form of recessive dystrophic EB.

SHORT-CHAIN COLLAGENS

Type VI Collagen and Collagenous Microfibrils

Type VI collagen is essentially a glycoprotein with a short triple-helical core, which forms a distinct subclass of microfibril-forming collagen and is characteristically organized into an extensive filamentous network in the extracellular matrix of virtually all connective tissues (Fig. 14) [19,321]. It was originally isolated as a disulfide-bonded collagenous fragment in pepsin digests of vascular tissues, and designated "intima collagen." Many difficulties were initially encountered in isolating intact collagen VI because of its insolubility in most physiological buffers, and this led to the assumption that it constituted a minor component of connective tissues. However, the use of improved extraction procedures showed that this collagen represents a significant component of many tissues, notably skin and cornea [225,322–324], and the increased yields also facilitated the elucidation of the structure and details of the molecular assembly of intact type VI collagen.

Type VI collagen is unusual among the collagen family in possessing a particularly short triple-helical domain (105 nm) and exceptionally large N- and C-terminal globular domains that account for more than two-thirds of the total mass of the molecule [325,326]. It occurs as a heterotrimer composed of three genetically distinct subunits, [α1(VI)α2(VI)α3(VI)]. A number of studies have shown the synthesis of the three chains of collagen VI to be differentially regulated in cell culture and to be influenced by exogenous cytokines [327,328].

The three genetically distinct constituent chains of collagen VI show significant variation in their molecular masses (Fig. 14) [223,321,325,326]. The α3(VI) chain with an M_r of 260,000–280,000 is much larger than the partially homologous αl(VI) and α2(VI) chains (both M_r 140,000) (Fig. 14A) [321,329,330]. Despite this discrepancy in molecular mass, the lengths of the triple-helical sequences of all three chains are virtually identical (335–336 residues). The elucidation of the cDNA sequences of the chick and human collagen VI chains has revealed the molecule to have a multidomain structure with a number of potentially functional motifs, including 11 potential cell-binding RGD (Arg–Gly–Asp) sequences within the helical region [16,331–337]. The globular domains of each α chain contain three homologous motifs encoded by 200-base repetitive domains and designated N1, C1, and C2 in the human molecule. These exhibit significant sequence identity with the collagen-binding A domains of von Willebrand factor (vWF), cartilage matrix protein, some integrins, and complement components. The α3(VI) chain is the largest and one of the most novel collagen chains sequenced to date, with an extended N-terminal globule (1,804 residues, deduced M_r 343,000) containing nine additional motifs similar to the type A repeats of von Willebrand factor (encoded by 200-base repeats), and a C-terminal globule with three additional unrelated motifs (C3 to C5) in the most distal sequence. The C3 domain, a lysine and proline (KP)-rich region in the human, but not the chick, shares some homology with several proline-rich salivary proteins, and contains threonine repeats that may be utilized for O-linked glycosylation. The C4 domain has features typical of the structurally important type III repeat of fibronectin, and although overall sequence identity is rather low, this domain could form analogous rod-like elements with binding sites for heparin and cells. The most C-terminal domain (C5) is highly homologous to a variety of serine protease inhibitor sequences, and exhibits 42% identity with aprotinin and 50% identity with human urinary trypsin inhibitor.

Multiple alternative splicings of the N-terminal vWF type A repeats of the α3(VI) chain, apparently generated by exon skipping, have been detected at the cDNA level, which are presumed to give rise to the multiple forms of α3(VI) detected at the protein level as a ladder of polypeptides upon electrophoresis [338–340]. In addition, three α2(VI) variants with distinct C-termini arise because of an alternative splicing mechanism involving both mutually exclusive utilization of two exons and selective usage of an internal splice site. The spliced collagen VI isoforms exhibit distinct tissue-specific patterns and may impart subtly different functional properties [340].

The process of type VI collagen polymerization follows a route quite dissimilar to that of any of the other known collagens. The assembly of type VI monomers and their association into dimers and tetramers occurs intracellularly [321,341,342], and there is no evidence that processing of the α chains is a necessary prerequisite for assembly [343]. However, discrepancies between the deduced M_r (340,000) and the electrophoretically determined M_r (280,000) of α3(VI) suggest partial processing, and this is confirmed by the demonstration of the loss of the Kunitz module and possibly other adjacent modules from the α3(VI) chain [16].

The intracellular association of the three constituent α-chains into monomers is probably stabilized by the formation of interchain disulfide bridges. Dimer formation is brought about by the lateral aggregation of two antiparallel monomers with their helical rods staggered and the C-terminal regions overlapping by about 75 nm. The subsequent parallel alignment of two dimers with their N-terminal ends in register gives rise to the tetramer, the secreted form of type VI collagen and the basic unit of type VI collagen microfibrils (Fig. 9). The dimers are thought to be stabilized by disulfide bonds formed between the single cysteine residues present within the helices of α1(VI) and α2(VI), while a corresponding cysteine in the helix of α3(VI) may participate in tetrameric associations [333]. In addition, disulfide bonds formed between the clusters of cysteines found at the junctions between the N- and C-termini and the triple helix contribute to the high thermal stability and protease

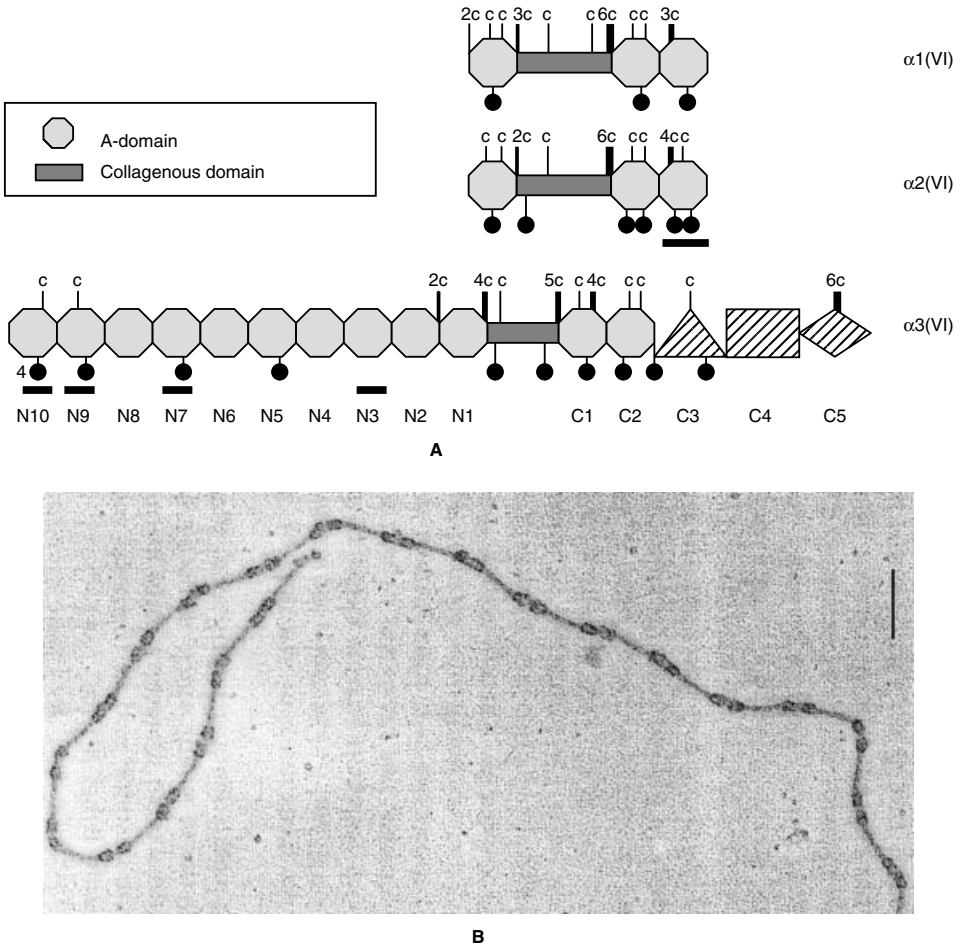

Figure 14. Molecular organization of type VI collagen. **A**. Line diagrams illustrating the dimensions and domain structures of the collagenous and noncollagenous regions of the α1(VI), α2(VI), and α3(VI) chains of type VI collagen. The noncollagenous regions of all three chains comprise a number of motifs designated N1, C1, and C2 in the case of α1(VI) and α2(VI) chains, and N1–N10 and C1–C5 in the case of the α3(VI) chains. Triple-helical domains are represented as dark shaded bars. The A-domains that flank the collagenous regions are indicated as shaded octagons (⬡), and the positions and numbers of cysteine residues (c) and N-linked carbohydrate attachment sites (🍡) are shown. The unique domains C3-C5 in the α3(VI) chain are indicated as lightly shaded motifs. Underlying solid bars indicate alternatively spliced A-domains **B**. Rotary shadowing image of long, thin (4 nm) type VI collagen microfibril of characteristic 105 nm periodicity that comprises tetrameric units in end-to-end association. The type VI collagen was isolated from fetal calf skin by bacterial collagenase digestion under non-reducing conditions, and subjected to a subsequent gel filtration step. The bar represents 100 nm.

resistance of the collagen VI helix. These assembly details were established by electron microscopic studies of pepsin-solubilized and intact collagen VI molecules synthesized in culture, and the various intermediate molecular forms have been visualized [341]. Once in the extracellular space, the tetramers aggregate end-to-end by the interaction of the outer N-terminal globular domains, giving rise to characteristic long, thin, beaded filamentous structures with a periodicity of 100 nm and a diameter of 3–5 nm. Such intact collagen VI microfibrillar macroassemblies have now been isolated from various fetal and adult tissues and visualized by rotary shadowing [227] (Fig. 14B). Ultrastructural analysis of tissues has also provided evidence for alternative collagen VI aggregates occurring as broad-banded fibrils of 100 nm periodicity, and these have been variously described as "zebra collagen," "Luse bodies," and fibrous long-spacing (FLS) collagen. Such structures apparently arise as a result of lateral aggregation of tetramers (in register), and have been identified in a number of normal tissues such as intervertebral disk and synovium and in pathological tissues including tumors and osteoarthritic cartilage [344–346].

Mutations in the *COL6A1*, *COL6A2*, and *COL6A3* genes encoding the three α chains have recently been linked to the rare autosomal dominant disorder, Bethlem myopathy (MIM 158810) (see also Chapter 26, Part VI, this volume), which is characterized by contractures of multiple joints and generalized muscular weakness and wasting [347–350]. One pathogenetic mechanism proposed is haploinsufficiency of the affected α chain and reduced production of structurally normal type VI collagen molecules. The presence of appropriate levels of type VI collagen in the pericellular matrix of muscle cells thus appears to be essential for normal myotubule stability and function. Type VI collagen interacts with basement membrane type IV collagen, disturbance of which may also contribute to the pathogenesis of Bethlem myopathy [351,352].

Several studies have demonstrated that type VI collagen interacts with cells through both integrin- and nonintegrin-mediated receptors [353–358]. For example, it promotes neural crest cell attachment and migration through multiple cooperative binding sites within triple-helical and globular domains. Type VI collagen also regulates normal and transformed mesenchymal cell proliferation *in vitro* and both increases cell survival and prevents anti-β1-integrin-mediated apoptosis [358,359]. Colocalization and ligand binding studies *in vitro* indicate that type VI collagen can interact with a number of other matrix molecules including hyaluronan, types II and XIV collagens, decorin, biglycan, and the cell membrane-bound chondroitin sulphate proteoglycan NG2 receptor [16]. The widespread distribution of collagen VI between collagen fibers and near the surface of cells, together with its cell-adhesion [353–358,360–364] and matrix-binding [352,353,360,365–367] capacities, have led to the proposal that type VI collagen microfibrils perform a crucial bridging function between cells and matrix, which may be of particular significance in influencing cellular phenotype and function, and directing tissue (re)modeling [19,321,364].

Collagen Types VIII and X

Types VIII and X collagens are true structural collagen members of a family of short-chain collagen-like proteins sharing a condensed gene structure, a triple helical domain and a highly conserved carboxyl terminal noncollagenous (NC1) domain (Fig. 15) [16,39]. This family also includes the C1q component of complement, conglutinin, serum mannose-binding protein, hibernation proteins, cerebellin, and ACRP30, an abundant serum protein implicated in energy homeostasis and obesity [21–32]. Types VIII and X collagens possess striking structural similarities at nucleotide and amino acid levels, and are approximately half the size of fibrillar collagens. A number of immune defense and cytokine molecules that are not structural elements of extracellular matrices, and are therefore not classified as "collagens", have collagenous sequences and NC1-like sequences that are homologous to collagens VIII and X (see Table 2).

Type VIII collagen was first detected as a product of bovine aortic and rabbit corneal endothelial cells and designated EC collagen [368,369]. It is also expressed by proliferating vascular smooth muscle cells, mast cells, and certain epithelial and tumor cell lines [368–371]. Type VIII collagen is present in subendothelium and medial layers of the vasculature, embryonic heart and placental capillaries, Descemet's membrane of the eye, renal glomerulus, and several structures of neural crest origin [372–376]. It is markedly up-regulated following vascular injury and in atheroma [377,378]. In contrast, type X collagen has a very restricted tissue distribution, being primarily a product of hypertrophic chondrocytes in that part of the endochondral growth plate destined for matrix mineralization [379–383]. It is also expressed at the margins of epiphyseal cartilage during fracture repair and in osteoarthritis and in the intervertebral disc [384–386].

Type VIII collagen comprises two distinct chains, α1(VIII) and α2(VIII) (Fig. 15) [16,39]. The human α1(VIII) primary translation product comprises 744 amino acids; it contains a triple-helix-forming collagenous sequence of 454 residues with eight imperfections in the Gly–X–Y sequence, a large globular noncollagenous carboxyl terminal (NC1) domain of 173 amino acids, and a noncollagenous amino-terminal (NC2) domain of 117 amino acids. The human α2(VIII) chain has a triple-helical domain of 457 residues, with eight imperfections in similar positions to those of α1(VIII), and a carboxyl terminal NC1 domain of 167 residues; the full primary structure of the amino-terminal NC2 domain has not yet been reported. The human α1(X) collagen chain is 680 amino acids in length; it has a short NC2 domain of 56 amino acids followed by a collagenous domain with 463 residues and eight imperfections, and an NC1 domain of 161 amino acids [16]. Bovine type X collagen has two cysteine residues within the fourth imperfection of the collagenous domain, and these participate in disulfide bonding in the assembled homotrimer.

The chain composition and molecular organization of type VIII collagen remain unresolved. Recent *in vitro* studies have demonstrated that recombinant α1(VIII) and α2(VIII) chains each form highly stable homotrimers (T_ms of 45°C and 42°C for $[\alpha1(VIII)]_3$ and $[\alpha2(VIII)]_3$, respectively), and heterotrimers $[\alpha1(VIII)]_2\alpha2(VIII)$ and $\alpha1(VIII)[\alpha2(VIII)]_2$ can also assemble [387,387a]. Available biochemical evidence from tissue extracts suggests that in Descemet's membrane, type VIII collagen molecules are heterotrimeric, with two α1(VIII) chains and one α2(VIII) chain [19,39]. By contrast, type X collagen is a homotrimeric molecule $[\alpha1(X)]_3$ with a melting temperature of 47°C. The triple-helical stabilities of collagens VIII and X are due largely to their high hydroxyproline contents.

The importance of the NC1 domains of types X and VIII collagens is illustrated by their high degree of conservation between family members and species, and reinforced by the fact that Schmid type metaphyseal chondrodysplasia (MIM 156500) is caused by mutations in *COL10A1* that are clustered in the NC1 domain [47,145,388,389] (see also Chapter 23, Part II, this volume). The amino-terminal one quarter of the NC1 domain is quite different between the three α chains, but the carboxyl three-quarters is highly homologous at both nucleotide and amino acid levels and includes a number of conserved tyrosine residues [16]. *In vitro* translation studies have demonstrated that the intact NC1 domain spontaneously trimerizes, and that calcium or microsomal membranes and associated chaperone proteins prevent the not yet folded collagenous domain from interfering with the folding and trimerization of the nascent NC1 domain. New information regarding the three-dimensional structure of monomeric and trimeric NC1 has emerged from 2.1 Å resolution crystal structure studies of ACRP30 (adipocyte complement-related protein of 30 kDa, or AdipoQ) and the subsequent molecular modeling of the NC1 domain of types VIII and X collagens (Fig. 15), which show putative asymmetric trimers composed of three 10 β-sheet jellyroll motifs [389,390]. The high thermal stability of trimerized α1(X) NC1 domains appears to reflect the increased numbers of hydrophobic contacts formed upon trimerization, with additional contributions from a hydrophobic region at the base of the NC1 domain and the 27 amino acid sequence present at the amino terminus of the NC1 domain. The NC1 domains of α1(VIII) and α1(X) each have an unpaired cysteine residue, while α2(VIII) NC1 has two cysteine residues; these residues may participate in disulfide bonds that stabilize supramolecular aggregates. The α1(X) NC1 domain also has a putative N-glycosylation site. The NC2 domains of α1(VIII) and α1(X) are structurally quite distinct, and thus may confer on each molecule unique interactive features. Both domains have an alkaline pI (~10.0 and 10.4, respectively) and could interact electrostatically with polyanionic molecules.

Full-length recombinant α1(VIII) and α2(VIII) chains have an electrophoretic mobility consistent with molecules of

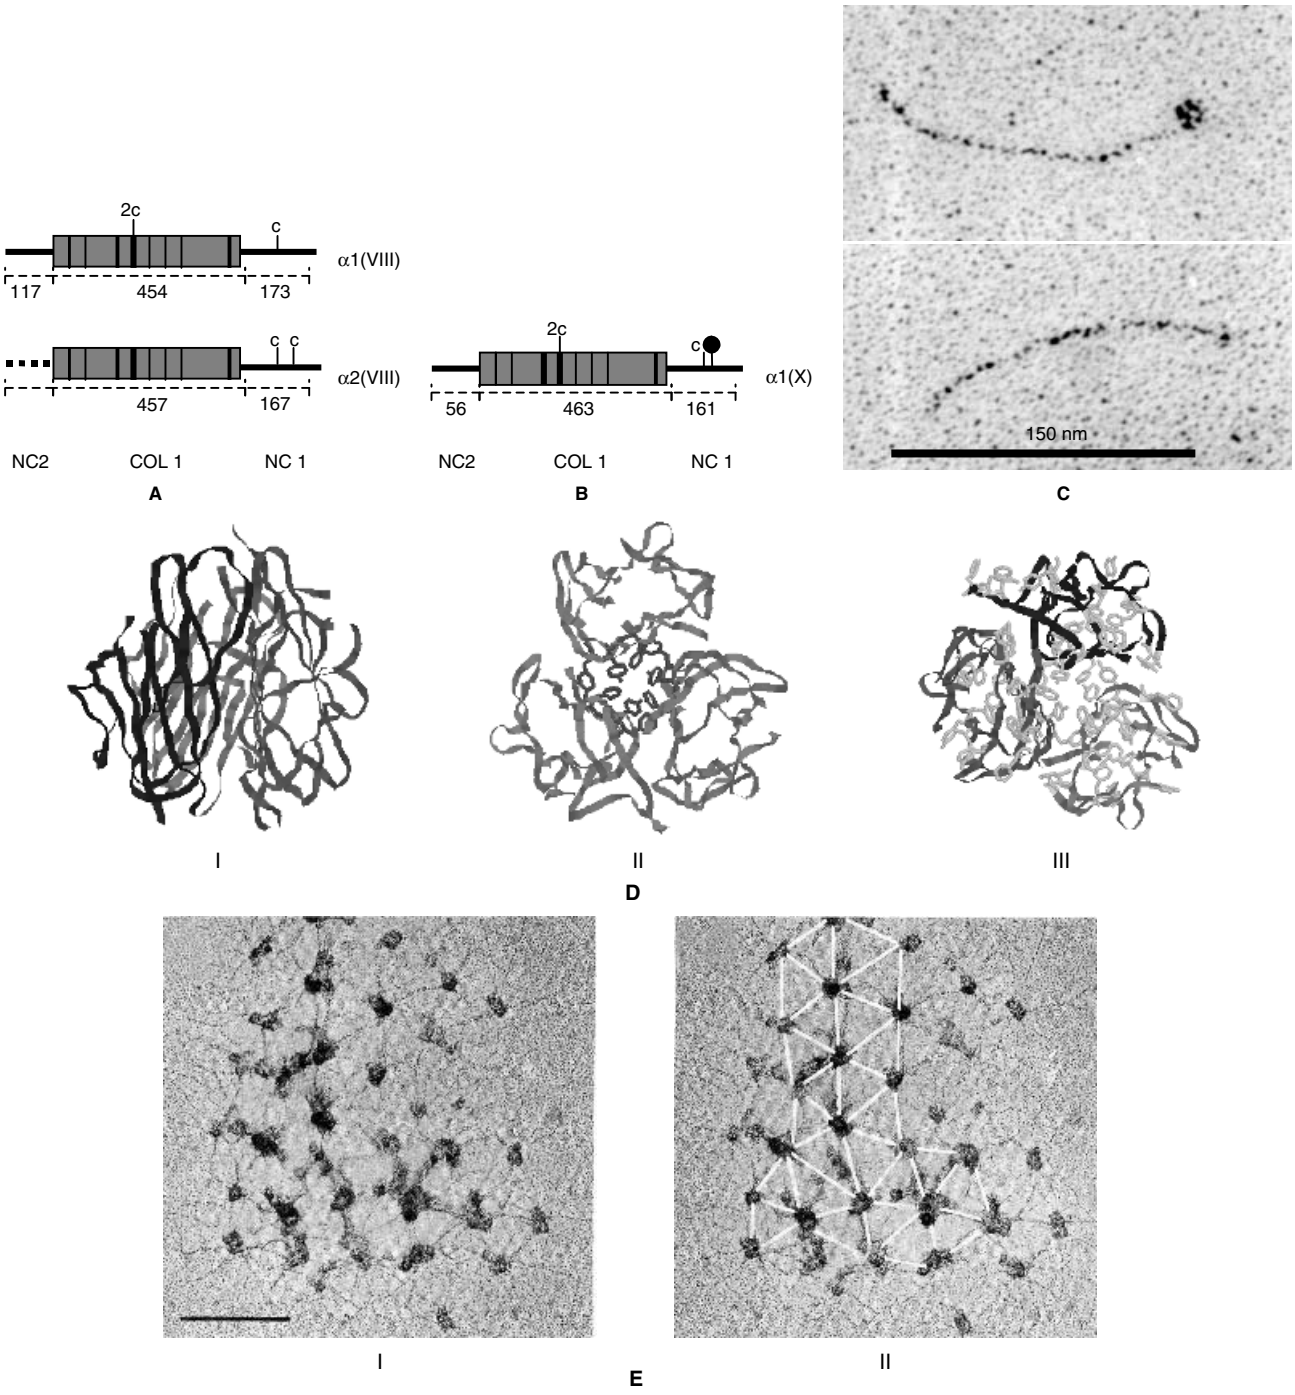

Figure 15. Molecular organization of types VIII and X collagens. **A** and **B**. Line diagrams illustrating the dimensions and domain structures of the collagenous and noncollagenous regions of the α1(VIII) and α2(VIII) chains of type VIII collagen and the α1(X) chain of type X collagen. Triple-helical domains are represented as dark shaded bars and noncollagenous domains as lines. Imperfections within the triple-helical regions are indicated by vertical lines. The positions and numbers of cysteine residues (c), and an N-linked carbohydrate attachment site (🍍), are indicated. The numbers of amino acid residues comprising each domain are indicated below the individual chains. **C**. Rotary shadowing images of pepsinized (lower) and intact (upper) type X collagen monomers showing the length of the helical domain to be approximately 150 nm (bar). The C-terminal non-collagenous (NC1) domain is clearly visible in the intact monomer as a small globule that is removed by pepsin digestion. **D**. Three-dimensional models of the trimeric form of the NC1 domain of the α1(VIII) chain of type VIII collagen, highlighting the cluster of core hydrophobic residues that are important in stabilizing the trimers. I = exterior face; II = vertical view of interior showing hydrophobic core residues. III = vertical view showing internal and external hydrophobic residues. **E**. Rotary shadowing image showing an extended network of type X collagen aggregates formed *in vitro* by incubating purified chick type X collagen in PBS at 34°C. The regularly spaced nodules of aggregated carboxyl terminal noncollagenous domains are interconnected by filamentous structures formed via interactions between triple helices. The hexagonal nature of the type X collagen lattice is highlighted in micrograph (**b**). The bar represents 200 nm. ~80 kDa, and trypsin and chymotrypsin resistant fragments have an M_r of ~60 kDa [387]. However, "intact" type VIII collagen chains isolated from Descemet's membrane have a reported M_r of ~61 kDa, and the presence of additional dimeric β forms of 120 kDa and trimeric γ forms of 170 kDa suggest possible intermolecular cross-linking. Pepsin treatment of tissue-derived type VIII collagen yields ~50 kDa fragments. Full-length recombinant α1(X) chains expressed in underhydroxylated form in mammalian cells migrate with an apparent M_r of 75 kDa, and after pepsin treatment, a 62 kDa band remains [235]. In contrast, SDS-PAGE studies of intact α1(X) chains extracted from chick and mammalian tissues indicate a relative molecular mass of 59 kDa with an additional related form of 49 kDa, while disulfide-bonded chains of ~120 kDa have been observed in long-term cultures [381]. Pepsin treatment of these chains generated ~45 kDa resistant fragments. The molecular basis of these size discrepancies is unknown, but could reflect processing events. Type VIII collagen is degraded by neutrophil elastase [391], and type X collagen is cleaved by matrix metalloproteinase 1 (MMP-1) at two sites [392].

Type VIII collagen is a major structural component of the hexagonal lattice-like network structure characteristic of Descemet's membrane, the specialized basement membrane laid down by corneal endothelial cells [372–374,393]. Similar type X collagen-containing network-like structures have been localized to pericellular regions of hypertrophic chondrocytes, and are disrupted in transgenic mice with a dominant interference phenotype for this collagen [394,395]. It remains unclear whether these collagens can adopt other supramolecular forms. Rotary shadowing visualization of native intact type X collagen molecules has revealed a relatively short triple-helical segment (132 nm) with globular "knobs" at each end corresponding to NC2 and NC1 domains (Fig. 15) [396]. Thermal aggregation products of type X collagen molecules have been shown to include unique hexagonal lattice structures *in vitro*, while similar type VIII collagen-based hexagonal lattices have been observed in cell layers of cultured bovine corneal endothelial cells. It is not known how molecules of such dimensions relate to the hexagonal lattice-like structures of Descemet's membrane with reported dimensions of ~160 nm unit structure (Fig. 9). Supramolecular assembly is thought to be driven, in part, by interactions between NC1 domains that, in the case of type X collagen, have long been known to have the potential to aggregate [379,396]. Other molecules of this short-chain collagen-like family (e.g., conglutinin, mannose-binding lectin) can interact via their carboxyl terminal (NC1-like) domains to form biologically active oligomers (frequently triple-helical hexamers).

The function of type X collagen is not known. Because the hypertrophic zone is structurally the weakest point within the growth plate, type X collagen may provide reinforcement as the matrix weakens. Type X collagen apparently also occurs in association (largely surface) with type II collagen fibrils, which probably represents a secondary association of newly synthesized type X collagen molecules with pre-existing type II collagen fibers [397,398]. It remains unclear whether type X collagen plays a role (direct or indirect) in the initiation of matrix mineralization. Certainly, modulation of collagen X gene expression in hypocalcemic and normocalcemic rickets with agents that promote mineralization (e.g., calcium β-glycerophosphate) or inhibit it (e.g., levamisole, an inhibitor of alkaline phosphatase) implies a functional relationship between type X collagen deposition and the mineralization of cartilage [399]. It is conceivable that type X collagen provides an appropriate structural support that is permissive for calcification and allows for the remodeling phases associated with vascular invasion and bone development. Little is known of the biological role of type VIII collagen. In the vasculature, it is associated with elastic fibers [376,400], and may serve as a structural and adhesive support for vascular smooth muscle cells, and it may also be involved in mineralization associated with vascular disease. The specific molecular interactions of types VIII and X collagens with cells and their surrounding matrix remain to be defined.

FACIT COLLAGENS

Collagen types IX, XII, XIV, XVI, and XIX are partially homologous, multidomain molecules, possessing structural features that have resulted in their classification as fibril-associated collagens with interrupted triple helices, or FACIT collagens (Fig. 16) [16,37,38,401,402]. Type XX collagen is a newly identified member of the FACIT family of collagens [402a]. These genetically and immunologically distinct collagens are characterized by short triple-helical domains interrupted by noncollagenous sequences. They share regions of high sequence homology and distinct structural characteristics, but they also exhibit extreme divergence in molecular mass (60 kDa to at least 220 kDa), in the size and sequence of their amino and carboxyl termini, and in the proportion of the molecule devoted to the interrupted collagenous domains. For example, 10% of α1(XII), 16% of α1(XIV), and 59% of α1(XVI) polypeptides are collagenous. The COL1 domain of type IX collagen has been used as a "signature" to identify other FACIT collagens, and is characterized by a pair of precisely conserved cysteine residues and by replicated imperfections in the triple helix [16,403]. Conservation of this triple-helical domain is a critical feature that facilitates lateral association with the surface of collagen fibers. Chain selection, registration, and assembly of FACIT collagens are directed by the COL1 domain and the adjacent five residues of the NC1 domain. Rotary shadowing analysis has revealed large structural differences in the domains projected into the fibrillar space, which reflects the low homology between the noncollagenous domains of these collagens and, presumably, the fine function of these species within a specified tissue [401,402,404,405]. The FACIT collagens are not capable of forming fibers or other supramolecular structures. Instead, types IX, XII, and XIV collagens have been shown to decorate the surfaces of interstitial collagen fibers and to act as molecular couplers that organize and anchor the fibrils in defined three-dimensional patterns within the matrix by means of interactions with other ECM components [406–410].

The tissue distribution of each of the FACIT collagens is unique and often highly tissue-specific. Type IX collagen is a fairly major component of type II collagen-containing tissues such as cartilage (up to 5% of pepsin-extracted collagen), intervertebral disc, and the vitreous humor [402]. Type XII collagen is localized in type I collagen-containing dense connective tissues such as tendons, ligaments, perichondrium, and periosteum [411]. Type XIV collagen is found mainly in tissues rich in type I collagen, particularly in regions in which high mechanical stresses are involved, such as bone-ligament junctions [412–414]. It is also present in basket-like structures around hair follicles and in cartilaginous tissues that contain type II collagen. Type XVI collagen has a broad tissue distribution, being localized predominantly in heart, kidney, intestine, ovary, testis, eye, arterial wall, and smooth

muscle [16,415]. Type XIX collagen is expressed in human rhabdomyosarcoma and fibroblast cell lines [416,417].

Type IX Collagen

Type IX collagen is the prototype molecule of the FACIT collagens (Fig. 16) [16,402]. It was first identified as disulfide-bonded triple-helical fragments in pepsin digests of mammalian cartilage [418–421], which could be separated from type II collagen by differential salt fractionation. A combination of biosynthetic studies and cDNA sequence data [422] subsequently revealed the complex structure of the intact form of the molecule to have an M_r of 300,000 and a length approximately two-thirds that of types II and XI collagens. It exists as a heterotrimer composed of three

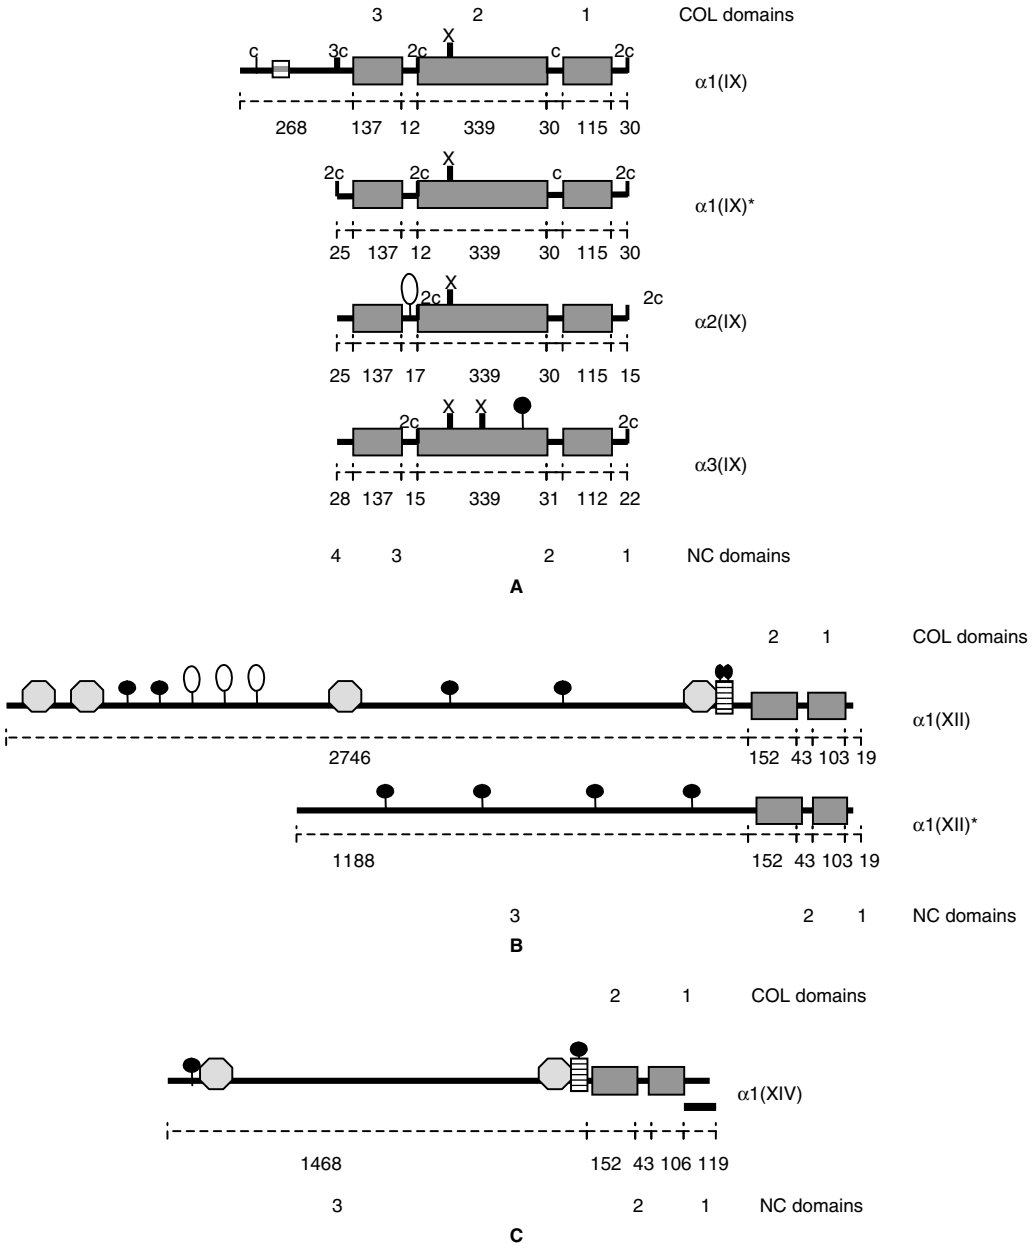

Figure 16. Molecular organization of the FACIT collagens. **A–E**. Line diagrams illustrating the dimensions and domain structures of the component chains of type IX collagen (**A**), type XII collagen (**B**), type XIV collagen (**C**), type XVI collagen (**D**), and type XIX collagen (**E**). The triple-helical (COL) domains are represented as dark shaded bars, and the noncollagenous (NC) domains as lines. The sequences of the COL1 domains of the FACIT collagens are homologous. Alternatively spliced sequences are highlighted as α1(IX) and α1(IX)*, and α1(XII) and α1(XII)*, and, in the case of type XIV collagen, as a heavy line below the diagram. The positions and numbers of cysteine residues (c), N-linked carbohydrate attachment sites (♀), A-domains (octagons) (◯), PARP (proline and arginine-rich protein) domains (▯), and glycosaminoglycan attachment sites (♀) are indicated. The numbers of amino acid residues comprising each domain are indicated beneath the individual chains. **F**. Rotary shadowing images of type XII collagen monomers. The very large NC3 domain is apparently arranged in a trident shape reminiscent of the type VII collagen NC2 domain. Bar = 100 nm. (Courtesy of Dr B. Dublet and Prof. M. van der Rest.)

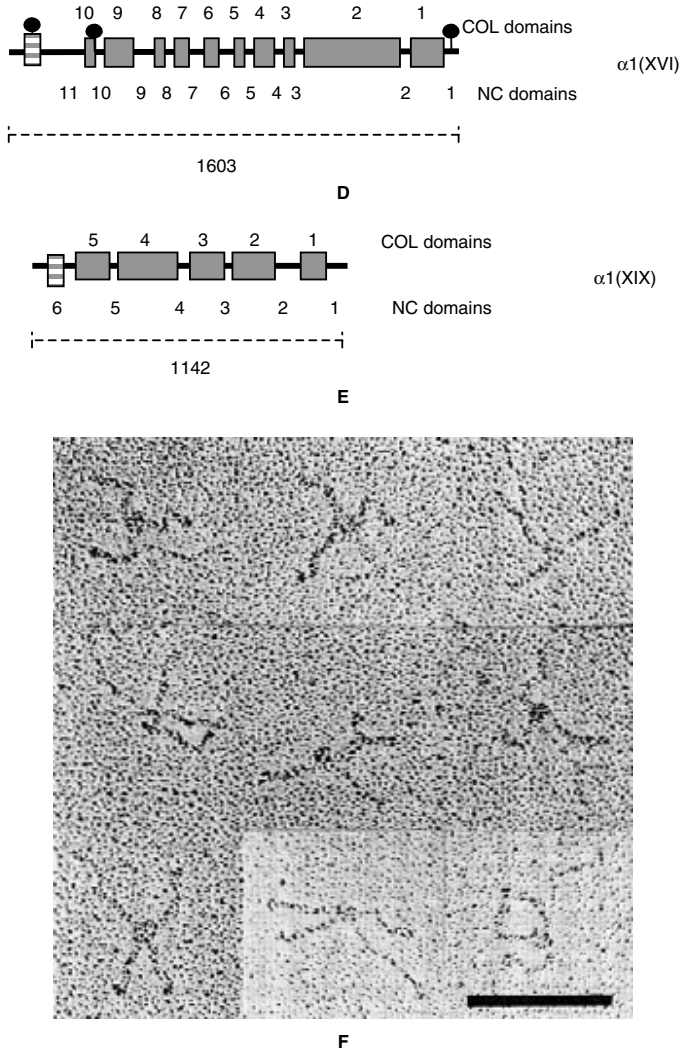

Figure 16. (*Continued*)

genetically distinct chains designated α1(IX), α2(IX), and α3(IX), which are associated into an interrupted triple helix that comprises a short arm and a long arm connected by a flexible "hinge" (see Fig. 17A). There is no evidence that any processing of collagen IX occurs as a necessary prerequisite for molecular association with the fibrillar collagens. Type IX collagen has three collagenous domains (COL1–COL3) that can be recovered as pepsin-resistant fragments, and four noncollagenous domains (NC1–NC4), and is stabilized by interchain disulphide bonds located within NC1, NC2, and NC3 (Fig. 16A). The α1(IX) chain is the longest chain, with the large NC4 domain at the amino-terminus of the short arm, which is seen as a globule in electron micrographs. Type IX collagen was the first collagen to qualify for the classification of proteoglycan, with the α2(IX) chain being able to act as a core protein for a covalently attached chondroitin sulfate (or dermatan sulfate) side chain [406,423,424]. Serine 167 of the NC3 domain of α2(IX) has been identified as the glycosaminoglycan attachment site (see Figs. 16A and 17). Type IX collagen can exist in both proteoglycan and nonproteoglycan forms *in vivo*, and the length of the glycosaminoglycan chain is both species- and tissue-dependent. In developing chick, the expression of much shorter type IX collagen molecules has been demonstrated in nonchondrogenic, mesenchymal regions of the developing limb, notochord, and various ocular tissues including cornea and vitreous [425–428]. These molecules contain an α1(IX) collagen chain that lacks the amino-terminal globular NC4 domain characteristic of the cartilage form and instead contains a short alternative sequence and a significantly longer glycosaminoglycan chain [429]. These differences arise as a consequence of the use of widely separated alternative transcription start sites in the α1(IX) gene. Homologous α1(IX) transcripts have also been detected in human fetal tissues, and in mouse the short form has been detected in the heart and eye [401,410,427,428]. mRNAs for the three type IX collagen α chains are generally coordinated in cartilage, but differences are apparent in noncartilaginous tissues in which type IX collagen is present at low levels.

The association of type IX collagen with type II collagen fibrils in cartilaginous tissues has been well studied [16].

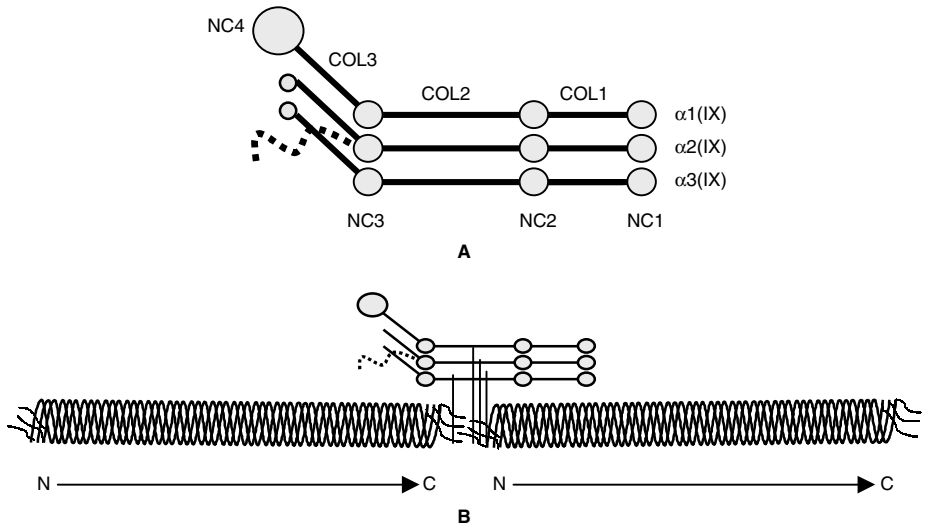

Figure 17. Molecular organization of type IX collagen, and its association with type II collagen fibrils. **A**. The three α chains of type IX collagen are aligned such that the COL1 and COL2 domains can form triple helices. Serine 168 of the NC3 domain of α2(IX) is an attachment site for glycosaminoglycans (•••••). The nonhelical NC3 region forms a 'hinge'; it contains 12,17, and 15 residues in the α1(IX), α2(IX) and α3(IX) chains, respectively, which causes a sharp kink. **B**. The long arm comprising NC1, COL1, NC2, and COL2 lies along the surface of the type II collagen fibril, and is covalently linked by lysine/hydroxylysine-derived cross-links (shown by vertical lines) to the N-telopeptides in the fiber via sites on all three chains in the amino-terminal region of COL2; the α3(IX) COL2 domain is also cross-linked to the C-telopeptide of type II collagen. The short arm comprises COL3 and NC4, and projects into the interfibrillar space. Cross-links between type IX collagen and type II collagen probably help stabilize the COL2 triple helix. COL1 may be partially stabilized by interactions with type II collagen to which it lies adjacent and runs antiparallel.

The long arm comprising NC1, COL1, NC2, and COL2 lies along the surface of the type II collagen fibril (Figs. 9 and 17) and is covalently linked by lysine/hydroxylysine-derived bonds to the N-telopeptides in the fiber via sites on all three chains in the amino-terminal region of COL2; the α3(IX) COL2 domain is also cross-linked to the C-telopeptide of type II collagen [16]. The short arm comprises COL3 and NC4, and projects into the interfibrillar space. The nonhelical NC3 region forms the "hinge"; it contains 12,17, and 15 residues in the α1(IX), α2(IX), and α3(IX) chains, respectively, which causes a sharp kink. Recently, the association of recombinant collagen IX α chains into homotrimeric and heterotrimeric molecules has also been described [430,431].

Studies on the thermal stabilities of the COL domains have shed new light on the structural organization of type IX collagen [432]. Melting curves reveal that unfolding of COL1 occurs at 40.6°C, that of COL2 at 39.6°C, and that of COL3 at 49.0°C. The high thermal stability of COL3 may be due to the presence of a high proportion of hydroxyproline residues (186/1000 residues). COL3 may be further stabilized by the cross-linking of the adjacent NC4 region (which has a basic pI) to nonfibrillar matrix material such as glycosaminoglycan chains in the extracellular matrix (perhaps glycosaminoglycans attached to an NC3 domain of an adjacent type IX collagen molecule). Disulfide links between the three α chains also affect the thermal stability of the trimer; for example, cysteine residues in the NC3 region of each α chain probably participate in disulfide bonds that hinder the unzipping of α chains between long and short arms. It has been suggested on the basis of the lower thermal stabilities of the COL1 and COL2 domains that type IX collagen may be stabilized by the presence of type II collagen fibrils [432]. Cross-links between type IX collagen and type II collagen probably help stabilize the COL2 triple helix, while COL1 may be partially stabilized by interactions with type II collagen to which it lies adjacent and runs antiparallel, and by cross-linking the α3(IX) NC1 domain to α1(IX) or α3(IX) sites on adjacent type IX collagen molecules also cross-linked to the fiber.

Type IX collagen locks onto specific sites on the surface of the quarter stagger lattices of type II collagen fibers, thereby sterically hindering the insertion of additional type II collagen molecules in its vicinity [406]. It competes with type II collagen for lattice positions, having the effect of progressively reducing type II collagen fiber diameter when fibrillogenesis *in vitro* is carried out at increasing type IX collagen concentrations. In tissues, type IX collagen appears to be nonuniformly distributed along fibers, and may play a role at fibril intersections. A new model of type IX collagen association with type II collagen fibrils has been proposed on the basis of the different thermal stabilities of the COL domains [432]. It has been suggested that type IX collagen could fold through 180° at NC2, allowing COL1 to run along an adjacent gap zone in a parallel direction. This would place the NC1 domain close to a further type IX collagen molecule to which it could cross-link. This scheme is consistent with the location of previously described cross-links, provides a structural reason for the NC interruptions in the Gly−X−Y sequence, a purpose for NC2 in terms of equipping COL1 with more flexibility for weaving into the gap region, and a reason for the precise lengths of COL2 and COL1 (454 residues). Moreover, it allows speculation that this structural alignment would allow COL1 to fill the gap region and inhibit nucleation of mineralization at this site, and consequently prevent any calcification of articular and other cartilage. If the COL1 were to be inserted into the gap region of an adjacent fiber, this would lead to a fibrillar network structure.

Naturally occurring mouse mutants lacking α1(IX) are viable and show no detectable abnormalities at birth, but show signs by 4 months of joint disease and, in time, develop a degenerative osteoarthritis with flattened articulating surfaces and epiphyses [433–435]. Transgenic mice expressing mutant α1(IX) chains with an in-frame deletion of COL2 progressively develop joint and intervertebral disc degeneration with age [434]. These animal models confirm an important role for type IX collagen in the long-term mechanical stability and function of the type II collagen fibril framework of cartilage. Moreover, mutations in the genes for α1(IX) and α2(IX), respectively, have been linked to multiple epiphyseal dysplasia [436–438] (see also Chapter 23, Part II, this volume).

Type XII Collagen

Type XII collagen was discovered through the isolation and sequencing of cDNAs from an embryonic chick tendon library that revealed a multidomain species exhibiting remarkable homology to the COL1 domain of the type IX collagen α chains (Fig. 16) [16,411,439,440]. It is the product of a single gene and exists as a homotrimer, $[\alpha1(XII)]_3$, the individual α1(XII) chains having an M_r of 220,000. Each α chain contains non-triple-helical sequences of relative molecular mass 190,000 arranged in a very large amino-terminal domain (NC3) and two shorter domains (NC2 and NC1), and only two short triple-helical domains (COL2 and COL1), which can be observed after pepsin digestion as unreduced fragments of M_r 46,000 and 32,000, respectively [404,405]. While the homology between the COL1 domains of types IX and XII collagens corresponds to an overall amino acid sequence identity of greater than 50%, no identity is apparent between the remaining collagenous sequences of the two species [405]. Within the noncollagenous sequences, partial homology is observed between the NC3 domain of type XII collagen and NC4 of type IX collagen, although the NC3 domain of type XII collagen is much larger than the corresponding type IX collagen NC3 domain. Large and small spliced forms of type XII collagen occur that share a common signal peptide but differ in the size of the NC3 domain (Fig. 16) [16]. The large form of NC3 is ~320 kDa and comprises 18 fibronectin type III repeats, four von Willebrand factor-like repeats, and a PARP (proline- and arginine-rich protein) motif. The short form is ~220 kDa and lacks the first two von Willebrand factor A repeats and the first eight fibronectin type III repeats. Three potential glycosylation sites are present in the fourth, fifth, and sixth fibronectin type III repeats, and in some tissues such as fetal bovine cartilage, the larger spliced form can carry a glycosaminoglycan and thus act as the core protein of a proteoglycan. The large form has a more restricted expression in embryonic tissue than the smaller form, which is particularly abundant in the dermis. Heterotrimers comprising short- and long-form chains are also possible, which, together with variable glycosylation of the long form, allows a large number of possible isoforms. Structural variants of the carboxyl terminal NC1 domain of collagen XII generated by alternative splicing have been described [441]. A new nomenclature has now been proposed, with type XIIA-1 and XIIB-1 collagens having a long NC1 form, and types XIIA-2 and XIIB-2 a short alternative NC1 domain.

Rotary shadowing images reveal type XII collagen molecules to have a thin (often kinked) collagenous tail of 75 nm attached through a central globule (NC2) to three extended arms, each 60 nm in length and corresponding to the NC3 domain (Fig. 16F) [19]. The role of type XII collagen remains to be defined, but it is envisaged as associating with type I collagen fibrils through its triple helical tail, with the NC3 domain being free to project outward from the fibril surface and to interact with other matrix components [401]. Indeed, immunohistochemical analysis of embryonic chick tendon using immunogold labeling has revealed type XII collagen molecules to be distributed along type I collagen-containing fibrils. This arrangement remains to be verified, however, and it should be noted that there is no strict codistribution of types I and XII collagens in some tissues such as bone, cornea, and scleral ossicles. Moreover, experiments have failed to reveal the existence of covalent cross-links between type XII collagen and type I collagen. Indeed, type XII collagen does not possess a domain homologous to COL2 (IX) and therefore is not cross-linked to either itself or other collagens via lysine/hydroxylysine-derived bonds, and it can readily be extracted from tissues by low-molarity NaCl solutions. No direct interactions of NC3 with monomeric fibrillar collagens or with collagen fibers have been demonstrated *in vitro*. However, the NC3 domain does contribute significantly to the contraction of collagen gels, a model system for studying the interaction of mesenchymal cells with a fibrous collagen substrate; perhaps by moderating interfibrillar interactions, these molecules influence extracellular matrix deformability [442]. Type XII collagen can be incorporated *in vitro* into acid-soluble type I collagen fibrils during, but not after, fibril formation. Type XII collagen interacts with the glycosaminoglycan chain of decorin and the protein core of fibromodulin [16]. The smaller chains resulting from NC3 alternative splicing interact weakly with heparan sulfate via their carboxyl terminal domains, while the larger forms have additional, stronger heparin-binding sites. Like type IX collagen, there is no evidence that any processing of type XII collagen occurs as a necessary prerequisite to matrix deposition.

Type XIV Collagen

Type XIV collagen was first isolated as disulfide-bonded triple-helical fragments of its COL1 domain from pepsinized fetal bovine skin and tendon; its amino acid sequence is strikingly homologous to the corresponding domains of homotrimeric type XII collagen (64% primary structure identity) and, to a lesser extent, of type IX collagen (Fig. 16) [16,405,413,414]. Each chain consists of two collagenous triple-helical domains (COL1 and COL2) and three noncollagenous domains (NC1–NC3). The NC3 domain comprises eight fibronectin type III repeats, two von Willebrand factor-like domains, and a PARP repeat. The NC3 domain is closely related to the noncollagenous protein undulin, which may be a proteolytic fragment or an alternatively spliced variant of type XIV collagen. As with collagen XII, the NC3 domain influences human fibroblast migration in collagen gels [442]. Two variants of type XIV collagen exist that differ in their NC1 domains and that may arise by alternative splicing [441]. In addition, alternative 5′ untranslated regions suggest differential splicing at the 5′ end of α1(XIV) transcripts. Type XIV collagen can exist in a proteoglycan form in some tissues (e.g., fetal bovine cartilage) [16]. This collagen can be extracted from tissues with low-molarity NaCl solutions because it is not covalently cross-linked within the extracellular matrix.

Type XIV collagen is thought to bind to collagen fibers via its NC1 and COL1 domains, while COL2 and NC3 are thought to extend into the extracellular space and to participate in interactions with other components of the interstitial matrix. There is no direct evidence for the binding of type XIV collagen to cells or to types I, III, or V collagens *in vitro*, but associations with type VI collagen, heparan sulfate proteoglycan, and a variant of the CD44 cell surface receptor have been demonstrated [16]. Type XIV collagen also binds decorin, a proteoglycan associated with collagen fibrils, and procollagen I N-proteinase, which may be important during fibrillogenesis, as discussed earlier.

A physiological role for gelatinases (specifically MMP-2 and MMP-9; see Chapter 7, this volume) has been indicated in degradation of the COL1 domain of type XIV collagen, and possibly in structural remodeling associated with other FACIT collagen-associated matrix changes in development [443].

Type XVI Collagen

Type XVI collagen was first identified as a novel collagenous polypeptide encoded by cDNA clones isolated from a human fibroblast cDNA library [415,444]. Biosynthetic studies using stably transfected kidney cell clones, and human fibroblasts and smooth muscle cells, indicate that type XVI collagen is a disulfide-bonded homotrimer comprising 200–220 kDa α1(XVI) chains [444]. The overall structural arrangement of α1(XVI) differs significantly from that of other known collagen chains, although it does possess several structural features characteristically seen in members of the FACIT collagen family (Fig. 16) [16,445]. The complete primary structure consists of 10 collagenous domains, most of which are short (15–138 amino acids), with the exception of COL2, which is relatively large (422 amino acids), interspersed among 11 noncollagenous domains. The collagenous domains contain numerous non Gly–X–Y imperfections that could make the molecule rather flexible. Except for a large amino-terminal NC11 domain of 312 residues that contains a PARP domain, most of the NC domains are short (11–39 residues) and cysteine-rich. In particular, two cysteine residues regularly located in the amino-terminal region of each noncollagenous segment may contribute to triple-helix formation of the adjacent amino-terminal collagenous domain by forming stabilizing disulphide bonds in the following carboxyl terminal noncollagenous region, and to stabilizing the three-dimensional structure of the molecule. The two cysteine residues separated by four amino acids at the COL1/NC1 junction, and the size of the COL1 domain, are characteristic of the FACIT collagens. There is also some homology between the α1(XVI) NC11 domain, the NC4 domain of type IX collagen, and the NC3 domain of type XII collagen.

Similarities between type XVI collagen and other FACIT collagens raise the possibility that this collagen may also serve as a molecular bridge responsible for maintaining the structural integrity of the extracellular matrix. One interesting difference is that the NC11 domain, homologous to the NC4 domain of type IX collagen, which has a pI of ~10 and is thought to interact with polyanions in the extracellular matrix, has a pI of ~7 and probably has unique interactive properties. Studies of recombinant NC11 suggest that type XVI collagen may be processed with the release of the PARP domain, resulting in a protein comprising chains of 150–160 kDa [444,445]. Type XVI collagen expression by human skin fibroblasts is enhanced in fibrotic skin diseases [446], and modulated by basic fibroblast growth factor (bFGF) and transforming growth factor-β (TGF-β) [447].

Type XIX Collagen

Type XIX collagen was originally discovered through cDNA cloning of a human rhabdomyosarcoma cell line [416]. The predicted polypeptide comprised 1,142 amino acid residues including a 23-residue signal peptide and five collagenous domains (COL1–COL5, varying between 70 and 224 amino acids, and all together comprising 832 residues) interspersed and flanked by six noncollagenous (NC) domains of 19, 31, 23, and 44 residues (Fig. 16) [16,417]. It is a relatively poorly characterized member of the FACIT collagens with limited homology to the others. The COL1 domain is smaller than the COL1 domains of types IX, XII, XIV, and XVI collagens, although the arrangement of two cysteine residues near its carboxyl terminus and two imperfections are conserved. The amino-terminal region of COL1 contains only the PARP domain similar to types IX and XVI collagens and differs from those of types XII and XIV collagens.

The expression pattern has recently been established in developing embryonic and adult organisms [448]. Type XIX collagen mRNA can be detected as early as 11 days of gestation and in all embryonic tissues, except the liver, of 18-day embryonic mouse. In contrast, only a few adult tissues (brain, eye, testis) accumulate this mRNA, but transcripts are at least ten times more abundant in adult than in fetal brain [449]. Biochemical and immunohistochemical characterizations indicate that human collagen XIX constitutes a novel class of basement membrane collagen [450]. The chain composition and molecular organization of type XIX collagen is unknown. However, polyclonal antibodies against α1(XIX) collagen react with a 150 kDa protein in neutral salt extracts of adult mouse brain tissue. After digestion with bacterial collagenase, this protein migrates under nonreducing conditions with an apparent M_r of ~400 kDa, probably representing a homotrimeric form of type XIX collagen [450]. An unusual number of alternatively spliced variants of type XIX collagen in human rhabdomyosarcoma and glioma cell lines have been reported [16]. However, transcripts from normal tissues consistently yield a single hybridizing species, and multiple forms of type XIX collagen may be a feature only of tumor cell lines.

Molecular modeling of the conserved cysteine residues at the COL1/NC1 junction indicate that intrachain disulfide bonds probably form, unlike the situation with other FACIT collagens for which experimental evidence demonstrates that their carboxyl termini participate in intermolecular disulphide interactions. Thus, the same sequence motif, $Cys–(Xaa)_4–Cys$, may result in two distinct protein structures depending on the arrangement of disulfide bonds.

Type XIX collagen expression in the embryo does not follow the patterns of the major fibrillar collagens (types I/III and II, respectively), for it occurs in both cartilaginous and noncartilaginous tissues. Its abundance in brain and expression by glial cells suggests a potential role as a connecting bridge within proteoglycan networks or as an anchor for the surrounding cells. Type XIX collagen thus appears to play a role distinct from that of other FACIT collagens in the assembly of specialized structures in developing embryonic matrices and in the maintenance of specific adult tissues.

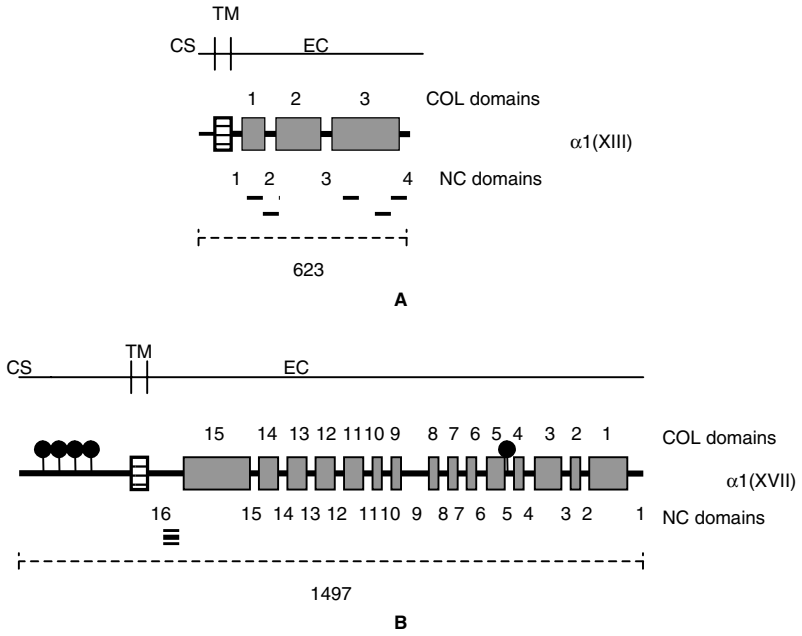

Figure 18. Molecular organization of the transmembrane collagens. Line diagrams illustrating the dimensions and domain structures of the component α1 chains of type XIII collagen (**A**) and type XVII collagen (**B**). The triple-helical (COL) domains are represented as dark shaded bars, and the noncollagenous (NC) domains as lines. Alternatively spliced type XIII collagen sequences are highlighted as single lines below the diagram. In the case of type XVII collagen, the major epitope recognized by autoantibodies in the sera of patients with both bullous pemphigoid and herpes gestationalis is in the extracellular domain immediately after the transmembrane domain, which is highlighted as triple lines below the diagram. The positions of N-linked carbohydrate attachment sites (♆), and PARP (proline- and arginine-rich protein) domains (▯) are shown, and the numbers of amino acid residues comprising the chairs are indicated beneath each CS, cytosolic domain; TM, transmembrane domain; EC, ectodomain.

TRANSMEMBRANE COLLAGENS

Types XIII and XVII collagens are genetically and immunologically distinct nonfibrillar collagens that each contain a hydrophobic transmembrane segment and are integral plasma membrane proteins (Fig. 18) [16,451–468,471–474]. These collagens are not homologous in sequence or in general molecular appearance but, because both are membrane-associated collagens expressed in mesenchymal tissues, they have been grouped together to comprise a new subgroup, transmembrane collagens. Several other transmembrane molecules with collagenous sequences have also been described; these include a bacteria-binding plasma membrane protein (MARCO; macrophage receptor with collagenous structure) and types I and II macrophage scavenger receptors [469,470], which have a broad polyanion-binding ability and participate in macrophage-associated functions such as host defense and inflammation. The presumed or confirmed orientation of all these plasma transmembrane molecules is with their amino-terminal regions situated intracellularly and their collagenous domains in the extracellular space [459,463]. This so-called "type II" orientation occurs in only 5% of plasma transmembrane proteins, and the presence of collagenous sequences may dictate such an arrangement. The direction of triple-helical folding in the transmembrane collagens remains to be determined. Unlike the fibril-forming collagens, in which three α chains associate through carboxyl terminal interactions after release into the endoplasmic reticulum lumen then form triple-helices proceeding toward the amino-terminus, the transmembrane collagens have their amino termini inserted into the rough endoplasmic reticulum before carboxyl terminal association and triple helix formation. Thus, formation of the triple helix might involve carboxyl to amino folding, with the resulting torsional tension relieved somehow by rotation of the transmembrane domains of the three polypeptides in the membrane, or the three chains might associate at their amino termini and then fold in an amino to carboxyl terminal direction. There are as yet no experimental data to resolve these possibilities.

Type XIII Collagen

Type XIII collagen is a short-chain collagen that is expressed at low levels in virtually all tissues examined to date, including fetal bone, cartilage, intestine, skin, striated muscle, and placenta. This distribution suggests that type XIII collagen may serve a general function in connective tissue [16,454,455,459]. Human type XIII collagen has been extensively characterized through human cDNA and genomic clones, but until the recent cloning of mouse type XIII collagen [455,456], the extreme amino-terminal sequence had not been predicted. The polypeptide consists of three collagenous domains (COL1–COL3) and four noncollagenous domains (NC1–NC4) (Fig. 17) [16][4]

[4]Historically, nonhelical, noncollagenous (NC) domains have been numbered from the carboxyl-terminal domain [16]. In the cases of collagen VII and collagen XIII, the NC1 domain is now accepted to be the amino-terminal noncollagenous region and numbering is from the amino-terminal domain.

A striking feature of type XIII collagen is that sequences corresponding to ten exons of the human gene undergo freely combinatory alternative splicing during the processing of the primary transcripts, and are generated by exon skipping (of exons 3B, 4A and 5 in COL1; exons 12 and 13 in NC2; exons 29 and 33 in COL3; exon 37 at the COL3/NC4 junction) [451–455]. Splicing is predicted to affect the structures of the NC4, COL3, NC2, and COL1 domains, and at least 12 mRNA species exist through the alternative expression of exons 3B-5, 12, and 13, and distinct differences in the proportions of the variant mRNAs have been observed in cultured cell lines and tissues. Furthermore, four combinations of alternatively spliced exons 29–37 have been found among cDNA clones isolated from human endothelial cells and HT1080 fibrosarcoma cells, and additional combinations are predicted to occur. The length of human α1(XIII) collagen chains may vary between 697 and 609 amino acids depending on the composition of alternatively spliced exons involved. The functional significance of this complex pattern of alternative splicing is not known.

The complete primary structure of mouse type XIII collagen shows that mouse cDNA extends further in the 5′ direction than the previously identified human clones and contains a new in-frame ATG codon for translation initiation that results in elongation of the amino-terminal noncollagenous domain by 81 amino acids [16,456]. These amino-terminal sequences lack a typical signal sequence but include a highly hydrophobic segment that clearly fulfils the criteria for a transmembrane domain. The longest possible coding region of mouse α1(XIII) represents 739 residues, but the length of the deduced polypeptide can vary markedly depending on the complex alternative splicing of mRNAs, and the calculated M_r of mouse type XIII collagen is between 58.3 and 69.7 kDa. An expressed sequence tag (EST) database search provided the corresponding sequence of the human upstream 83 amino acids that are ~90% similar to the extreme amino-terminal mouse sequence [456]. The human sequence also lacks a signal peptide, but the presence of a highly hydrophobic region of 23 residues located at residues 37–59 that fulfils the criteria for a transmembrane domain indicates that human type XIII collagen is probably located on the plasma membrane with a short cytosolic amino-terminal portion and a long collagenous extracellular portion. Western blotting of human HT1080 whole-cell extracts using peptide antibodies generated to unspliced type XIII collagen NC1 and NC3 domains revealed bands of >180 kDa representing disulfide bonded multimeric polypeptide forms that resolved upon reduction to 85–95 kDa bands that are probably a mixture of splice forms of monomeric α1(XIII) chains [453]. Although type XIII collagen appears to be synthesized as a homotrimer of three α1(XIII) chains, it is not known whether the three chains within a molecule exhibit identical splicing. The chains were susceptible to bacterial collagenase digestion, and contained the predicted amino-terminal extension and the transmembrane segment. Immunoprecipitation of biotinylated type XIII collagen from surface-labeled HT1080 cells, subcellular fractionation, and immunofluorescence labeling have confirmed that human type XIII collagen molecules are, indeed, located in the plasma membrane of these cells. The presumed cytosolic amino-terminal part of the NC1 domain includes a putative protein kinase C phosphorylation site (threonine, residue 6).

Type XVII Collagen

Type XVII collagen is the 180 kDa bullous pemphigoid antigen (also known as BPAG2 or BP180), a hemidesmosomal component expressed in stratified squamous epithelia of the skin, oral cavity, and uterine cervix [16,460,462–464,471], and α1(XVII) mRNA has also been detected in the heart [472]. This protein was originally recognized as an autoantigen in bullous pemphigoid and herpes gestationalis [47,145,465,466]. Its deduced primary structure predicts a "type II" orientation integral transmembrane protein of 1497 amino acids, with an amino-terminal intracellular domain of 466 amino acid residues, a transmembrane domain of 23 residues, and a highly interrupted collagenous carboxyl terminal extracellular domain of 1008 amino acid residues. The α1(XVII) chain comprises 15 collagenous domains (COL1–COL15) ranging from 15 to 242 amino acid residues in length, and 16 noncollagenous domains (NC1–NC16) (Fig. 17) [16]. The large, mainly cytosolic amino terminal NC16 domain contains 566 amino acids. Type XVII collagen has been solubilized from a bovine mammary gland epithelial cell line using detergent and purified by immunoaffinity chromatography using a monoclonal antibody to the bullous antigen, and shown to be a homotrimer [461]. Rotary shadowing images of trimeric type XVII collagen molecules show a quaver-like molecule consisting of a globular head (partially cytosolic NC16 domain), a central 60–70 nm rod (large COL15 domain), and a flexible tail (constituting ~66% of the molecule and comprising an interrupted collagenous domain) [461,462]. Moreover, recombinant extracellular fragments of human type XVII collagen show a low-M_r form with an elongated conformation. Immunoelectron microscopy demonstrates that antibodies against recombinant ectodomain fragments bind to structures outside the keratinocyte plasma membrane along the skin basement membrane.

Molecular genetic studies in an epithelial cell line indicate that the amino-terminus plays a role in targeting and polarizing type XVII collagen within the hemidesmosome [474], while a short noncollagenous extracellular region at the cell membrane is important for interaction with other hemidesmosomal components, including the α6 subunit of α6β4 integrin. This region also contains the major epitope recognized by autoantibodies in the sera of patients with both bullous pemphigoid and herpes gestationalis [465,466,475]. The use of domain-specific antibodies has shown that in skin and epithelial cells, at least, this collagen occurs in two triple-helical forms — a full-length homotrimeric transmembrane protein (3 × 180 kDa chains) and a soluble extracellular domain that is a specific proteolytic cleavage product of the full-length molecule [467,476]. The intact form has a globular intracellular domain that is disulfide bonded intramolecularly and an N-glycosylated extracellular domain that is triple-helical at physiological temperatures. The soluble form is a triple helical N-glycosylated molecule of three 120 kDa chains. Because only a single 6 kb mRNA has been detected, it appears that the 120 kDa polypeptide is generated post-translationally. Moreover, keratinocytes harboring a homozygous nonsense mutation in *COL17A1* synthesize neither the 180 kDa polypeptide nor the 120 kDa form. Treatment of these cells with a synthetic furin propeptide convertase inhibitor prevents the formation of the 120 kDa form. These data indicate that the soluble 120 kDa form is a specifically cleaved extracellular domain of type XVII collagen generated through furin-mediated proteolytic processing [476]. Type XVII collagen is thus the first collagen with

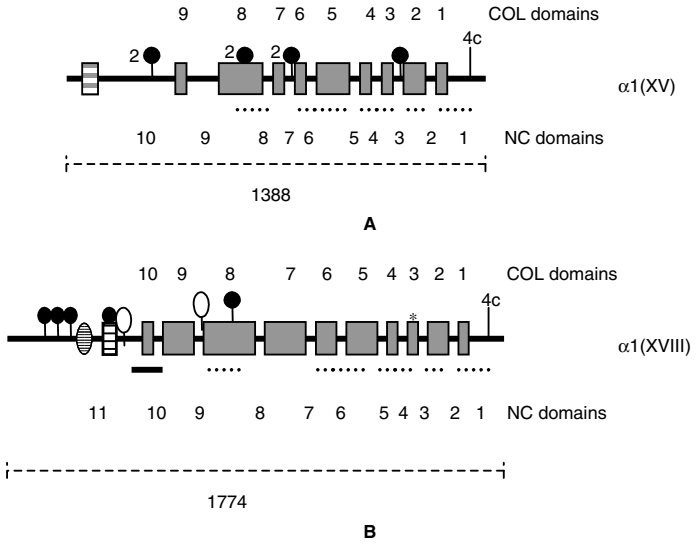

Figure 19. Molecular organization of the MULTIPLEXIN collagens. Line diagrams illustrating the dimensions and domain structures of the component α1 chains of type XV collagen (**A**) and type XVIII collagen (**B**). The triple-helical (COL) domains are represented as dark shaded bars, and the noncollagenous (NC) domains as lines. An alternatively spliced sequence of type XVIII collagen is highlighted as a heavy line beneath the diagram. Regions of high homology between types XV and XVIII collagens are shown as dotted lines beneath each diagram. The positions and numbers of cysteine residues (c), N-linked carbohydrate attachment sites (🌳), PARP (proline and arginine-rich protein) domains (▯), the amino-terminal frizzled motif (🌰), an RGD putative cell attachment sequence (✻), and two glycosaminoglycan attachment sites of type XVIII collagen (♀) are indicated. The numbers of amino acid residues comprising the individual chains are indicated beneath each.

a specifically processed, soluble triple-helical extracellular domain to be described. The role of this soluble extracellular domain is not known, but its loss from the cell surface may influence signal transduction and/or cell attachment to the basement membrane during proliferation and differentiation.

The functions of type XVII collagen are not known. As a transmembrane component of hemidesmosomes, it is likely to play a role in maintaining linkage between intracellular and extracellular structural elements, and in anchoring epithelia to underlying basement membranes. This concept is supported by observations made in pathological skin conditions [475]. In bullous autoimmune skin diseases, the presence of autoantibodies reactive against type XVII collagen is associated with diminished epidermal–dermal cohesion. Heritable skin blistering disorders of the junctional epidermolysis bullosa group are associated with mutations in the gene for type XVII collagen (see Chapter 15, this volume). Several mutations in the *COL17A1* gene (all in regions encoding the extracellular region) have been identified that result in premature chain termination and absence of the protein [465,466]. These mutations have been linked to the nonlethal junctional blistering disorder, generalized atrophic benign epidermolysis bullosa, in which the tissue separates within the cutaneous basement membrane zone at, or just below, the level of hemidesmosomes. Genotype-phenotype correlations and the molecular mechanisms underlying the phenotypes remain unclear. However, the recent elucidation of collagen XVII molecular interactions in hemidesmosome plaques with keratin [471], catenin [477], and bullous pemphigoid antigen 1 (BPAG1) [478], has provided new insights into the role of this collagen in skin.

MULTIPLEXIN COLLAGENS

Types XV and XVIII collagens are homologous members of a subfamily of collagens designated MULTIPLEXINS (multiple triple-helix domains and interruptions) due to the occurrence of multiple collagenous and noncollagenous sequences (Fig. 19) [16,479–484]. Types XV and XVIII collagens are highly homologous in seven of their collagenous domains, which are similar in size and in the positions of triple-helical imperfections within them. However, the two collagens also differ in the number of collagenous domains they possess. Moreover, the different lengths of the dissimilar collagenous domains make it impossible to align fully the two homologous polypeptides, and thus it is unlikely that they are different α chains of the same collagen. The most striking homology between these collagens is found in the most carboxyl terminal noncollagenous NC1 domains, the structures of which are unique to these two collagens [16,484]. These domains contain two regions of sequence homology, separated by a variable region. The second of these homologous regions includes a unique pattern of four conserved cysteine residues that is regarded as a signature of MULTIPLEXIN collagens. Both collagens possess a number of Ser–Gly sequences within noncollagenous sequences that are potential attachment sites for glycosaminoglycan chains, as well as a number of N-linked oligosaccharide attachment sites, suggesting these collagens may be extensively glycosylated *in vivo*. Mouse type XVIII collagen exists as three polypeptide variants with three N-terminal noncollagenous domains of differing lengths, and two N-terminal variant human α1(XVIII) chains have also been identified [485].

Types XV and XVIII collagens are both found in most basement membrane zones, but some tissue-specific differences exist [486–490]. Type XV collagen is expressed widely in basement membrane zones of the vasculature and many internal organs, including placenta, adrenal gland, kidney, heart, skeletal muscle, ovary, and testis, and the main producers of type XV collagen are mesenchymally derived

cells (fibroblasts, muscle cells, endothelial cells) [490]. Type XVIII collagen is a ubiquitous basement membrane component [485]. The short variant is the most common form, being found in conventional basement membranes of blood vessels and epithelia in heart, kidney, placenta, prostate, ovary, skeletal muscle, and small intestine. The long variant is very strongly expressed in liver, while its strongest signals in fetal tissues occur in kidney and liver; minor expression of both variants is observed in other tissues. The most obvious differences in distribution between the two molecules are the strong type XV collagen expression in muscle tissues, and the high levels of type XVIII in liver. The functions of types XV and XVIII collagens are not yet known, but in view of their homology, may be similar. They may contribute to the structural and functional integrity of basement membranes.

Type XV Collagen

Type XV collagen was first identified by screening a human placental library with a DNA fragment encoding a chick fibrillar collagen sequence [16,479–482]. The NC1, COL1–COL6, and COL8 domains, and an amino-terminal PARP motif in NC10 are homologous to those of type XVIII collagen [16] (Fig. 19). The complete deduced primary structure of human type XV collagen comprises 1388 residues, including a putative signal peptide of 25 residues, and has a calculated M_r of 140 kDa. It is characterized by a 577-residue collagenous sequence with nine collagenous domains of Gly–X–Y triplets (COL1–COL9) separated by eight interruptions of 7–45 residues (NC2–NC9), flanked by an amino-terminal noncollagenous NC10 domain (530 residues) and a carboxyl terminal NC1 domain (256 residues). The NC10 domain possesses a segment of ~200 residues that is homologous to the extreme amino-terminal portion of thrombospondin-1; this sequence has two conserved cysteine residues and is also found in the amino-terminal noncollagenous domains of several other collagen α chains, these being α1(V), α1(XI), α2(XI), α1(XII), α1(XIV), α1(XVI), and α1(XIX). The only function mapped to this sequence in thrombospondin-1 is heparin binding, but the residues critical for this function are not conserved among the above collagens. The NC10 domain of type XV collagen also has four tandem repeated amino acid segments homologous to rat cartilage proteoglycan core protein.

The molecular structure of type XV collagen is unknown and the protein has not yet been isolated. However, polypeptides of 125 kDa and 116 kDa have been identified by Western blotting of HeLa cell lysates and placenta homogenates using antisera raised against bacterially expressed recombinant protein representing the first half of the noncollagenous carboxyl terminal NC1 domain [16,490]. Differences between the molecular mass of the α1(XV) chain calculated from sequence data and that estimated from the Western blots suggest that the amino-terminal domain may be processed.

Type XVIII Collagen

Type XVIII collagen was first cloned from a mouse liver cDNA library, and the full deduced human and mouse primary structures have recently been determined [16,483–488] (Fig. 19). Two variant forms of the human α1(XVIII) chain (1336 and 1516 residues, respectively) have been reported, with predicted M_rs of 136 and 154 kDa, respectively. The short and long human forms also have different signal peptides. The 1336 residue variant contains a 33 residue signal peptide and the 1516 residue variant a 23 residue signal peptide. The NC11 domain of the short variant comprises 303 residues, and that of the long variant 493 residues. The collagenous sequence in both variants is 688 residues in length and consists of ten collagenous domains (COL1–COL10), varying in length from 18 to 122 residues, and separated by noncollagenous domains (NC2–NC10) of between 12 and 26 residues. The region of human NC11 common to both variants contains two conserved cysteine residues also found in the mouse polypeptide, and has a 200-residue sequence that is homologous with an amino-terminal segment of thrombospondin-1.

Two sequences conforming to a consensus sequence for the attachment of glycosaminoglycans occur in the NC11 and NC9 domains and type XVIII collagen has been shown to exist as a basement membrane heparan sulfate proteoglycan in human kidney and placenta, and in several chick tissues [489]. As such, it is the first member of the collagen family known to have heparan sulfate side chains. COL3 also contains an Arg–Gly–Asp (RGD) putative cell attachment motif. However, only weak adhesion promoting activity has been observed, and current evidence indicates that type XVIII collagen does not serve as a dominant cell adhesion molecule. An alternative splicing event encompassing the last amino acid of human NC11, COL10, and most of NC10 has been identified [485–487]. In the mouse, three α1(XVIII) variants have been detected, with a second "long" variant generated by alternative splicing of the primary transcript. An alternative upstream promoter directs the expression of the murine long forms. The longest form, which has not been identified in humans, contains a segment of 110 residues with 10 cysteine residues that is designated a "frizzled" motif (fz); such motifs are found in frizzled proteins that resemble the G-protein-coupled membrane receptors needed for the establishment of cell polarity in epidermis and which are found in the *Wingless* signaling pathway in *Drosophila* [491]. The fz domain of type XVIII collagen may be involved in transmembrane signaling.

In human type XVIII collagen, the NC1 domain is 312 residues long and contains four cysteine residues. A peptide comprising the most carboxyl terminal 184 amino acids of type XVIII collagen was isolated from a murine hemangioendothelioma cell line as a 22 kDa inhibitor of angiogenesis called endostatin [492]. This sequence corresponds to amino acid residues 1154–1336 in the human α1(XVIII) chain, and is the best conserved sequence between the two species. A related structure (54% sequence identity) exists at the same location in collagen XV. The crystal structure, function, and tissue forms of the NC1 domain of type XVIII collagen containing endostatin have been reported [493–495]. Recombinant NC1 aggregates noncovalently into a globular trimer (38 kDa) that can be partially cleaved by proteolysis into several monomers (25–32 kDa) related to endostatin. The amino-terminal part of NC1 associates to form stable trimers that may be important in triple helix formation (~50 residues per chain; appear ultrastructurally as stalks). This is the first direct evidence that type XVIII collagen can form homotrimers. There is also a central proteinase-sensitive hinge region, and a carboxyl terminal globular endostatin domain (~3 nm diameter). Proteolytic release of endostatin can occur through several pathways (11 positions in the hinge region are sensitive to proteolysis), which may facilitate a switch from a matrix-associated to a soluble endocrine form. Endostatins have also been obtained as highly soluble

monomers with compact folding, and form autonomous folding units. Both intact NC1 and endostatins bind fibulin-1, fibulin-2, and heparin (the latter probably through the endostatin sequence), but NC1 also binds sulfatides, laminin-1, and perlecan. Circulating forms of endostatin may be involved in the hemostatic control of angiogenesis. Thus, the NC1 domain serves disparate functions in oligomerization, in association with extracellular matrix components, and as a potent regulator of endothelial cell proliferation.

The molecular structure of type XVIII collagen is unknown. Type XVIII collagen protein has been detected in Western blots of extracts of mouse embryonic stem cells as a 200 kDa band, which corresponds to the short form.

COLLAGEN — THE FUTURE

The complexity of the family of collagenous proteins has become increasingly apparent over recent years, and numerous aspects of these molecules still remain to be revealed. Many new family members have now been identified by cDNA cloning techniques, but yet more molecules with collagenous domains will undoubtedly be identified on completion of the elucidation of the human genome. Several of the more recently identified collagens have been classified because they contain one or more Gly–X–Y collagenous domains, although their molecular and macromolecular forms and potential structural roles remain undefined. A number of other molecules that contain collagenous domains, e.g., members of the macrophage scavenger receptor family, are not classified as collagens. It may now be appropriate to reappraise the original definition of a collagen as a triple-helical molecule that contributes structurally to the extracellular matrix.

Structure-function determination is a major goal in current collagen research. In the past few years, recombinant expression approaches and mouse models have increasingly been employed to generate new insights into structure-function relationships. Studies of mutant collagen molecules and their macromolecular organization in the heritable collagen diseases are not only helping to elucidate genotype-to-phenotype relationships, but also their physiological structural and functional properties. Detailed knowledge of the biological properties and roles of the different collagens may, in time, form a basis for the functional classification of collagens.

The diagnosis and treatment of fibrotic, diabetic, and aging conditions is a major focus of interest. The discovery of the key fibrillar procollagen N- and C-proteinases, the actions of which lead inexorably to the deposition of insoluble collagen fibrils, has opened the way for development of new generation synthetic inhibitors to manage fibrosis. Proteolytic fragmentation of collagens forms the basis of a burgeoning pharmaceutical industry in the development of assays for collagen fragment detection in body fluids.

Much remains to be understood about the complex pathway of synthesis and assembly of collagen molecules, which is one of the most complex of all protein assembly mechanisms and is, therefore, potentially the most susceptible to genetic mutation. Recent advances in cell biology approaches are leading to major new insights into how cells direct and regulate chain selection and triple-helix formation within the secretory pathway, and how misfolded forms are recognized and removed. Molecular understanding of these fundamental cellular and molecular mechanisms forms the foundation for the development and production of a new generation of "designer" collagens for a host of therapeutic, biotechnological, and cosmetic applications [496].

RECENT DEVELOPMENTS

Basic Principles of Triple-Helix Conformation and Stability

Guest triplets of the form Gly–X–Hyp and Gly–Pro–Y have been used to quantify the conformational propensities of all 20 amino acids for the X and Y positions in the context of a $(Gly–Pro–Hyp)_8$ host peptide, highlighting the highly stabilizing nature of imino acids and the destabilizing effects of Gly and aromatic residues. The high propensity of ionizable residues in the X position indicates the importance of interchain hydrogen bonding, directly or through water, to backbone carbonyl or hydroxyproline residues [497].

Type VI Collagen

Mutations in the α2(VI) chain have been shown to cause Ullrich syndrome, a recessive congenital muscular dystrophy associated with severe reduction of collagen VI [498]. This disease shares some clinical features with Bethlem myopathy, but displays a more severe course. (In respect of both conditions, see also Chapter 26, Part VI, this volume).

Type VIII Collagen

The endothelial corneal dystrophies cause endothelial cell dysfunction and corneal decompensation. Causative mutations have been identified in *COL8A2*, which encodes the α2 chain of type VIII collagen, in familial and sporadic cases of Fuchs corneal endothelial dystrophy (FEDC; MIM 136800) and posterior polymorphous corneal dystrophy (PPCD; MIM 122000) [499].

Type XVIII Collagen

Mutations have been identified in the *COL18A1* gene that result in Knobloch syndrome (MIM 267750), an autosomal recessive disorder characterized by the occurrence of high myopia, vitreoretinal degeneration with retinal detachment, macular abnormalities and occipital encephalocele [500] (see also Chapter 26, Part VII, this volume). Thus, collagen XVIII has a major role in determining retinal structure and in closure of the neural tube.

Novel Collagens

α1(XX) is a new member of the FACIT collagen subfamily, which has been identified in chick [501]. It has sequence similarities to collagen types XII and XIV, but the cDNA predicts that the α1(XX) polypeptide is smaller than the short forms of collagens XII and XIV. It is present in cornea, skin, cartilage and tendon, and is expected to bind to collagen fibrils, the amino-terminal domains projecting away from the fibrillar surface. The cloning of collagen type XXIII, present in the cornea, has been reported [502].

Chapter 2, Part II

Collagen: Gene Structure

Mon-Li Chu and Darwin J. Prockop

Department of Dermatology and Cutaneous Biology, and Department of Biochemistry and Molecular Pharmacology, Jefferson Institute of Molecular Medicine, Jefferson Medical College, Thomas Jefferson University, Philadelphia, Pennsylvania 19107 (M.-L.C.); Center for Gene Therapy, Tulane University Medical Center, New Orleans, Louisiana 70112 (D.J.P.)

INTRODUCTION

Collagens are now known to constitute a family of more than 19 proteins. On the basis of the structure and function of the proteins, the collagens are generally divided into two categories: fibrillar collagens that form discrete fibrils with a characteristic cross-striated pattern, and nonfibrillar collagens that do not form cross-striated fibrils. The structures of the genes for collagens also appear to divide the proteins into two categories in that the genes for fibrillar collagens have similarities that distinguish them from the genes for nonfibrillar collagens and from the genes for most other proteins.

The first collagen gene clones isolated were for the proα2(I) chain of type I procollagen from chicken by de Crombrugghe and associates [1] and by Boedtker and her associates [2]. Work in their laboratories over several years defined the unusual structural features of the genes for fibrillar procollagens, including the 54-bp motif seen in the exons coding for the triple-helical domains. Boedtker and her associates completely defined the structure of the chick proα2(I) gene, the first collagen gene so defined [3]. Strategies modeled after those of de Crombrugghe et al. and Boedtker et al. were used by our own research group to prepare the first genes for human collagens [4]. Subsequently, a series of different and powerful strategies became available and were used to isolate genes for other collagens. At least 33 collagen genes coding for various collagen types have been completely or partially characterized to date (Table 1).

The large amount of information now available about the structures of collagen genes has a number of important applications. One of these is to provide the necessary database for identifying mutations in the genes that can cause human diseases [5]. In this chapter, we concentrate primarily on the structures of collagen genes in humans. The extensive literature about collagen genes in other vertebrates is not discussed except when data for human collagen genes have not been reported.

CHROMOSOMAL LOCATIONS OF COLLAGEN GENES

The chromosomal locations of most collagen genes have now been defined in both human and mouse genomes. Most genes are widely scattered throughout the genome but a few are clustered (Table 1). For example, the proα1(I) gene of type I collagen, *COL1A1*, is found on chromosome 17, while the proα2(I) gene, *COL1A2*, is on chromosome 7 [6,7]. However, there are several chromosomal loci where two or more collagen genes are clustered. The genes for the α1(IV) and α2(IV) chains of type IV collagen, *COL4A1* and *COL4A2*, are found at the tip of chromosome 13 [8–11]. The genes are coded for on opposite strands of the DNA with the first exons separated by no more than about 130 bp [12,13]. This unusual clustering of two genes for two polypeptides of the same protein means that the regulation of expression of the two genes must involve some complex mechanism. Similar head-to-head arrangements are found for the α3(IV) and α4(IV) collagen genes, *COL4A3* and *COL4A4*, on chromosome 2, and for the α5(IV) and α6(IV) collagen genes, *COL4A5* and *COL4A6*, on chromosome X [14–16]. The distances between the *COL4A3* and *COL4A4* genes and between the *COL4A5* and *COL4A6* genes are reported to be 5 and 442 bp, respectively [17,18].

Similarly, the genes for the α1(VI) and α2(VI) chains of type VI collagen, *COL6A1* and *COL6A2*, are in a head-to-tail orientation on the long arm of chromosome 21, approximately 150 kb apart [19,20]. The gene for type XVIII collagen, *COL18A1*, is also located close to the two genes for type VI on chromosome 21 [21]. Two additional collagen genes, for types X and XIII, are found in this gene cluster on mouse chromosome 10B5-C1, although the type X and XIII genes are scattered on human chromosome 6 and 10, respectively [22,23]. The order of these genes on mouse chromosome 10 is (cen-*Col10a1*-*Col13a1*-*Col6a1*-*Col6a2*-*Col18a1*-tel). In addition, the genes for type III collagen, *COL3A1*, and the α2(V) chain of type V collagen, *COL5A2*, are closely associated in the long arm of human chromosome 2 [24–26]. The 3′-ends of these two genes have been mapped to a 35 kb region [27], but their orientation has not yet been established. Also, the genes for the α1 chain of type IX collagen (*COL9A1*), type XII collagen (*COL12A1*), and type XIX collagen (*COL19A1*) are found in the long arm of chromosome 6. The gene order appears to be *COL19A1*-*COL9A1*-*COL12A1* [28–30].

GENES FOR THE THREE MAJOR FIBRILLAR COLLAGENS

The Proteins for Which They Code

The three major fibrillar collagens are types I, II, and III (see Part I of this chapter). Type I collagen is the most abundant structural protein in the body and is the major protein constituent of tissues such as skin, bones, and tendons. Type II collagen is the characteristic collagen of articular cartilage, but it is also found in the eye and it appears transiently in many tissues during embryonic development. Type III collagen is generally associated with type I collagen, but is found in lesser amounts. In addition, the aorta and other large blood vessels appear to be particularly rich in type III collagen.

The three major fibrillar collagens show a great deal of similarity at the protein level. Each is first synthesized as a procollagen containing N- and C-terminal propeptides

Figure 1. Schematic drawing of a molecule of type I procollagen. (Reproduced from Prockop and Kivirikko [132] by permission of the New England Journal of Medicine.)

(Fig. 1). The separate domains of the proteins are very similar, but there are some differences (Table 2). The N-propeptide of the proα2(I) chain is considerably shorter than that of the other chains. The N-propeptide of the proαl(II) chain has a larger triple-helical region than the other N-propeptides; its Gly–X–Y sequence is interrupted by a short globular sequence. Type III procollagen differs from type I and type II in that its major triple-helical domain is 15 amino acids longer.

The Triple-Helical Domains

The gene structures of the three major fibrillar collagens also show a great deal of similarity (Table 1). The basic structure consists of 52 exons (Fig. 2). In the *COL1A1* gene, exons 33 and 34 found in the other genes are fused, and this fused exon is usually referred to as "33/34." In the *COL2A1* gene, two additional exons called 2A and 3B (Fig. 3) code for the N-terminal domain. Exon 2A is alternatively spliced in the processing of mRNA [31]. In the *COL3A1* gene, exons 4 and 5 are fused into a single exon called "4/5." One feature of the genes is that most of the major triple-helical domain of each protein is coded for by 42 exons that have striking similarities (Fig. 2). Another striking feature of the exon structure is that most of the exons are 54 bp and the others are either twice 54, three times 54, or combinations of 45 and 54 bp exons (Fig. 2 and Table 3). In all cases, each exon begins with a complete codon for glycine, and the exon codes for a discrete number of Gly–X–Y tripeptide units. Still another feature is the conservation of exon structures among the different genes and throughout evolution. Except for the fused 33/34 in *COL1A1*, the four genes for the three fibrillar collagens have the same exon sizes. In addition, the sizes of the exons are identical in human, rodent, and chick. Hence, there appears to be some common ancestry in evolution of the gene structures and probably selective pressure on maintaining the features of the gene structure.

The Propeptides

The similarities among the gene structures for the three fibrillar collagens extend to the propeptides. As indicated in Figure 3, the basic structure of the N-propeptides is coded for by six exons. In the various collagens, exon 1 contains 119–156 bp of noncoding sequences plus 70–103 bp of coding sequences, including sequences coding for the signal peptides. Exons 2A and 2 code for a cysteine-rich domain and appear to be the most variable among the gene structures. Exon 2 of the *COL1A2* gene is only 11 bp. Exon 2A in *COL2A1* is similar to exon 2 in the *COL1A1* and *COL3A1* genes. However, the transcribed RNA is alternatively spliced so that the codons of exon 2A are missing from some of the mRNA for type II procollagen [32–36]. The mRNA containing this exon, α1(IIA), is preferentially expressed in differentiating cartilage and noncartilaginous tissues during embryonic development, whereas the mRNA lacking it, α1(IIB), is primarily expressed in chondrocytes. Exons 3 to 5 code for a short triple-helical domain. Exon 6 in all four genes for fibrillar collagens is a junction exon containing the site at which the propeptides are cleaved by either a procollagen N-proteinase specific for type I and type II procollagen or a separate procollagen N-proteinase specific for type III procollagen. Exon 6 also contains a few codons for the initial Gly–X–Y sequences of the major triple-helical domain of the protein.

The gene structures coding for the C-propeptides also show a great deal of similarity (Fig. 4). Exon 49 is the junction exon in which the first 45 or so bp code for the last repeating Gly–X–Y sequences of the triple-helical domain. Exon 49

TABLE 2. Comparison of the Sizes of the Domains of Human Type II Procollagen with the Same Domains of Type I and Type III Procollagens[1]

Domain	Amino Acid Residues			
	Proα1(I)	Proα2(I)	Proα1(II)	Proα1(III)
N-Terminal Domain	161	79	112	153
Signal peptide	22	22	21,23, or 25	24
N-Propeptide	139	57	91,89, or 87	129
Cys in N-propeptide	10	2	1	11
Triple helix in N-propeptide	48	42	16 + 63	39
Collagen Domain	1,057	1,039	1,060	1,068
N-Telopeptide	17	11	19	14
Triple helix	1,014	1,014	1,014	1,029
C-Telopeptide	26	15	27	25
C-Terminal domain				
C-Propeptide	246	247	245	246
Carbohydrate sites	1	1	1	1

[1]Data for type I procollagen are from Bernard et al. [172], Kuivaniemi et al. [173], and Tromp [144]. Data for type II procollagen are from Baldwin et al. [174]. Data for type III procollagen are from Ala-Kokko et al. [175].

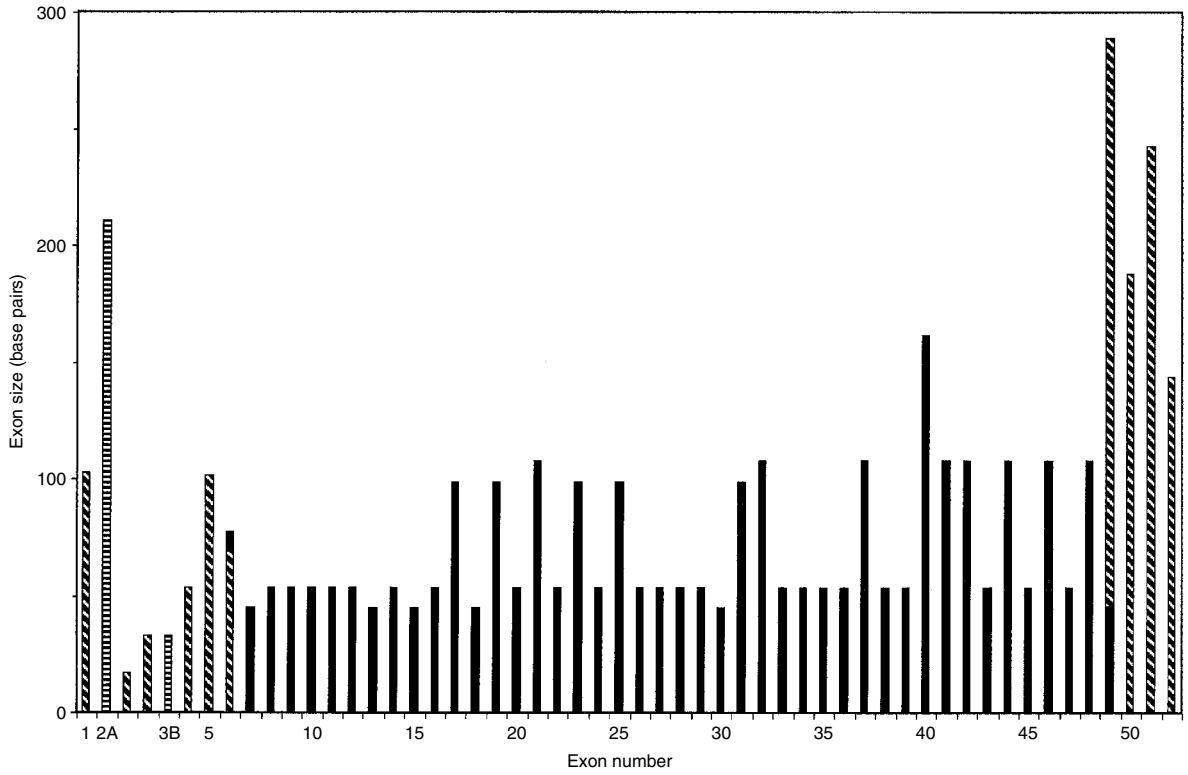

Figure 2. Prototypic structure of exons in genes for fibrillar collagens. The exon sizes shown apply to the human type II procollagen gene as defined by the references cited in Table 1. With minor modifications, the exons for other fibrillar collagens are the same size. The differences among the four genes for types I, II, and III procollagens are: (1) type II procollagen has two exons (2A and 3B) not found in the other genes; (2) exons 4 and 5 are fused in the gene for type III procollagen; (3) exons 33 and 34 are fused in the gene for the proα1(I) chain of type I procollagen (Table 3). Symbols: Solid bars, exons for the major triple-helical domain of the α1(II) chain; hatched bars, exons coding for the N- and C-propeptides. As discussed in the text, exon 2A of the type II procollagen gene is alternatively spliced in transcripts of the gene.

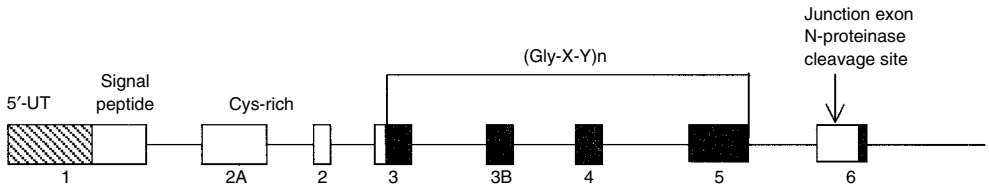

Gene	Exon 1 (bp) (5′-UT +Coding)	Exon 2A (bp)	Exon 2 (bp)	Exon 3 (bp) Globular + (Gly-X-Y)n	Exon 3B (bp)	Exon 4 (bp)	Exon 5 (bp)	Exon 6 (bp) Globular + (Gly-X-Y)n
α1(I)	119 + 103	---	195	26 + 9	---	36	102	63 + 9
α2(I)	135 + 70	---	11	15	---	36	93	45 + 9
α1(II)	156 + 85	213	17	6 + 27	33	54	102	69 + 9
α1(III)	120 + 79	---	203	24 + 27	---	144		54 + 27

Figure 3. Prototypic structure of exons coding for the N-propeptides of the major fibrillar collagens I, II, and III. The top of the figure presents the exon structure of type II procollagen. Variations of the structure for type I and type III are presented below. Data are from references indicated in Table 1.

Figure 4. Prototypic structure of exons coding for the C-propeptides of the major fibrillar procollagens I, II, and III. The structure at the **top** is type II procollagen. Variations on this structure are shown **below**. Three of the four genes have more than one polyadenylation site. Data are from references indicated in Table 1.

also contains 214–244 bp coding for globular sequences that include the C-terminal telopeptide and the site at which a procollagen C-proteinase cleaves the propeptides. Exons 50 and 51 and the coding region of exon 52 are very similar in size among the four genes. Exon 51 contains a coding sequence for Asn–X–Thr, which is a single site for the attachment of a mannose-rich carbohydrate to the C-propeptide of each of the proα chains. In each of the four genes, Exon 52 contains 144 bp of coding sequence plus a variable amount of 3′-noncoding or 3′-untranslated sequences.

5′- and 3′-Noncoding Regions

Analysis of mRNAs for the proα1(I) chain of chick type I procollagen and the proα1(III) chain of chick type III procollagen demonstrates that the 5′-untranslated regions contain two or more AUG triplets preceding the AUG that serves as a site for initiation of translation [37]. A sequence of about 50 nucleotides surrounding the latter AUG is conserved in the mRNAs, and contains an almost ideal inverted repeat structure that can form an apparently stable stem-loop structure. The structure initially suggested that the conserved sequences may play a role in determining expression or translation of the mRNAs by varying the extent to which stem-loop formation occurs, thereby permitting or preventing use of the critical AUG sequence for translation. The same sequences are conserved in the three genes for type I and type III procollagens in man [38–40], but the critical structure is not found in the 5′-untranslated region of type II procollagen [41]. Subsequent studies suggested, however, that the highly conserved sequences in the 5′-untranslated region do not generally function in the regulation of either transcription or translation [42].

The three major fibrillar collagen genes (*COL1A1*, *COL1A2*, and *COL1A3*) have more than one polyadenylation site in the 3′-end of the genes [38,43,44]. As a consequence, multiple mRNA transcripts with varying lengths of 3′-untranslated region are produced from each gene (Fig. 4). The two major transcripts of the *COL1A1* gene differ by as much as 1 kb in the 3′-noncoding region. It is not clear whether the multiple mRNA species differ in stability or translational efficiency.

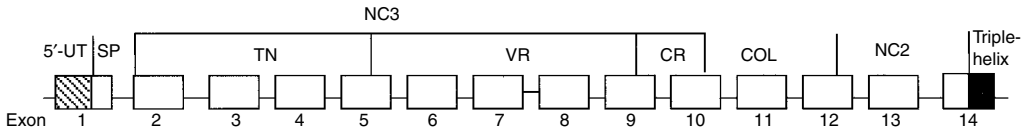
GENES FOR MINOR FIBRILLAR COLLAGENS: TYPES V AND XI

At least two other types of collagen, V and XI, belong in the class of fibrillar collagens [45]. Type V collagen is found in small amounts, usually as a heterotrimer of $[\alpha1(V)]_2\alpha2(V)$ chains, in tendon and other tissues that are rich in type I collagen. However, it is also found in even smaller amounts in tissues that produce type II collagen. Type V collagen also exists as an $[\alpha1(V)]_3$ homotrimer or an α1(V)α2(V)α3(V) heterotrimer (see Part I of this chapter). Type XI collagen is a heterotrimer of α1(XI), α2(XI), and α3(XI) chains, in which the α3(XI) chain is identical to the α1(IIB) variant of type II collagen. It is found in relatively small amounts in cartilage and other tissues rich in type II collagen, but is also found in tissues synthesizing type I and III collagens. Because heterotypic molecules consisting of both type V and XI chains are found *in vivo* [46], these two collagen types are thought to constitute a single collagen type.

The gene structures of type V and XI collagens show considerable divergence from those of the major fibrillar collagens. The genes for the α1 chain of type V collagen, *COL5A1*, and the α2 chain of type XI collagen, *COL11A2*, each contain 66 exons [47–49]. The sizes of the two genes, however, differ markedly. The *COL5A1* gene appears to be greater than 750 kb in size with a large first intron over 500 kb long, whereas the *COL11A2* gene is only 28 kb in size. The exon numbers are greater than those found in the major fibrillar collagen genes because both the N-propeptides and the triple-helical domains are encoded by six to eight more exons.

Propeptides

The N-propeptides of the α1(V) and α2(XI) collagen chains are encoded by 14 exons (Fig. 5), as compared with 5-8 exons for the α chains of the major fibrillar collagens. This reflects



Gene	Exon 1 (bp)	Exon 2 (bp)	Exon 3 (bp)	Exon 4 (bp)	Exon 5 (bp)	Exon 6 (bp)	Exon 7 (bp)	Exon 8 (bp)	Exon 9 (bp)	Exon 10 (bp)	Exon 11 (bp)	Exon 12 (bp)	Exon 13 (bp)	Exon 14 (bp)

Figure 6. Prototypic structure of exons coding for the C-propeptides of the minor fibrillar procollagens V and XI. The structure at the top is α1(V) procollagen. Variations on this structure are shown below.

differences in the domain structure of the N-propeptides of the two groups of fibrillar collagens. In type V and XI collagens, exon 1 encodes 232–318 bp of the 5′-untranslated region plus 79–109 bp of the coding sequence. Exons 2–9 and the 5′-end of exon 10 code for a large globular domain at the amino terminus of the N-propeptide, NC3, which shares little homology with the cysteine-rich region of the major fibrillar collagens. Exons 10–12 code for an interrupted collagenous domain, and exons 12–14 code for a short non-collagenous region (NC2) preceding the triple-helix. The NC3 domain contains three parts: a basic subdomain, an acidic variable region, and a short constant region. The basic subdomain has been isolated as a proline and arginine rich peptide (PARP) from tissues and is homologous to the N-terminus of thrombospondin-1 [50]. Similar motifs are also found in several nonfibrillar collagens (see below), and the motif is referred to as TN (thrombospondin N-terminal motif) or PARP. The α2(V) chain does not contain the TN motif. In type V and XI genes, the exon sizes are conserved in all subdomains of the N-propeptides, except for the acidic variable regions (Fig. 5). Moreover, exons coding for the acidic regions of the two type XI chains are subjected to alternative splicing, thereby leading to further variations in the N-propeptide sequences [51–55].

The exon organization of the regions coding for the C-propeptides of type V and XI collagens is similar to that for the corresponding region of the major fibrillar collagen genes, but with some differences (Fig. 6). The C-propeptide

of the α1(V) chain is encoded by 5, not 4 exons, because the sequence equivalent to exon 50 of the major fibrillar collagen genes is split into two separate exons, i.e. exons 63 and 64. The gene for the α2(XI) chain lacks the second of the two exons, and also the penultimate exon is 27 bp shorter than the corresponding exon of the gene for the α1(V) chain. Thus, the C-propeptide of the α2(XI) chain is shorter by about 30 amino acids than the corresponding domains of the other fibrillar collagens.

Triple-Helical Domains

The triple-helical domains of the α1(V) and α2(XI) chains are encoded by 47 and 48 exons, respectively (Table 3). Like the major fibrillar collagen genes, most exons are 54 bp, 45 bp, or 108 bp in size, and begin with complete codons for glycine residues. The first and last exons are junction exons, which encode both the propeptides and the triple-helical domain. However, each of the four 99 bp exons found in the major fibrillar collagen genes is split into two exons of 45 and 54 bp. As a result, type V and XI collagen genes lack exons of 99 bp, and contain more exons of 54 and 45 bp. In addition, they do not have the 162-bp exon found in the major fibrillar collagen genes, but do contain exons of 36 and 90 bp that are not found in the major fibrillar collagen genes. The exon sizes of the *COL5A1* and *COL11A2* genes are identical except that Exon 48 in the *COL5A1* gene is split into two exons of 54 bp in the *COL11A2* gene.

GENES FOR THE NONFIBRILLAR COLLAGENS

Type IV

Type IV collagen is the major collagen of basement membranes [56] (see also Part I, this chapter). There are six genetically distinct α chains. The α1(IV) and α2(IV) chains are found in all basement membranes, whereas the α3(IV), α4(IV), α5(IV), and α6(IV) chains have a more restricted tissue localization. Mutations in the latter group are found in patients affected with Alport syndrome or leiomyomatosis associated with Alport syndrome [57] (see also Chapter 25, this volume). Type IV collagen chains are characterized by the presence of N- and C-terminal globular domains that apparently are not cleaved during the processing of the protein. Also, the central triple-helical domain of the protein is characterized by a series of noncollagenous sequences that interrupt the Gly–X–Y sequences required for folding into a triple-helix.

Type IV collagen genes are exceedingly large in size and appear to have large introns near their 5′-ends. For example, the *COL4A1* gene is larger than 160 kb, and the *COL4A5* and *COL4A6* genes are approximately 230–250 kb and 425 kb in size, respectively (Table 1). The first intron of the *COL4A1* gene is more than 30 kb long and the second intron of the *COL4A6* gene is as much as 340 kb in size [58,59]. These large introns may contain regulatory elements controlling gene expression or may include another gene.

The primary structures of type IV collagen α chains suggest that they belong to two conserved subgroups, one consisting of the odd-numbered chains (the α1-like) and the other of the even-numbered chains (the α2-like). The gene structures support this classification and suggest that type IV collagen genes may have evolved through two separate events [59,60]. The first may have been a tandem duplication and later divergence of an ancestor gene to generate a primordial pair of α1 and α2 genes. The second event may have involved further duplication of the primordial gene pair onto two other chromosomes so that each odd-numbered gene is paired head-to-head with an even-numbered gene (Table 1).

The structure of the *COL4A1* gene [58] differs from the structures of the major fibrillar collagen genes in that only two of the exons are 54 bp, and only three are 45 bp (Fig. 7 and Table 4). The first 19 exons for the triple-helical domain

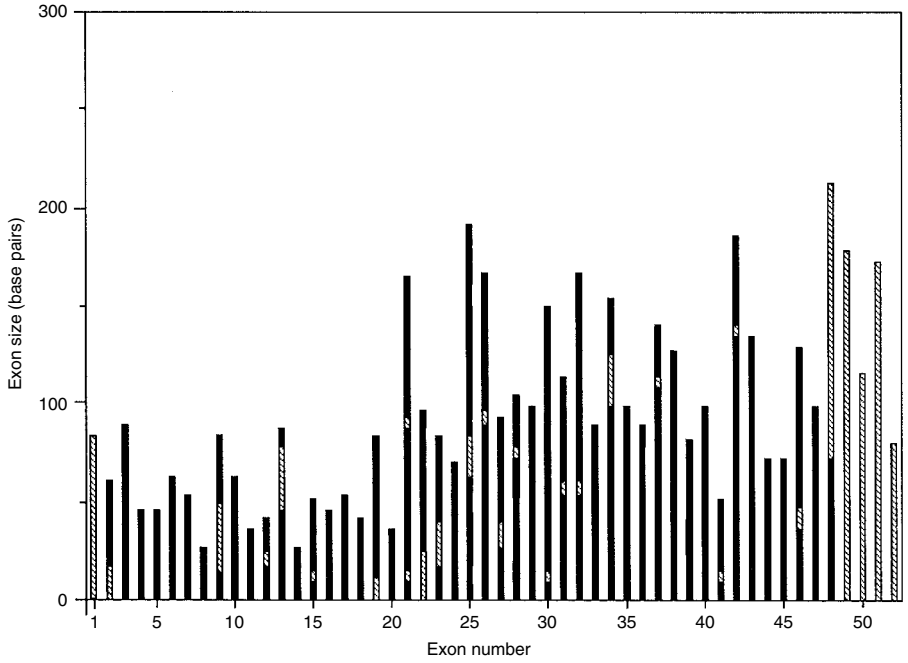

Figure 7. Sizes of exons in the gene for the α1(IV) chain of human type IV collagen. Data are from Soininen et al. [58]. Symbols: Solid bars, codons for Gly–X–Y sequences; hatched bars, codons for non-triple-helical sequences.

begin with complete codons for glycine, but thereafter most of the exons begin with split codons for glycine in which the first G of the codon is in the preceding exon. Another feature is that although the gene for the α1(IV) chain has remarkable differences from the genes for fibrillar collagens, the number of exons is again 52.

The exon structure of the *COL4A5* gene is quite similar to that of the *COL4A1* gene, having 41 exons of identical sizes [60]. The split codons are also conserved. The gene has one less exon than the *COL4A1* gene because exons 19 and 20 that are separate in the *COL4A1* gene are fused (Table 4). The C-terminal noncollagenous region, NC1, of the *COL4A5* gene undergoes alternative splicing in human kidney and skin tissues [61]. Skipping of exon 50 introduces a stop codon at the first codon of exon 51, and the resultant α5(IV) chain lacks 84 amino acids in the NC1 domain. Exons coding for the NC1 domain of the *COL4A3* gene are also alternatively spliced from the mRNA. In this case, two exons are subjected to alternative splicing, yielding α3(IV) variants with NC1 domains of 232, 60, and 199 amino acids [62–64]. The multiple forms of NC1 domains in the α3(IV) and α5(IV) chains in the kidney may lead to autoimmune glomerular diseases.

The structures of the three even-numbered genes differ considerably from those of the odd-numbered genes [59,65–67]. The mouse α2(IV) gene, human α4(IV) gene, and human α6(IV) gene contain 47, 48, and 46 exons, respectively (Table 5). The NC1 domains of the α2-like genes are encoded by 3, not 5 exons. As with the α1-like genes, most exons in the second halves of the genes begin with split codons. Exons coding for the central portion of the triple-helical domains (exons 17–26) are most variable among the α2-like genes. The *COL4A4* gene has a small exon of only 9 bp (Exon 43), which is not found in the *Col4a2* and *COL4A6* genes.

The *COL4A4* and *COL4A6* genes each contain two promoters that are differentially utilized in tissues, resulting in α4(IV) chains with different 5′-untranslated sequences and α6(IV) chains with different signal peptides [17,18]. The alternative transcripts have different tissue distribution but the functional significance of this is not clear.

Type VI

Type VI collagen consists of three different α chains and it is ubiquitously distributed [68]. It appears to account for as much as 10–20% of the collagen synthesized by cultured skin fibroblasts. Mutations in type VI collagen genes cause Bethlem myopathy (MIM 158810) (see also Chapter 26, Part VI, this volume), a childhood onset muscular dystrophy with joint contractures [69]. The protein forms an unusual microfibrillar structure in which the monomers coil around each other to form dimers and tetramers. The monomer, consisting of α1(VI), α2(VI), and α3(VI) chains, has only a very short triple-helical domain of 335–336 amino acids, which is flanked by large N- and C-globular domains. The α1(VI) and α2(VI) chains, each of about 1000 amino acids, are highly homologous, whereas the α3(VI) chain is almost three times the size of the α1(VI) and α2(VI) chains because of much larger N- and C-globular domains.

The triple-helical domains of the α1(VI) and α2(VI) chains are each encoded by 19–20 exons that are generally multiples of 9 bp and begin with complete codons for glycine [70,71]. Some of the exons are 54 and 45 bp but most are 63 bp or other sizes (27,36, and 72 bp) that do not reflect the 54 bp unit (Table 6). The exon size patterns for the triple-helical domains of the two genes are almost identical, except that exons 17 and 18 in *COL6A1* are fused in the *COL6A2* gene. With only minor differences, exons coding for the triple-helical domain of the α3(VI) chain are similar in size to those of the *COL6A1* and *COL6A2* genes [72].

By contrast, there is less conservation of the exon structures of the globular domains, which primarily consist of motifs similar to the A domains of von Willebrand factor (vWF A) [73–77]. The vWF A motifs in the N- and C-globular domains of the three chains are encoded by one to four exons. The α3(VI) chain contains a total of 10 consecutive vWF A motifs, N10-N1, in the N-terminal globular domain. Except for N1, which is encoded by two exons, the other nine vWF A motifs are each encoded by a single exon [74]. Because of alternative splicing of exons coding for domains N10, N9, N7, and part of N3, the α3(VI) chains contain varying numbers of vWF A domains [74,76]. The alternative splicing pattern differs between normal and tumor cells [74]. Except for the exon coding for N3, the corresponding exons in the chick α3(VI) collagen gene are also alternatively spliced and the multiple transcripts are differentially expressed in embryonic chicken tissues [78,79]. Alternative splicing also occurs with the *COL6A2* gene, in which the last two exons are alternatively spliced to vary the C-terminal amino acid sequence [73]. The gene also has two promoters, producing mRNAs with different 5′-untranslated regions [75].

Type VII

Type VII collagen is the major component of the anchoring fibrils that connect epithelia to underlying stroma [80] (see also Chapter 15, this volume). It is a homotrimer of α1(VII) chains with a long, interrupted triple-helical domain flanked by non-collagenous domains at the N- and C-termini.

The *COL7A1* gene contains 118 exons and is apparently the most complex gene described to date [81,82]. Yet its size of 31 kb is very compact because of small introns with an average length of 188 bp. The triple-helical domain with 19 interruptions in the Gly–X–Y sequences is encoded by 81 exons (Table 7), the last of which is a junction exon encoding also the beginning of the C-terminal globular domain, NC2. All exons coding for uninterrupted Gly–X–Y sequences start with complete codons for glycine and are multiples of 9 bp in size. However, exon sizes found in fibrillar collagen genes are not predominant. Only 4 exons are 54 bp, 12 exons 45 bp, and 1 exon 108 bp. The most predominant exon size is 36 bp (a total of 25 exons). In addition, there are 8 exons of 63 bp, 5 exons of 72 bp, 6 exons of 81 bp, and 3 exons of 27 bp. The largest interruption in the Gly–X–Y sequence is 39 amino acids and encoded by three exons (exons 70–72).

The N-globular domain, NC1, primarily contains two types of conserved protein motif, i.e. nine fibronectin type III (FN III) repeats and two von Willebrand factor A (vWF A) motifs. The FN III repeats are each encoded by two exons as are those in the fibronectin gene, and the two vWF A motifs are encoded by four and three exons, respectively. A proline- and cysteine-rich domain unique to type VII collagen is encoded by two exons.

The C-terminal globular domain, NC2, is encoded by six exons in addition to the junction exon. Within this region, a Kunitz serine protease inhibitor motif is encoded by the penultimate exon, and the acidic region is encoded by the four preceding exons plus the junction exon. The majority of exons in the NC1 and NC2 domains begin with split codons.

Types VIII and X

Type VIII collagen, expressed by corneal and vascular endothelial cells, and type X collagen, found in the zone of hypertrophic cells of cartilage, share similar protein and gene structures. Genes for type VIII and X collagens are unusual in the collagen family in that they contain only 3–4 exons (Table 8) and most of the coding sequences, including all the Gly–X–Y codons and codons for the globular C-terminus, are found in the large exon at the 3′-end of the gene [83–88].

Types IX, XII, XIV, XVI, and XIX

Collagen types IX, XII, XIV, XVI, and XIX belong to the FACIT (fibril-associated collagens with interrupted triple helices) subgroup of collagens [89]. They comprise several collagenous domains interspersed with noncollagenous domains and have a characteristic C-terminal collagenous domain, COL1. The COL1 domains are of similar size and contain two Gly–X–Y imperfections. Two cysteine residues separated by three other amino acids are found at the end of each COL1 domain. Another common feature is the presence of a TN (thrombospondin) motif in one of the noncollagenous domains.

Type IX

Type IX collagen is found predominantly in cartilage, and is also found in ocular tissue [90]. One of the three different chains contains a site to which a large glycosaminoglycan is attached, and forms a covalent crosslink with fibrils of type II collagen. Each of the three chains contains three collagenous domains, COL1–COL3 numbered from the C-terminus, which are separated by noncollagenous domains, NC1–NC4.

NC1

[1]Data from Christiano et al. [81].

[2]NC: noncollagenous domain; COL: collagenous domain; vWF A: von Willebrand factor type A-like motif; CP: cysteine- and proline-rich domain; FN III: fibronectin type III-like motifs; KM: Kunitz serine protease inhibitor motif.

Analysis of mRNA transcripts of the α1(IX) gene indicates that it is transcribed from two different start sites in cartilage and cornea of chick embryos. Transcription in the cornea begins from a site that is 20 kb downstream from the promoter used in cartilage [91]. Because transcription begins from the second downstream site, the protein in cornea lacks the large globular domain of 266 amino acids comprising the N-terminal NC4 domain, which contains the TN motif, found in the cartilage protein. The expression of the two different forms of the α1(IX) chain is regulated

[1]Data for the rabbit α1(VIII) gene are from Yamaguchi et al. [86] and data for the human α1(X) gene are from Reichenberger et al. [85]. Exons for the human α1(VIII) collagen gene that have been defined [155] are shown in parentheses.

[2]Rabbit α1(VIII) collagen gene.

[3]UT: untranslated region; NC: noncollagenous domain; COL: collagenous domain.

during chondrogenesis [92–94]. The downstream start site is located within intron 6 of human, mouse, and chick α1(IX) collagen [91,95,96]. Because the promoter is located only a short distance upstream from Exon 7, it is spliced directly to Exon 8. The NC4 domains of the α2(IX) and α3(IX) chains are similar to that of the short form of the α1(IX) chain and contain only three amino acids.

The *COL9A1* gene is 90 kb in size and contains 38 exons (Table 9). By contrast, the *COL9A2* and *COL9A3* genes are only about 15 kb and 23 kb in size, respectively, and each consists of 32 exons [96,97]. The exon size patterns of the three genes are essentially the same except for an additional seven exons coding for the NC4 domain of the long form of the α1(IX) chain (Table 9). Exons coding for the NC3 domains and the junction exons in the beginning of the COL3 domains also differ in size among the genes. For example, exon 2 in the *COL9A3* gene encodes one less Gly–X–Y sequence than its counterpart in the other two genes, but the difference is compensated for by one additional Gly–X–Y coding sequence in exon 4 of the *COL9A3* gene.

The COL2 domains of the three chains contain no interruptions of the Gly–X–Y sequences. Eleven of the 17 exons coding for each COL2 domain are 54 bp long. Other exons are 72, 45, and 36 bp in size, i.e. multiples of 9 bp. The last two exons in the COL2 domain are unusual in that they are separated by introns between the X and Y codons. In the COL3 domain, three exons are 54 bp, and other exons are 36 bp, 63 bp, and 24 bp in size. Exons in the COL1 domain also are unusual. They do not show the 9-bp size pattern and the last two exons begin with split codons for glycines.

Types XII and XIV

Collagen types XII and XIV are highly similar in primary structure and both are found in small amounts in association with type I collagen [98,99]. They are homotrimers of α1(XII) or α1(XIV) chains with two collagenous domains, COL1 and COL2, and three noncollagenous domains, NC1–NC3 [30,100,101]. The N-terminal NC3 domains of both collagens are extremely large and are present in two vastly different forms. The long form of type XII collagen contains 18 FN III motifs and 4 vWF A domains, whereas the short form lacks 8 FN III repeats and two vWF A domains in the N-terminus [101,102]. These two forms, however, are not generated by alternative promoters like the long and short forms of the α1(IX) collagen transcripts. Instead, they are products of alternative splicing of internal exons [103]. The long NC3 form is found primarily in embryonic tissues, whereas the short form is the predominant species in adult tissues. Further variation in the coding sequence is found in the 3′-end of rat and mouse α1(XII) collagen genes [104]. Mutually exclusive use of the last two exons, each containing a polyadenylation site, results in the long and short forms of the C-terminal NC1 domain. The long form, containing an extended acidic region followed by a basic region, is found primarily in ligament and tendon, whereas the short form has a broader tissue distribution.

The structures of the exons encoding NC1, COL1, and part of the NC2 domain of the chick type XII gene that have been analyzed [105] suggest that the gene is similar to the type IX collagen genes (Table 9).

Types XVI and XIX

Collagen types XVI and XIX contain more collagenous domains (a total of 5–10) than other members of the FACIT group and share higher sequence similarity with each other than with other FACIT members [106–108]. The gene for type XIX collagen, *COL19A1*, contains 51 exons that span more than 250 kb of genomic DNA [109]. The gene structure shares some similarity with that of the type IX collagen genes. The COL1 domain is encoded by exons that begin with split codons and are not integers of 9 bp (Table 10). Exons coding for the rest of the collagenous domains start with complete codons for glycine and essentially all are multiples of 9 bp in size. The most predominant exon size is 54 bp (a total of 14). Seven exons are 45 bp, five are 36 bp, four are 63 bp, and one each is 27 and 90 bp. Moreover, exons coding for the NC6 domain, which contains a TN motif, are similar in size to those encoding the NC4 domain of the *COL9A1* gene, which also contains a TN motif.

The gene structure for the TN motif in the NC11 domain of the mouse α1(XVI) collagen chain resembles that for the TN motif in the NC6 domain of *COL19A1* [110]. Exons coding for the collagenous domains that have been defined are 45 bp, 36 bp, and 54 bp in size and begin with intact codons for glycine. The exon organization thus supports the evolutionary relationship among FACIT members.

Type XIII

Type XIII collagen is distributed in very small amounts in many tissues [111]. It is an integral membrane protein with a transmembrane domain near the N-terminus [112]. The α1(XIII) chain has three collagenous domains, COL1–COL3 numbered from the N-terminus, and four noncollagenous domains, NC1–NC4. A noteworthy feature of type XIII collagen is that at least 10 exons encoding not only the noncollagenous but also the collagenous domains are

Exons that differ in size between the type IX collagen genes are shaded.

alternatively spliced from the mRNA [113–116]. Therefore, the protein synthesized from the gene must vary considerably in structure.

The *COL13A1* gene is more than 130 kb in size and contains 42 exons [117,118]. The first exon encodes the 5′-untranslated region, a short cytoplasmic domain, and the transmembrane domain (Table 11). The last exon starts with the translational stop codon and contains only the 3′-untranslated sequence. Exons coding for uninterrupted collagenous sequences start with complete codons for glycine, except for exon 3, which starts with a split codon for glycine. Exon 3 is 8 bp long (Table 11) and is the shortest exon found in collagen genes known to date. The most frequent exon size is 27 bp (a total of 10 exons). Four exons are 54 bp, four are 45 bp, and the rest are 36, 63, 81, and 153 bp in size.

Four exons in the COL1 domain, two exons in the NC2 domain, and four exons in the COL3 domain are alternatively spliced in human tissues [118]. Exons that are alternatively spliced in mouse and human tissues are not always the same [116]. The alternatively spliced exons can be present or absent in any combination, but there are some common splice variants. The alternative splicing of exons 14 and 15, which code for the NC2 domain, shows tissue-specific differences that are conserved in mouse and human tissues.

Types XV and XVIII

Collagen types XV and XVIII are expressed in the basement membrane zones of many organs [119,120]. Both contain large N-terminal and C-terminal noncollagenous domains connected by a central triple-helical segment, which consists of 9–10 collagenous domains interrupted by short noncollagenous sequences [21,121,122]. The N-terminal noncollagenous domains of both collagens each contain a TN motif, and seven of their collagenous domains share sequence similarity. The C-terminal noncollagenous domains of the two collagens are highly conserved with 55% identity in nucleotide sequence. Of interest is that a fragment of the C-terminal noncollagenous domain of type XVIII collagen, endostatin, has been shown to be an angiogenesis inhibitor [123].

Human α1(XV) and mouse α1(XVIII) collagen genes are similar in size and exon-intron organization [124,125]. The *COL15A1* gene is 145 kb long and contains 42 exons and the *Col18a1* gene is 102 kb long with 43 exons (Table 12). The two genes have 25 exons of nearly identical sizes, and the similarity even extends to the size of some introns. For

[1]Data are from Hägg et al. [124], and Rehn et al. [125].

[2]UT: untranslated region; SP: signal peptide; COL: collagenous domain; NC: noncollagenous domain; NC1′, the alternative N-terminal domain that contains sequence homologous to frizzled proteins; TN: thrombospondin N-terminal motif.

[3]Alternative promoter

[4]Collagenous domain without Gly–X–Y imperfection.

example, the first intron in both genes is very short (71 and 89 bp), whereas the second intron is exceedingly long (50 and 55 kb). The *Col18a1* gene contains one more exon (exon 3) than the *COL15A1* gene. Exon 3, located more than 50 kb downstream from exon 1, corresponds to an alternative promoter and also contains an internal splice donor site. Transcription from the alternative promoter together with the utilization of alternative splice donor sites results in two different N-terminal sequences, a short form with a 239-residue noncollagenous sequence and a long form with an additional 247 residues, which contains a cysteine-rich sequence homologous to that found in frizzled proteins [119,126]. Transcription from the upstream promoter gives rise to a third kind of α1(XVIII) chain with a different signal peptide and N-terminal noncollagenous sequence.

The central collagenous regions of the *COL15A1* and *Col18a1* genes are encoded by 25 and 29 exons, respectively. Eight exons in the *COL15A1* gene and 13 exons in the *Col18a1* gene encode uninterrupted collagenous domains, of which only one in each gene is 54 bp long. The other exons are 27, 36, 63, 72, and 81 bp in size, all being integers of 9 bp. However, the two genes do have exons of different sizes. For example, the *Col18a1* gene has four 27-bp exons, whereas the *COL15A1* gene has no 27-bp exons. In addition, the *COL15A1* gene contains an 81-bp exon not found in the *Col18a1* gene, whereas the *Col18a1* gene has a 72-bp exon not found in the *COL15A1* gene. In both genes, split codons are found in two consecutive exons that code for the collagenous domains.

The TN motif in the N-terminal noncollagenous domain of each gene is encoded by a large exon of about 550 bp that starts with a split codon. This is in sharp contrast to the exon structures of TN motifs in other collagen genes, which are encoded by multiple exons. The last three exons encoding the C-terminal NC1 domain are highly conserved between type XV and XVIII collagen genes, consistent with the high sequence similarity between the NC1 domains of the two collagen types.

Type XVII

Type XVII collagen, a component of hemidesmosomes in the skin basement membrane zone, is another collagen type with a transmembrane domain [127,128]. The α1(XVII) collagen chain consists of an intracellular noncollagenous domain at the N-terminus, a transmembrane segment, and an extracellular collagenous domain [129].

The *COL17A1* gene is approximately 52 kb long and contains 56 exons. The translation start site is located in exon 2 [130]. The intracellular domain is encoded by exons 2–17, with exon 17 also coding for the transmembrane segment (Table 13). Exons 18–56 code for the extracellular domain, which comprises 15 uninterrupted collagenous domains separated by short noncollagenous sequences.

[1] Data are from Gatalica et al. [130].

[2] Abbreviations: UT: untranslated region; ICD: intracellular domain; TM: transmembrane domain; NC: noncollagenous domain; COL: collagenous domain.

Exons 18 and 47 encode noncollagenous sequences only, and exon 56 also contains a noncollagenous sequence at the C-terminus of the chain. The largest collagenous domain of 242 amino acids is encoded by exons 19–34. The remaining collagenous domains are relatively short, ranging from 15 to 45 amino acids. A total of 17 exons encode only uninterrupted Gly–X–Y sequences, of which 15 exons are multiples of 9 bp in size. The exon sizes do not show the 54 bp exon pattern, the most frequent size being 36 bp. The most unusual feature is that all exons encoding collagenous sequences begin with a phase I split codon, in which the intron is found between the first and second base of the codon.

CONCLUDING REMARKS

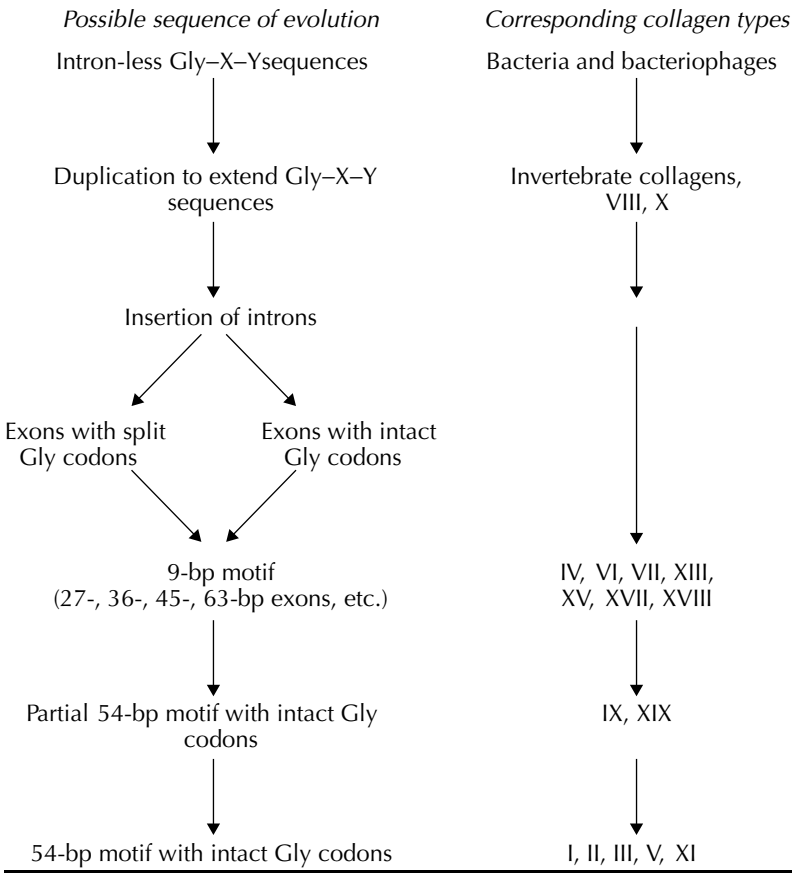
The unusual exon-intron structures of the genes for collagens have stimulated speculation as to how the genes evolved (Table 14). As pointed out by Engel [131] and Engel and Bächinger [131a], short sequences coding for Gly–X–Y tripeptides characteristic of collagens are found in bacteria and bacteriophages, organisms whose genomes do not contain introns. Therefore, one assumption as to how the genes evolved is to say that codons for repetitive Gly–X–Y tripeptides were first duplicated to extend and then separated by the insertion of introns. The introduction of introns occurred by two major mechanisms. One provided exons with split codons for glycine. The other mechanism provided exons with intact codons for glycine. Because the exons began either with intact or split glycine codons, a 9-bp motif appeared to develop, with exons of 27-, 36-, 45-, 54-, and 63-bp exon sizes. The exons gradually evolved toward more uniform structures in which a 54-bp motif was established and in which the exons began with intact glycine codons.

ELECTRONIC DATABASES

DNA sequences of many human collagen genes have been completely determined and are available in the public database <http://www.ncbi.nlm.nih.gov/Entrez/>. These include *COL1A1* (Accession no. AF017178), *COL1A2* (AF004877), *COL2A1* (L10347, AC004801), *COL4A5-COL4A6* (AL034369, AL109943, AL031177), *COL6A1–COL6A2* (AP001759, AJ011932), *COL7A1* (L23982, AC005903), *COL8A1* (AC024938), *COL9A2* (AF019406), *COL9A3* (AF026801), *COL10A1* (AL121963), *COL11A2* (U32169, AL031228), *COL12A1* (AL096771, AL080250), and *COL18A1* (AL163302).

For other collagen genes, only partial sequences or sequences of the complete exon/intron boundaries are available. These include *COL4A1* (M36963, M26576–26550), *COL4A3* (AF218541), *COL4A4* (Y17396–Y17443), *COL9A1* (AF036110–AF036130), *COL13A1* (M68974–M69010), *COL15A1* (AF052956–AF052975), *COL17A1* (U76564–U76604), *COL19A1* (AB004584–AB004688, AB004634).

TABLE 14. Possible Scheme for the Evolution of Exons Coding for Collagens



Partial sequences of many collagen genes can also be found in the "htgs" database of unfinished Human Genome sequences, which consist of unordered DNA pieces. These include *COL3A1* (AC066694), *COL4A1* (AC016380), *COL4A2* (AL159153), *COL4A4* (AC073149), *COL5A1* (AP001160), *COL5A3* (AC008742), *COL6A3* (AC025933, AC025895, AC025878), *COL8A1* (AC024938), *COL8A2* (AC012141), *COL9A1* (AC067861), *COL15A1* (AL354923), *COL16A1* (AL355514), *COL17A1* (AL360170).

RECENT DEVELOPMENTS

Since the completion of this chapter, the draft human genome sequences have appeared (see *http://www.ncbi.nlm.nih.gov/*, *http://genome.cse.ucsc.edu*, and *http://www.ensembl.org*). Many of the human collagen genes have been completely sequenced and hence their precise sizes and exon-intron structures are now known. However, there are still gaps in many collagen gene loci.

Two new collagen types have been identified. The complete cDNA sequences of the chick α1(XX) and human α1(XXI) chains have shown that they both belong to the FACIT collagen subfamily [176,177]. The *COL21A1* gene is located on human chromosome 6p11-12. Complete cDNA or genomic sequences of four additional collagen chains have been characterized [178] (and Manuel Koch, personal communication). The collagen gene family thus consists of at least 25 types.

ACKNOWLEDGMENT

Part of the work described here was supported by research grants NIH AR38912 and GM43852. The authors gratefully acknowledge a careful list of corrections and suggestions for this chapter by the editors.

Chapter 3

Elastin and the Microfibrillar Apparatus

Joel Rosenbloom and William R. Abrams

Department of Anatomy and Histology, School of Dental Medicine, University of Pennsylvania, Philadelphia, Pennsylvania 19104

INTRODUCTION

The physiologic function of many tissues requires that they possess elastic properties. Thus, the vertebrate body is encased in a deformable skin, and during systole the work of the heart is absorbed by expansion of the great vessels, which then elastically recoil during diastole, maintaining the blood pressure and assuring continuous perfusion of the tissues. These elastic properties are largely due to the presence of elastic fibers in the extracellular matrix. Although the elastic fibers may quantitatively comprise only a relatively small but important proportion of the total weight of some tissues, such as the skin (2–4%), in others, such as the large arteries and certain specialized ligaments, they are major components and may comprise greater than 50% of the dry weight. In the light microscope, the highly refractive elastic fibers are difficult to identify unequivocally with conventional stains such as hematoxylin/eosin and must be identified by characteristic staining reactions, such as those with orcein, resorcin-fuchsin, tetraphenyl porphinate, or other multicomponent stains [1,2]. Although these stains are relatively specific for elastic fibers, they do not provide unequivocal identification, and immunolocalization and ultrastructural analysis may be necessary. Electron microscopic examination of elastic fibers has revealed that they are comprised of two morphologically distinguishable components [3–5] (Fig. 1). The amorphous component, so named because it usually does not possess any apparent repeating structure or banding pattern, is quantitatively the larger portion, composing upward of 90% of the mature fiber. The microfibrillar component, as its name implies, is found as small fibrils approximately 10–12 nm in diameter, located primarily around the periphery of the amorphous component but, to some extent, interspersed within it. Although the exact composition of the microfibrils remains to be defined, they contain several glycoproteins [6], including fibrillin [7]. The name "elastin" has been reserved for the protein that makes up the amorphous portion of the elastic fiber and is primarily responsible for its elastic properties.

Early work on the histochemistry and chemical and physical properties of elastin has been reviewed by Partridge [8]. The present chapter focuses on the proteins and encoding genes of the elastic fiber.

CHARACTERIZATION OF ELASTIN

Isolation and Purification of Elastin

Because of the extensive cross-linking of elastin and its resultant great insolubility under all conditions in which there is no appreciable cleavage of peptide bonds, early purification methods employed relatively nonspecific and fairly harsh conditions, such as extraction of tissues with 0.1 M NaOH at 98 °C for 30 to 60 minutes [9], or repeated autoclaving in water until no further protein was solubilized. The resulting insoluble residue of these procedures was operationally taken to be elastin. However, the vigorous extraction procedures may result in significant peptide bond cleavage in the elastin, as well as destruction of the microfibrillar component. Milder methods have been developed in which the elastin polypeptide chains are recovered largely intact and which yield a protein fraction derived at least partially from the microfibrillar component. In one procedure that has been used and frequently adapted, the tissue is first extracted with 5 M guanidine, which removes the soluble collagen, glycoproteins, and proteoglycans, followed by digestion of the remaining contaminating insoluble collagen with highly purified bacterial collagenase [10]. At this stage, the elastic fibers contain amorphous and microfibrillar components, while no collagen or other proteins can be visualized in the electron microscope. The peripheral microfibrils are then solubilized by a second extraction with 5 M guanidine containing β-mercaptoethanol, leaving an insoluble elastin residue. The soluble proteins in this fraction are rich in acidic and other hydrophilic amino acids as well as being unusually rich in cysteine. Electrophoretic analyses have demonstrated that this fraction is a complex mixture of proteins and glycoproteins, some of which are derived from the microfibrillar component (see below) [6,11].

Although the amino acid composition of insoluble elastin prepared from several tissues by guanidine extraction is similar to that of elastin prepared by hot alkali extraction, this milder procedure may not be adequate for removal of all contaminating proteins and glycoproteins from tissues containing smaller proportions of elastin, and additional steps have been added in other purification schemes [12]. These have included extraction with detergent solutions, digestion with other proteolytic enzymes, such as trypsin, against which elastin is resistant, and reaction with cyanogen

Connective Tissue and Its Heritable Disorders, pages 249–269

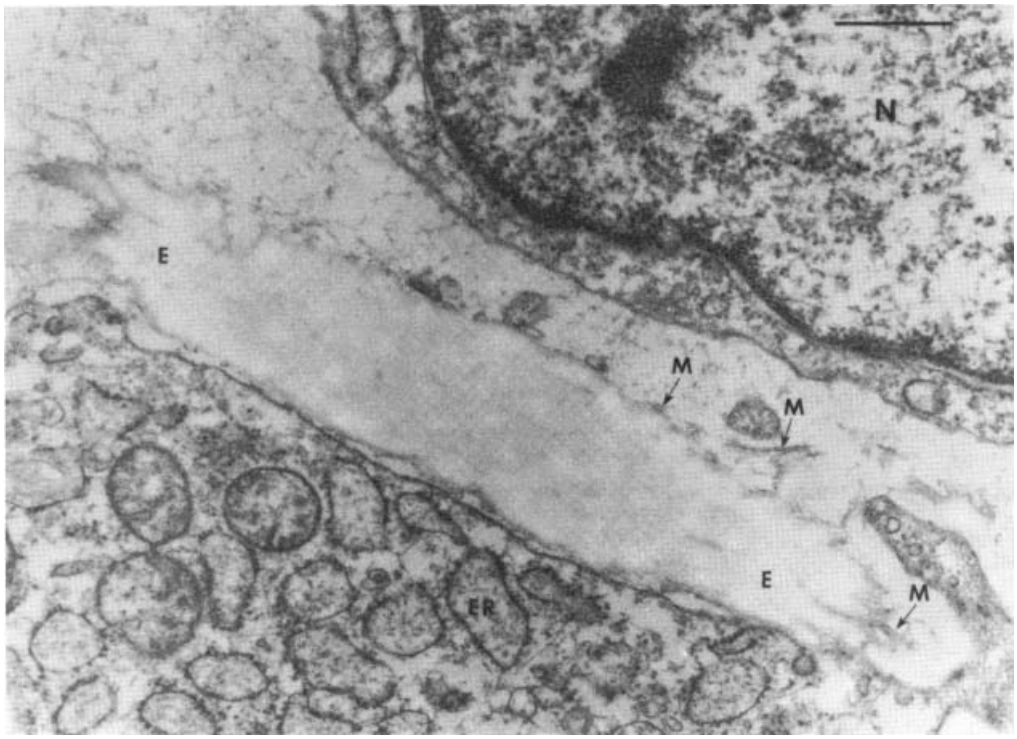

Figure 1. Electron micrograph of 15-day chick embryo aorta. A forming elastic fiber is situated between two cells; the nucleus (N) of one and the endoplasmic reticulum (ER) of the other are marked. bromide in formic acid because it is generally agreed that most elastins contain no methionine (for exceptions, see Table 1). Depending on the starting tissue, one or another of these modified procedures should be suitable for preparing acceptable elastin comparable in purity to that prepared by the classical hot alkali treatment.

Occurrence of Elastin

Early work on the analysis and characterization of elastin was carried out largely on samples isolated from ligamentum nuchae or the aorta of mammals [8]. Consistent with its unique physical properties, the amino acid composition of elastin is peculiar, consisting of approximately 33% glycine, 10–13% proline, and more than 40% other hydrophobic amino acids. There are very small amounts of hydrophilic or charged amino acids. The amino acid composition is sufficiently similar to that of collagen to have suggested that it may be an unusual form of collagen. Although thorough analyses have clearly shown that this is not the case, there is limited evidence for a distant homologous relationship at the amino acid sequence level [13].

A very extensive survey of the occurrence and amino acid composition of elastin throughout the animal kingdom was carried out by Sage and Gray [14]. Analyses were performed on samples, mostly from the aorta and related vessels, from representative species of all vertebrate phyla and a number of invertebrate phyla. The elastin was purified by a relatively nondegradative procedure involving defatting of the tissue, extraction with a concentrated guanidine solution containing β-mercaptoethanol, and, finally, autoclaving. Where they could be compared, the resulting preparations had amino acid compositions very similar to that of elastin prepared using alkali extraction, cleavage with cyanogen bromide, or digestion with proteolytic enzymes. The results appeared very clear-cut with respect to the distribution of elastin within the vertebrate phyla. Elastin was found in every vertebrate species examined except for those in the *Agnatha* (jawless fish or cyclostomes). Later studies on the lamprey identified a novel protein, lamprin, that shares some chemical and physiologic features with elastin but is clearly distinct from it [15,16]. Although the amino acid compositions of all elastins have similar general characteristics in that they contain desmosines (cross-links characteristic of elastin) and are rich in glycine, proline, and hydrophobic amino acids and poor in hydrophilic ones, there is significant variation in composition among species within a phylum and considerable variation among phyla. Representative compositions are given in Table 1, which also contains some analyses of Starcher and Galione [12], who used a modified isolation method including digestion with CNBr. In contrast to previous results obtained solely with mammalian and avian elastins, in which histidine, methionine, and cysteine were found to be absent, these amino acids were found in the elastins of many reptiles, amphibians, and fish. Consideration of the changes in composition during evolution suggests that the earliest elastin was similar in amino acid composition and cross-linking to that of mammalian elastin, although there has been a progressive increase in hydrophobicity with evolutionary time. This trend toward greater hydrophobicity may be related to a parallel change in systolic blood pressure, which also increases from a low of 30 mm Hg in fish and

amphibians to 120–150 mm Hg in mammals and birds. Hydrophobic effects may play a major role in the mechanism of elastin fiber formation and rubber-like elasticity.

Sage and Gray [14] did not find elastin in any invertebrate species, either by chemical or histologic methods, and this suggests that the earlier histologic identifications of elastin in invertebrates, based on characteristic staining reactions, were probably in error. It is true that other rubber-like proteins such as resilin [17], abductin [18], and an octopus elastomer [19] occur in the invertebrates, but they are not related to elastin because they do not contain characteristic desmosine cross-links and have distinctly different amino acid compositions.

Identification of Tropoelastin and the Primary Structure of Elastin

Although elastin can be partially solubilized by nonspecific hydrolysis with weak acids or alkali, the resulting peptides (called α-elastin when oxalic acid is used) are very heterogeneous and difficult to resolve because of their similarity in amino acid composition and chemical properties. This greatly limited sequence analysis to a few dipeptides, such as Ala–Leu and Leu–Ala [20]. The major significant achievements before the late 1960s were the elucidation of the structure of the desmosine cross-links by Partridge and his colleagues [21] and the demonstration that these were derived from lysine residues [22,23].

A major advance in elastin chemistry came about with the isolation of a soluble protein clearly related to elastin. It had been observed in nutritional studies involving trace metals that animals on a copper-deficient diet suffered aneurysms of the aorta and other defects that could be attributed to a decreased content of the amorphous component in their elastic fibers. This led to the isolation of a soluble polypeptide from the aorta of copper-deficient pigs [24]. The relationship of this protein, now called tropoelastin, to insoluble elastin was solidified by the work of Sandberg et al. [25], who showed that its amino acid composition was very similar to that of insoluble elastin except for the absence of cross-links and a corresponding increase in lysine residues. The total lysine content is 38 residues/mol in tropoelastin compared with about 6 residues/mol in mature elastin. Peptide maps obtained by pancreatic elastase digestion demonstrated that although insoluble elastin and the soluble protein tropoelastin share a number of peptides, there are peptides that are unique to each because of the retention in tropoelastin of many lysine residues. Tropoelastin has been isolated from copper-deficient chicks and calves and from lathyritic animals [26–29] (lathyrism being induced by feeding animals β-aminopropionitrile, an inhibitor of lysyl oxidase, the enzyme responsible for initiating cross-link formation). In addition to their similarity in amino acid composition, the tropoelastins from all species share a number of features, including a molecular weight of 72,000–74,000, unusually high solubility in concentrated solutions of short-chain alcohols, and a negative temperature coefficient of solubility in salt solutions [30,31]. This last property leads to the phenomenon of coacervation, or phase separation, of tropoelastin from a cold solution when the temperature is increased to greater than 25 °C.

The peptides resulting from tryptic digestion of porcine tropoelastin have been fractionated by ion-exchange chromatography and sequenced by automated Edman degradation [32,33]. Two classes of tryptic peptides were found: (i) small ones, rich in alanine, which are derived from regions that will form the cross-links; and (ii) larger peptides rich

in hydrophobic residues, which are derived from the regions responsible for the elastic behavior. Two of the small peptides, Ala–Ala–Ala–Lys and Ala–Ala–Lys, are repeated six times per mole of tropoelastin, while several others are repeated twice. As shown later by sequencing of cDNA (see below), these small peptides are spaced throughout the tropoelastin, being separated by the larger hydrophobic segments. Within some of the larger hydrophobic peptides, smaller limited repeats are discernible. Such repeating sequences have raised the possibility of a secondary helical structure, the β-spiral, peculiar to elastin in a portion of the molecule [34], but considerable evidence supports the concept that elastin is largely a random coil [35–37]. The sequences of the larger peptides derived from porcine tropoelastin show that although glycine constitutes approximately one-third of the residues in elastin, it is not found regularly as every third amino acid and there are numerous occurrences of glycine residues being adjacent to one another, unlike in the sequences found in collagen. However, chick tropoelastin does contain a collagen-like stretch of 17 Gly–X–Y triplets, of which most are Gly–Val–Pro [13]. Presumably, this region cannot form a collagen triple helix because proline is usually in the third rather than second position. However, this finding raises the possibility that the collagens and elastin do have a distant homologous phylogenetic relationship. Nevertheless, the apparent marked difference between chick and porcine tropoelastin, as well as differences in the amino acid composition of many other elastins (Table 1), suggests that exact interspecies homology is low. Presumably, such variation may occur because there are many ways to form a random coil, probably the major factor in the properties of elastin, and selective constraints are less than for ordered proteins. As noted, there is a preferential occurrence of prolyl residues on the amino side of glycine, with proline found only rarely on its carboxyl side.

BIOSYNTHESIS OF ELASTIN

The isolation and characterization of tropoelastin from copper-deficient animals suggested that this 72 kDa polypeptide was a soluble intermediate in the biosynthesis of insoluble elastin. To delineate the role of tropoelastin in the biosynthetic pathway, tissues and cells that rapidly synthesize elastin were incubated with radioactive amino acids, and the soluble labeled proteins were extracted and characterized [38,39]. Tropoelastin was identified by polyacrylamide gel electrophoresis in sodium dodecyl sulfate, by its solubility in aqueous alcohol solutions, by its labeling pattern with various amino acids, by its resistance to cyanogen bromide degradation, and by immunoprecipitation with affinity-purified antibody to insoluble elastin. Additional evidence for the legitimate role of tropoelastin as a biosynthetic intermediate came from the observation that when isolated [^{14}C]lysine-labeled porcine tropoelastin was incubated with fresh preparations of normal newborn pig aorta, labeled desmosines, as well as lysinonorleucine and merodesmosine, could be recovered [40]. It was found that the intracellular pathway appears to be the classical one (i.e., synthesis on membrane-bound polysomes, transport to the Golgi apparatus, and packaging into secretory vesicles) followed by a number of secreted proteins [41], and approximately 20 minutes were required for the synthesis of the tropoelastin molecule and its secretion into the extracellular matrix [42]. Agents such as brefeldin A, monensin, and colchicine, which disrupt the pathway at various points, inhibit secretion significantly [39]. Furthermore, when elastogenic cells were treated with bafilomycin A1, a vacuolar H^+/ATPase inhibitor that prevents acidification of the *trans*-Golgi network and endosomal compartments without disrupting intracellular organelle formation, tropoelastin secretion was diminished and intracellular accumulation of tropoelastin was detected in the *trans*-Golgi network and small secretory vesicles [43]. These results suggest that, after exiting the Golgi, tropoelastin may be targeted to an acidic compartment prior to transport to the cell surface.

Although some of the prolyl residues in tropoelastin are hydroxylated posttranslationally, unlike the case of collagen, in which hydroxyproline stabilizes the triple helix and inhibition of hydroxylation inhibits secretion [44–46], inhibition of hydroxylation of proline in tropoelastin does not inhibit the rate of tropoelastin secretion, and the function of hydroxyproline, if any, in tropoelastin is unknown [39,47]. It has been suggested that ascorbic acid, a cofactor in the hydroxylation reaction, although not altering the synthesis of tropoelastin, markedly inhibits the accumulation of insoluble elastin [48]. It is conceivable that ascorbic acid mediates an increase in the degree of prolyl hydroxylation of tropoelastin, which interferes with fibrillogenesis and/or stabilization of elastic fibers. It is interesting that elastin isolated from aortas of Marfan syndrome patients shows considerably increased levels of hydroxyproline. It has been suggested that this may explain, at least in part, some of the compromised tensile strength properties of the aortas of Marfan patients [49], but the relation of this finding to mutations in fibrillin (see below) is not clear. Also, unlike the fibrillar collagens, tropoelastin is incorporated without proteolytic cleavage into the insoluble fiber [50].

The control of elastin synthesis has been investigated in a number of developing embryonic systems, including chick and sheep aorta and sheep nuchal ligament. In these systems, measurements of functional elastin mRNA by *in vitro* translation have demonstrated a strong correlation between messenger levels and the rate of elastin synthesis in the tissue, suggesting that the rate of synthesis is controlled by the mRNA level [51–54]. Northern hybridization experiments using cloned elastin cDNA as probe demonstrated that the functional mRNA levels are a reflection of the actual levels and confirmed the conclusion that the rate of elastin synthesis is largely controlled by the level of elastin mRNA [55,56]. In these Northern hybridization experiments, the probes hybridized to a 3.5 kb message, consistent with there being 2.5 kb of coding sequence, corresponding to about 800 amino acids, and an approximately 1.0 kb 3′ untranslated segment (see below). These results, considered collectively, strongly support the proposition that tropoelastin is the primary elastin gene product.

Cross-Linking

A critical feature of the elastic fiber, crucial to its proper function, is the extensive extracellular cross-linking of tropoelastin. This cross-linking is mediated by the enzyme protein-lysine 6-oxidase (lysyl oxidase; EC 1.4.3.13), which oxidizes selective lysine residues in peptide linkage to α-aminoadipic δ-semialdehyde (trivial name allysine). This is the same enzyme involved in collagen cross-linking, and its isolation, purification, assay, and properties are discussed in detail by Kagan [57]. Experiments using highly purified preparations of lysyl oxidase and pure collagen or elastin have demonstrated that the enzyme functions better on insoluble forms of the substrates. Thus, preincubation of soluble collagen to allow aggregation, or of tropoelastin to allow coacervation, results in increased oxidation by a

given amount of enzyme. This observation is consistent with the finding that a substantial amount of lysyl oxidase is associated with insoluble fibers (possibly with microfibrils) in the connective tissue matrix. The enzyme-substrate complex can be visualized using fluorescently tagged antibody against lysyl oxidase, and the enzyme can be extracted using high concentrations of urea, with retention of enzymatic activity upon removal of the urea by dialysis. When fibroblasts are grown in culture under conditions in which the majority of the collagen is secreted into the medium, lysyl oxidase also is found largely in the incubation medium, comparatively little being associated with the cell layer. These findings suggest that the enzyme acts in the extracellular space.

The course of cross-link formation in elastin is similar to that in the collagens, but hydroxylysine and histidine residues are not involved because there are none in mammalian and avian elastins, and some of the final products of the series of aldol, and aldimine condensations, the desmosines, are absent from the collagens. There are two bifunctional cross-links: dehydrolysinonorleucine, formed from one residue of allysine and one of lysine, and allysine aldol, formed from two residues of allysine. Their structures and those of the desmosines are shown in Figure 2 (for a review of cross-linking in collagen and elastin, see [58]). Dehydrolysinonorleucine also occurs as the reduced, and thus stabilized, secondary amine lysinonorleucine. Allysine aldol, shown as the dehydrated aldol, may be hydrated *in vivo*. A trifunctional cross-link, dehydromerodesmosine, which is also shown in Figure 2, may also be present in the reduced form *in vivo*. Although desmosine and isodesmosine are tetrafunctional, it is likely that each cross-link normally joins only two chains [59]. The lysine residues that serve as cross-links in elastin occur as pairs, mainly in polyalanine sequences, and, in contrast to the variability seen in the hydrophobic domains, there is strict conservation, especially in the numbers of residues between lysines. The conformation of the alanine-rich cross-linking domains is essentially α-helical [60], and the lysine residues are always separated by two or three alanines. In an α-helix, each residue is related to the next by a translation of 1.5 Å along the helix axis and a rotation of 100°, forming a rod-like structure with side chains extended outward in a helical array.

Thus, the side chains of amino acids separated by two or three residues in the linear sequence are spatially close to one another on the same side of the helix, whereas side chains of amino acids separated by one or four residues are situated on opposite sides of the helix and are unlikely to make contact (Fig. 3). These positional considerations have suggested that a critical step in the cross-linking pathway is the formation of a bifunctional "within chain" cross-link intermediate, which then condenses with another bifunctional intermediate on a second chain to form the tetrafunctional desmosine cross-links [61]. Alternatively, they could form by several routes by the repeated addition of single residues of lysine or allysine, with dehydromerodesmosine as an intermediate. Overall, desmosine formation requires an oxidation (loss of two protons). Perhaps there is a balance in the reduction of dehydrolysinonorleucine and dehydromerodesmosine.

Insofar as is known, all reactions subsequent to the oxidative deamination of lysine are spontaneous. Whether they occur essentially randomly between residues in the highly mobile elastin chains or in an ordered manner remains to be proven. In a very illuminating paper [62], Mecham and co-workers have presented strong chemical evidence that a major cross-linking site is formed through the association of sequences encoded by exons 10,19, and 25, and that three chains are joined by one desmosine and two lysinonorleucine cross-links. The data indicate that domains 19 and 25 join two chains by a desmosine cross-link, while domain 10 of a third chain bridges domains 19 and 25 through lysinonorleucine cross-links. It should be noted that domains 19 and 25 contain three lysine residues that can participate in cross-link formation. These findings, together with the high degree of sequence conservation for these three domains, suggest that these regions may have an important function in nucleating polymerization and alignment of tropoelastin monomers. Table 2 shows that there is an approximate balance of the various cross-links and cross-link precursors in mature elastin. About four of the lysine residues found in tropoelastin remain unaccounted for in elastin, either because of losses during analysis or because of their possible involvement in other unidentified derivatives (see below). The

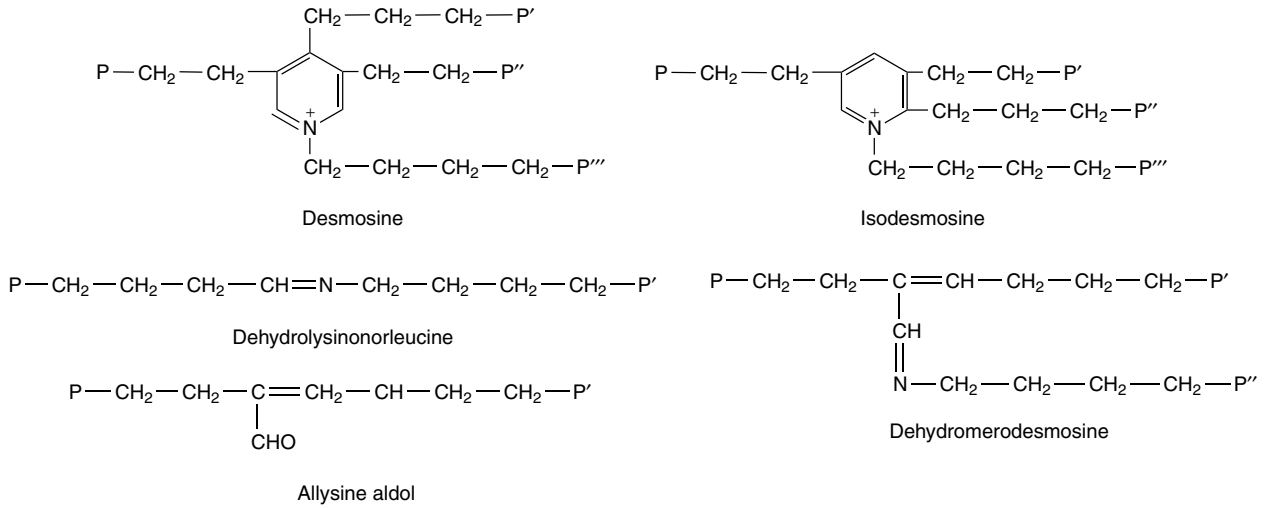

Figure 2. Structure of elastin cross-links.

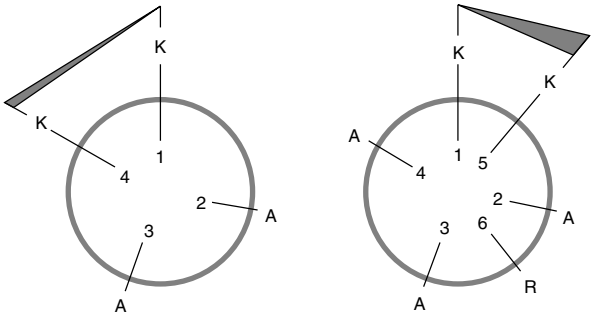

Figure 3. Cross-sectional view of the cross-linking regions of elastin containing lysine (K) and alanine (A) residues drawn as an α-helix. The polypeptide main chain forms the inner part of the helix, with side chains extending outward in a helical array. When the sequences found in elastin are substituted into the side chain positions, beginning with position 1, it can be seen that lysine side chains in the 4 or 5 position are close to the side chain of lysine 1 and able to form the ''within chain'' cross-link that is the precursor of the tetrafunctional desmosine cross-link. If lysines were to be in positions 3 or 6, they would be on the opposite side of the helix from lysine 1 and, hence, could not interact with it. Position 6 is frequently occupied by a phenylalanine or tyrosine residue.

TABLE 2. Numbers of Cross-link and Cross-link Precursors in Mature Elastin

Cross-link	Lysine Equivalents (Residues/mol Tropoelastin)
Desmosines	15
Merodesmosine	2
Lysinonorleucine	3
Allysine aldol	6
Allysine	2
Lysine	6
Total Residues	34

net result is a highly insoluble polymer in which some type of interchain lysine-derived cross-link occurs about every 65–70 residues as calculated from the cross-link content and mechanochemical properties [63], in good agreement with the sequence data discussed below.

BASIS OF ELASTIC PROPERTIES

Elastic recoil is a critical property of several tissues and organ systems. For example, during an average lifetime, the elastic fibers in the aortic arch undergo more than a billion stretch/relaxation cycles. Because the turnover of elastin appears to be quite low [8], individual fibers can conceivably last a lifetime. The rather amazing durability of the elastic fiber suggests that the elastomeric force results not from the stressing of chemical bonds, which could result in progressive deterioration, but rather results, upon stretching, from a decrease in the number of conformations accessible to the cross-linked polypeptide chains. The increase in the number of conformational states upon removal of the stretching force provides the free energy for elastic recoil. In other words, like a true rubber, the elasticity is due to an increase in entropy upon relaxation. This view has been essentially proven by a number of physical studies [64–66].

Structural Models

Determination of the structure of elastin, other than the primary amino acid sequence, has proven difficult. Elastic fibers yield only broad rings upon X-ray diffraction, indicating little short-range order [67]. Similarly, study of individual elastic fibers by polarized light microscopy has indicated that elastin is optically isotropic [63]. Nuclear magnetic resonance studies on elastin have clearly shown that the backbone chain of the protein is highly mobile, with individual residues in the chain able to rotate freely in three dimensions [35,37]. Although these observations have indicated that elastin exists predominantly in a kinetically free, largely random coil network, some observations suggest regions of local order in the molecule. For example, circular dichroism spectra indicate that the alanine-rich sequences in the cross-link regions are in an α-helix [60]. In addition, some electron microscopy studies have suggested the presence of a filamentous substructure. Whereas freeze-fracture electron microscopy of unstretched elastin revealed an isotropic structure, samples that had been stretched 150–200% appeared to contain ordered filaments approximately 13 nm in diameter [68]. Negative staining of insoluble elastin revealed a filamentous network, with the filaments having a diameter of 3–5 nm [69].

Urry and co-workers have carried out a variety of physical/chemical studies on α-elastin (peptides solubilized by hydrolysis of insoluble elastin with oxalic acid solutions) as well as on a number of synthetic polypeptides, some of which are found as limited repeating units in elastin, such as (Val–Pro–Gly–Val–Gly) and (Val–Ala–Pro–Gly–Val–Gly) [34,70]. Based on these studies and the observation that under certain circumstances elastin polypeptides can be found in thin filaments, Urry has proposed that a significant proportion of the hydrophobic segments of elastin are found in a structure designated a β-spiral, a loose water-containing helical structure in which β-turns act as spacers between suspended segments of the helix.

From these rather different views of the elastin molecule — one in which the polypeptide chain is largely a random coil and the second in which it is a β-spiral — two alternative structural models have been developed to explain the elastic force

In the first model, elastin is a network of largely random chains within the elastic fibers, which behave according to the classical theory of rubber elasticity [36,64–66]. In this model, the collection of chains has a random distribution of end-to-end chain lengths and displacement from this position of highest entropy provides the source of the elasticity.

In contrast, in the second model, Urry [34,70] has proposed that the entropic elasticity derives from the β-spiral structure, with essentially fixed end-to-end chain lengths. The peptide segments suspended between the β-turns are free to undergo large-amplitude, low-frequency rocking motions called librations. Upon stretching, there is a decrease in amplitude of the librations, which results in a large decrease in the entropy of the segment, and this provides the driving elastomeric force for return to the relaxed state.

It should be emphasized that while these models differ in their molecular conformational details, both rely on an entropy-driven mechanism to provide the elastomeric force. Further studies are required to prove whether either of these models is uniquely valid or whether the structure of elastin incorporates some features of each. Figure 4 presents a diagrammatic representation of cross-linked elastin in the

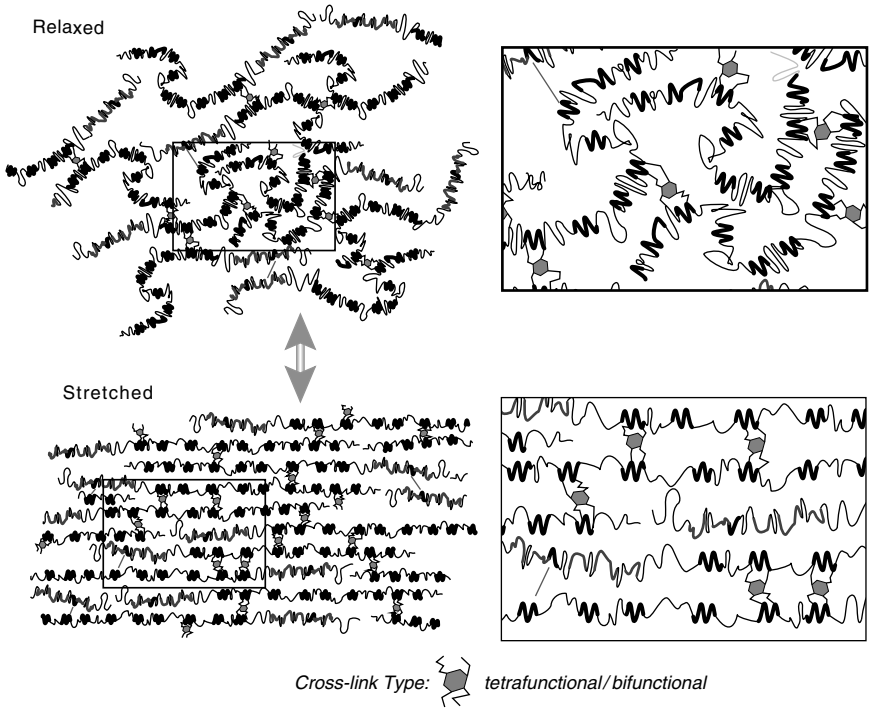

Figure 4. Diagrammatic representation of cross-linked elastin in relaxed and stretched states. The potential cross-linking domains, some of which are probably in an α-helical conformation, are in bold. For clarity of presentation, only some of the tetrafunctional desmosine or bifunctional cross-links are shown. The hydrophobic domains in the relaxed state are probably largely random coils, although limited portions may exist in a β-spiral conformation (see the text). In the stretched state, the imposed force brings the chains into relative alignment and limits their conformational freedom.

relaxed and stretched states. The figure emphasizes the limitation of motion and relative alignment of the chains imposed by the stretching force. Upon release of the force, the chains return to a more random state.

MOLECULAR BIOLOGY OF THE ELASTIN GENE (MIM 130160)

Analysis of Elastin cDNA

Analysis of cDNAs from a number of species, including man, have demonstrated that tropoelastin consists predominantly of alternating hydrophobic and paired lysine-rich domains, as indicated by open and filled boxes in Figure 5 [71–76]. The segregation of domains is conveniently visualized when the amino acid sequences are analyzed for the distribution of hydrophobic and hydrophilic segments. A graphic display of such an analysis (Fig. 5) permits ready identification of the lysine-rich potential cross-linking sequences, which project as relatively hydrophilic regions. Thus, the domain structure of the protein is a reflection of the gene in which functional domains are usually segregated into separate exons. In general, there is good agreement at the nucleotide and encoded amino acid sequence levels among the mammalian elastins, which differ, however, in multiple segments from those of the chicken. Among mammalian elastins, most amino acid substitutions are of a conservative nature, but some significant differences do exist. For example, near the center of bovine and porcine tropoelastins, a pentapeptide, GVGVP, is repeated 11 times, but this repeat segment is considerably different and more irregular in human tropoelastin and is replaced in rat tropoelastin by GVGIP [73–76]. Similarly, in human tropoelastin a hexapeptide, GVGVAP, is repeated seven times, but only five times, with conservative substitutions, in bovine tropoelastin, and it is absent altogether from rat, tropoelastin [74]. However, in the rat, several expansions of hydrophobic segments have occurred, significantly increasing the overall size of rat tropoelastin (cf. the sizes of rat and human exons 7, 22, and 30 in Fig. 6). In contrast, the length of cross-linking segments is highly conserved, indicative of a strong functional requirement (Fig. 6). Four exons (nos. 6,10,12, and 35) have a dual hydrophobic and cross-linking character, which suggests that they may play a critical role in molecular assembly of the cross-linked fiber. The chicken sequence is quite homologous to the mammalian sequences for the first 302 and last 57 residues [72]. In the central portion, although some segments are homologous, major differences do exist, which appear to be due to insertion, duplication, and deletion events. The most striking of these differences is the occurrence in chicken tropoelastin of the repeating tripeptide $(GVP)_{12}$ (residues 374–409), which is not found in the mammalian elastins. The presence of this repeating tripeptide suggests that elastin may have a distant evolutionary relationship to collagen. All in all, these observed variations suggest that a particular number of amino acids and a precise sequence in a given hydrophobic region are not critical to the adequate functioning of the molecule, although there appears to be a strong tendency to conserve the size of the total polypeptide chain to 750–800 residues.

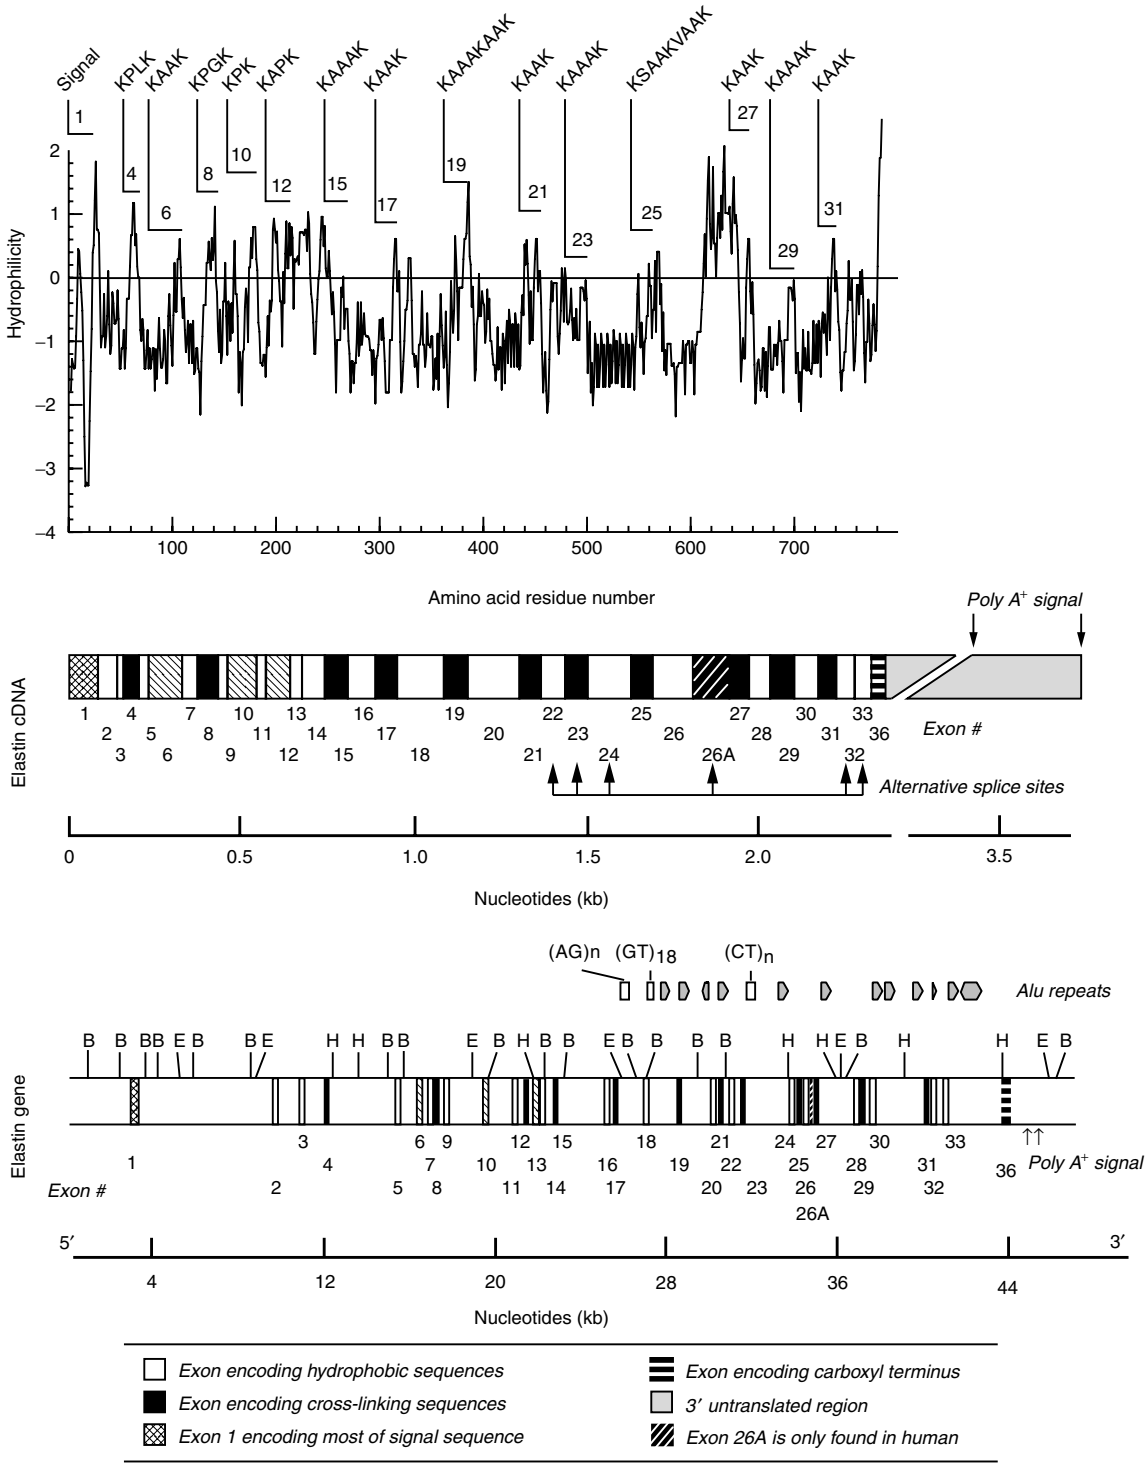

Figure 5. Diagrammatic representation of human elastin gene and cDNA and hydrophilicity/hydropathy analysis of tropoelastin by the method of Kyte and Doolittle [146]. The cDNA is divided into exons, which are numbered starting at the 5′ end and correspond to the gene diagram. To preserve a numbering system consistent with homologous sequences in the bovine and rat genes, the most 3′ exon has been designated 36 in the human gene. Exons 34 and 35, found in other species analyzed, are absent from the human gene. Restriction sites indicated in the gene are: B, *Bam*HI; E, *Eco*RI; H, *Hind*III. In the hydropathy diagram, the hydrophilic peaks correspond for the most part to potential cross-linking domains, and the numbers above these peaks identify exons. In the single-letter amino acid code, K corresponds to lysine, P to proline, L to leucine, A to alanine, G to glycine, S to serine, and V to valine. Most of the signal sequence is encoded by exon 1.

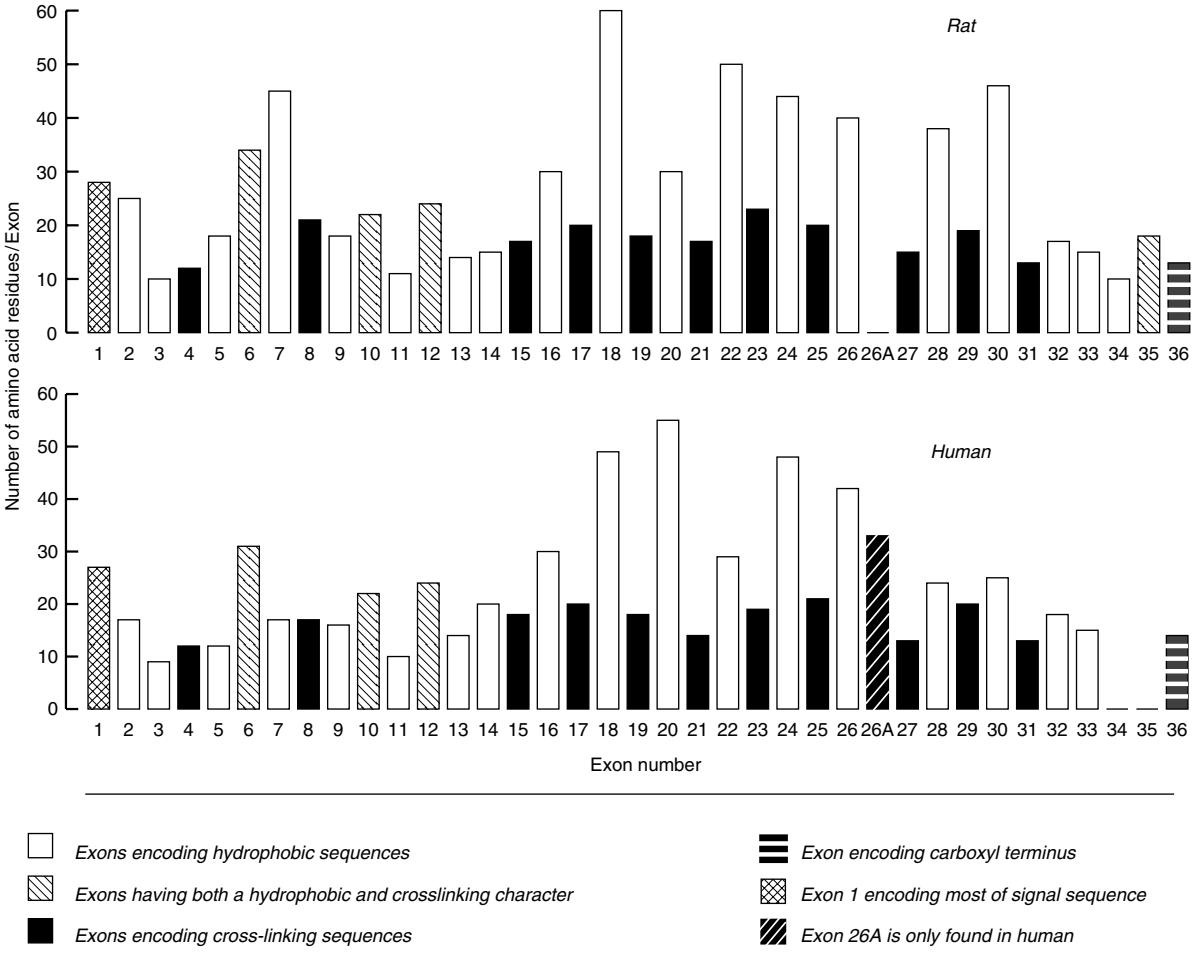

Figure 6. Comparison of exon sizes in elastin genes. Sizes for the entire human gene were determined by cDNA and genomic sequence analysis. The rat exon sizes were estimated by comparison with the human and bovine genes and by using the hydropathy analyses illustrated in Fig. 5, making the assumption that sequences encoding hydrophobic and cross-linking domains are segregated in separate exons.

In the cross-link domains, the lysines usually occur in pairs. This arrangement supports the suggestion that a given desmosine/isodesmosine serves to join only two tropoelastin molecules rather than the four that are theoretically possible. It is also apparent that these potential cross-linking sequences are not uniformly distributed and occur at shorter intervals in the first 200 residues, resulting in an asymmetry of the molecule. In addition, the potential cross-linking sequences in the first 200 residues frequently contain a proline or other residue between the lysine residues instead of the usual alanine. The conformation of tropoelastin in the cross-linking segments containing alanine residues is largely α-helical, which is undoubtedly important in the alignment and condensation of the lysine residues in desmosine formation. In contrast, the presence of proline residues clearly disrupts α-helix formation, and these segments may participate in cross-links other than the desmosines, such as the difunctional cross-link lysinonorleucine. The 200-residue amino-terminal segment of tropoelastin ends in a tyrosine-rich region, the function of which is unknown, but it may be involved in interaction with other matrix macromolecules or with the cell surface, mediating alignment of the molecules within the fiber. In two instances (exons 19 and 25), three lysines are found near one another, and they may have a critical role in cross-linking the tropoelastin, as discussed above.

There is rather extensive (80%) nucleotide homology in the 3′ untranslated region (Fig. 7), suggesting that this region may have a function either in stabilizing the mature mRNA or even in modulating translation. Additionally, all the cDNAs encode an unusual, highly conserved carboxyl terminal segment, GGACLGLACGRKRK, the highly basic character of which suggests that it may interact strongly with acidic microfibrillar proteins (see below).

Analysis of the Elastin Gene

The elastin gene exists as a single copy, and the human gene has been localized to chromosome7q11.1-q21.1 [77]. Analysis of the entire bovine and human genes has demonstrated that rather small exons (27–186 bp) are interspersed between large introns, resulting in a low coding ratio of about 1:20 [73–75,78] (Fig. 5). Another important characteristic is that hydrophobic and cross-link domains of

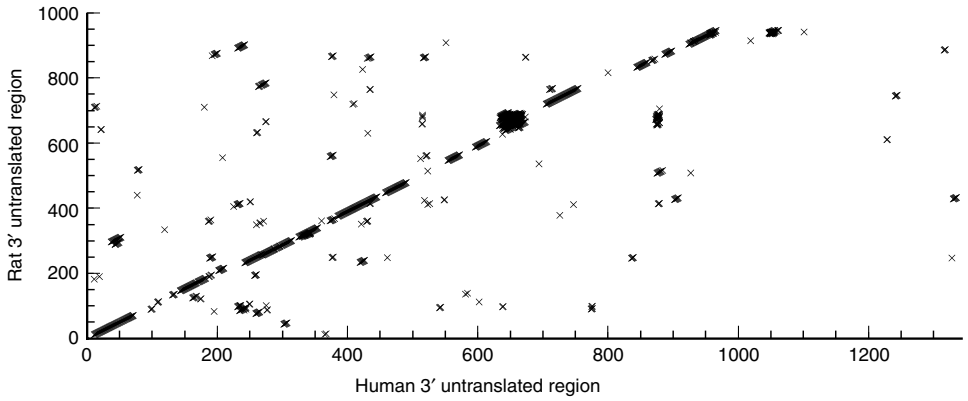

Figure 7. Comparison of the 3′ untranslated region of rat and human elastin cDNAs. The sequences were compared using the Wisconsin Sequence Analysis Package Program Compare, Version 8, Genetics Computer Group. Note the striking regions of homology scored on the diagonal.

the protein are encoded by separate exons, so that the domain structure of the protein is a reflection of the exon organization of the gene. Although all the exons are multiples of three nucleotides and glycine is usually found at the exon/intron junctions, the exons do not exhibit any regularity in size as is found in the fibrillar collagen genes. All exon/intron borders have the same phasing. Thus, the second and third nucleotides of a codon are included in the 5′ exon border, while the first nucleotide of a codon is found at the 3′ border of the previous exon. This consistent structure permits extensive alternative splicing of the primary transcript in a cassette-like fashion while maintaining the reading frame. Sequences homologous to exons 34 and 35 in other species are not found in the human gene. It is not presently known whether this difference has any functional significance.

The introns contain an unusual abundance of *Alu* repeat sequences clustered in introns toward the 3′ end of the gene (Fig. 5). In the human genome, *Alu* repeat sequences occur about once every 4 kb of genomic DNA, but in the elastin gene these sequences occur at about four times that frequency. In addition to *Alu* repeats, rather long stretches of alternating purines or pyrimidines occur. The function, if any, of these repetitive elements remains to be determined, but they may facilitate recombinational events. In other human genes, deletions apparently mediated by recombination between repetitive sequences have occurred, resulting in hereditary diseases, and evidence for genomic instability in regions of human DNA enriched in *Alu* repeat sequences has been presented [79–82], but no mutations in the human elastin gene, possibly mediated by similar mechanisms, have been found. However, disruption of the elastin gene has been shown to be the cause of supravalvular aortic stenosis, either as an isolated finding or as part of the Williams syndrome, and some of these cases may involve such recombinations (see Chapter 12, this volume). Several informative polymorphisms have been identified by PCR and restriction endonuclease analysis in the human elastin gene [83].

Alternative Splicing of Elastin mRNA

Analysis of bovine, human, and rat elastin cDNAs has clearly demonstrated alternative splicing of the primary transcripts [73–76,84]. In most cases, splicing occurs in a cassette-like fashion in which an exon is either included or deleted, but occasionally a splicing event may divide an exon, as in the case of exons 24 and 26. Both hydrophobic and cross-link domains are affected, so that two cross-link domains may be brought into apposition (deletion of exon 22) or the interval between cross-link domains may be increased (deletion of exon 23). It is not known whether these variations have any functional significance, although clearly a tighter or looser fiber network could be produced. S1 nuclease mapping experiments using elastin mRNA isolated from developing bovine and rat tissues have demonstrated that alternative splicing of some exons occurs frequently, but in the majority of cases it is infrequent [75,77]. These experiments indicate that splicing may be developmentally controlled and tissue-specific. They also suggest that the splicing pattern in the adult may differ significantly from that occurring during development. Translation of the alternatively spliced transcripts would result in significant primary sequence variation among individual tropoelastin molecules, and it is likely that such differences explain the finding of variant isoforms of tropoelastin in several species [85,86]. It remains to be determined whether variation in splicing occurs in disease situations. The possible variable expression of exon 26A in human elastin is particularly intriguing, because this segment, which is highly hydrophilic and atypical in amino acid sequence for elastin, appears rarely to be expressed under normal circumstances. Inclusion of this sequence might substantially alter the properties of the elastic fiber.

Regulation of Elastin Gene Expression

Sequence Analysis of the Promoter and Transcription Initiation

The elastin promoter does not appear to contain a functional canonical TATA sequence, and it is likely that the CAAT sequences are not functional (Fig. 8). The proximal promoter region is G + C-rich (66%), with a high frequency of CpG dinucleotides [75,78]. These features have previously been associated with the promoters of so-called "housekeeping genes," but more tissue-specific genes are being found to possess them as well, so that the distinction between these classes is now breaking down [87]. As with many genes, the elastin promoter contains a remarkable constellation of potential binding sites for transcription regulatory factors indicative of complex regulation (Fig. 8). These binding sites include multiple SP1 and AP-2 binding

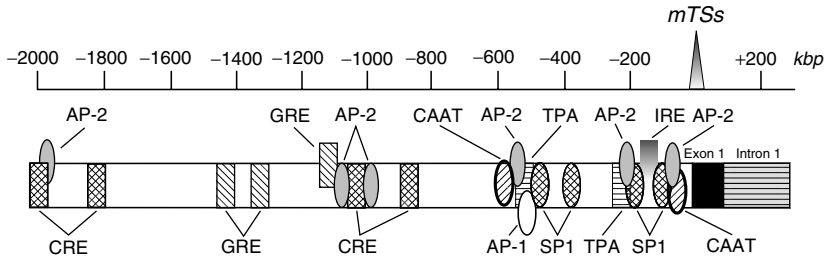

Figure 8. Schematic representation of the human elastin gene promoter. CRE, cAMP responsive element; GRE, glucocorticoid responsive element; IRE, insulin-like growth factor responsive element; TPA, 12-O-tetradecanoylphorbol-13 acetate; AP-1, activator protein responsive element–1; AP-2, activator protein responsive element–2; CAAT, CAAT–box; SP1, a GC–rich-binding zinc finger protein responsive element; mTSs, multiple transcription start sites.

sites, glucocorticoid-responsive elements (GRE), and TPA- and cyclic AMP (CRE)-responsive elements. The absence of a TATA box in the putative promoter region suggested that there may be multiple sites of transcription initiation, and S1 protection and primer extension analyses have shown this to be so [78]. It remains to be determined whether the multiple initiation has any physiologic significance and whether there is any relationship between the position of transcript initiation and the pattern of alternative splicing.

Functional Analysis of the Human Elastin Promoter

Transient transfection analyses using promoter/reporter gene constructs have demonstrated the presence of multiple positive and negative regulatory elements within 5.2 kbp of the elastin promoter and indicated that the core promoter necessary for basal expression is contained within the region −128 to −1 [88]. The positive regulatory and core promoter activities may be explained, at least in part, by the presence of multiple SP1 and AP-2 binding sites within these regions, which may act as general enhancer elements, and DNAse footprinting experiments have indicated that SP1 and AP-2 sites interact with their respective *trans* factors. This notion is supported by the observation that deletion of the segment −134 to −87 containing three putative SP1 binding sites reduced the activity to 10–20% of the reference −475 to −1 construct.

Significantly, when tissues of transgenic mice utilizing 5.2 kbp of the human elastin promoter were analyzed, there was reasonable correspondence between expression of the endogenous gene and the transgene within the tissues [89]. Nevertheless, because of some inconsistencies between the expression of transfected genes and the endogenous gene, collectively these observations suggest that not all elements for tissue- and development-specific expression of the elastin gene reside within the 5.2 kb promoter region tested. It has been observed in a number of genes, including three collagen genes, that the first intron contains segments that act as enhancer elements of promoter activity. Comparison of the intron sequences of the bovine and human elastin genes revealed regions of strong homology only in the first intron, which may contain regulatory elements.

Modulation of Expression by Hormones, Growth Factors, and Cytokines

Transcriptional Regulation

The elastin promoter contains three putative glucocorticoid response elements, which may be functionally active because glucocorticoids have been shown to increase elastin expression in the developing chick aorta, fetal rat lung, and cultured fetal bovine nuchal ligament fibroblasts [90–92]. However, it is clear that glucocorticoid effects on elastin production are context-dependent and that the hormones can either up- or down-regulate elastin production depending on the developmental stage and tissue. For example, glucocorticoids have been reported to down-regulate elastin synthesis in normal cultured human fibroblasts but not in those from keloids [93]. Direct proof that any of these effects are regulated at the transcriptional level is still lacking, and glucocorticoids may act through modulation of production of one or more cytokines.

Insulin-like growth factor-I (IGF-I) has been shown to significantly enhance elastin gene expression in rat neonatal aortic smooth muscle cells both *in vitro* and *in vivo* [94]. Transient transfection experiments with elastin promoter constructs demonstrated that the IGF-I was acting at the transcriptional level and that the responsive element was located between bases −195 and −136 [95]. Gel shift and DNA footprinting analyses suggested that IGF-I acts by releasing a transcriptional repressor, possibly SP3, which binds to an element located between −137 and −127 [96]. This sequence has homology to a retinoblastoma control element. In contrast, recombinant tumor necrosis factor-α (TNF-α) markedly suppressed elastin mRNA levels in cultured human skin fibroblasts and rat aortic smooth muscle cells and also suppressed the expression of elastin promoter constructs in transiently transfected cells, again indicating regulation at the transcriptional level [97]. Detailed analysis of the mechanisms involved strongly suggested that the down-regulatory effect of TNF-α was mediated through *jun/fos* binding to an AP-1 site located at −223 to −229 in the elastin promoter. Basic fibroblast growth factor has also been shown to reduce significantly elastin mRNA and protein levels, and the effect appears to be achieved at the transcriptional level [98]. Conflicting evidence has been presented on the effects of interleukin-1β. One group reported that the cytokine inhibited elastin synthesis and decreased elastin mRNA steady-state levels in cultures of a particular subtype of neonatal rat lung fibroblast [99], whereas another group reported that the cytokine increased elastin gene expression in cultured human skin fibroblasts, apparently at the transcriptional level [100].

Post-Transcriptional Regulation

Although it is quite possible that general transcription factors interact with other factors yet to be identified to achieve regulation of elastin expression, other mechanisms

must be considered. Presently, there is no evidence for translational control of elastin mRNA, but strong evidence for either up- or down-regulation of tropoelastin expression through alteration of elastin mRNA stability by several modulators has been presented. Elastin production, as determined by ELISA, was increased approximately threefold when porcine smooth muscle cells were incubated with TGF-β1 [101]. Although the human promoter may respond to TGF-β [102], the major effect of TGF-β is to increase elastin production by message stabilization [103,104]. Treatment of cultured human fetal lung fibroblasts with TGF-β1 produced a more than tenfold increase in elastin expression with no alteration in transcription but with increased message stability. A phosphatidylcholine-specific phospholipase C, a protein kinase C, and a *ras* -superfamily member are involved in mediating elastin message stabilization [104,105]. When cultures of elastogenic fetal bovine chondrocytes were exposed to 10^{-7} M 12-O-tetradecanoylphorbol-13-acetate (TPA), tropoelastin mRNA levels decreased greater than tenfold, and this was paralleled by a decline in the production of tropoelastin [106]. As determined by nuclear-runoff assay and transient transfection with a human gene promoter-CAT construct, tropoelastin transcription was unaffected by exposure to TPA. The half-life of tropoelastin mRNA in control cells was estimated to be about 20 hours, but exposure to TPA reduced this to 2.2 hours. Similarly, 10^{-7} M 1,25-dihydroxyvitamin D_3, a rather high unphysiologic dose, produced a marked decrease in steady-state and functional levels of tropoelastin mRNA, but transcription was not affected [107]. Collectively, these data indicate that tropoelastin expression can be controlled by post-transcriptional mechanisms.

Potential Morphogenetic Role of Elastin

The potential morphogenetic role of elastin may be critical in developing strategies to treat complex destructive diseases affecting the lung. Masaro and Masaro [108] reported that treatment with all *trans*-retinoic acid reversed the destructive effects of pancreatic elastase administration in a rat emphysema model. It had previously been shown that retinoic acid could increase elastin production in neonatal rat lung fibroblast cultures [109].

MICROFIBRILS

On electron microscopic examination, the microfibrils are seen to consist of apparently tubular structures, about 10–12 nm in diameter (Fig. 1), which possess different staining properties and susceptibilities to enzymatic digestion from amorphous elastin [6]. At high resolution, the microfibrils appear in cross-section as an outer electron-dense shell surrounding an inner lucid core and in longitudinal section as a beaded chain, suggesting that they may be composed of more than one protein. Apparently similar microfibrils are present in many tissues, including those that contain abundant elastin as well as those in which there is no visible or immunoreactive elastin, such as the ocular ciliary zonule and the periodontal ligament. In the dermis, the microfibrillary bundles that connect the deep dermal elastic plexus with the dermo-epidermal junction region are seen to consist of microfibrils indistinguishable from those associated with elastic fibers. In their superficial distribution, no immunoreactive elastin is associated with them, but as they traverse the dermis they are associated with an increasing amount of amorphous elastin.

Because of their insolubility and apparent complexity, chemical characterization of the microfibrils progressed slowly until the late 1980s. The problem of identifying structurally important components was compounded by observations localizing small amounts of several proteins, including amyloid P and decay-accelerating factor, to the elastic microfibrils by immunoelectron microscopy [110,111]. Although they may have some functional role, it is very unlikely that any one of them is a major structural component of the microfibrils. Nevertheless, within the last few years, great progress has been made in the convincing identification of certain proteins as structural components. These structural proteins can conveniently be divided into two groups based on their molecular size: those larger than 125 kDa and those smaller than 115 kDa. Table 3 lists these proteins and provides some distinguishing features, including their human chromosomal location. The larger-molecular-weight group consists of three gene families: fibrillins, latent TGF-β binding proteins (LTBPs), and fibulins. Significantly, these three families share protein domain motifs, as discussed below.

Fibrillins

The largest of these proteins and quantitatively the most important are the fibrillins, 350 kDa glycoproteins that form an integral part of the microfibril structure [7,112]. Electron microscopic images of monomeric fibrillin prepared from human fibroblast cultures reveal an extended flexible molecule approximately 148 nm long and 2.2 nm wide. Multiple fibrillin molecules probably align in a parallel head-to-tail fashion to form a major portion of the microfibrils. Molecular cloning studies have so far identified two distinct homologous human genes encoding fibrillin proteins, one (*FBN1*) located on chromosome 15q15–q21 and the other (*FBN2*) on chromosome 5q23–q31 [113,114]. Analysis of the deduced fibrillin amino acid sequences demonstrated that the proteins contain multiple repeats of a sequence motif previously observed in epidermal growth factor, having six conserved cysteines [115]. Many of these repeats contain consensus sequences that have been associated with calcium binding. A second motif containing eight cysteines, originally found in LTBPs [116], has also been identified in the fibrillins (Figure 9 compares the structures of the FBNs and LTBPs.) Of great interest is the report of a protein in jellyfish having extensive homology to mammalian fibrillin, which identifies fibrillin as a very ancient protein that evolved well before elastin [117].

Latent TGF-β-binding Proteins

Several members of the LTBP family have been cloned and shown to contain repeating domains similar to those found in FBN1 and FBN2 [116,118–122]. TGF-β is always secreted as a latent complex, and in some cases this complex is bound to an LTBP [119,121]. To date, four distinct LTBPs have been cloned and characterized, ranging in size from 125 kDa to 205 kDa. The function of LTBPs remains to be determined since it is clear that they are not necessary to maintain TGF-β in an inactive form and they do not appear to bind mature TGF-β. Although LTBPs may facilitate the secretion of TGF-β or binding of the inactive complex to the cell surface where activation takes place, they are also found as free proteins associated with components of the extracellular matrix. Immunohistological studies have localized both LTBP1 and LTBP2 to microfibrils in elastic fibers, strongly suggesting that one or more of the LTBPs may be a component of these fibrils [119,122]. Within the matrix, the LTBPs may act as a reservoir of TGF-β, which can be

TABLE 3. Microfibrillar Component Proteins

Microfibrillar Protein	Characteristic Features	Human Chromosomal Locus
Fibrillins	350 kDa	
FBN1 (MIM 134797)	Contain EGF and TGF-β- binding protein motifs.	15q15–q21
FBN2 (MIM 121050)		5q23–q31
Latent TGF-β-Binding Proteins (LTBP)	150–205 kDa	
LTBP1 (MIM 150390)	Contain EGF and TGF-β-binding protein motifs.	2p12–q22
LTBP2 (MIM 602091)	Secreted as a complex with latent TGF-β but also found as free proteins.	14q24
LTBP3 (MIM 602090)		11q12
LTBP4		19q13.1–q13.2
Fibulins	100–240 kDa	
FBLN1 (MIM 135820)	Contain EGF and anaphylatoxin motifs.	22q13.3
FBLN2 (MIM 135821)		3p24–p25
Microfibril–Associated Glycoproteins (MAGP)		
MAGP1 (MFAP2) (MIM 156790)	31 kDa; widely distributed in microfibrils.	1p36.1–p35
MAGP2 (MP25) (MIM 601103)	25 kDa	12p12.3–p13.1
Microfibril–Associated Proteins		
MFAP1 (MIM 600215)	Very acidic.	15q15–q21
MFAP3 (MIM 600491)		5q32–q33.2
MFAP4 (MIM 600596)	Frequently deleted in Smith–Magenis Syndrome[1]	17p11.2
MP70 (βig-h3), (MIM 601692)		5q31
Lysyl Oxidase (MIM 153455)	Probably not a structural component.	5q23–q31
Emilin (gp115) (MIM 130660)		Not known

[1]The Smith–Magenis syndrome (MIM 182290) is a multiple congenital anomaly/mental retardation syndrome in which patients manifest a complex phenotype that includes brachycephaly, midface hypoplasia, prognathism, a hoarse voice, growth and mental retardation, speech delay, hyperactivity, and self-destructive behavior. The clinical phenotype ranges from mild to severe.

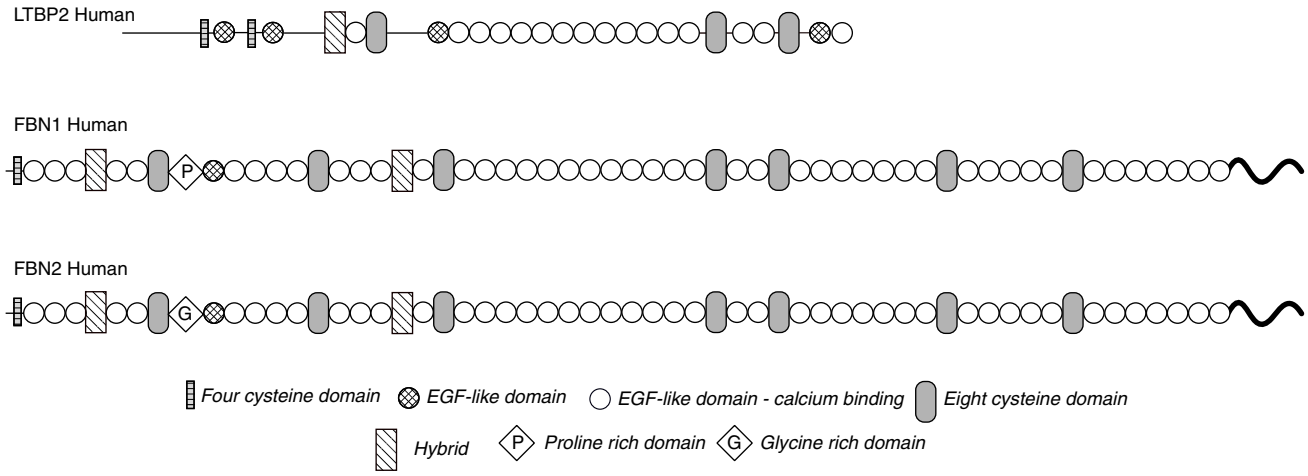

Figure 9. Schematic diagram of the domain structures of the *LTBP* and *FBN* gene families. Schematic representations of the domain structures of human *FBN1* (fibrillin gene found on human chromosome 15), *FBN2* (fibrillin gene found on human chromosome 5), and *LTBP2*. Phylogenetic analysis indicates that the two gene families are related.

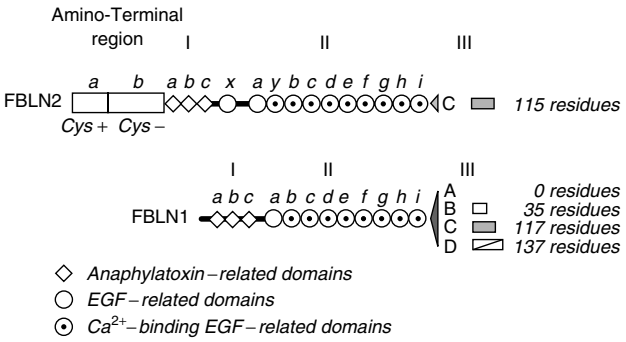

Figure 10. Domain models of fibulins (FBLN)1 and 2. The unique amino-terminal globular region in FBLN2 consists of a Cys-rich (a) and a Cys-free (b) segment. The carboxyl-terminal region III of FBLN1 exists in four alternatively spliced forms, whereas only a homolog of variant C has been detected in FBLN2.

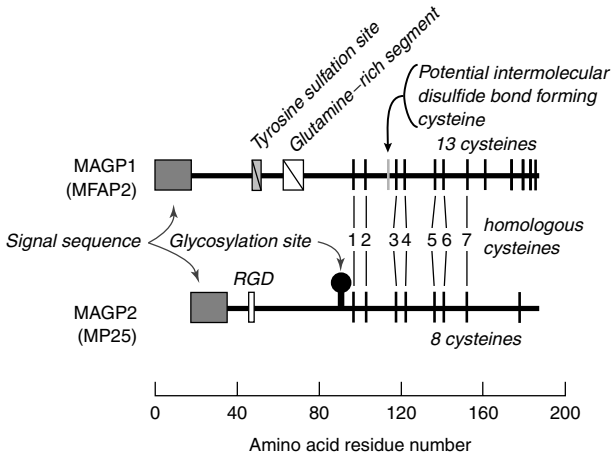

Figure 11. Schematic diagram of the structures of MAGP1, and MAGP2. The unpaired cysteine in MAGP1, which may be involved in intermolecular disulfide bonding, is indicated on the diagram. RGD (Arg–Gly–Asp) indicates a potential integrin receptor binding site.

quickly released and activated in response to various agents, including cytokines and proteases found in the inflammatory response.

Fibulins

The fibulins (FBLNs) are extracellular matrix and blood glycoproteins that can bind fibronectin and can self-associate [123,124]. Molecular cloning has identified two distinct fibulin genes (Table 3). The deduced amino acid sequences reveal that the molecules are modular, having several types of repeated cysteine-containing motifs, including EGF-like and anaphylatoxin-like domains. FBLN1 is alternatively spliced, and four forms have been identified, which differ from one another at their carboxyl termini (Fig. 10). The fibulins are expressed in all major tissues with the exception of the brain, and transcripts are found in fibroblasts and several epithelial, but not endothelial, cells. Fibulin protein is found widely distributed in connective tissues throughout the body. FBLN1 was found to be particularly evident in the basal lamina surrounding smooth muscle cells in blood vessels and in association with elastic fibers in the dermal layer of the skin. However, it did not appear to be associated with the microfibrils that contained fibrillin but was located primarily within the amorphous elastin rather than surrounding it [125].

Other Microfibrillar Proteins

A number of other proteins unrelated to the FBNs, LTBPs, or FBLNs appear to be microfibril constituents. When bovine nuchal ligament, a tissue rich in microfibrils, was extracted with reductive saline, five major bands having M_rs of 340, 78, 70, 31, and 25 kDa were identified upon gel electrophoresis [126]. Molecular cloning of the 25 kDa and 31 kDa components, which were designated microfibril-associated glycoproteins (MAGP), demonstrated that the two share limited regions of homology (Fig. 11) [127,128]. The deduced primary structure of the 31 kDa MAGP1 indicates that it contains two structurally distinct regions; the amino-terminal half of the protein is rich in glutamine, proline, and acidic amino acids, whereas the carboxyl-terminal half contains all 13 of the cysteine residues and most of the basic amino acids.

Further molecular studies have demonstrated that it is highly likely that the 70 kDa component is derived from the 78 kDa protein and, surprisingly, that they are identical to a protein, βig/h3, previously cloned from the lung adenocarcinoma cell line, A549 [129] (see also Chapter 26, Part I, this volume). The 340 kDa component is the bovine homolog of FBN1. The observation that these proteins can be extracted from tissues by several solvents, provided they contain a strong reducing agent, suggests that intermolecular disulfide bonding is an important feature of the association of the polypeptide chains in the fibrils. However, it is also possible that other types of bonds, including those formed by transglutamination, or even derived from oxidation of lysine residues, may be involved. Other candidate microfibril components include the enzyme lysyl oxidase [130], a 115 kDa protein called emilin [131], and several proteins designated microfibril-associated proteins (MFAP) [132–134]. One of the latter, MFAP1, is remarkable in that it is extremely acidic, with glutamic acid comprising 23% and aspartic acid 6% of the residues. The extremely acidic nature of the protein suggests that it may have an important function in the assembly of the very basic tropoelastin molecules.

FIBER ASSEMBLY

Information on fiber assembly is limited, but the notion that secreted tropoelastin molecules simply diffuse onto the surface of growing fibers where they bind and become cross-linked seems inadequate to explain the efficiency of the assembly process, the variable form of elastic fibers in different tissues, and the nonrandom nature of the cross-links [135]. This variability argues for a more directive role of the cell in fiber assembly. It is likely that assembly requires helper proteins both inside and outside the cell. Elastin fibrillogenesis takes place at sites close to the cell membrane, generally in infoldings of the cell surface [136]. Microfibrils are the first visible components of elastic fibers, forming a plexus upon which elastin appears as an amorphous material in discrete loci within each microfibrillar bundle. These amorphous areas gradually coalesce and generate the central core of elastin. The majority of microfibrils are progressively displaced to the outer aspect of the fiber, a position they retain in the mature tissue. The observation that microfibrillar aggregates take the form and orientation of presumptive

elastic fibers suggests that they direct the morphogenesis of elastic fibers by acting as a "scaffold" on which elastin is deposited. This appears to be true not only in developing tissues but also in autografts of regenerating skin [137]. Microfibrils may serve to align tropoelastin molecules in precise register so that cross-linking regions are juxtaposed prior to oxidation by lysyl oxidase.

How secretion of tropoelastin is targeted to sites of elastic fiber assembly remains unknown. The proper folding and trafficking of tropoelastin is thought to be mediated by intracellular chaperones, possibly BiP and FKBP65, which manifests prolyl *cis–trans* isomerase activity [138]. The relationship, if any, of these chaperones, which appear to be localized in early compartments of the secretory pathway, to the 67 kDa elastin-binding protein previously described [139] remains to be determined. Unequivocal identification of the binding protein has not been made, and candidates include the 67 kDa high-affinity laminin receptor, galactosyltransferase, 5′nucleotidase, and several others (for a review, see [140]). Hinek et al. [141] have suggested that the 67 kDa protein is an enzymatically inactive, alternatively spliced form of β-galactosidase, which binds tropoelastin in the endoplasmic reticulum and chaperones its secretion to assembly sites on the cell surface designated by cell-matrix receptors that interact with microfibrillar proteins [139]. At the plasma membrane, tropoelastin may remain bound to the 67 kDa protein until interaction with a microfibril induces the transfer of tropoelastin to the growing fiber. Biochemical studies have shown that the 67 kDa elastin-binding protein is a galactoside lectin and that its affinity for elastin is greatly diminished by interactions with carbohydrates. It is possible that galactosyl residues on microfibrillar glycoproteins provide specific signals for the release of tropoelastin at sites of fiber assembly. Supporting a matrix-assembly function for the 67 kDa protein are studies showing inhibition of elastin fiber assembly by the addition of lactose or galactose sugars to the culture medium of elastin-producing cells [142]. In the presence of lactose, the majority of newly synthesized tropoelastin is prematurely released directly into the medium from the cell layer before it can be transferred to acceptor sites on microfibrils. The 67 kDa membrane-associated protein that specifically binds tropoelastin also binds the hexapeptide Val–Gly–Val–Ala–Pro–Gly (found seven consecutive times in human elastin and five consecutive times in bovine elastin) [139]. The synthetic hexapeptide and tropoelastin are also chemotactic for ligament fibroblasts and monocytes [143]. The 67 kDa protein is associated with two other integral membrane proteins of 61 kDa and 55 kDa. Taken together, these observations suggest that the 67 kDa protein may be an elastin receptor, possibly transmitting a signal to the interior of the cell through association with the 61 kDa and 55 kDa proteins. Such a receptor could be involved in modulating the position of the cell surface where tropoelastin secretion is taking place and/or modulating the association of the cell surface with the growing elastic fiber, thereby affecting the form of the fiber.

Persuasive evidence exists that the carboxyl-terminal end of tropoelastin mediates interactions with microfibrils. This portion of the molecule contains two cysteine residues, which can form a disulfide bond that stabilizes a positively charged pocket suitable for binding acidic microfibrils [144]. This segment binds the 31 kDa MAGP1, and monospecific antibodies directed against either the carboxyl portion of tropoelastin or a domain near the amino terminus of MAGP1 block elastic fiber assembly [145].

RECENT DEVELOPMENTS

Elastin

Previous studies demonstrated that basic fibroblast growth factor (bFGF) decreases elastin gene transcription. Recent studies have provisionally identified the *cis* element and *trans*-acting factors responsible. The bFGF-responsive element has been localized to −564 to −558 of the elastin promoter. The data indicated that bFGF induced expression of the transcription factor Fra1, which binds to the element as a heterodimer with c-Jun to form an inhibitory complex [148]. In other work, Keeley and co-workers have identified a GA-rich sequence in the 3′-UTR of elastin mRNA which is highly conserved in several species, and which preferentially binds proteins found in tissues rapidly synthesizing elastin [149,150]. Since these proteins are particularly abundant when elastin mRNA is stable, they postulated that they may be involved in such stabilization. The GA-rich segment does not resemble other known *cis*-acting 3′-UTR sequences affecting mRNA stability and no other relevant occurrences of the sequence were identified in the data base.

Fibrillins

The genomic organization of the *FBN1* gene has been revised. Previously, the existence of three exons upstream of the exon containing the putative initiating methionine raised the possibility that alternative isoforms varying at their N-termini existed. New data that demonstrate extreme conservation between the human and porcine genes argue against this possibility and for a single translational start site [151].

Much recent work has centered on the interaction of the fibrillins with other components of the elastic fiber. The amino terminal domains of fibrillin-1 and fibrillin-2 have been shown to interact with tropoelastin in solid-phase binding assays [152]. A folded secondary structure of the fibrillin molecules was necessary for binding, which was mediated by ionic interactions involving the lysine side chains of tropoelastin. Mature elastin, the lysine side chains of which form crosslinks, did not bind. These results support the concept that fibrillins play an important role in elastic fiber assembly by binding tropoelastin and perhaps facilitating side chain alignment and crosslinking. Several studies have highlighted the importance of fibrillin/proteoglycan interactions for normal microfibril formation. Decorin interacts with MAGP-1 and fibrillin-1 individually and with both proteins to form a ternary complex [153]. Fibrillin-1 has also been shown specifically to bind heparin/heparan sulfate through both calcium-dependent and calcium independent sites [154]. Inhibition of sulfation or the attachment of glycosaminoglycans to core proteins can result in a significant reduction of the fibrillin network.

Latent TGF-β-binding Proteins

The ability of the members of the LTBP-fibrillin family to associate via their 8-Cys repeats with TGF-β isoforms has been analyzed [155]. TGF-β1 associates with the third 8-Cys repeat of LTBP-1 through the latency-associated peptide (LAP) by direct cysteine bridging. LTBP-1 and LTBP-3 efficiently bound all TGF-β isoforms, while LTBP-4 had a much weaker binding capacity. In contrast, LTBP-2, as well as fibrillin-1 and fibrillin-2, did not bind. A short, specific TGF-β-binding motif that contained a hydrophobic interaction surface was identified in the TGF-β-binding 8-Cys repeats.

Deletion of the *Ltbp2* gene in mice is embryonically lethal, death occurring between E3.5 and E6.5 [156]. Expression could not be detected in E6.5 embryos, but was detected in E3.5 blastocysts. These results imply that LTBP-2 performs a yet undiscovered function in early development, perhaps in implantation. The distribution of LTBP-1 has been examined in cultures of differentiating mouse embryonic stem (ES) cells [157]. During *in vitro* differentiation of embryoid bodies, extracellular fibers containing LTBP-1 colocalize with specific differentiating cell lineages, including endothelium. The results suggested that during differentiation of ES cells, LTBP-1 facilitates endothelial cell organization via a TGF-β-dependent mechanism.

Fibulins

Fibulin-1 and fibulin-2 have previously been identified as basement membrane and microfibrillar proteins with a broad binding repertoire for other extracellular ligands. Two novel fibulins, fibulin-3 and fibulin-4, have been cloned and shown to be most closely related to fibulin-1C [158]. They consist of a C-terminal globular domain III, also shared by the fibrillins, a central rod-like element composed of five calcium-binding epidermal growth factor-like (EG) modules and an N-terminal interrupted EG module which replaces the anaphylatoxin-like modules of the other fibulins. Both novel fibulins are expressed in several human tissues with particularly strong expression in the heart. Immunohistology of adult mouse tissues has shown that fibulin-3, fibulin-4, and fibulin-1 have overlapping but distinct extracellular tissue localizations, with particularly prominent staining of some large and small blood vessels.

EMILINs

The EMILINs (**e**lastin **m**icrofibril **i**nterphase **l**ocated prote**ins**) comprise a new extracellular glycoprotein family. First isolated from chicken aorta, they are now known to be widely distributed in association with elastin and localized at the interface between elastin and microfibrils [159]. Two human EMILINs have been cloned and are characterized by a C-terminal gC1q globular domain, a short collagenous sequence, a long coiled-coil region and a new cysteine-rich N-terminal domain also found in the protein multimerin. The gene for EMILIN-1 was mapped to chromosome 2p23 overlapping the promoter of the ketohexokinase gene [160]. The gC1q domain can form relatively stable homotrimers, which process is followed by the multimeric assembly of disulfide-bonded protomers.

Lysyl Oxidase

Several cDNAs and genes encoding lysyl oxidase-related proteins have been described. These lysyl oxidase-like proteins were identified by overall sequence homology and the presence of conserved domains, including the copper-binding site, and lysyl and tyrosyl residues known to be involved in the formation of the lysyl tyrosyl-quinone cofactor found in lysyl oxidase [161]. Presently, three human lysyl oxidase-related proteins have been identified. Multiple functions previously attributed to lysyl oxidase, such as tumor suppression, cell growth control and chemotaxis, possibly unrelated to amine oxidase activity, may be performed by these or other novel lysyl oxidase-like proteins.

Chapter 4

Glycosylated Matrix Proteins

Dick Heinegård, Anders Aspberg, Ahnders Franzén, and Pilar Lorenzo
Department of Cell and Molecular Biology, Lund University, BMC, plan C12, SE-221 84 Lund, Sweden

INTRODUCTION

Connective tissues have many features in common, including resisting and dissipating mechanical load and providing shape, as well as acting to provide barriers regulating water flow and diffusibility of macromolecules. These common properties are reflected by their composition, many matrix constituents being shared among tissues, and others having similar structural and functional properties.

There are, however, connective tissues with rather distinct properties and, therefore, a partly different composition. One such example is bone, in which the major constituent, hydroxyapatite mineral, is important for tissue properties. At the same time, some of the features of bone, including mineralization and expression of select matrix molecules, are observed in pathology (e.g., in atherosclerotic lesions).

In view of the many common features among connective tissues, we have chosen to focus on cartilage and bone, covering many aspects of connective tissues. It is important to stress that the description is largely representative for other tissues.

Skeletal tissues play key roles in our ability to move and to maintain this function over many years. Rigid bones are thus used as levers, with mobility being contributed by the joints. Articular cartilage plays a fundamental role in providing low-friction movement as well as in absorbing and distributing mechanical load. The shape and organization of the skeletal elements are strictly directed toward achieving optimal function. In development, the shape of the skeleton is largely laid down as a cartilage scaffolding, providing the template for subsequent bone formation. In this process of endochondral bone formation, the cartilage undergoes distinct developmental changes and is eventually replaced by bone, except in the articulating cartilage of the joints.

Bone and cartilage are dynamic tissues, such that there is a continuous turnover in response to altered load and mechanical fatigue. A number of matrix proteins provide key elements in this process as building blocks that are assembled into the intricate organization of the tissue extracellular matrix. Others have roles in catalyzing the assembly process, and yet others send signals back to the cells about the properties of this matrix.

In recent years, an increasing number of cartilage and bone matrix proteins with functions in forming the tissue structure as well as in the remodeling process have been identified. Although our knowledge of specific functions of the particular proteins is somewhat limited, this information is being assembled and provides new insights into tissue properties.

Overall, we can view both cartilage and bone as composite materials. In cartilage, an organic matrix is made up of rope-like structures of collagen II fibers [1–3] that are linked together by a number of collagen-binding proteins. These latter also appear to provide linkage to other matrix constituents. In this fibrous network, large, extremely anionic proteoglycans provide a fixed charge density that maintains a high osmotic pressure, thereby promoting water retention [4–6]. The proteoglycans are also bound to other matrix constituents, including collagen, via a number of interactions.

In bone, the major organic component is collagen I, which forms the structural framework for the deposition of hydroxyapatite mineral, which is the predominant inorganic component. Together, these constituents form the rigid structure of bone. Other matrix constituents play important roles in regulating the deposition and organization of hydroxyapatite, such that there is always a thin layer of nonmineralized osteoid tissue.

An important feature in skeletal biology is a variable, pronounced mechanical load that will induce cellular responses [7–9]. When the load is abnormal, it may accelerate induction of material fatigue. An altered direction or magnitude of the load will result in a modified mechanical environment that induces remodeling of the tissue. In cartilage, this occurs with gradual modifications within the maintained scaffold of the tissue, where the general architecture remains intact, possibly because the collagen fibers play a fundamental role that should not be compromised. The collagen thus only turns over very slowly in comparison with, for example, the large proteoglycans [10]. In bone, on the other hand, remodeling occurs through the removal of the mineralized matrix by specialized cells, osteoclasts, creating a tissue defect that is then filled with new bone by another set of cells, osteoblasts. One consequence of these different modes of turnover is that cartilage changes its composition with aging and in disease, while bone maintains a much more conserved composition, although the total amount of tissue may change when whole tissue segments are replaced at appropriate locations. Thus, in pathological conditions, the most marked feature is an

Connective Tissue and Its Heritable Disorders, pages 271–291

imbalance between the removal and building up of bone, with an overall loss of bone mass.

The increasing understanding of the roles of the many different matrix constituents involved in these processes provides an essential background for understanding the changes occurring in the tissues, with regard to both the formation of new tissue and the modifications of existing tissue.

Cartilage and bone, being rather different in structure and composition, are treated separately below, with the focus being on the noncollagenous proteins in their matrices.

CARTILAGE

The cartilage matrix, as illustrated schematically in Figure 1, consists of a fibrillar network based on collagen fibrils dispersed in an environment of highly negatively charged aggrecan molecules that form large supramolecular aggregates. A number of noncollagenous proteins, often substituted with oligosaccharides, polysaccharides, phosphate, and sulfate, contribute to the properties of the matrix by cross-bridging the various constituents, including the collagen fibrils. Also, among these molecules, some play apparent roles in catalyzing and regulating matrix assembly.

As depicted in Figure 1, the matrix can be divided into domains. The pericellular matrix contains molecules that provide feedback by interacting with cell surface ligands. The territorial domain contains a set of molecules, one of the roles of which is to protect cells and regulate early steps in matrix assembly. The interterritorial matrix, at a larger distance from cells, appears to play a primary role in contributing mechanical properties.

To understand the combined properties of the molecules in the assemblies that constitute the matrix, it is important to know the properties of the individual constituents. Following, is an account of some of the known key features of the various matrix constituents, excluding collagenous molecules, although information is provided on noncollagenous molecules that interact with collagens.

Aggrecan

Aggrecan, the large aggregating proteoglycan in cartilage ($M_r \sim 3 \times 10^6$), and versican (see below) in other tissues, play major roles in providing fixed charge groups that attract counter-ions. Thereby, an osmotic pressure is created in the cartilage, retaining water and restricting water flow [4,11–14]. Thus, the proteoglycan exerts a swelling pressure within the tissue, which is resisted by the collagen network [15]. One consequence of this striving to retain water is that deformation is counteracted and limited when the tissue is loaded. This is of essence for the function of aggrecan in taking up and distributing load over the cartilage tissue and further onto the underlying bone. In fact, the charge density of aggrecan is so extreme that it creates a very high swelling pressure in the tissue [4,13,14]. Over the years, considerable information on the detailed structure of aggrecan, its interactions, and its turnover has been gathered [6,16,17]. Thus, aggrecan contains several structural domains (Fig. 2). The core protein of $M_r \sim 210$ kDa contains an N-terminal domain, G1, that binds specifically ($k_d 10^{-8}$ M) [18] to hyaluronan via a decasaccharide sequence [18,19]. The binding of hyaluronan depends on an immunoglobulin fold, of which G1 contains two. Some information on the folding of these structures and their interaction with hyaluronan can probably be derived from data on TSG-6, another related hyaluronan-binding protein [20]. The binding of aggrecan to hyaluronan is such

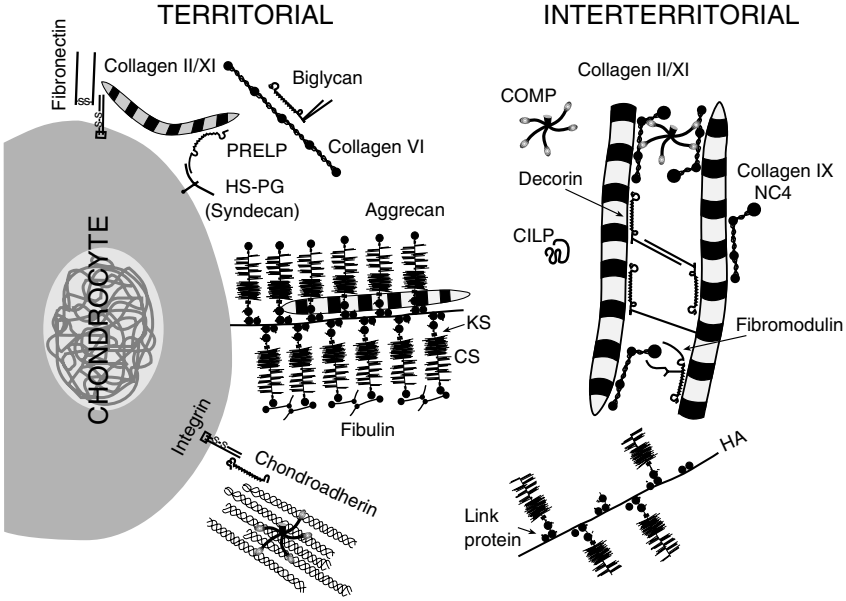

Figure 1. Schematic illustration of the organization of cartilage matrix and its molecular constituents. The composition and organization of the matrix is illustrated. Only those macromolecules are depicted for which there is available information on localization and/or interactions with other matrix constituents. The territorial matrix close to cells contains a number of matrix molecules that interact with cell-surface molecules, including receptors such as integrins. This compartment also includes aggrecan arranged in close association with cells and with collagen fibrils. The interterritorial matrix at a greater distance from cells contains interconnected collagen fibrils and interspersed aggrecan molecules having formed aggregates with hyaluronan. PRELP, proline- and arginine-rich end leucine-rich repeat protein, HS-PG, heparan sulfate proteoglycan; COMP, cartilage oligomeric matrix protein; CILP, cartilage intermediate layer protein; NC4, noncollagenous domain 4.

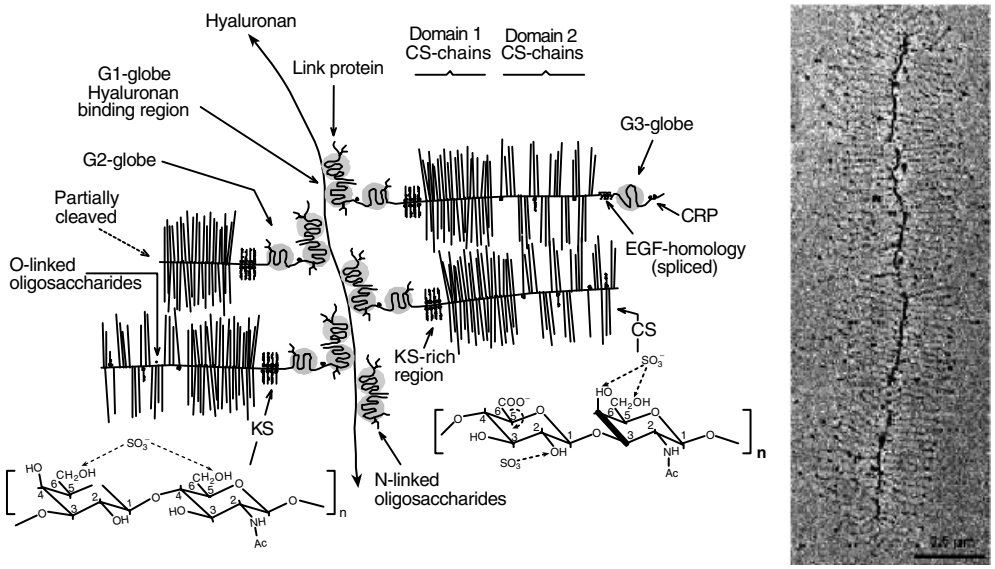

Figure 2. Schematic illustration of the aggrecan aggregate with hyaluronan. Several aggrecan molecules interact with hyaluronan, and the complex is stabilized by link protein. The aggrecan core protein contains glycosaminoglycan chains differently organized toward the N-terminus compared with toward the C-terminus. These glycosaminoglycan chains are composed of a number of repeat disaccharide units (illustrated) for CS approximately 40 and for KS 10–30. A rotary shadowing electron-microscopic picture of the aggregate illustrates the overall dimensions, where each side-chain filament represents an aggrecan molecule. The central core is hyaluronan with bound G1 and link protein. This electron-microscopic picture was kindly provided by Dr. Matthias Mörgelin, Lund University. CS, chondroitin sulfate; KS, keratan sulfate; CRP, complement regulatory-like protein; EGF, epidermal growth factor.

that more than one hundred aggrecan molecules may bind to a single, very long filament of hyaluronan, thereby forming complexes that may reach micrometers in dimension [17]. Such complexes are formed with hyaluronan bound at the cell surface [21], as depicted in Figure 1, as well as in various compartments in the matrix. This binding is stabilized by an additional protein, the link protein, that is homologous to the G1 domain and binds with the same specificity and affinity to hyaluronan [18] and the G1 domain [22,23]. This ternary complex is very stable and functionally not dissimilar to a covalent bond.

A second globular domain, G2, shows extensive homology to the G1 domain but lacks the ability to bind to hyaluronan [17,24,25]. The two domains are separated by a short, extended interglobular stretch of amino acids. This may be cleaved either between the amino acid sequences Pro–Glu–Asn and Phe–Phe–Gly (metalloproteinases) or between Glu–Gly–Glu and Ala–Arg–Gly (aggrecanase, ADAMTS) [26,27] in both normal and pathological turnover. Following G2, there is an extended domain carrying the majority of the some 30 relatively short keratan sulfate chains [28,29]. These chains contain a variable 5–20 disaccharide repeat of galactose and N-acetyl-glucosamine, the latter carrying a 6-O-sulfate group (Fig. 2). The polymer also contains extra sulfate groups at certain galactose residues, with the result that regions of higher charge are present [30]. The majority of the keratan sulfate chains are bound to a polypeptide motif of six amino acid residues in a continuous 23-fold repeat in bovine aggrecan [28,29]. The number of repeats in this domain varies among species [31].

The next major part of the core protein carries chondroitin sulfate chains attached in their reducing termini to serine residues via a xylose followed by a galactose-galactose-glucuronate sequence, which is followed by the repeat disaccharide shown in Figure 2 [32]. This is the domain carrying the majority of the charged groups and, indeed, one function of this part of the proteoglycan is to fix these charged groups in the matrix [4]. Thus, each of these chains contains, on average, some 40 to 50 repeat disaccharides of glucuronate and N-acetyl-galactosamine, the latter carrying an O-sulfate group at the 4 or 6 position [33,34], (Fig. 2). The sulfation pattern varies with age and in disease [35]. The distribution of the approximately 100 chondroitin sulfate chains is variable along this part of the core protein. Thus, two subdomains with somewhat different clusterings of these chains are observed [24,25,36], as indicated in Figure 2. Overall, however, the packing of the charged chondroitin sulfate is high.

There are additional carbohydrate substituents in the form of some 40 mucin type O-glycosidically linked oligosaccharides. These are linked to serine and threonine in the protein core via an N-acetylgalactosamine residue carrying a galactose-sialic acid disaccharide at the 3 position and an N-acetylglucosamine-galactose disaccharide in the 6 position [37]. This galactose is substituted with sialic acid in the oligosaccharide structures, while in keratan sulfate it is extended by a variable number of the repeat disaccharide shown in Figure 2. Interestingly, in fetal life there is little keratan sulfate in aggrecan, and all sites are occupied by the O-glycosidically linked oligosaccharides, totaling some 70 [38]. There appears to be a gradual replacement of these aggrecan molecules by those of the adult type with keratan sulfate through adolescence.

In the C-terminal part of the molecule, the globular G3 domain consists of a variably spliced EGF (epidermal growth factor) homology motif [39], a lectin homology motif, and a complement regulatory protein (CRP)-like

motif [25,36]. Data indicate that the lectin-like region may bind monosaccharides [40]. However, the best characterized interactions are from protein to protein, involving fibulins [41,42] as well as tenascin [43]. The interaction with fibulin involves several calcium-binding EGF repeats in the protein. Both the fibulins and the tenascins have the ability to self-interact to form multimers. Thus, this interaction of the C-terminal domain of the aggrecan may play an important role in linking cartilage molecules into a network, as illustrated in Figure 1. It is of interest to note that the fibulins are present in developing and growing young cartilage [44] but notably absent from adult normal cartilage [42]. Also, adult cartilage contains a much lower proportion of aggrecan containing the G3 domain, apparently as a result of progressive cleavage of the molecule, as indicated in Figure 2. We may therefore assume that this interaction of aggrecan with fibulins represents another molecular complex that primarily has a role in matrix assembly.

A very large complex of many aggrecan molecules bound to hyaluronan in cartilage is likely to have important functions in sequestering molecules in the matrix and in regulating the diffusion of nutrients and molecules participating in the assembly of the matrix, as indicated in Figure 1. It has actually been demonstrated that aggrecan, via its keratan sulfate-rich domain, appears to bind tightly to collagen *in vitro* ($k_d 10^{-8}$ M) [45]. In the tissue, collagen fibers in the pericellular and territorial domains are found located in the interior of the aggregate [45], as illustrated in Figure 1. The binding in the tissue should be much tighter, being multimeric as a result of the multimolecular assemblies in the aggregate and of collagen. It is particularly interesting that aggregates are already apparently formed at the cell surface, being bound to hyaluronan present there [21]. As a consequence, it is likely that the pericellular environment is organized in a way that may be important for promoting matrix assembly.

Aggrecan in Disease

A prominent feature of joint disease is that the levels of aggrecan in articular cartilage are considerably reduced. This happens as a result of the proteolytic degradation of aggrecan molecules, a process in which at least two distinct enzymes appear to be involved. The major activity seems to be that of the so-called aggrecanase, recently shown to be a member of the ADAMTS family of zinc-binding metalloproteinases [46–48]. Apparently, several of these enzymes [49] are responsible for both normal aggrecan turnover and increased turnover upon immobilization of the joint and, particularly, the increased release in many inflammatory processes, such as reactive arthritis [50]. Even though there may be extensive loss of aggrecan from the tissue in such conditions, the process can apparently be reversed since the outcome is usually complete restitution.

Other metalloproteinases that cause release of aggrecan result in a different pattern of cleavage. Thus, enzymes such as stromelysin (MMP-3) cleave between an asparagine residue and a phenylalanine residue in the interglobular domain between G1 and G2 (–Pro–Glu–Asn Phe–Phe–Gly–) [51,52]. Aggrecanase, on the other hand, cleaves between a glutamic acid and an alanine residue in this interglobular domain (–Glu–Gly–Glu Ala–Arg–Gly–) [26,49,51–53]. There are additional cleavage sites in the domain carrying the chondroitin sulfate chains [54]. The relative role of the activity of metalloproteinases such as stromelysin and aggrecanase is not clear, although it may be speculated that they may have different relative activities in different pathological joint conditions.

One consequence of the loss of aggrecan from the tissue, and thereby the loss of fixed charged groups, is that the osmotic environment is altered and the ability to retain water impaired. This causes a less efficient distribution of load over the tissue, and the process may become a vicious circle with impaired ability of the cells to accomplish repair.

In both osteoarthritis and rheumatoid arthritis, loss of aggrecan is a typical finding. However, very early in the process of osteoarthritis, the level of aggrecan appears quite conserved in cartilage. At the same time, the staining of fixed charged groups, by, for example, alcian blue, ruthenium red, and toluidine blue, may be impaired, possibly due to blocking of the polyanionic groups by other newly synthesized matrix proteins laid down in the matrix (P. Lorenzo, M. Bayliss, and D. Heinegård, unpublished).

Versican

Versican is a proteoglycan with a wide distribution among connective tissues, including blood vessels and cartilage. This proteoglycan is also present in brain. It has a number of features in common with aggrecan [55]. Versican contains an N-terminal hyaluronan-binding motif and a C-terminal globular domain homologous to corresponding domains in aggrecan. Its central extended domain carries the glycosaminoglycan chains [55–57], typically chondroitin sulfate. Versican, in contrast to aggrecan, contains no G2 globular domain, thus only having two globules.

Altogether, the two molecules have many properties in common. These include a capacity to bind tightly to hyaluronan in an interaction stabilized by link protein [56,57]. The C-terminal domain also shares many features of the homologous domain of aggrecan. The C-type lectin motif in this domain binds tightly to tenascin-R. This interaction is common for all four molecules of the hyaluronan-binding proteoglycans (i.e., aggrecan, versican, neurocan, and brevican) [43,58]. In contrast, only aggrecan and versican show a pronounced binding to fibulins 1 and 2 [41,42]. This binding depends on divalent cations and involves EGF domains in the fibulins. It is of particular interest that this interaction may play roles in matrix buildup by providing a bond between one set of molecular complexes in the form of versican aggregates to other putatively network-forming molecules such as fibulins and tenascins. The central domain where the glycosaminoglycan chains are attached is quite variable in that there are variants resulting from differential splicing. There are four such variants, V0, V1, V2, and V3 [59–61]. The number of glycosaminoglycan chains varies from 5 to 23 depending on which alternatively spliced exons are present. The V0 and V1 forms are present in most tissues, while the V2 forms show a more restricted distribution in brain compartments [62]. It appears that the V2 variant represents a regulating factor in axonal growth [63]. The V3 variant has so far only been observed at the mRNA level. The overall functional implications of this variability are currently not apparent. Although it can be speculated that versican may play a role in contributing a negative fixed charge density to tissues, it is not clear how similar this may be to the contribution of aggrecan to cartilage properties. Other possible roles for versican are in tissue assembly and in regulating cellular activities [64].

The Collagen Network

A major constituent of cartilage is the collagen fiber network, which consists predominantly of collagen II, with

a very minor proportion of collagen XI molecules [65] (see also Chapter 2, Part I, this volume). Some of these fibers are also associated with collagen IX at their surfaces, as indicated in Figure 1, to a large extent covalently cross-linked to the collagen II in the fibrils [66]. Collagen IX contains globular domains, in which the basic C4 domain extends out and away from the collagen fiber, free to interact with surrounding matrix constituents.

The collagen fibers are of variable dimensions, such that they are thinnest closer to cells and much more variable and of larger diameter further away in the interterritorial matrix [67]. The process of collagen fibril assembly is regulated by constituents produced by the cells, which also produce molecules that provide the completed fibril with a surface coat that enhances its ability to interact with other surrounding fibrils.

Following is an account of molecules with the ability to bind to the collagen fiber and to modulate fibril assembly.

Thrombospondins

There are currently five known members of the thrombospondin family (see also Chapter 5, this volume). In cartilage, COMP (cartilage oligomeric matrix protein), or thrombospondin-5, is particularly prominent, but thrombospondins −1 and −4 have also been identified in this tissue [68,69]. COMP is found primarily in cartilage and related structures such as meniscus and intervertebral disc. It is also present in structures with related morphology, such as pressure-loaded parts of tendons [70–74]. Very low levels (several orders of magnitude less) may be found in tissues such as synovial capsule [75]. The proteins of this family form two distinct subgroups, being either homotrimers or homopentamers.

COMP — cartilage oligomeric matrix protein. COMP is a classical example having five identical subunits, each with a molecular mass of about 87 kDa [76]. The subunits contain important elements found also in other connective tissue proteins, including calcium-binding modules [72]. The subunits are linked together close to their N-termini in a heptad-repeat structure [77], which is further stabilized by disulfide bonds. The portion of the molecule containing the heptad repeat has been expressed in recombinant form and its structure determined by X-ray crystallography [77]. Interestingly, it forms a central hydrophobic channel, where retinoids and 1,25-dihydroxyvitamin-D_3 appear to be possible ligands. In view of the close proximity of COMP to cells in growing cartilage [78], this may imply a function in the delivery of these hydrophobic factors to cells. The C-terminal part of each chain forms a globular structure, apparently in an overall design suitable for cross-bridging several other matrix components.

COMP shows a distinctly different distribution in adult cartilage from that in young immature cartilage, including the proliferative zone of the growth plate, in which it is particularly abundant. Thus, in young cartilage there is a pronounced pericellular distribution, whereas in older cartilage the protein appears to be restricted to the interterritorial matrix at a distance from the cells [78]. Whether this results from a difference in structure of the COMP molecule resulting in a different ability to interact, or whether it is dependent on changes in other matrix proteins, is not clear. There are indeed some changes in COMP structure with aging, albeit not in the protein itself. Thus, the oligosaccharide substituents differ between young and old cartilage. At all times, the middle of the three putative carbohydrate attachment sites is not occupied; the C-terminal site carries an N-glycosidically linked oligosaccharide, which is the same in the two age groups, while the N-terminal site shows differences. In the adult, at this site, there is only one type of oligosaccharide, which differs from the four different substituents observed in young tissue [76]. The implications of these differences are not yet clear.

Thrombospondin-1. Thrombospondin-1 is structurally related to COMP but shows considerable structural differences. It contains three subunits of approximately 130 kDa, which are considerably larger than those of the COMP subunit [79]. These chains are also bound in a heptad-repeat structure located at a similar distance from the C-terminus as in COMP, leaving a free, extended N-terminal domain that contributes heparin-binding properties to the molecule. Also, the chains of thrombospondin-1 have a globular domain at their C-termini.

It is likely that many of the functional properties of the thrombospondins are shared among the various members of the family. However, whereas, for example, thrombospondin-1 contains a heparin-binding domain and has well-documented cell-binding properties, this is not the case for COMP. Other functions are most likely shared and are discussed for COMP only.

Function of COMP. Details of the functional role of thrombospondins, such as COMP, in cartilage are not well-known. However, mutations affecting the calcium-binding motif, impairing calcium binding, result in severe growth disturbances; e.g., multiple epiphyseal dysplasia or pseudoachondroplasia [80] (see also Chapter 23, Part II, this volume). One may conclude that part of the phenotype depends on the deposition of the mutated COMP in the endoplasmic reticulum of the cells, thereby disturbing trafficking and secretion. This may occur through the intracellular formation of complexes between the mutated COMP and other molecules perhaps specific for the chondrocyte. One such molecule may be collagen IX, which has been demonstrated in intracellular deposits [81]. Indeed, more recent data show that collagen IX interacts with COMP at $k_d 10^{-9}$ M regardless of the presence of the mutation [82].

It has been reported that COMP can bind to cells [83], but details of this interaction have not been elucidated. It is not clear whether this is direct binding to a cell-surface receptor or whether it involves secondary interactions with other matrix constituents. There is no identifiable cell-binding motif in COMP that is common to all species. In some species, the protein contains an Arg–Gly–Asp (RGD) sequence implicated in integrin binding, but in others this is lacking. Also, the prevalence in proteins of this sequence is much more common than the ability of proteins to bind cells. An additional piece of information to consider is that, in normal adult articular cartilage, the protein is located at a distance from the cells [78], thereby automatically excluding direct interactions.

One clue to the function of COMP was obtained from studies with collagens I and II, to which the protein was demonstrated to bind with dissociation constants of the order of $k_d 10^{-9}$ M via the C-terminal globular domains present on each chain. This interaction is dependent on the presence of zinc ions, and calcium does not seem to promote the interaction. There are four apparently identical COMP-binding sites on the collagen molecules. However, a single COMP molecule cannot span two such sites in a single molecule. Therefore, it is likely that COMP will cross-bridge to neighboring collagen molecules, perhaps thereby

playing a role in fibril assembly and/or stability, as indicated in Figure 1. More recent data indicate that COMP may also bind to collagen IX [82], as indicated in Figure 1. In view of the presence of covalently cross-linked collagen IX on the surfaces of collagen II fibers [66], this would provide a site for interactions of COMP also with collagen fibrils. This may also provide an explanation for the fact that mutations in collagen IX result in a phenotype similar to that of pseudoachondroplasia or multiple epiphyseal dysplasia [84].

Matrilins

Matrilin-1, also named CMP (cartilage matrix protein) [85–87], is the first described member of a novel family of connective tissue proteins. Matrilins -1 and -3 are particularly prominent in cartilage [88]. Indeed, matrilin-1 is selectively found in some cartilages, including tracheal, nasal, ear, and epiphyseal cartilage, while it is absent from adult articular cartilage and intervertebral disc structures [89]. It is a trimer with three identical subunits, each with a molecular mass of around 50 kDa. The subunits are held together by a coiled-coil domain, and the interaction appears to be stabilized by disulfide bonds. A functional structure present in all matrilins is the von Willebrand factor A domain (vWF A). Matrilin-1 contains two such domains, while matrilin-3 contains only one [88,90,91] The vWF A domain would be expected to contribute collagen-binding properties to the matrilins. Indeed, it has been shown that matrilin-1 can bind to collagen and appears to colocalize with collagen in cartilage [92]. In addition to their collagen-binding properties, it appears that matrilins may self-assemble, forming their own network [93], probably through the vWF A domains. The much increased accumulation of the protein in cartilage with age [94] may involve the formation of large complexes and perhaps its own fibrillar structure.

The detailed functions of the several members of this family are, however, not clear, and their potential for variability is extended through their being able to form multimers with combinations of various subunits. Thus, a composite protein containing subunits of both matrilins -1 and -3 is present in cartilage [95,96]. As a consequence, there are several levels of fine-tuning of the functions of the matrilins.

LRR Leucine-Rich Repeat Proteins

LRR (leucine-rich repeat) proteins (Figure 3) constitute a family of proteins with a central domain containing a number of repeats of approximately 25 amino acids with leucine residues at conserved locations. In the extracellular matrix, there are nine known closely related such proteins with core proteins of molecular weights around 40 kDa. These are decorin [97], biglycan [98,99], asporin [100], fibromodulin [101], lumican [102], keratocan [103], PRELP [104], osteoadherin [105], and chondroadherin [106], containing 10–11 repeats. There are also three members with six repeats yielding core proteins of around 30 kDa: mimecan/osteoglycin [107], epiphycan/PG-Lb [108,109], and opticin [110]. Little is known of the functions of some of these (keratocan, mimecan, opticin, and epiphycan), and they are not further detailed here. From X-ray crystallographic studies of another LRR protein, ribonuclease inhibitor [111], some information on the structure of the repeats can be inferred [112], albeit that this protein has a larger number of somewhat longer repeats. Studies of the ribonuclease inhibitor showed each repeat to comprise a β-strand and a parallel α-helix in a hairpin structure aligned parallel to a common axis creating a horseshoe-shaped structure, the outer face of which is

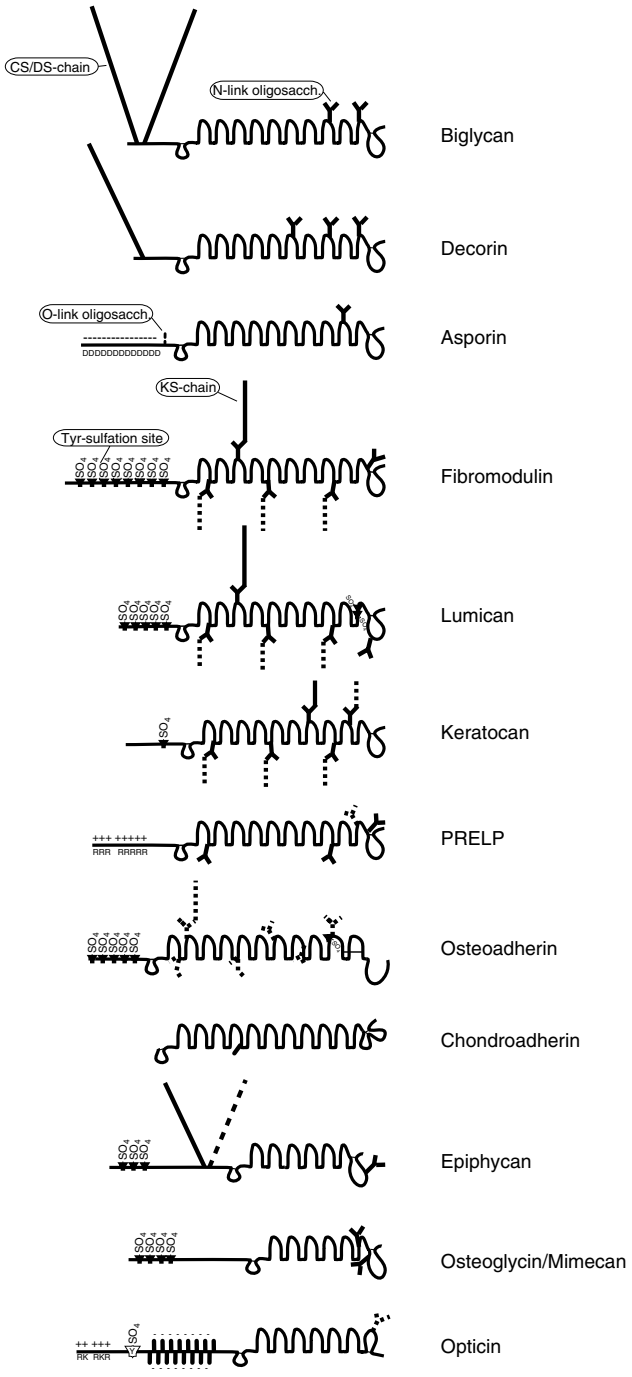

Figure 3. Extracellular matrix LRR proteins. The 10–11 leucine-rich repeats in the larger proteins and 6 such in the smaller ones are indicated and are surrounded by disulfide loop structures as outlined. Most of the proteins contain an N-terminal domain containing various substituents from long glycosaminoglycan chains to tyrosine sulfate-rich sequences. In the case of PRELP, there are no substituents on the N-terminal extension, but the protein has functionally active clusters of basic amino acids. Opticin contains an array of O-glycosidically linked oligosaccharides. There are N-glycosidically linked oligosaccharides attached at sites in the repeats, as indicated. In some cases, these are extended into keratan sulfate chains. Dashed lines indicate possible substituents. LRR, leucine-rich repeat; CS, chondroitin sulfate; DS, dermatan sulfate; KS, keratan sulfate.

formed by the α-helix, while the inner surface is made up of the β-sheet. This β-sheet is the primary structure interacting with other proteins. The repeat region is flanked by disulfide loops. The majority of LRR proteins have an N-terminal extension with distinct functional properties, as detailed in the sections that follow. In osteoadherin, there is also an extended C-terminal domain.

In general, LRR proteins can be divided into subfamilies on the basis of their gene structures and sequence homologies. Thus, decorin, biglycan, and asporin form one subfamily and fibromodulin, lumican, keratocan, osteoadherin, and PRELP another, while chondroadherin is distinct. The molecules with a lower number of repeats are again distinct and form a fourth subfamily. One central function of LRR proteins appears to be to interact with other matrix constituents, primarily collagens and, in some cases, cells.

Decorin and biglycan. Decorin and biglycan are encoded by genes containing eight exons. The biglycan gene maps to chromosome X (Xq28), while the decorin gene maps to chromosome 12 (12q23) in human [113] and chromosome 10 in mouse [114]. The proteins are rather ubiquitously distributed among tissues. The two proteins contain N-terminal extensions with either one (decorin) or two (biglycan) glycosaminoglycan chains (Fig. 3). The chains vary among tissues but are commonly dermatan sulfate containing two types of repeat disaccharide, one of which is iduronate-N-acetyl-galactosamine primarily sulfated at the 4 position. Some of the units, in addition, carry a sulfate at the iduronate. The other repeat is a glucuronate-N-acetyl-galactosamine with a sulfate in the 4 or 6 position. The two building blocks are then united in variably long stretches forming a rather complex extended structure with a large variability among tissues [115] as well as during growth and in pathology. Available data indicate that these chains provide functional properties, including the ability to self-interact [116] and to bind to other matrix constituents. In addition, the glycosaminoglycan chains of biglycan mediate binding to α-dystroglycan [117]. There are also N-glycosidically linked oligosaccharide substituents as indicated in Figure 3.

Both decorin and biglycan are synthesized with a propeptide of as yet unknown function. In tissue studies, it has been shown that the propeptide is sometimes cleaved off but that in other cases the proteoglycan in the tissue still contains the propeptide [118,119]. It has been proposed that the propeptide has a role in the processing of the proteoglycan [118].

Decorin has been shown to bind to cells, particularly colon carcinoma cells [114,120]. Cells with bound decorin show growth arrest [121], indicating that decorin may play a role in the regulation of cell behavior.

Decorin and biglycan share the feature of binding to collagen [122–124], as indicated in Figure 1. In the case of decorin, this has been shown to involve the repeat domain, where repeats 4 and 5, particularly, show a tight binding, with a dissociation constant in the nanomolar range [125,126]. However, other parts of the repeat domain are involved in strengthening the interaction. Decorin binding occurs at a site very close to the C-terminus of collagen I and also close to one of the intermolecular cross-linking sites of the collagen heterotrimers [127]. Decorin core protein [128], as well as its glycosaminoglycan chains [129,130], has been shown to occur bound to collagen fibers in the tissue. The proteoglycan or its core protein can modulate collagen fibril formation *in vitro*. Therefore, it may have a role in collagen fibril assembly and maintenance of the fibrillar network. This contention has been corroborated by results from decorin gene inactivation. Decorin knockout mice have an altered skin phenotype, the skin being fragile, with reduced tensile strength [131]. Collagen fibrils in both skin and tendon of these animals show increased size and irregular contours. This is in accord with the previously demonstrated inhibitory effect of decorin on collagen fibrillogenesis *in vitro* [122,132–134].

Decorin also appears to have the capacity to bind fibronectin [135], a prominent matrix protein in many tissues (see also Chapter 5, this volume), albeit a very minor constituent of articular cartilage. Binding to thrombospondin-1 has also been implied [136]. The role of these interactions is not clear, although there are indications that cell binding may thereby be modulated [136,137].

Biglycan does not appear to bind to collagen fibrils. Precipitation assays *in vitro* show that decorin is effectively precipitated by forming collagen fibers, whereas biglycan is not [125]. However, biglycan binds to collagen VI *in vitro* (as indicated in Fig. 1) using the same site as decorin [138]. The dissociation constant, k_d, is approximately 10^{-9} M, and the binding site is located close to the junction between the triple-helical and the nontriple-helical domains in the N-terminal part of collagen VI [138]. Whether biglycan has a role in regulating collagen VI beaded filament assembly is not known. Interestingly, the biglycan null mouse has particularly marked bone alterations [139], but it is not known whether alterations in the collagen VI network are a component of these bone changes.

More recently, an interaction of biglycan with α-dystroglycan has been demonstrated [117]. This interaction is mediated by the glycosaminoglycan chains of biglycan. Such interactions open up entirely new possibilities for associations between molecules in the extracellular matrix. In this particular case, the result may be an interaction between cells and their surrounding matrix.

Asporin. Asporin [100,140] is a novel member of the subgroup of LRR proteins comprising decorin and biglycan. Asporin is very closely related to decorin, showing the characteristic motif of the C–X3–C–X–C–X6–C sequence and the typical gene of 6 exons found in decorin and biglycan [141]. Asporin, however, is not a proteoglycan, containing no glycosaminoglycan chains. Although asporin contains a propeptide sequence, this differs considerably in its N-terminal region [100,140]. However, as in most of the LRR proteins, this domain is anionic, having a stretch of between 11 and 15 amino acids of consecutive aspartic acid residues. Asporin also differs in glycosylation in containing only one, albeit variable, N-glycosidically linked oligosaccharide. It also appears to contain one O-glycosidically linked oligosaccharide [100].

Asporin is found in cartilage and in tissues rich in smooth muscle cells such as uterus and aorta. Its role in the tissues is not clear, although preliminary data indicate that it may interact with collagen [100]. The protein migrates as a 39 kDa protein upon SDS-polyacrylamide gel electrophoresis [100].

Fibromodulin, lumican, and keratocan. These proteins, illustrated in Figure 3, are encoded by genes containing three exons, the major protein portion of each being encoded by the second exon [142]. They show a wide tissue distribution, although one somewhat more restricted than that of decorin and biglycan. The N-terminal extension of

bovine fibromodulin contains some eight sulfated tyrosine residues [143], as illustrated in Figure 3. Similarly, lumican has the typical motif for several tyrosine sulfate residues, albeit somewhat fewer than fibromodulin [144]. Keratocan contains even fewer putative tyrosine sulfation sites [103]. Fibromodulin and lumican have one or two keratan sulfate chains bound via typical N-glycosidic linkage to any of four of the putative sites for N-glycosylation [101,145–147] (Fig. 3). Because little is known about the functional properties of keratocan, this protein will not be further discussed. However, fibromodulin and lumican both bind to fibrillar collagen, as indicated in Figure 1, and inhibit fibril formation *in vitro* [124,133,134]. Fibromodulin has been demonstrated to occur bound to collagen fibers in cartilage and localized to the fiber gap region [67]. Interestingly, the quantity of protein bound varies with the thickness of the collagen fiber, such that thinner fibers have a higher density of bound fibromodulin molecules [67].

Despite the *in vitro* inhibition of collagen fibrillogenesis, fibromodulin null mice unexpectedly show a higher proportion of thin collagen fibrils in tendon [148]. There are also alterations of the collagen network in cartilage. Lumican protein is increased some fourfold in the fibromodulin knockout mouse. At the same time, lumican mRNA in tendon is less in the knockout mouse than in the wild type [148]. This indicates that the increased level of protein is due to decreased degradation rather than enhanced synthesis. An explanation was obtained in studies of the binding of lumican and fibromodulin to collagen, in which the two proteins bound to the same site, although the binding of fibromodulin was four to five times stronger [149]. The two molecules bind to forming collagen fibers with dissociation constants in the range of 1–10 nM. Thus, the picture emerges that, in collagen fibril assembly *in vivo*, early fibrils have bound lumican, which, at some stage, is replaced by fibromodulin that may then have a role in the further assembly of formed fibrils to result in thicker-diameter aggregates.

The lumican knockout mouse, on the other hand, shows thicker and irregularly shaped collagen fibers in skin [150] and other tissues, reminiscent of the decorin knockout mouse. It is not clear whether there are secondary changes in any of the related molecules in the lumican and decorin null mice.

PRELP (proline- and arginine-rich end leucine-rich repeat protein). PRELP was first isolated from articular cartilage [151]. It contains a leucine-rich domain similar to that of the other members of the family. It is closely related to fibromodulin and, most closely, to osteoadherin. Its structure, however, differs significantly in the N-terminal extension [104], indicated in Figure 3. This part of the protein contains clustered arginine and proline residues indicative of heparin-binding activity. In fact, it can be shown that the molecule binds to heparan sulfate and heparin via this domain with binding constants in the order of $k_d 10^{-8}$ M [152], as indicated in Figure 1. Indeed, cells attach to PRELP via heparan sulfate chains on their cell-surface proteoglycans, such as syndecan (Bengtsson, Heinegård, and Aspberg, unpublished results), as indicated in Figure 1. In view of the fact that PRELP can also bind collagen with a nanomolar dissociation constant (Bengtsson, Heinegård, and Aspberg, unpublished results), it is possible that the molecule can serve as an anchor from the matrix back to the cell. This is likely to create a different type of signal from that traditionally elicited by ligand binding to integrin receptors.

Chondroadherin. Chondroadherin, illustrated in Figure 3, differs from other members of the leucine-rich repeat region family in having no N-terminal extension and a short C-terminal extension [106]. The latter is cleaved off in a proportion of the molecules present in the tissue. As indicated previously, chondroadherin has a different gene organization, with four exons [153], and differs also at the protein level in having an extra disulfide bond in the C-terminal loop structure. There is no, or potentially only one, carbohydrate substituent in chondroadherin and no hexosamine. Thus, this is the only member of this family of proteins with no N-glycosidically linked oligosaccharide. However, the serine residue corresponding to position 123 in the human protein contains a substituent, indicated in Figure 3, that may contain a xylose residue [106,154].

Chondroadherin has been shown to bind cells via their $\alpha_2\beta_1$ integrins [155], as illustrated in Figure 1. Usually, cells spread when integrin binding occurs, but in the case of chondroadherin binding, cells remain rounded, although the synthesis of matrix constituents is altered [155] (Johnson, Olsson, and Heinegård, unpublished results). Integrin binding to chondroadherin does elicit signals, since tyrosine phosphorylation reactions are induced (Johnson, Olsson, and Heinegård, unpublished results). These effects, resulting from chondroadherin binding to cells via $\alpha_2\beta_1$ integrin receptors, are different from those elicited by collagen binding to the same integrin, which does result in cell spreading [155].

A further interaction of chondroadherin has been identified. Upon the induction of mild proteolysis by endogenous proteinases, complexes of collagen monomers with bound chondroadherin are released from cartilage explants [156]. The collagen appears to have been processed for assembly, because no propeptides are present. Two binding sites can be demonstrated, and an identical pattern is observed when recombinant chondroadherin is added back to collagen monomers. Thus, it seems that chondroadherin may have a role in modulating interactions at the cell surface and perhaps also in early collagen fibril assembly, as indicated in Figure 1.

Chondroadherin is particularly enriched in the lower proliferative, prehypertrophic area of cartilage growth plate, where the major mRNA message can also be detected [157]. This localization, to an area with decreasing cell proliferation, is consistent with a role of the protein in regulating cell growth.

Epiphycan and mimecan. These two proteins represent a distinct group within the LRR family. Each contains six leucine-rich repeats [107,108,158,159] and shows some 50% amino acid identity to the others. Their gene organization is different in that they comprise seven exons, the coding sequences being located in exons 5–7 [160,161]. Both proteins have an N-terminal extension with putative sites for tyrosine-O-sulfation.

Epiphycan appears as a chondroitin/dermatan sulfate proteoglycan in the growth plate. Mimecan, on the other hand, can occur as a keratan sulfate proteoglycan in cornea [107], while in other tissues the oligosaccharides do not become extended with polylactosamine sulfated disaccharides to form keratan sulfate. A fragment of mimecan, isolated as osteoglycin, lacks the N-terminal domain carrying the tyrosine sulfate but retains other structural features [107].

Opticin. This protein, originally identified in the eye, is present in the retina as well as in ligaments and skin [110]. The mature protein has an M_r of some 35 kDa. It has

six leucine-rich repeats in the central domain. There is an additional repeat in the C-terminal cysteine cluster. The N-terminal extension of the protein shows the unique presence of a number of O-glycosidically linked oligosaccharides [110] in a structure reminiscent of that in mucins, as indicated in Figure 3.

General comments on the LRR-protein family. With a number of extracellular matrix LRR proteins identified, some overall features can be deduced. There are four subfamilies, with decorin, biglycan, and asporin constituting class I; fibromodulin, lumican, keratocan, PRELP, and osteoadherin constituting class II; epiphycan, mimecan, and opticin constituting class III, and chondroadherin class IV. The genes of the LRR proteins appear to be arranged in clusters of four. Decorin, lumican, keratocan, and epiphycan (classes I, II, II, and III, respectively) map to chromosome 12q23. Asporin, osteoadherin, and mimecan (classes I, II, and III, respectively) are found on chromosome 9q32. *ECM2*, a gene encoding LRR protein containing an amino-terminal von Willebrand factor repeat, is located in the same region [162]. Fibromodulin, PRELP, and opticin (classes II, II, and III, respectively) are positioned on chromosome 1q32. Biglycan (class I) differs from the others in not being part of a cluster. The gene for this protein is found in isolation on the X chromosome. A picture is emerging showing that several duplications have occurred during evolution, with an ensuing clustering of the LRR genes. The biglycan gene may then have relocated to the X chromosome. Alternatively, there may be four more LRR protein genes remaining to be identified, one on chromosome 1 and three on the X chromosome.

Perlecan

This very large protein, having a core protein exceeding 400 kDa (467 kDa in man) [163–165], usually carries three heparan sulfate chains, sometimes fully or partially replaced by chondroitin sulfate chains, in its N-terminal domain [163,166], as well as at least one chain in its C-terminal portion [167]. It is built from a number of modules found in many other connective tissue proteins. These include LDL-receptor class A modules, a large number of Ig-like repeats, several laminin-1 EGF-like repeats, and laminin-1 globular homology 1 and 2 modules, as well as a number of EGF-like repeats [163–165].

As expected, perlecan interacts with a number of other proteins, including integrins, dystroglycan, collagens, and laminins. The proteoglycan also binds and sequesters growth factors, particularly from the FGF (fibroblast growth factor) family [165,168]. Perlecan is found particularly in basement membranes, which were the original sources of the isolated proteoglycan. Subsequently, it has been identified in cartilage [169–171], where it appears after collagen II during development.

Significant progress in understanding perlecan biology has been made in studies of mice with the core protein gene inactivated [168,172]. The majority of such mice die during embryonic development (stages E10–E12). The mice show cardiac defects [168], apparently resulting from a deficient basement membrane, although its formation appears normal. The mice also show defects in cephalic development. Those mice that survive embryonic development die at birth or during the neonatal period. They show extensive chondrodysplasia with abnormal endochondral ossification [168]. Although cartilage formation appears normal, the turnover of growth cartilage, in particular, shows major alterations. Thus, the collagen network is deficient, with a much decreased number of collagen fibrils [168]. At the same time, the synthesis of a number of matrix proteins, including collagen II, matrilin-3, and COMP, is increased 3–5-fold as demonstrated by mRNA Northern blot assay.

It was suggested that one role of perlecan is to neutralize proteinases that function in normal cartilage turnover, particularly that of the growth plate [168]. Alternatively, the phenotype observed in the perlecan knockout mouse may have resulted from a perturbed homeostasis of growth factors [173] in the absence of perlecan.

CILP (Cartilage Intermediate Layer Protein)

CILP (cartilage intermediate layer protein) was initially isolated from articular cartilage but is present also in other cartilages, although it is restricted to this type of tissue [174]. Cloning of cDNA and the consequent deduced amino acid sequence indicated that the gene codes for a larger precursor protein that actually contains two different proteins [175]. The N-terminal part contains the approximately 82 kDa CILP protein and the C-terminal part another protein that, in terms of sequence homology, corresponds to a previously described nucleotide pyrophosphohydrolase (NTPPHase) [176]. The precursor protein is cleaved by a furin type proteinase at the time of secretion such that the two proteins are only found separately in the extracellular environment [175].

There are few examples of one gene encoding two different proteins. The CILP gene is organized in nine exons [177]. Surprisingly, the C-terminal portion of CILP and the entire NTPPHase are encoded by exon 9, such that the border between the two proteins occurs within this exon.

CILP, although markedly up-regulated in early osteoarthritis (Lorenzo, Bayliss, and Heinegård, unpublished results), has no known function, and its sequence represents an entirely novel protein [175]. CILP is not distributed evenly throughout articular cartilage but is particularly enriched in the middle to lower portions of the tissue [174]. This suggests some special functional requirement of this part of the tissue in which CILP is found. The enzyme NTPPHase may play a role in generating pyrophosphate, which, in turn, may be involved in the formation of calcium pyrophosphate precipitates and/or inhibit hydroxyapatite crystal growth [178]. Thus, the up-regulation of this molecule in osteoarthritis may be particularly significant in the regulation of mineral homeostasis and, perhaps, the formation of crystal deposits [179].

Fibronectin

Fibronectin (see also Chapter 5, this volume) is not a cartilage-specific component, although a specific splice variant is present in this tissue [180,181]. It promotes cell binding via the $\alpha_5\beta_1$ integrin receptor and also via a number of other integrins. Fibronectin contains the classical cell-binding sequence identified as arginine-glycine-aspartic acid (RGD) by Pierschbacher and Ruoslahti [182]. Indeed, cell binding to immobilized fibronectin can be inhibited by the addition of RGD-containing short peptides, which are able to saturate the integrins while being unable to form bridging structures. Fibronectin contains domains that promote binding to other matrix components as well as an additional cell-binding sequence, LDV (Leu–Asp–Val) [183]. Thus, its heparin-binding domains appear to play a role in concert with integrin binding in promoting cell division and growth [184]. Collagen binding provides a means of anchorage to the matrix [185]. In addition, fibronectin has the ability to self-interact to form its own fibrillar network [186–188]. A role for fibronectin in joint disease, such as osteoarthritis,

is indicated by its up-regulation in this condition [189], whereby it may play a role in regulating cellular responses to events in the matrix.

Interestingly, fragments of fibronectin containing only the heparin-binding sequence have been shown to modify cell behavior [190]. Thus, when such fragments are injected into joints, they may induce catabolic events [191,192]. It is possible that one mechanism involved in cartilage breakdown in joint disease is the prior formation of fibronectin fragments.

Other Proteins in Cartilage

There are a number of other proteins that have been studied in cartilage. These include a 39 kDa protein (GP-39, YKL-40), which is found predominantly in the more superficial parts of articular cartilage [193,194], although it is also found in other tissues, including the intestine, liver, and synovial capsule [195,196]

A further protein, containing γ-carboxyglutamic acid, is matrix Gla protein [197–199], which has a ubiquitous distribution in a number of tissues, including blood vessels and cartilage. This low-molecular-mass protein appears to play a role in the regulation of calcification. Upon gene inactivation in mice, the prominent phenotype is of excessive, lethal calcification of blood vessels within the first months of life of the animals [200].

A novel proteoglycan, containing both keratan sulfate and chondroitin sulfate chains, is present primarily in the superficial part of the articular cartilage and is also produced in the synovial capsule [201,202]. Little is known of its functional properties.

BONE

Throughout life, a hallmark of bone is a dynamic remodeling process, outlined in Figure 4 (see also Chapter 1, Part III, this volume). In this process, bone tissue that has been fatigued is removed and replaced by newly formed bone. The process also serves to modify the architecture of the bone in its adaptation to altered load. In certain disease states and in post-menopausal women, the intricate balance between the degradation and removal of bone tissue on the one hand and the synthesis and formation of new tissue on the other is disturbed, such that over each remodeling cycle there is a net loss of bone. This eventually leads to mechanical failure in osteoporosis. To understand these processes to develop novel therapeutic interventions, it is essential to learn not only about tissue breakdown but also about factors involved in the recruitment of bone-forming cells and the formation of new tissue. As indicated schematically in Figure 4, the breakdown process is accomplished by osteoclasts and the synthesis by osteoblasts.

The Bone Breakdown Process

The overall breakdown process is initiated by stimuli from osteocytes and/or bone lining cells that, when sensing a particular altered mechanical stimulus, appear to produce proteinases that initially degrade the thin osteoid layer covering bone. Among other factors, they also produce osteopontin, which binds particularly to the mineral phase, as outlined schematically in Figure 4. Thus, the bone surface covered with the cell-binding osteopontin will be exposed and participate in recruiting osteoclastic precursor cells derived from the monocyte lineage. Binding to osteopontin via their $\alpha_v\beta_3$ integrin receptors will transmit signals to the cells that, in concert with growth factors, particularly the RANK (receptor activator of c-jun N-terminal kinase)-ligand, TNF (tumor necrosis factor)-α [203–205], and M-CSF (macrophage colony stimulating factor) [206,207], are likely to affect the differentiation of the precursor cells into mature osteoclasts. Growth factors produced by the osteoblasts/osteocytes also participate in the process. Cells developing into mature osteoclasts progressively form a ruffled border region, beneath which are secreted protons to dissolve the mineral, proteolytic enzymes to dissolve the organic matrix, and enzymes that accomplish dephosphorylation of phosphoproteins, such as osteopontin and BSP (bone sialoprotein) [208]. An essential feature of the resorption process is that the osteoclast ruffled border region is sealed off from the surroundings, forming an extracellular, lysosome-like compartment. This is achieved by the clear zone rim of the osteoclast contact area [207, 209], where the cells attach to the bone surface, as is illustrated in Figure 4. Thereby, an enclosed domain is formed, beneath which enzymes and protons can be retained in sufficiently high concentrations for efficient activity.

In this process, the osteoclast forms a resorption pit, and when it leaves the area a novel bone surface will be exposed. This appears to serve as a substratum for the recruitment of cells that will accomplish the formation of new bone to replace that removed. The cells recruited form new bone tissue initially in the form of nonmineralized osteoid, which subsequently becomes mineralized in a series of tightly regulated processes. Bone contains a number of matrix proteins, which appear to play important roles in different phases of the remodeling process. An account of some of these proteins and their known functions follows.

Osteopontin

Osteoclasts bind to the mineralized matrix of bone via their $\alpha_v\beta_3$ integrin receptors [210,211]. Thus, it has been shown that competitors for integrin interaction, including short RGD (arginine-glycine-aspartic acid)-containing peptides, can inhibit bone resorption *in vitro* [212,213]. As illustrated in Figure 4, a multitude of data indicate that the ligand for the integrin involved in osteoclast binding is the phosphorylated glycoprotein osteopontin [214], which contains an active RGD cell-binding sequence [215]. Several clustered sequences of phosphorylated serine residues [216] in combination with stretches of polyaspartic acid are likely to provide for binding of the protein to the hydroxyapatite mineral [217,218]. Thus, the protein is, *de facto*, bifunctional and should have the potential to attach cells to the mineral phase.

The synthesis of osteopontin is up-regulated by 1,25-dihydroxyvitamin-D_3 [219]. Transforming growth factor (TGF)-β also up-regulates its production, while glucocorticoids have a down-regulatory effect. In bone, osteopontin is primarily produced by osteoblasts, which are often seen surrounding osteoclasts in areas of bone resorption [220]. It can bind to isolated osteoclasts *in vitro* via their $\alpha_v\beta_3$ integrin receptors [221,222]. Direct evidence for a role for osteopontin in the bone resorption process was obtained in immunolocalization studies using immunogold electron microscopy of areas in bone displaying osteoclasts. Osteopontin appeared to be localized almost exclusively at the clear zone of the cells, representing the attachment areas, while none was detected in the ruffled border regions [211,222,223]. Other areas of bone more distant from osteoclasts showed only small amounts of osteopontin. Furthermore, the $\alpha_v\beta_3$ integrin cell surface receptor was found to be enriched several-fold in the clear zone area of the osteoclast, with little staining in the ruffled border resorption area

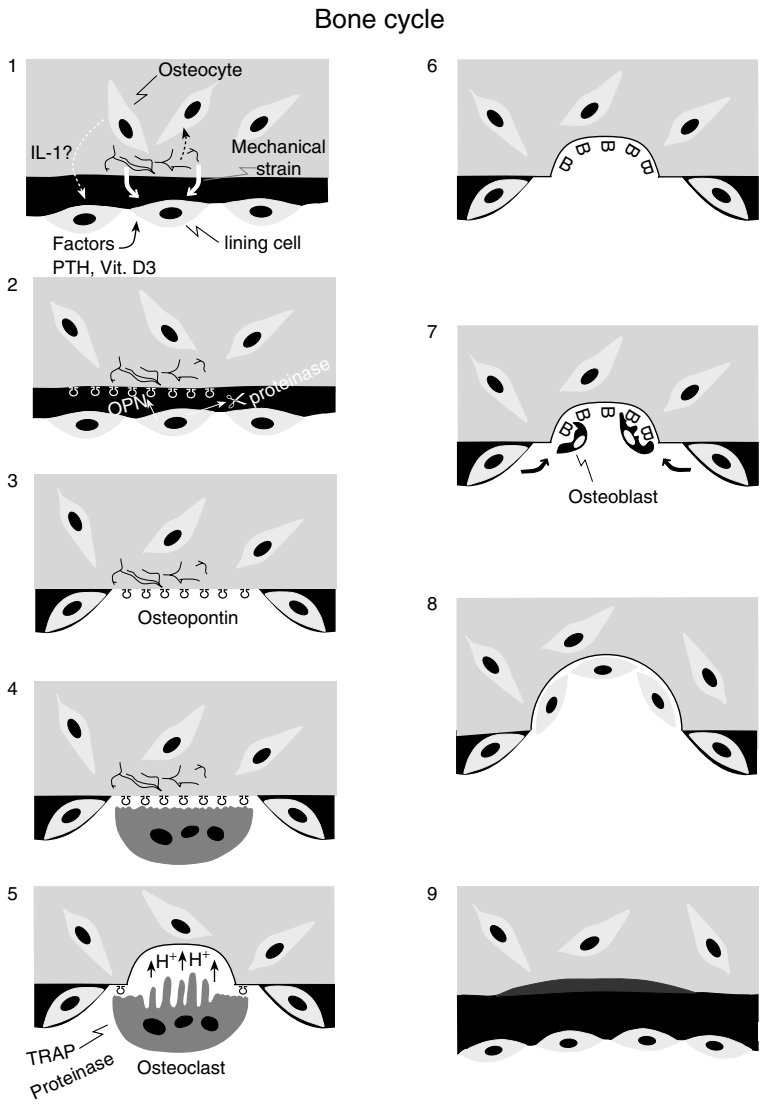

Figure 4. Schematic illustration of the bone remodeling cycle and molecular constituents involved. The catabolic phase includes the triggering of lining cells/osteoblasts/osteocytes to remove the thin layer of osteoid and to condition the bone matrix to recruit osteoclast precursor cells. This activity includes the deposition of the cell-binding matrix protein, osteopontin. The osteoclastic precursor cells develop into resorbing osteoclasts, each with a central ruffled border region dissolving mineral as well as digesting the organic matrix, and a peripheral clear zone area where attachment and sealing occurs. The resorption pits resulting from osteoclastic activity recruit novel osteoblasts essential for new bone tissue formation. IL-1, interleukin-1; PTH, parathyroid hormone; OPN, osteopontin.

of the membrane [210,211,222–225], as outlined schematically in Figure 4 (section 5). Osteopontin production in bone appears to occur exclusively in osteoblasts, in which both mRNA and protein can be detected [220,226], while osteoclasts residing in the bone are devoid of immunoreactivity at the electron microscope level [223]. Thus, it appears that the mature osteoclast is bound via its $\alpha_v\beta_3$-integrin receptor to osteopontin at the mineralized bone surface. Verification that early events in osteoclast binding also involve osteopontin was obtained in studies of the mutant *ia/ia* rat [223], which develops osteopetrosis. This appears to be due to a failure in osteoclast maturation, in which the cells are primarily arrested at the stage at which they have a large clear zone but no significant ruffled border domain. The mechanism may involve the intracellular retention of secretory vesicles that do not fuse with the plasma membrane. Accordingly, there is no secretion of proteinases and other enzymes necessary to accomplish bone resorption. Interestingly, none of these vesicles contain osteopontin [223], indicating that osteoclasts do not produce the protein. Furthermore, osteopontin is localized facing the whole clear zone area, and there is very pronounced enrichment of the $\alpha_v\beta_3$ integrin receptor along the corresponding region of the cell membrane, as indicated in Figure 4 (section 4). It is likely that osteoclastic precursor cells bind to osteopontin and that one of the signals inducing their differentiation into mature, resorbing osteoclasts is triggered by this interaction. Further work is necessary to substantiate this hypothesis, but additional support for a role

of osteopontin in bone resorption has been obtained in gene inactivation studies. Thus, the osteopontin null mouse shows a developing osteopetrosis, although this is slow and only readily apparent in old animals (Franzén, Hultenby, Reinholt, and Heinegård, unpublished results). This indicates an altered, defective osteoclast anchorage due to the lack of osteopontin. Further evidence for a key role of osteopontin in bone resorption is that the accelerated bone resorption that follows ovariectomy does not occur in mice with an inactivated osteopontin gene [227].

An additional potential role of osteopontin in bone mineralization is possible because it is found highly enriched at the mineralization front [226]. In support of this supposition, it has been shown that osteopontin can inhibit mineral growth *in vitro* [217,218].

Osteopontin is also produced by numerous other cells, including smooth muscle cells in atherosclerotic lesions, kidney tubular epithelial cells, macrophages in placenta, a number of cancer cells, and even microglial cells in the brain [228]. Some of its functions in these situations may be related to cell activation and migration in defense reactions and wound healing.

BSP — Bone Sialoprotein

BSP (bone sialoprotein) is restricted to bone, possibly having a role in the buildup phase of the tissue. Thus, it is particularly enriched in areas where new bone is formed by osteoblasts, and an example is its high abundance at the interface between bone and cartilage in the growth plate [78,220,229]. BSP is clearly an osteoblast product, as shown by both immunolocalization and *in situ* hybridization [78,220]. It is also found at sites of new osteoid production. Interestingly, BSP contains a cell-binding sequence that, albeit containing RGD and primarily binding to the $\alpha_v\beta_3$ integrin [230–232], can also bind to other integrins. BSP can bind to the mineral phase of bone, possibly via its multiple phosphorylated serine residues, as well as a tyrosine sulfated domain, around the cell-binding sequence in the C-terminal region of the molecule [233]. A high degree of substitution, particularly by O-glycosidically linked oligosaccharides, provides additional negative charge. Further, extended, long polyglutamic acid sequences contribute charge and possibly mineral binding. The finding that many of the sites exist with or without substituent (Zaia, Boynton, Heinegård, and Barry, unpublished results) indicates a possible modulation of functionality of the protein.

In vitro BSP can bind to osteoblasts as well as osteoclasts [221]. *In vivo*, however, it shows no significant presence at sites around osteoclasts [220,234]. The production of BSP by osteoblasts is regulated in the opposite way from that of osteopontin, that is, it is up-regulated by glucocorticoids [235] but pronouncedly down-regulated by 1,25-dihydroxyvitamin-D_3 and TGF-β. It is attractive to hypothesize a role for BSP in osteoblast function and perhaps bone formation. It may also play a role in osteocyte function, because it can be demonstrated in bone at sites appearing to represent the extensions of osteocytes [220].

Osteoadherin

Osteoadherin (Fig. 3) is a member of the LRR protein family [105]. It has the capacity to bind to osteoblasts via their $\alpha_v\beta_3$-integrin receptors [236]. The protein was isolated originally from bovine bone, in which it occurs as a keratan sulfate proteoglycan [236], although this appears not to be the case in other species. Interestingly, the isolated protein occurs in apparently stoichiometric quantities in a disulfide-linked complex with osteonectin/SPARC [236]. The cell-binding activity of osteoadherin appears not to be influenced by the presence of osteonectin. The active site for cell binding has not been identified, but osteoadherin does not contain the traditional RGD amino acid sequence that is typically involved in $\alpha_v\beta_3$-integrin binding. The structural features of osteoadherin are slightly different from those of other LRR proteins in that there is a larger C-terminal extension [105]. Similarly to other members of the family, there is an N-terminal domain apparently containing tyrosine sulfate. There are also unique sulfated tyrosine residues in the more C-terminal part (Önnerfjord, Gantcheva, and Heinegård, unpublished results), as illustrated in Figure 3.

The functional role of osteoadherin in bone is presently not clear, but its expression is particularly abundant along bone trabeculae [237] in a pattern not dissimilar to that of BSP. It is therefore possible that it is also involved in the building up of bone by osteoblasts.

Osteonectin/SPARC

This approximately 40 kDa protein appears to have roles in regulating cellular activities. It is particularly abundant in bone, in which the protein was first detected [238], but is expressed and present in many other tissues, including basement membranes, in which it has been referred to as BM-40 [239,240]. It contains several EF-hands mediating calcium binding [239]. *In vitro* studies show osteonectin to have particular roles in modulating cell division and cell migration [241–243], although these effects appear not to involve direct cell binding. However, the protein has been shown to interact with collagen [244], and the fact that the cell-binding protein osteoadherin is isolated as a complex with osteonectin may provide clues for understanding the effect of osteonectin on cells. Inactivation of the osteonectin gene results in particular effects on eye development and leads to the development of cataracts [242].

Osteocalcin

Osteocalcin is an abundant low-molecular-mass bone protein of less than 10 kDa [245,246]. It is unique in containing carboxyglutamic acid residues, more commonly found in blood coagulation factors. This represents a post-translational modification of three of the glutamic acid residues and provides extra charge and enhanced calcium binding. The role of the protein in bone is not quite clear, but its synthesis is regulated by factors that influence bone turnover, such as 1,25-dihydroxyvitamin-D_3 [247]. Upon gene inactivation, mice display increased bone formation [248,249], indicating a role for the protein in regulating osteoblastic functions.

Other Bone Proteins

There are numerous other proteins in bone, including thrombospondin-1 [83,250]. This protein can bind cells and influences cellular activities [251–253]. It also plays a role in angiogenesis, much like another member of the family, thrombospondin-2 [254]. Indeed, animals with an inactivated thrombospondin-2 gene show alterations in bone mineral density [255], perhaps an effect of altered blood vessel formation.

Bone, in addition, contains abundant proteins not synthesized in the tissue. Thus, α_2 HS glycoprotein is very abundant, particularly in growing bone [256–258]. Its exact role in the tissue is not clear.

CONCLUDING REMARKS

Our increasing understanding of the molecular constituents of bone and cartilage provides important clues to the organization of the tissues and to understanding the processes of remodeling. This involves the breakdown and rebuilding of the tissues and is a key element in normal homeostasis and in dealing with altered mechanical requirements. Such knowledge is of paramount relevance in understanding alterations in disease states, including those with a genetic background caused by mutations in particular genes. Conversely, the study of altered phenotypes and tissue properties following such gene mutations will provide additional information about the specific functions of a given protein. Seen against the background of a rapidly increasing incidence of diseases affecting bone and cartilage, including osteoarthritis, osteoporosis, and rheumatoid arthritis, we need to expand our knowledge of molecular mechanisms to enhance the potential for developing new means of specific therapeutic intervention.

RECENT DEVELOPMENTS

Mutations in the perlecan gene (*HSPG2*) have recently been identified in several different human chondrodysplasias [259,260] with phenotypes similar to that observed in mouse gene targeting experiments [261,262].

We have previously shown that the LRR protein PRELP binds heparin and heparan sulfate [263]. We have now found PRELP to be present at the basement membrane/stromal junction in many tissues and able to bind both perlecan in the basement membrane and collagen in the stroma, suggesting that this LRR molecule may be involved in basement membrane anchoring.

Chapter 5

Adhesive Glycoproteins

Klaus von der Mark and Lydia Sorokin

Nikolaus-Fiebiger Center for Molecular Medicine, Friedrich-Alexander University, Erlangen-Nuremberg, Department of Experimental Medicine I (K.v.d.M.) and Interdisciplinary Center for Clinical Research (L.S.), Glückstrasse 6, D-91054 Erlangen, Germany

INTRODUCTION

The formation of tissues and organs in the early embryo, their development and growth, their destruction and regeneration in the adult, and their pathological alterations are the result of complex, tightly regulated patterns of cellular activities and interactions, including proliferation, migration, adhesion, differentiation, matrix production, and programmed cell death. In recent years, it has been firmly established that cell interactions with the extracellular matrix are often critical during these processes [1–4]. In searching for the cellular effectors in the matrix, numerous extracellular glycoproteins have been isolated and characterized, which have specific adhesive affinities on the one hand for the cell surface and on the other for other molecules of the matrix.

These glycoproteins are able to regulate cellular activities both directly, through interaction with cell-surface receptors, in particular integrins, and indirectly by structuring a defined three-dimensional extracellular matrix, which is required by most cells to express their tissue-specific features. The number of extracellular, adhesive glycoproteins seems boundless, and the literature on them has virtually exploded since the first edition of this volume. The expansion of our knowledge of matrix proteins is best illustrated by the laminin field, in which 12 or more* different laminins are known at present in contrast to three laminin isoforms known in the early 1990s.

The best-studied and longest-known matrix glycoprotein with adhesive properties is fibronectin, although collagen and its denatured form, gelatin, have been used for cell-adhesion studies for more than 30 years. Numerous large, extracellular glycoproteins have since been discovered, such as the laminins, tenascin/cytotactin, thrombospondin, vitronectin, osteopontin, chondroadherin, and others. Each has different patterns of affinities for both cells and other matrix molecules. It is unlikely that all relevant proteins have yet been found.

Much of our knowledge of the role of adhesive glycoproteins in modulating cellular functions is based on *in vitro* experiments using isolated, purified matrix components as substrates for cell biological studies. Most cells show multiple interactions with different adhesive components, and this is consistent with the presence on them of several types of matrix receptors. Depending on the experimental system, cells recognize various matrix components with a wide range of specificities and affinities, and the cellular response depends on the concentration, purity, and spatial arrangement of the proteins offered as substrates. Thus, the evaluation of the specificity and affinity of cell-protein interactions *in vitro* is subject to individual interpretation, and the classification of a glycoprotein as being "adhesive" or not has frequently been preliminary and controversial.

Collagens are not only the major structural glycoproteins in connective tissues, but they also exhibit multiple interactions with cells [2,5–8]. Among the 20 collagen types known in 2000, types I, II, IV, and VI have been the most intensively studied in terms of cell adhesion; we therefore focus on the adhesive aspects of these collagens, as the other collagens are considered in Chapter 2 of this volume.

In view of the space restrictions on this chapter, we have excluded matrix glycoproteins such as osteopontin, osteocalcin, matrilin, and others, which are dealt with in Chapter 4, although they do display adhesive properties. Similarly, a number of small proteoglycans such as decorin, biglycan, fibromodulin, lumican, and others, undergo specific interactions with other matrix proteins and cell surfaces and could be included in this chapter, but they also are dealt with in Chapter 4, together with the large proteoglycans. Fibrinogen and von Willebrand factor are considered to be major adhesive glycoproteins, but because they are not integral constituents of the extracellular matrix, they are also excluded.

Common Features of Adhesive Glycoproteins

Three criteria may be used to identify adhesive glycoproteins as a distinct group of matrix proteins. (1) The typical adhesive glycoprotein is an extracellular, multidomain, and multifunctional protein bearing various binding regions for both cells and other matrix components. In most cases, the domains can be isolated by limited proteolysis; they are independently active and retain their affinities to other macromolecules or cells, independently of the rest of the molecule (Fig. 1). They often coincide with distinct structural elements common to several adhesive glycoproteins, such as fibronectin type III homologies, EGF (epidermal

*At the time of going to press, this number had increased to 15.

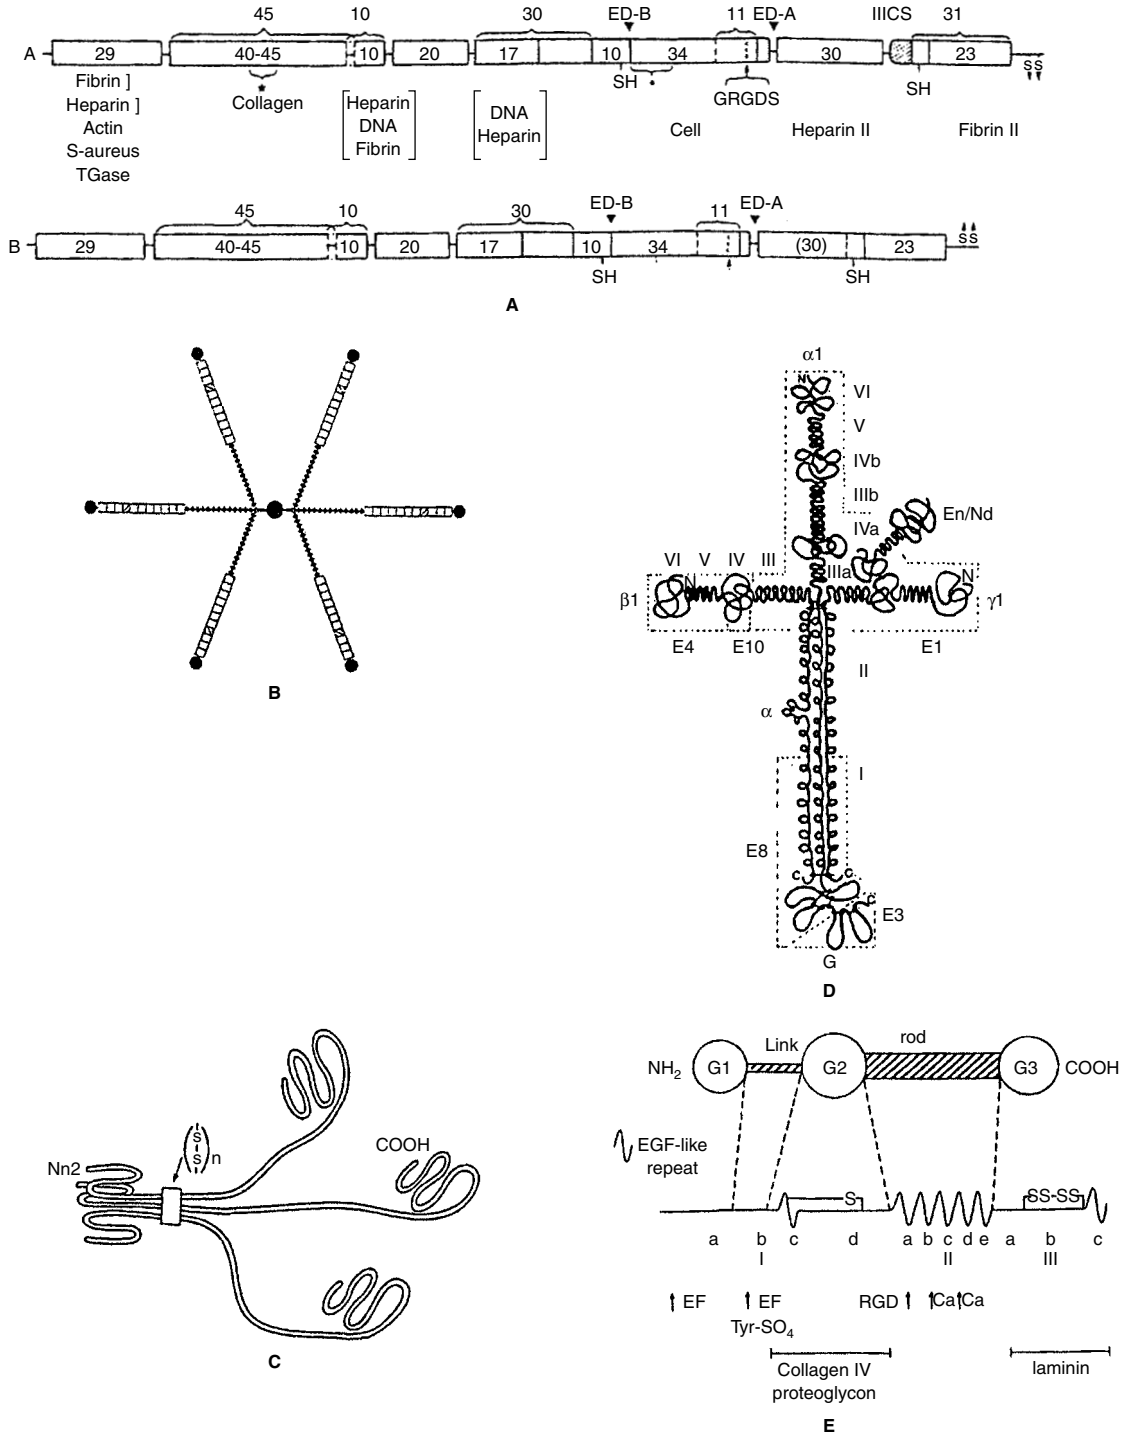

Figure 1. Structural Models of Adhesive Glycoproteins. **A:** Alignment of functional domains of the fibronectin A and B chains and their interactions with other macromolecules. Numbers indicate the molecular weights of the domains in kDa. (Reproduced from [54] with permission.) **B:** Model of tenascin. In each half, three subunits assemble to triplets to meet in the center globule. See Figure 3 for structural details. Reproduced from [187] with permission. **C:** Model of thrombospondin. (Reproduced from [28] with permission.) **D:** Laminin model. The Roman numerals indicate discrete structural domains (see also Fig. 3); α = α-helical domains; G =carboxyl-terminal globular domain. Elastase-derived (E) fragments are marked with dashed lines. Nidogen binding to the γ1 chain is indicated (En/Nd) (modified from [502]). Reproduced from Sasaki et al. [501] with permission. **E:** Model of nidogen (entactin). Correlation between the morphological domain structure of nidogen and subdomains predicted from the amino acid sequence and the localization of functional sites. Ib-d, IIa-e, and IIIa-c refer to these subdomains. S denotes extra disulfide bridges besides those in EGF-like repeats. EF and Ca indicate putative calcium-binding sites; Tyr-SO_4, tyrosine sulfation site; and RGD, a putative cell-binding sequence. Major binding domains for laminin-1, collagen IV, and proteoglycan are identified by horizontal bars (from [312]).

growth factor)-like repeats, VWA (von Willebrand domain A)-like domains, or the NH_2-terminal sequence of type I procollagen (Fig. 3). (2) Many glycoproteins contain short peptide sequences that are essential (but not always sufficient) for their adhesive properties, such as the amino acid sequence Arg–Gly–Asp (RGD) in fibronectin, vitronectin, and osteopontin, which functions as a major cell-recognition site [9,10]. The discovery of this versatile cell-binding site has opened new experimental pathways to elucidate specific molecular mechanisms of matrix effects on cells. (3) Their interaction with cells is mediated by specific transmembrane receptors, the integrins or transmembrane heparan sulfate proteoglycans (syndecans, glypicans, CD 44, and others). A selection of *in vitro* and *in situ* effects of RGD-containing peptides in cell biology illustrates the wide spectrum of activities associated with this sequence: RGD-containing peptides inhibit the adhesion to fibronectin, vitronectin, thrombospondin, and laminin fragments of numerous cells, including normal and transformed fibroblasts, epithelial cells, hematopoietic cells, and various embryonal cells [9,11]; they block the migration of neural crest cells *in vitro* and *in vivo* [7] and interfere with amphibian and *Drosophila* gastrulation [12–14] and the metastasis of B16 melanoma cells [15,16]. GRGDS (Gly–Arg–Gly–Asp–Ser) can serve as substrate for cell adhesion, is chemotactic for fibroblasts, mediates cell-cell adhesion, and triggers somite segmentation [3,17].

In this chapter, we try to summarize present knowledge about the major adhesive glycoproteins (Table 1), focusing on their common structural and functional features and on their interaction with cells. In view of the several thousand publications solely on fibronectin and laminin published to date, the citation of published work in this chapter has had to remain selective and incomplete. However, comprehensive overviews on fibronectin can be obtained from several review articles [17–20] and two excellent books [21,22]. A number of informative review articles are also available for the laminins [23–25], thrombospondins [26–28], tenascins [29–32], and vitronectin [33–35]. The adhesive properties of matrix proteins, their specificities, and their roles in cellular function cannot be understood, however, without reference to cellular matrix receptors, in particular the integrins and cell-surface heparan sulfate proteoglycans. For this reason, a short overview of these receptors stands at the end of the chapter, although it can only remain very general in light of the fact that over 12,500 articles on integrins have been published at the time of writing.

FIBRONECTIN

Fibronectin occurs both as a soluble, monomeric molecule with an M_r of 540 kDa in plasma and other body fluids and in polymeric, fibrillar form on the cell surface, in the interstitial space, and in thrombi. The independent discovery of fibronectin, the "prototype of a cell adhesion protein" [17], in the early 1970s in several laboratories as a result of completely diverse lines of investigation illustrates its multifunctional, complex nature. During a search for transformation-sensitive cell-surface proteins in fibroblasts, fibronectin was identified and extracted with urea from cell cultures [36–39]. By immunoelectronmicroscopy, the protein was also identified as an integral component of peri- and extra-cellular matrix fibers [40–41]. It was found to be homologous to a previously isolated plasma protein ("cold insoluble globulin" [42]) and was identified as the major cell-adhesion-promoting activity in plasma [43–45]. Another group discovered this same protein while searching for gelatin-binding activity in serum [46].

Structural and immunological comparison of the isolated molecules, and cleavage into smaller fragments retaining the originally addressed functions, demonstrated that the plasma and cell forms of fibronectin were very similar. Sequence analysis at both protein and cDNA levels revealed the existence of three dominant splice regions in the fibronectin gene, potentially giving rise to up to 20 different splice variants [47,48]. All fibronectin molecules are composed of two nearly identical subunits, with various binding regions arranged in a linear fashion (Figs. 1A, 2d, 3). At least two cell-binding domains [49–52] are identifiable in addition to a gelatin-binding domain [53,54], a self-assembly site involved in the formation of fibrils [55–57], three heparin-binding sites, and other domains binding to DNA, proteoglycans, fibrin, and hyaluronic acid [22,54,58].

The broad interest fibronectin is receiving in cell biology and pathology reflects its wide range of biological activities and its ability to regulate cellular activities *in vitro*. Fibronectin has been shown to promote migration and proliferation of embryonic and tumor cells *in vitro* and *in vivo* and to control cell differentiation, cell shape, and cytoskeletal organization. It is also involved in wound healing, hemostasis, metastasis, and control of tissue and organ development.

The key role of fibronectin in early embryonic development became strikingly evident after complete fibronectin gene inactivation by homologous recombination [59]. Mouse embryos deficient in both alleles of the fibronectin gene (fibronectin knockout mice) died at early stages. The fetuses lacked somites and notochord and showed an abnormal heart and vasculature and a deformed neural tube. This phenotype underlines the importance of fibronectin for the proliferation, differentiation, and migration of mesodermal cells.

Cellular Origin and Distribution

Hepatocytes secrete into human plasma a soluble form of fibronectin [19,60]. Following blood coagulation, about 150–250 μg/mL of fibronectin, which is partially degraded by proteases of the coagulation cascade, remains in serum. Soluble forms of fibronectin are also found in most other body fluids, such as synovial fluid [61], seminal plasma [62], saliva, and cerebrospinal fluid [21], but only in μg amounts per mL. In cultured fibroblasts from many species, including chick, rat, human, hamster, and mouse, fibronectin is secreted and can be identified on the cell surface or in the pericellular matrix by immunofluorescence and by surface iodination [39]. Most other mesenchymal cells, such as chondrocytes [63], myoblasts [64], and also epithelial cells [65,66], show pericellular labeling with anti-fibronectin in cell culture. Transformed cells produce less fibronectin and show less on their surfaces; however, exogenously added fibronectin binds to the cell surface and restores the normal fibroblastic phenotype [67,68]. This puzzling phenomenon may find its explanation in a phosphorylation of integrin receptors and a resulting change in the interaction with talin and the formation of adhesion plaques and stress fibers in transformed cells [69].

Extensive immunohistological surveys have located fibronectin in most embryonic mesenchymal tissues [70], and in all reticular and connective tissue fibers, for example, in liver, kidney, and lung [71,72]. It is also associated with basement membranes [73,74], although it is probably not an integral constituent of the basal lamina [75,76].

TABLE 1. Adhesive Glycoproteins

Name	Mol. Mass kDa	Subunits kDa	Cellular Receptors	Cell-Binding Motif	Cellular Origin, Tissue Distribution	Remarks
Fibronectin (FN)	500	A: 250 B: 250	α5β1, α3β1, αvβ1, αvβ3/β6 integrins α4β1 integrin syndecans	GRGD(S) REDV	Most mesenchymal and epithelial cells Plasma FN: hepatocytes	At least 8 splice variants monomer in plasma extracellular fibrils
Tenascin-C (TN-C)	~1200	190,200, or 220	α2β1 α9β1, αvβ3	RGD	Embryonic mesenchyme, tumors, glioma cells, brain, cartilage, skin	Synonyms: cytotactin, hexabrachion Transient in development and wound healing; tumor marker
Tenascin-R (TN-R)	960	160		RGD		Role in neuronal guidance
Tenascin-X (TN-X)	?				Embryonic tissue	
Thrombospondin TSP-1 TSP-2	 450 450		αvβ3 syndecans CD47/IAP, CD36	RGD WSXWSXW-XXCSVTGC	Platelet granules fibroblasts smooth muscle	Role in hemostasis, cell proliferation, collagen fibril assembly, neurite outgrowth
Vitronectin (VN)	70	70	αvβ1, αvβ3, αvβ5	GRGDS	Serum, liver	Binds PAI-1; thrombin-antithrombin complex, collagen; role in extracellular proteolysis
Laminins 1–12 (LN)	500-900	α, β, γ	α1, α2, α3, α9 − β1, α6β1, α6β4, α7β1	RGD (cryptic) ?	Epithelial, endothelial cells, embryonic fibroblasts, myoblasts, tumor cells	LN-1 (EHS-Lam) embryonic LN2/4 in muscle, LN5 skin BM, LN 8,10: endothelial cells
Nidogen/ Entactin	150	150			Embryonic mesenchyme, epithelia	Binds specifically to the γ1 chain of laminins
Collagen I Collagen II	290	$\alpha1(I)_2$ α2(I) $\alpha1(II)_3$	α1β1, α2β1, α3β1 syndecans α10β1	GFQGER in α1(I) chain	Fibroblasts, osteoblasts, almost all tissue cells Chondrocytes	Fibril- forming collagens
Collagen IV	450	$\alpha1(IV)_2$ α(IV)	α1β1, α2β1	(R, G, D) (nonlinear)	Epithelial cells, myoblasts, basement membranes, tumor cells	Forms cross-linked network
Collagen VI	400	α1, α2 α3		RGD	Fibroblasts, chondrocytes, ligaments	Microfibrillar collagen, highly disulfide cross-linked

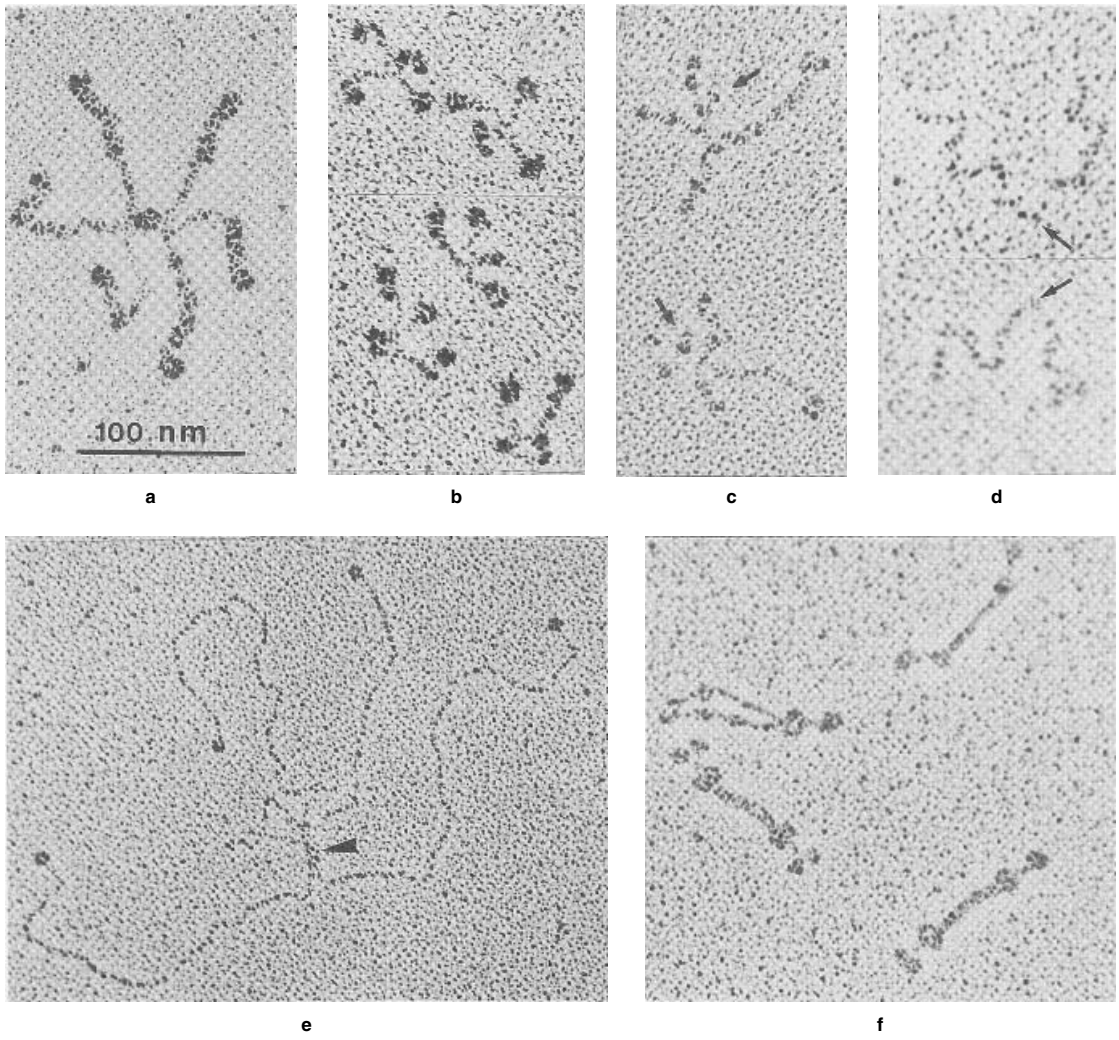

Figure 2. Ultrastructural images of adhesive glycoproteins revealed by rotary shadowing electron microscopy. (**a**) Tenascin-C from chick embryo fibroblast cultures, showing its six-armed ''hexabrachion'' structure (reproduced with permission from [217]). (**b**) Thrombospondin from human platelets (reproduced with permission from [28]). The bolas-like structure is caused by the globular domains at the carboxyl terminus of each of the three chains. The fourth globule consists of the associated three amino termini. (**c**) Laminin-1-nidogen complex from mouse EHS basement membrane tumor. Three short arms and one long arm comprise the laminin molecule. Nidogen (arrow) is bound to domain III of the B chains (see Fig. 1). Nidogen is indicated by an arrow. (**d**) Fibronectin from human plasma; two long, flexible arms are linked together at their carboxyl termini by a cystine bridge (arrows). (**e**) Human type IV procollagen tetramer from PYS (parietal yolk sac) cell cultures. Four molecules assemble through their aminotermini (''7S domains'', arrowhead). The globules represent the non-triple-helical carboxyl-terminal (NC1) domains. (**f**) Human type VI collagen tetramers from human placenta (for structural details, see Chapter 2, this volume). All figures are printed at the same magnification.

Primary Structure

Fibronectin consists of two polypeptide chains, each about 2500 amino acid residues long, that are covalently linked at the carboxyl terminus by cystine bridges (Figs. 1A, 3). The fibronectin gene exists in only a single copy, which is 50 kb long and contains 47 exons [77,78]. Therefore, both chains are either identical or may differ as a result of differential splicing. The entire amino acid sequence has been determined for human plasma fibronectin by cDNA sequencing [78,79] and for bovine plasma fibronectin by protein sequencing [80,81]; rat and chick fibronectin sequences are also available [21,82]. The two polypeptide chains are identical (with the exception of the short IIICS domain, which is lost in one chain of plasma fibronectin by differential splicing; see below) and consist of three types of structural repeat (''homologies''): nine type I repeats (each 45 amino acid residues long) at the amino end and three at the carboxyl terminus; two type II repeats (each of 60 amino acid residues) after the first six type I repeats; and 15–16 type III repeats (90 amino acid residues each) in the middle of the molecule (Fig. 3) (for reviews, see [22,83]). Each repeat is encoded by a single exon. Type I and II homologies, which are disulfide-bonded loops, have also been found in factor XII and plasminogen activator, in gelatinases, and in the seminal plasma proteins PSPA3 and PDC 109 [84], among others. Type I modules are linked together by β-strands with little flexibility and thus confer rigidity on this part of

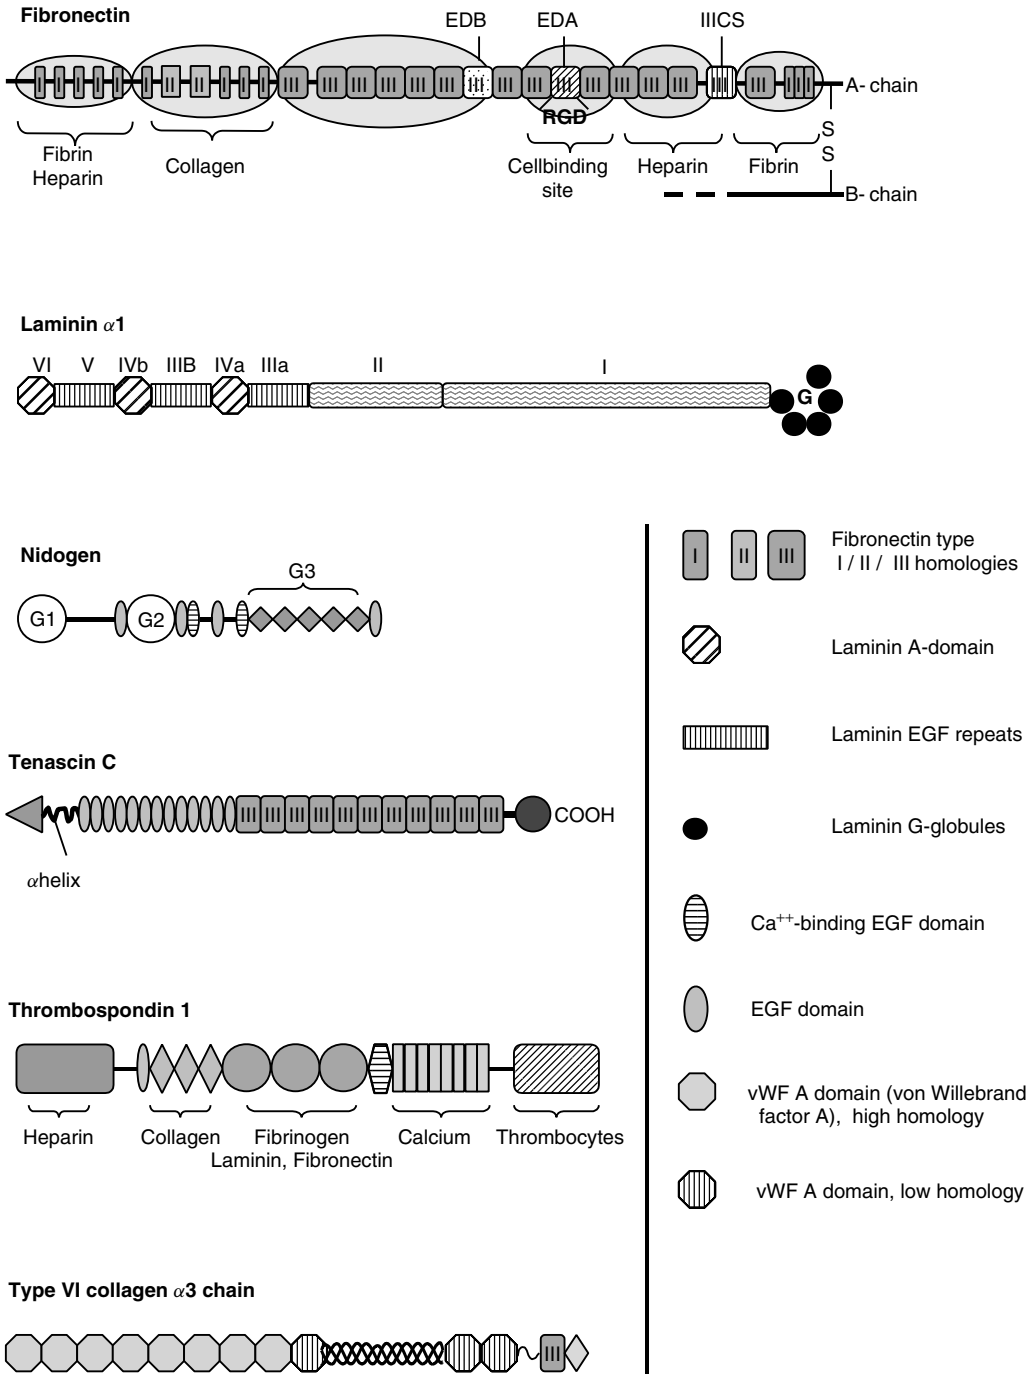

Figure 3. Modular Structure of Matrix Macromolecules. The general theme of adhesive matrix proteins appears to be a reiteration and amplification of structural motifs. A series of the most frequent recurrent motifs is shown. In **fibronectin**, three repeat types are found (12 class I; two class II; and 17 class III). Two of the type III repeats, EDA and EDB, can be differentially spliced, and in IIICS the splicing is complex (after [58] and [17]). Type III repeats are also found in tenascin-C (below) and other proteins. In **laminins**, the motifs are different; in the short arms of the molecules, globular domains (VI and IV) are separated by regions of cysteine-rich EGF-like repeats (V and III), while in the long arm, long regions of α-helix (II and I) are seen [132,501]**.** In **nidogen**, the EGF-like repeat is found again. Nidogen consists of three globular domains (G1-G3), with two of the globules (G2 and G3) connected by a rod-like segment containing two EGF-like and two Ca- binding motifs (after [360]). In **tenascin C**, each arm of the hexamer extends from a central N-terminal globule, followed by $13\frac{1}{2}$ EGF-like repeats and a number of fibronectin type III repeats which may be interrupted by fibronectin type I repeats depending on the splice variant. The arms end with a C-terminal globular domain (after [187]). The motifs in **thrombospondin** (here TSP-1) have not yet been found elsewhere, but the terminal globular domains are separated by seven distinct regions, three of which (circles) are reiterations (after [26,28]). **Collagen VI** has 17 von Willebrand factor (vWF A)-like repeats per trimer, eight strongly and three weakly homologous in the α3 chain and three weakly homologous in each of the α1 and α2 chains. Each chain also bears several RGD-sequences in the triple helical part [466].

the fibronectin molecule [85]. Type II homologies are also constituents of prothrombin [28] and tenascin (see below). Structural analysis of the type II-like domain of PDC 109 by nuclear magnetic resonance (NMR) revealed several loops forming a tight globular structure with a surface-exposed hydrophobic depression, a potential ligand-binding site 1 [84]. Type III homologies are found in 2% of all animal proteins, including, for example, tenascin, and collagens XII and XIV. They are composed of seven β-strands, forming two layers of β-sheets, which are held together by hydrophobic forces. The FN-III$_{10}$ module contains the cell-binding sequence, RGD, at the apex of a loop in a rather flexible conformation, allowing it to adopt more than one conformation when interacting with different integrin receptors.

The widespread occurrence of the conserved structural repeats in many extracellular macromolecules, and the fact that each repeat is encoded by one exon, indicates that fibronectin and many other extracellular matrix molecules have evolved by gene duplication and exon shuffling within ancestral precursors containing type I, II, and III repeats.

Carbohydrate, Sulfate, and Phosphate Groups

The fibronectin molecule contains 4–10% (wt/wt) carbohydrate, depending on its cellular origin. Fibronectin from transformed and embryonal cells contains more O- and N-linked carbohydrates than that from adult fibroblasts or plasma, which lacks the EIIICS segment with three carbohydrate binding sites in one chain. Placental and amniotic fluid variants also contain lactosaminoglycans in addition to the mannose- and sialic acid-containing N-linked sugars.

The carbohydrates protect fibronectin against proteolytic attack; whether they control the multiple interactions of fibronectin with cells and other macromolecules remains controversial. It has been reported that a secreted, nonglycosylated fibronectin, prepared in cell cultures in the presence of tunicamycin, was fully effective in mediating cell attachment and spreading [86]. Lack of carbohydrate may increase the interaction of fibronectin with gelatin and enhance its ability to promote the adhesion and spreading of fibroblasts [87].

Other post-translational modifications of fibronectin include phosphorylation of a serine residue at the carboxyl terminus and tyrosine sulfation in certain variants [88]. The biological function of these modifications is, however, unknown.

Splicing Variants

Variations in the solubility and subunit size of fibronectin from different sources had suggested heterogeneity among fibronectin molecules [89]. Sequencing of cDNA clones derived from different cells subsequently revealed the existence of at least ten different splicing variants, all derived from the same gene [17,47]. Two type III homologies, termed EIIIA and EIIIB (Fig. 3), may be completely spliced in or out; for example, they are both absent from plasma fibronectin but retained in fibronectin expressed in fibroblasts [90–92]. The EIIIB module is highly conserved among rat, human, and chicken; it is important for the conformation of fibronectin and contains the cryptic epitope responsible for fibril formation. Another domain, called V or IIICS (“connecting segment”), may also be partially spliced, giving rise to five splicing variants [91]. For example, in plasma fibronectin, the IIICS segment is partly spliced out by exon subdivision in one subunit [93]. The IIICS segment contains a second potential cell attachment site [51,94] and two binding sites for O- and one for N-linked oligosaccharides [81,92].

The role of some splice variants of fibronectin is still unclear. EIIIA expression is higher in transformed cells and tumors than in normal mammalian cells [95], but this is not observed in chick cells [69]. Using *in situ* hybridization and ribonuclease protection assays with probes specific for the spliced regions, fibronectin variants lacking either EIIIA or EIIIB sites were found to be distributed differently in the chick embryo [96]. In wound-healing experiments in adult rats, the fibronectin variant lacking both EIIIA and EIIIB, which is the major form in rat skin, was found in dermis and muscle, whereas the two segments were re-expressed in the fibronectin form found at the base of the wound [97].

Domain Structure and Molecular Interactions

Like most extracellular matrix molecules, the fibronectin molecule represents essentially a linear arrangement of modules that retain their structural and functional properties as isolated entities [98]: two or three fibrin-binding domains, a collagen-binding domain, two or three heparin-binding domains, at least two cell-binding domains, and a fibril-assembly domain (Fig. 3).

The multidomain structure of fibronectin has been discussed comprehensively in several review articles [17,22,58, 83,98]. Fibronectin binds not only to cells but also to a number of macromolecules, including denatured collagen I (gelatin) and, to a lesser extent, also native collagen [99], heparin [100], fibrin [101], thrombospondin [102], DNA [103], and actin [104]. The binding sites for these components are in separate domains; thus, fibronectin can undergo multiple simultaneous interactions with other molecules and with cells. Because the binding domains are generally more resistant to proteases than are their intervening bridges, they can be isolated as proteolytic fragments retaining full activity [50,98].

The amino-terminal 70 kDa domain is involved in matrix assembly and in fibronectin incorporation into the pericellular matrix of fibroblasts [105]. A 29 kDa fragment of this domain contains both a heparin- and a fibrin-binding site (see below); it is also involved in the binding of staphylococci to fibronectin [106–108], indicating that fibronectin might be a target for staphylococcal infection. In accordance with this notion, a fibronectin receptor has been identified in staphylococci and cloned [109,110].

Collagen-Binding Domain

The high affinity of fibronectin for denatured collagen (gelatin) ($k_d = 2–5 \times 10^{-9}$ M) [20] is unique and rather specific; thus, fibronectin can be purified from plasma by a single-step chromatography on gelatin-Sepharose to an extent of >90% purity [46,111]. Fibronectin also binds triple-helical collagen types I, II, III, IV, and V [99], but significantly only at 37 °C, when the collagen triple helix is partially denatured [112,113]. The general understanding is that fibronectin preferentially recognizes unfolded collagen structures. This is also supported by the fact that the fibronectin-binding sites in collagen types I and II are located in their single collagenase cleavage sites, where the triple helix is loosened [114]. The affinity of fibronectin for these sites may be sufficient to allow it to bind to collagens at 37 °C *in situ* thereby explaining the apparent codistribution of fibronectin and type I collagen in cell cultures and the electron-microscopical observation of fibronectin periodically decorating collagen type I fibrils [115].

The collagen-binding domain in fibronectin is located in a 40–45 kDa proteolytic fragment located next to the amino-terminal domain [53] (Fig. 1A). By preparing fusion proteins from overlapping cDNA clones from this region, the collagen-binding sequence has been restricted to 14 amino acid residues in the second type II repeat and the following type I repeat [79] (Fig. 3).

Fibrin-Binding Domains

Three binding sites for fibrin have been identified on each arm of fibronectin: one in the amino-terminal 29 kDa fragment [116], one close to the carboxyl terminus [118], and a third adjacent to the collagen-binding site, which is sensitive to trypsin and cathepsin D [117]. These interactions are of low affinity at 37°C but may be stabilized by covalent cross-linking through factor XIII (transglutaminase) [118]. In fibrinogen, the fibronectin-binding site is located in the carboxyl terminus of the α-chain.

Heparin-Binding Domains

The heparin-binding sites of fibronectin are most likely involved in the adhesion and spreading of certain cell types, such as 3T3 fibroblasts and melanoma cells. In these cells, but not in others, such as normal rat kidney (NRK) or NIL8 fibroblasts, the formation of focal adhesion plaques on fibronectin requires the presence of the heparin-binding domain in FN III repeats 12–14 [119,120] bound to syndecan [121–123]. One heparin-binding site is located in the amino-terminal domain; it is of low affinity and modulated by Ca^{2+}. The interaction is ionic and can be dissociated with 0.25 M NaCl. Heparin binding at the carboxyl-terminal site is stable up to 0.5 M NaCl and Ca^{2+}-independent [124].

Other glycosaminoglycans that bind to fibronectin are hyaluronan and chondroitin sulfate proteoglycan [125]. Hyaluronan binding is stable even at 1–2 M NaCl, suggesting a nonionic interaction [126].

Cell-Binding Domains

The search for the cell-binding site of fibronectin culminated in two exciting discoveries: the ubiquitous cell-binding motif, Arg–Gly–Asp (RGD), and the integrin superfamily of matrix receptors. Initially, the smallest fragment retaining cell-binding activity *in vitro* was a 75 kDa tryptic fragment [50]. For certain cells, such as NRK cells, activity could be retained in an even smaller 11.5 kDa pepsin fragment [127]. Sequencing of this peptide, and the production of progressively shorter, overlapping peptides for cell-adhesion experiments, finally narrowed the cell-binding activity down to the sequence Arg–Gly–Asp–Ser (RGDS) [50,128] in the 11th type III repeat (Fig. 3). The sequence motif, RGD, was later found in other extracellular cell-adhesive proteins, such as vitronectin (RGDV, Arg–Gly–Asp–Val) [129], fibrinogen [9], thrombospondin [130], collagen types I and VI [131], the α-chains of murine and human laminin [132], nidogen [133], von Willebrand factor, and others (for an overview, see [10]). The pentapeptide GRGDS supports cell adhesion when fixed to nonadhesive surfaces and strongly inhibits cell adhesion to fibronectin or vitronectin at concentrations between 0.1 and 0.5 μg/mL. Substitution of the aspartic acid residues in the peptide by glutamic acid (to give GRGES) completely abolishes its cell-adhesive activity, indicating high specificity of the cell-binding sequence [10].

An RGD-independent cell-binding site for melanoma cells has been located in the IIICS region of fibronectin [49]. Interestingly, adhesion of these cells is also inhibited by the GRGES sequence, which is completely inactive toward other cell types. Further analysis of this region has demonstrated two cell-binding sites, one in the amino-terminal part of the IIICS domain, which is recognized by melanoma and ganglion cells [134], and another near the carboxyl end of the IIICS domain, which contains an REDV sequence as the minimal cell-recognition signal.

Because the RGD sequence is not unique to fibronectin, the involvement of flanking sequences, distal adhesion elements, or conformational differences is postulated to explain the specificity of cell interactions with various glycoproteins. The elucidation of the exact mechanism of the molecular interactions among the various integrins and cell-binding structures of the glycoproteins is one of the most challenging tasks in current matrix research [135].

Fibronectin Monomers and Fibril Assembly

Although the fibronectin monomer as isolated from plasma appears as a thread-like molecule with the two chains unfolded by rotary shadowing (Fig. 2d), it is likely that the chains fold back in aqueous solution into a more globular molecule because of an alternating positive and negative charge distribution [82]. The assembly of monomers into fibronectin fibrils, such as observed on cell surfaces and in the interstitial space, requires the unfolding and activation of a cryptic site in the first type III repeat ($FN\text{-}III_1$) [55], which is then able to interact with another site in the fibronectin molecule to form fibrils [56,57] or a functionally distinct form, so-called "superfibronectin" [136]. Fibronectin assembly on cell surfaces is a multistep event and requires β1 or β3 integrins, while collagen and fibrinogen fragments may contribute to the unfolding process. Not all cells that synthesize fibronectin assemble fibronectin fibrils on their surfaces (e.g., macrophages [137], activated neutrophils [138], and activated T-lymphocytes [139]). This demonstrates that fibronectin fibril assembly is a cell-specific event involving distinct cell-surface molecules. Blocking antibodies against the β1 integrin subunit can prevent fibronectin assembly on the cell surface [140], which can be restored by the overexpression of β1 integrin subunits in β1 integrin-deficient cells [141]. Also, $\alpha v\beta_3$ integrin is able to induce fibronectin fibril formation [141], while other fibronectin receptors such as α4β1 or αvβ1 are unable to do so. Non-integrin membrane proteins such as syndecans or collagens [114] or a GGKD (Gly–Gly–Lys–Asp) membrane protein [142] may also promote fibril formation.

Biological Activities of Fibronectin

Cell Adhesion and Spreading In Vitro

The list of primary cells, cell lines, and tumor cells that have been shown to adhere to fibronectin *in vitro* [3,21] includes almost all embryonal and adult mesenchymal and epithelial cells and connective tissue cells; in addition, circulating lymphocytes and activated macrophages can be induced to become adherent to fibronectin.

Initial adhesion to fibronectin *in vitro* is inhibited by RGD peptides [50,128,143] and is usually followed by spreading and the formation of focal adhesion plaques, which involve the heparan sulfate-binding region. Immunofluorescence and electron-microscopical studies have suggested transmembrane linkages between extracellular fibronectin and intracellular actin filaments [144–146], which, via the mediators vinculin, talin, and fibulin, can bind to the cytoplasmic domain of the β-subunit of the α5β1 integrin fibronectin receptor [147–150].

Cell Proliferation and Migration

Fibronectin and vitronectin provide the major substrate in serum-containing cell culture, allowing the attachment and proliferation of anchorage-dependent cells. Fibronectin also stimulates the proliferation of myoblasts [151], keratinocytes [152], and hepatocytes [153] and allows the migration of neural crest cells [4] and melanoma and other carcinoma cells *in vitro* [15,16]. Other cells, such as myoblasts, are arrested by fibronectin and do not migrate [154,155]. The fact that cells adhere strongly to fibronectin, yet detach during mitosis and migration, illustrates the reversible character of fibronectin-cell interactions and reflects the degree of complexity of such interactions in tissues and organs.

Cell Shape and Differentiation

Cell spreading on fibronectin can induce the depolarization of epithelial cells and suppress the expression of differentiation markers, whereas laminin has the opposite effects (e.g., supporting the polarization of epithelial cells [156]). Spreading on fibronectin is also an early step in the dedifferentiation of chondrocytes [157,158] and myoblasts [159]. Moreover, fibronectin inhibits or delays several aspects of differentiation *in vitro*, such as the differentiation of keratinocytes [152], the formation of cartilage nodules in chondrocyte cultures, and the chondrogenic differentiation of limb bud mesenchyme [160]. On the other hand, transient expression of fibronectin during the condensation phase of limb bud mesenchyme [161–163] does suggest a role in chondrogenic differentiation *in situ*.

Role of Fibronectin In Vivo

The multiple effects of fibronectin on cells *in vitro* have been interpreted in terms of their possible physiological roles in plasma and the extracellular matrix. In plasma, fibronectin is assumed to have an opsonic effect on tissue-degradation products because of its affinity for denatured collagen, actin, DNA, and proteoglycans. As a major fibrillar component of blood clots, it certainly plays a central role in hemostasis and wound healing [164].

The location of fibronectin along migratory pathways in embryonic tissues indicates a controlling function in cell migration and proliferation [165–168]. Immunohistological studies suggest that neural crest cells can migrate along fibronectin-rich pathways in the early embryo [165,169]. Similarly, latex particles coated with the cell-binding domain of fibronectin are arrested in the chick embryo after microinjection, probably by binding to matrix receptors [170], while beads coated with the collagen- or heparin-binding domain of fibronectin are translocated ventrally. This illustrates the delicate balance between adhesion- and migration-stimulating activities of the extracellular matrix, which are influenced not only by the adhesive glycoproteins but also by the expression of matrix receptors at different sites and stages in development [17].

Another major function of fibronectin may be in the homing of lymphocytic cells. Whereas circulating lymphocytes do not bind fibronectin, activated T cells develop fibronectin receptors (VLA, very late antigens) and adhere to fibronectin and other matrix proteins, which may be the general mechanism by which inflammatory cells adhere to tissues during inflammation [18,171].

Until it is possible to probe at the immunocytochemical level for the specific signals generated by cell-fibronectin interactions, it will be difficult to identify particular functions of fibronectin in developing or adult tissues. The complexity of the analysis of such cell-fibronectin interactions is further illustrated by the fact that fibronectin is often interwoven with, or close to, other adhesive glycoproteins, such as collagens and laminins, which can have the opposite effect on cells *in vitro*. Antibody-blocking experiments *in situ* are subject to multiple artifacts, but useful information might be obtained from mutants with defects in fibronectin or its receptors should they be found.

TENASCIN

The tenascins are a family of large and complex extracellular glycoproteins ($M_r > 10^6$) with a unique molecular shape (Fig. 1B) and widespread tissue distribution. At present, five or six different tenascins are known (Tenascin-C, -R, -X, -Y, and -W), some of which occur as different splice variants. The six-armed tenascin-C (hexabrachion) consists of two three-armed units that are linked together at their amino ends by a central globule; each arm carries a further globule at its carboxyl-terminal end (Fig. 2a) [29–32,172,173].

Tenascin-C was independently discovered under different names in several laboratories. From glioma tumors, a "glioma mesenchymal extracellular matrix protein" [174] was extracted, which was later shown to be identical or homologous to the "myotendinous antigen M1" [175] and the "hexabrachion" molecule, a large, six-armed glycoprotein (Fig. 2a) coextracted with fibronectin from fibroblast cultures [176], "cytotactin" isolated from fetal chicken brains [177], and "J1 glycoprotein" involved in neuronal cell adhesion and neural development [178]. Tenascin-R (TN-R), a smaller molecule than tenascin-C (TN-C), has been originally discovered as "restrictin" in chicken brain [179] and as J1-160/180 (janusin) in rat brain [180]. TN-R is largely restricted to the central nervous system and the retina, where it plays a major role in neuronal differentiation and axonal growth (see below) [30].

Tenascin-X (TN-X), the largest of the five tenascins, is ubiquitously expressed in human fetal tissues, particularly blood vessels and skeletal, cardiac, and smooth muscle, but is absent from brain and testis [181]. Its distribution is nearly complementary to that of tenascin-C [182]. Tenascin-Y (TN-Y) has been found in chicken heart and skeletal muscle and, like tenascin-X, is structurally homologous to TN-C [29]; tenascin-W has been discovered in zebrafish [183].

Tenascin Structure

Tenascins are largely a composite of structural domains found in other molecules, with only short, tenascin-specific sequences (Fig. 3) [184–187]: the amino-terminal globular domain of each of the arms of TN-C is part of the central globule; it is followed by a short stretch of four α-helical heptad repeats, which allow the assembly of three arms into a triple-stranded coiled-coil structure in the connecting region [184,187] (Fig.1B). TN-C and TN-R, but not TN-X, contain a single cysteine residue at their amino terminus, which can connect two three-armed trimers to form the hexabrachion; yet, TN-R has been isolated so far only as a single trimer [188]. The α-helical part is followed by $13\frac{1}{2}$ EGF-like repeats in TN-C, four in TN-R, and 17 EGF repeats in TN-X. The outer, thicker arm of TN-C, representing two-thirds of each chain, consists of 8–16 fibronectin type III homologies (TNfnIII) containing numerous N-glycosylation sites [189]. Upon SDS-polyacrylamide gel electrophoresis, tenascin-C separates into three subunits of M_r 190 kDa, 200 kDa, and 230 kDa that are structurally related but differ in stretches of up to 273 amino acid residues due

to differential splicing of the same gene product (see below). Eight splice variants of TN-C have been found so far, all of which contain FN III repeats 1–8, which may be interrupted by additional other FN repeats [31] (Fig. 3). In TN-C, an RGD sequence has been located ten residues from the end of the third FN III domain [185,190]. This RGD sequence is involved in αv integrin-mediated cell adhesion of TN-C [191–193]; another cell-adhesive domain is located in the C-terminal globule [194] (see below) and shows 40% homology to the β- and γ-chains of fibrinogen.

Tenascin Distribution in Tissues

Tenascin-C shows two patterns of distribution: a transient appearance in certain embryonic tissues, in wound healing, and in tumors, and a permanent expression in some adult tissues, such as the myotendinous junction, nervous tissue, and cartilage [195]. During chick embryogenesis, TN-C appears first with gastrulation and subsequently in association with the basement membrane of the neural tube and in myotendinous junctions, smooth muscle, kidney, lung, and other tissues in the developing chick embryo [196,197]. Typical is the appearance of TN-C in certain cell-migration pathways [198,199].

The presence of TN-C is most prominent in the extracellular matrix of nervous tissues [174,197]. It is synthesized by astrocytes [174] and has been located in glial fibers in the neural tube and in the retina [198]. A characteristic feature of TN-C is its temporary and strictly spatially restricted appearance in certain embryonic mesenchymes. A strong expression of TN-C is found in maxillary mesenchyme during tooth development, but complete turnover follows differentiation of mesenchyme to odontoblasts. Generally, TN-C is pronounced in embryonic mesenchyme adjacent to epithelia, for example, in mesenchyme surrounding fetal glands and hair follicles, the developing kidney [201], and gut [202]. In the developing kidney, TN-C appears in the mesenchyme shortly after its interaction with epithelium [201], suggesting the induction of TN-C synthesis by the epithelium. In fact, an epithelial cell line (MDCK, Madin-Darby canine kidney) is able to stimulate significantly TN-C synthesis in melanoma cells, and mouse mammary epithelium induces tenascin-C synthesis in the adjacent stroma [203]. During limb bud chondrogenesis, TN-C is pronounced in the cartilage blastema but not in the surrounding mesenchyme [204,205]. It is also present in the perichondrium and in osteoprogenitor cells in endochondral bone formation, but is absent from bone matrix [204,205]. The localization of tenascin in bone marrow [206,207] and thymus [208] indicates a role for tenascin in hematopoiesis [209]. Adult tissues that have been shown to contain TN-C include brain [177,210], gizzard, skin [172,197], and cartilage [205,211,212].

There is considerable interest in the selective accumulation of tenascins in human tumors such as gliomas [174] and mammary tumors [172,213]. Tenascin is associated not only with malignant tumors, in particular breast, lung, and cervical carcinomas [214], but also with benign tumors, fibrocystic diseases, or neuroblastomas [213]. The majority of the tenascin in tumors is synthesized by stromal cells from the host tissue, but carcinoma cells may also be induced to produce tenascin. The role of tenascin in tumorigenesis is not yet clear. By cross-breeding TN-C-deficient mice with a strain that develops spontaneous mammary tumors, Talts et al. [215] demonstrated that the absence of TN-C had no effect on the number and size of tumors, their rate of proliferation, or apoptosis. Tumor organization, however, was different in the absence of tenascin, showing smaller tumor cell clusters and more monocytes in the stromal compartments. Similarly, tenascin is up-regulated in fibrotic tissues, such as the fibrotic liver, or in the heart muscle of myocarditis patients [216].

Adhesive and Antiadhesive Activities of Tenascin

Tenascins are involved in a variety of cellular interactions and activities that may, in part, appear conflicting, thus illustrating the complexity of tenascin function. Primary chick embryo and human fibroblasts, tumor cells, and endothelial cells attach to TN-C but do not spread [190,217]. TN-C also inhibits the adhesion of chick fibroblasts to fibronectin, and this inhibitory activity can be neutralized by a monoclonal antibody against the C-terminal part of the TNfnIII homologies [217]. The complex role of tenascin in regulating cell adhesion is best illustrated by its apparently "double-faced" (tenascin-R is also called "janusin" [239]) behavior toward nerve cells. TN-C promotes neurite outgrowth on polylysine coated culture substrates [173] but inhibits β1-integrin-mediated cell adhesion and neurite outgrowth on fibronectin [180,218]. Based on its localization, TN-C was originally thought to form a barrier to advancing neurites, but more recent evidence has indicated that it may guide axonal growth in both a permissive and a repellent way [219,220]. In fact, it has been shown that neurite outgrowth and neurite guidance are facilitated by distinct sequences within the alternatively spliced FN III repeats A–D of TN-C [221]. RGD- and αv-integrin-dependent adhesive activities of TN-C are located in the third FN III repeat [191–193], the same site that is responsible for glioma cell adhesion and migration on TN-C [222]. This is consistent with the observation that the migration of human glioma cells on tenascin is inhibited by function-blocking anti-β1, α2, and αv antibodies [223,224]. The β1-integrin-dependent cell adhesion and neurite outgrowth on fibronectin involves a disialoganglioside-mediated signaling mechanism [225].

Endothelial cell attachment and spreading on human tenascin is also mediated by α2β1 and αvβ3 integrins [226]. The RGD site is, however, cryptic and not accessible in the native, intact tenascin molecule due to sterical hindrance [193]. In addition to this attachment site, an RGD-independent adhesive epitope is located in the same FN III_3 repeat, which is, however, α9β1-integrin-dependent [194].

The antiadhesive effect of tenascin is probably the result of two independent mechanisms. One may be sterical hindrance of cell-adhesion receptors for other matrix components by the large, umbrella-like structure of the tenascin molecule, and the other may be an active process of cell rounding and detachment, mediated by integrin recognition of tenascin.

Tenascin also binds to cell surfaces and thus can agglutinate cells [227]. Previously, the agglutinating activity was believed to be associated with fibronectin; it is now known, however, to have originated in tenascin that had contaminated cellular fibronectin preparations.

In contrast to fibronectin, tenascin undergoes only a few, selective interactions with other macromolecules. It binds to heparin through its third TNfnIII repeat [228,229] and to fibronectin *in vitro*, yet with low affinity. More marked is its binding to large, aggregating chondroitin sulfate proteoglycans [230], such as versican and phosphacan, which copurify with cytotactin from embryonic chick brain [210,231].

Tenascin-C-Deficient Mice Develop Normally

Most surprisingly and, in part, disappointingly, the generation of a TN-C-deficient mouse by homologous recombination initially did not support such a significant role for TN-C in cell and tissue function as had been predicted from *in vitro* studies [232,233]. The mice were viable and fertile, and all tissues, including central nervous system, brain, lung, and thymus, developed apparently normally. Also, wound healing was not impaired [233]. Initial suggestions that a truncated form of TN-C was still expressed in the nervous system of TN-C knockout mice [234] have not been confirmed [235]. Substitution of TN-C functions by TN-R, TN-X, or TN-Y is highly unlikely in view of their completely different tissue distributions. More recently, however, careful investigation of the TN-C knockout mouse has revealed alterations in the structure of neuromuscular junctions and peripheral nerves [236,237] and suppression of hematopoietic activity [209]. Furthermore, corneal wound healing does seem affected [238]. Spontaneous carcinomas developing in TN-C-deficient mice developed to a different size and morphology from those in normal mice and were infiltrated by an excessive number of macrophages and monocytes [215]. Thus, while distinct functions of TN-C found at the cellular level *in vitro* may be redundant, a major role of tenascin may relate to the functionality of the entire organism, such as by supporting reparative and remodeling activities in response to stress and injury.

Tenascin-R — a Regulator of Neuronal Growth in the CNS

Tenascin-R (TN-R), previously discovered as restrictin [179,180,188] or janusin [239], is largely restricted to the central nervous system, where it seems to play a complex role in the guidance of axonal growth and neuronal differentiation [30,180]. TN-R is synthesized by oligodendrocytes during myelination [225] and other neuronal cells such as motoneurons in the spinal cord and horizontal cells in the retina; it concentrates around the nodes of Ranvier [240] and perineuronal nets.

From *in vitro* studies, a variety of functions have been ascribed to tenascin-R. It promotes the adhesion and differentiation of astrocytes and oligodendrocytes [180,241], and neurite outgrowth and neural polarization when offered as a uniform substrate [200], but repels growth cone progression and causes neurite defasciculation when offered as a substrate boundary with a neurite-outgrowth-promoting molecule [218]. The interactions of TN-R with neuronal cells are thus complex and may involve different cellular receptors. One of these is contactin F3/F11 (F3 in rodents; F11 in chicken), an adhesion molecule of the immunoglobulin superfamily, which is expressed predominantly by neurons [242]. TN-R and TN-C binding to the Ig-like domains of contactin causes clustering of the receptor and seems to induce tyrosine phosphorylation of *fyn*, an *src*-like kinase [243], suggesting that TN-R-elicited signals can be transmitted by the contactin molecule. Interestingly, the β2-subunit of the neuronal sodium channel contains an Ig motif that is structurally homologous to one of the six Ig motifs of contactin. In fact, TN-C and TN-R also bind to the purified sodium channel or a recombinantly produced β subunit, suggesting that tenascin may localize sodium channels in high density at axon initial segments and nodes of Ranvier [244]. This notion, however, was not confirmed by investigations into the TN-R-deficient transgenic mouse [240].

Cell-surface gangliosides also play a regulatory role in the adhesion and differentiation of oligodendrocytes. TN-R promotes the stable adhesion and differentiation of oligodendrocytes by a sulfatide-mediated autocrine mechanism; it is antiadhesive for ganglioside GD3-positive preoligodendrocytes and inhibits their integrin-dependent adhesion to fibronectin by a disialoganglioside-mediated signaling mechanism.

As a major constituent of the perineuronal matrix, TN-R is likely to interact with other matrix components. It codistributes with versican, a large hyaluronan-binding chondroitin sulfate proteoglycan in the cerebellum [245], and phosphacan, a nervous-tissue-specific chondroitin sulfate proteoglycan in retinal optic nerve and brain [246]. *In vitro*, TN-R binds to phosphacan with high affinity and can be isolated by affinity chromatography on the amino-terminal ECF domain of phosphacan [246,247].

The functions of TN-R suggested by these *in vitro* studies were partially confirmed by the analysis of a mouse deficient for TN-R in both alleles [240]. The TN-R-deficient mice were viable and fertile, similar to TN-C knockout mice [231,232], and the anatomy of all major brain areas and the myelin structure appeared normal, but a loss of immunoreactivity and a more diffuse distribution of phosphacan was observed [240]. Furthermore, measuring action potentials in optic nerves indicated a significant decrease in conduction velocity in the TN-R-deficient mice. The authors concluded from these and other observations that TN-R has an essential role in the formation of perineural nets and in the conduction velocity of optic nerves.

THROMBOSPONDIN

Thrombospondin-1 (TSP-1) was originally detected in platelets as the major high-molecular-weight glycoprotein (M_r 450,000) of α granules released after thrombin activation [248,249]. Like fibronectin, it is a normal constituent of both plasma and serum, and the extracellular matrix, but also plays a major role in hemostasis and angiogenesis as well as in matrix organization [26–28,250,251]. The three-armed molecule, with its remarkable, bolas-like shape (Fig.2b), is able to interact with a number of plasma proteins, such as fibrinogen, thrombin, and urokinase, and with matrix proteins, including fibronectin, collagens [252], and heparan sulfate proteoglycans. Furthermore, it regulates cellular activities such as proliferation and migration, not only by direct interaction with cell-surface receptors such as integrins, CD36, CD47, and syndecans. A new, exciting aspect of thrombospondin has arisen with the finding that a distinct peptide located in TSP-1 activates latent TGF-β [253] and TSP-1 thus may interfere with the regulation of collagen, fibronectin, and matrix metalloproteinase (MMP) synthesis.

Further proteins have subsequently been discovered that are similar to thrombospondin in protein structure and DNA sequence. Thrombospondin-2 (TSP-2), like TSP-1, is a three-armed molecule and shares several properties with it, such as inhibition of angiogenesis, impairment of wound healing [254], and control of collagen fibril arrangement [255]. TSP-3 [256–258], TSP-4 [259–262], and TSP-5 are five-armed molecules; TSP-5 is also called COMP (cartilage oligomeric matrix protein [263]) (see also Chapter 4, this volume), with predominant occurrence in cartilage. This chapter focuses predominantly on TSP-1 and TSP-2, which are, besides COMP/TSP-5, the most intensively studied members of the TSP family.

Thrombospondin Structure

Electron-microscopic investigation of TSP-1 by rotary shadowing (Fig. 2b) and sequence analysis revealed that the molecule is composed of three identical dumbbell-like subunits, each with a large globular domain at the carboxyl end and a small globular domain at the amino-terminal end (Figs. 1C, 3) [26,27]. The three arms are linked together by a central disulfide knot. Similarly to tenascin, each thrombospondin subunit of 1152 amino acid residues is composed of several structural domains (Fig. 3) and repeats that are post-translationally modified by glycosylation and β-hydroxylation of asparagine residues [26,250]. The middle part of each constituent subunit and part of the large C-terminal globule contain the binding sites for collagen, fibrinogen, laminin, and plasminogen. The globular domains at both ends of the subunits are unique sequences unrelated to other protein domains. The C-terminal 18 kDa fragment of each subunit contains the thrombospondin-specific sequence RYVVMWKIRVVM (Arg–Tyr–Val–Val–Met–Trp–Lys–Ile–Arg–Val–Val–Met), (4N1K motif), which plays a key role in TSP binding to cells. This interaction is mediated by the integrin-associated protein, CD47 [264,265].

The stalk region of the molecule begins at the amino end of each subunit, with a cysteine-containing sequence involved in trimer formation and three types of repeat domains (Fig. 3). The amino-terminal region of the 70 kDa domain contains a procollagen-like domain with 37% identity to the amino-terminal propeptide of type I collagen. It is followed by three type 1 repeats (''properdin repeats''), three type 2 repeats with EGF homology, and seven aspartic acid-rich type 3 repeats containing Ca^{++}-binding sites of the calmodulin/parvalbumin type. One TSP-1 molecule binds up to 35 Ca^{++} ions; the binding of Ca^{++} significantly affects the structure of TSP-1 and its resistance to proteases, as well as its function in tissues [266].

Both murine (*tsp-1*) and human (*TSP-1*) genes are about 20 kb in length, each containing 22 exons, and are transcribed and processed into mRNA species of 6 kb length. The human gene is located on human chromosome 15q15 and the murine gene on chromosome 2, band F. The promoter of the *TSP-1* gene contains multiple binding sites for transcription factors; for example, a serum response element. Splice variants of TSP-1 mRNA have been found in some tumor cell lines but not yet in tissues [267].

Cellular Origin and Tissue Distribution

After exposure to thrombin, platelets release thrombospondin from their α granules into the plasma (30–90 $\mu g/10^6$ platelets), some of which binds to the platelet surface. As a result of this release, the thrombospondin level increases several orders of magnitude, from 97–163 ng/mL in normal plasma to 15–17 μg/mL in serum after blood clotting; in blood clots it is uniformly incorporated into fibrin fibrils. Other major sources are human umbilical cord endothelial cells and aortic endothelial cells [268]. Thrombospondin synthesis *in vitro* has also been demonstrated in skin and lung fibroblasts [269,270], smooth muscle cells [271], keratinocytes [272], and monocytes and macrophages [273].

Thrombospondin-1 and thrombospondin-2 are developmentally regulated and expressed in a temporally and spatially restricted pattern in the developing organism [274]. By immunofluorescence staining, they have been located in a fibrillar distribution in vessel walls, skin, muscle, kidney, glandular epithelium, and embryonic basement membranes [275]; at the ultrastructural level, they appear as granular structures in the vicinity of cells. In cartilage, TSP-1, TSP-2, TSP-3, and TSP-5 (COMP) occur in different sites and at different developmental stages; TSP-1 is expressed in young proliferating cartilage, whereas TSP-3 occurs only in mature cartilage of the growth plate [258].

Cellular Interactions and Functions

Thrombospondin is a major regulator of hemostasis. It plays an important role in the second, irreversible phase of platelet aggregation by stabilizing the platelet-glycoprotein (GP) IIb-IIIa-fibrinogen complex [276,277], a reaction that can be inhibited by antithrombospondin antibodies [278]. Immunofluorescence analysis and cell-surface iodination have localized thrombospondin at the platelet surface [279]. A platelet glycoprotein of 88 kDa that has been identified as the thrombospondin receptor is probably identical to GP IV [280]. Binding of thrombospondin to platelets is inhibited by OK Mb, a monoclonal antibody against GP IV, but not by the tetrapeptide RGDS (Arg–Gly–Asp–Ser) [281]. The binding of thrombospondin to platelets increases dramatically in the presence of calcium; accordingly, cell adhesion to thrombospondin substrates is abolished by EGTA [130].

TSP-1 plays a key role in regulating angiogenesis by controlling the adhesion, proliferation, and migration of endothelial and smooth muscle cells [282–284]. TSP-2 has also been shown to inhibit angiogenesis [285]. The interaction of TSP-1 with endothelial cells is rather complex and dependent on its aggregation state: in insoluble, matrix-bound form, it promotes endothelial cell proliferation, whereas in soluble form it inhibits proliferation. It also inhibits chemotactic responses of endothelial cells [283] but supports chemotaxis of peripheral monocytes [286]. The importance of TSP-1 and TSP-2 in angiogenesis was confirmed by the results of studies on TSP-1-deficient mice, which showed delayed organization and prolonged neovascularization of skin wounds [287].

The adhesion of U937 monocytes, NRK cells, and endothelial and smooth muscle cells to thrombospondin substrates is inhibited by GRGDSP (Gly–Arg–Gly–Asp–Ser–Pro) and GRGDAC (Gly–Arg–Gly–Asp–Ala–Cys); in accordance with this finding, αvβ3-integrin-binding sites have been located on the TSP-1 molecule, indicating the involvement of integrins in TSP binding to these cells, although thrombospondin only supports their adhesion, not their spreading [130,288], and prevents the formation of focal adhesion plaques. In addition, thrombospondin promotes the RGD-independent haptotactic migration of smooth muscle cells [289] and human melanoma cells [290].

TSP-1 interacts also with cell-surface receptors other than integrins, particularly cell-surface heparan sulfate proteoglycans such as syndecans and CD36 [291], as well as CD47, an integrin-associated protein. By interaction with these receptors, thrombospondin is able to elicit various kinds of cellular signaling. It is able to regulate intracellular calcium levels in fibroblasts, a process involving the RGD motif in the type 3 repeats as well as the C-terminal globular domain [292]. Signaling via the 4N1K motif couples the CD47 transmembrane receptor to heterotrimeric G_i proteins [265].

Interactions with Other Molecules

Thrombospondin binds to plasma proteins involved in hemostasis and thrombosis, such as fibrinogen, fibrin,

plasminogen, and HRGP (hydroxyproline-rich glycoprotein), and to extracellular matrix components, including fibronectin, collagen, heparan sulfate proteoglycan, heparin, and laminin [250,293]. Among collagens, type V, which is generally the least interactive of all collagens studied, shows the highest affinity for thrombospondin [294]. Rotary shadowing analysis of the thrombospondin-collagen V complexes has shown that the type V collagen molecule binds to thrombospondin via the end of its triple helix [252]. Interestingly, the formation of collagen fibrils is significantly disturbed in TSP-1 and TSP-2 knockout mice [252,255].

The list of interactions of thrombospondin with structural molecules and enzymes involved in hemostasis and fibrinolysis is still growing. Elucidation of the molecular mechanisms of these interactions, and the affinities and molecular structures involved, might eventually help in understanding the complex role of this molecule.

VITRONECTIN

Vitronectin was identified as one of the major cell-attachment factors in serum. The 70 kDa protein has multiple functions as a regulator of proteolysis in blood and tissues and as a molecule protecting cells from cytolysis by complement factors. The various functions of this multidomain protein may be explained by its conformationally labile structure, which can be induced to take up different conformations [33–35,295,296].

Synthesis and Distribution

Vitronectin is found in serum concentrations of 300 μg/mL or more produced by hepatocytes [297], but it is also synthesized by other cell types, such as megakaryocytes [295] and neural crest cells [298]. Although vitronectin mRNA has been found in many embryonic murine tissues, the distribution of the protein in adult murine tissues is somewhat restricted to the extracellular matrix of vessel walls, skin, and bone [34].

As its name implies, vitronectin has an affinity for glass. It was first partially purified from serum over glass beads [299] and shown to promote the attachment and spreading of cells *in vitro*. Subsequently, it was used as an addition to serum-free media to promote cell attachment [297,300]. It can be isolated routinely in good yield from both serum and plasma using glass bead columns and anion-exchange chromatography [301].

The traditional tissue-culture growth-factor supplement, fetal calf serum, contains up to ten times as much vitronectin as fibronectin. Under normal culture conditions, it is probably the principal cell-attachment and spreading factor that cells use.

Structure

Vitronectin consists of four distinct domains; the amino-terminal domain, with 44 amino acids, is also called somatomedin B [302,303] and is found in serum as a separate entity after proteolytic processing. In the intact molecule, the somatomedin B domain is followed by a connecting segment, which is characterized by a cluster of negatively charged residues, including sulfated tyrosine residues. This domain carries an RGDV(F) sequence, 45 residues from the N-terminus, which represents the major cell-attachment site recognized by α3β1, αvβ3 $\alpha_{IIb}\beta3$ and αvβ5 integrins [129,304] and contains a cryptic collagen-binding site [293,305]. The C-terminal half of the molecule consists of two basic, hemopexin-like domains, which can interact with the acidic residues of the connecting segment of the same molecule, thus allowing the formation of intramolecular bonds or intermolecular bonds to form vitronectin polymers [306]. In an open conformation, these domains may also bind to heparin [303,307]. In addition, there is a glycosaminoglycan recognition site some 350 residues from the N-terminus, a site recognizing the thrombin-antithrombin complex [308], and a site permitting attachment to native collagens I and III [305].

Upon SDS-polyacrylamide gel electrophoresis, vitronectin shows two bands of 65 kDa and 75 kDa [297,309]. The 75 kDa form may be a precursor of the 65 kDa form produced by COOH-terminal proteolysis. Vitronectin has been cloned, and the cDNA codes for a protein of 52 kDa [308]; the difference in molecular weight from the above is due to N-linked sugars, the sequence having three consensus sites for N-glycosylation.

Functions

A specific feature of vitronectin is its ability to bind through its somatomedin B domain to PAI-1, the plasminogen activator inhibitor and member of the serpin (serine-protease inhibitor) family [302,310]. Furthermore, vitronectin can form complexes with thrombin and antithrombin and mediates endocytosis [293]. Thus, it is to be considered an important regulator of extracellular proteolysis, particularly of fibrinolysis in blood and tissues.

Because vitronectin can bind extracellular matrix components through its glycosaminoglycan and collagen recognition sites, and cells and platelets through its RGD sequence, it is tempting to infer that it has a role in thrombus building and removal following damage to the endothelium. Furthermore, vitronectin protects tissue cells from cytolysis by complement factors by blocking the membrane-binding site of the C5b-7 complex and preventing polymerization of complement factor C9 [311].

LAMININS

The laminins constitute a family of large adhesive glycoproteins, which occur predominantly in basement membranes and modulate diverse biological functions. They are heterotrimers composed of three chains, α, β, and γ (Fig. 1D), each chain being coded for by a separate gene [24,25,312,313]. To date, five α, three β, and three γ chains have been identified, which may combine to form at least 12 different isoforms [314–320] (Table 2). The genes coding for the individual laminin chains are grouped in relation to α (*LAMA*), β (*LAMB*), and γ (*LAMC*) chains, such that *LAMA1* codes for laminin α1, *LAMA2* codes for laminin α2, and so forth [25]. The heterotrimeric chain composition of 12 different laminin isoforms listed in Table 2 and illustrated in Figure 4 has been deduced from colocalization of chain-specific antibodies by immunohistochemistry and/or their ability to isolate or immunoprecipitate the heterotrimer. The existence of some laminin isoforms, however, such as laminins 3 and 9, is based entirely on colocalization of chain-specific antibodies, which is not sufficient to confirm the existence of such heterotrimer assemblies *in vivo*. The current data suggest that further novel laminin isoforms remain to be identified and characterized.

Primary Structure

Laminin-1, composed of α1, β1, and γ1 chains, was the first of the laminin isoforms to be identified. It was originally isolated from the culture medium of a murine embryonal carcinoma cell line, M1536-B3 [321], and subsequently in large

TABLE 2. The Laminin Family

Laminin Isoform	Chain Composition	Tissue Distribution
Laminin-1	α1β1γ1	developing epithelia
Laminin-2	α2β1γ1	muscle fiber, peripheral nerves
Laminin-3[1]	α1β2γ1	myotendinous junction?
Laminin-4	α2β2γ1	neuromuscular junction, glomerulus
Laminin-5	α3β3γ2	epidermis
Laminin-6	α3β1γ1	epidermis
Laminin-7	α3β2γ1	epidermis
Laminin-8	α4β1γ1	endothelium, smooth muscle, fat, peripheral nerves
Laminin-9	α4β2γ1	neuromuscular junction, glomerulus
Laminin-10	α5β1γ1	mature epithelium and endothelium
Laminin-11	α5β2γ1	neuromuscular junction, glomerulus
Laminin-12	α2β1γ3	surface of ciliated epithelia

[1] It is debatable whether laminin-3 exists *in vivo*; unpublished data have suggested the coexistence of laminin α1, β2, and γ1 chains at the myotendinous junction in human muscle (D. Gullberg, Uppsala, Sweden).

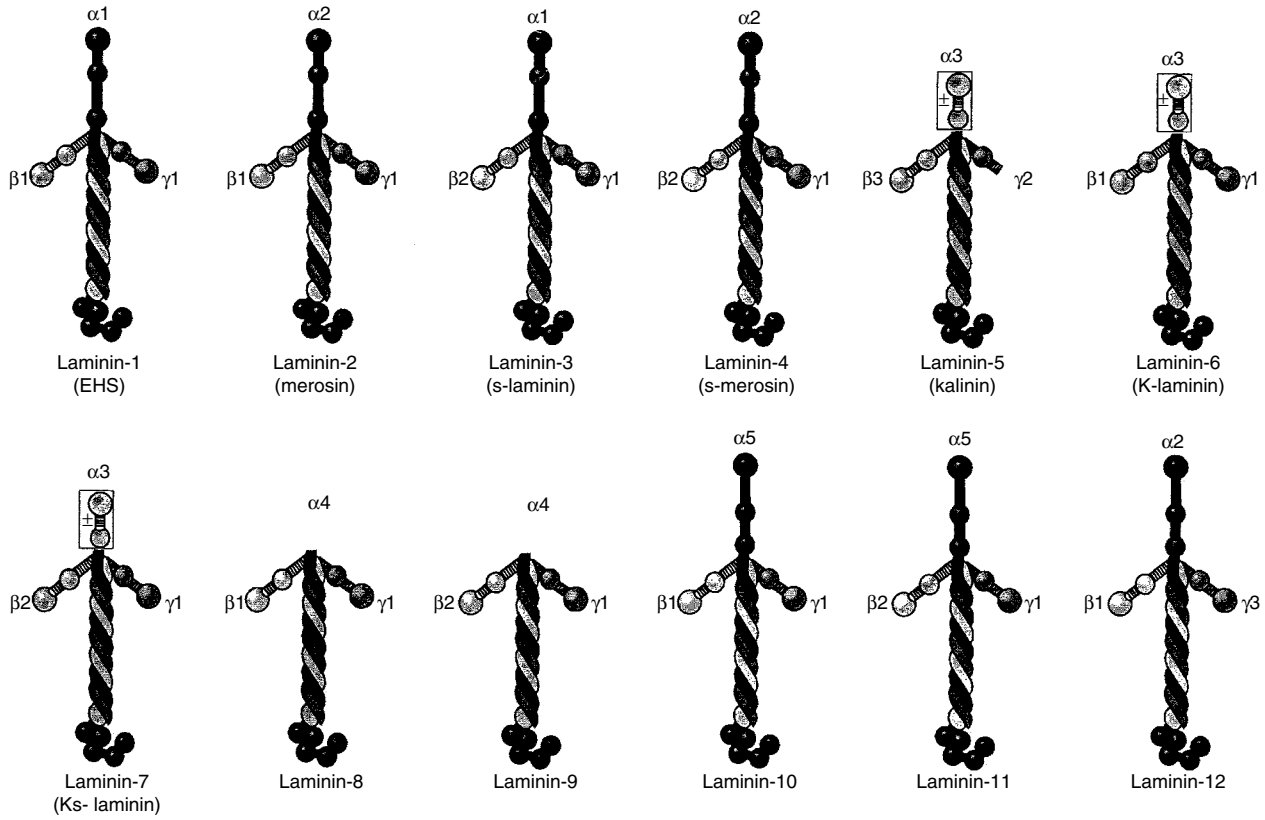

Figure 4. Laminin isoforms. To date, 12 different laminin isoforms have been identified, with distinct α, β, and γ chain compositions. Rotary shadowing has revealed laminins 1–4,10 (Drosophila-like) and 11 to be approximately cross-shaped molecules, the three short arms of which are formed by the amino-terminal portions of the α, β, and γ chains. Laminins 5–9 appear as approximately Y-shaped molecules in rotary shadowing due to reduced N-termini in the laminin α3 and α4 chains. The laminin α4 chain is N-terminally truncated, lacking domains IV–VI, while the α3 chain exists as two splice variants, one of which lacks N-terminal portions of the chain (boxed region). No rotary shadowing information is available for laminin-12. In all laminin isoforms, α, β, and γ chains unite in a coiled-coil α-helix in the central long arm and are disulfide-linked at the center of the cross and at the end of the long arm. Globular domains of the short arms are separated by EGF-like repeats. The large α-chain-derived globular domain at the end of the long arm, characteristic of α chains, is composed of five subdomains called G-globules (G1–G5) that are stabilized by disulfide bridges.

amounts from neutral salt extracts of the Engelbreth-Holm-Swarm (EHS) murine basement membrane tumor [322]. Much laminin is bound into the EHS tumor basement membrane in a calcium-dependent manner and can be rapidly extracted with EDTA, in conjunction with a 150 kDa subsidiary protein, nidogen/entactin [323,324]. This method has also allowed the extraction of various native laminin isoforms from murine [324,325], human [320,326–328], bovine [325,329], and chick tissues [330,331], from several cell lines [315,318,332–335], and from *Drosophila melanogaster* [336,337] and sea urchin [338].

Rotary shadowing electron microscopy of isolated laminins has shown them to be either cruciform, with three short arms (36 nm), each terminated by two globular domains, and a long central arm (77 nm) terminated by a single large globular domain, or approximately Y-shaped and lacking the central short arm (Fig. 2c). A current model [132] suggests that the laminins are disulfide-linked heterotrimers. All three chains align in the long arm and separate at the center of the cross, each to form one short arm [24,25,312,313] (see Fig 2c). Between 10% and 15% (wt/wt) of laminin is carbohydrate, mainly in N-linked form. Some 15 complex processed forms have been found, some containing unusual oligomeric lactosamine extensions [339], the functional significance of which is unknown.

Most laminin α, β, and γ chains share homologous structures, which include globular domains (domains IV and VI), cysteine-rich rod-like domains containing EGF-like repeats known as laminin-like EGF repeats (domains III and V), and domains forming the α-helical coiled coil of the long arm of the molecule (domains I and II), which is also revealed by circular dichroism measurements [340]. In addition, all laminin α chains identified to date contain a large C-terminal globular domain with five internal repeat motifs (G domain) (Figs. 1D, 3). However, variations occur in the extent of expression of these domains in different laminin chains. For example, laminin γ2 lacks domain VI and portions of IIIb [341,342], whereas laminin β3 lacks terminal domain VI [343], resulting in truncated molecules. In the case of laminin α3, the gene is differentially spliced, resulting in either a full-length polypeptide, laminin α3B, or a polypeptide that lacks domains VI, V, and IVb, laminin α3A [344]. The laminin α4 chain lacks the N-terminal globular domains (domains IV and VI) and portions of the rod-like region (domains V and IIIb) [315]. Truncation may also come about through proteolytic processing occurring after secretion, as shown for the laminin α3 chain [345] and the α2, β1, and γ3 chains of laminin-12 [320]. In contrast, in laminin α5, domain V is exceptionally long [317]. In all laminin chains, both the NH-proximal region of domain II and the COOH-proximal region of domain I have interchain disulfide bridges necessary for holding the heterotrimer together.

Structure-Function Relationships in Laminin Isoforms

Laminins are very large molecules, the α chains ranging in molecular weight from 165 kDa for laminin α3A to approximately 400 kDa for laminin α1 and α5 chains, while β and γ laminin chains vary from 105 to 210 kDa. The heterotrimeric molecules, therefore, are in the order of 500–900 kDa. To define the function of particular structural domains in these large molecules, protein fragments prepared by limited proteolysis have been employed in *in vitro* assays [346–348]. However, dissection of the biological functions of the various laminin domains has been complicated by the interweaving of α, β, and γ chains. Many activities disappear when the chains are separated, and slight perturbation of the tertiary structure, such as by heating [154], results in irreversible loss of function. Nevertheless, biologically active proteolytic fragments can be prepared, in particular by elastase digestion [346,348,349] (Fig. 1D). Peptic (P) and chymotryptic (C) fragments closely corresponding to some elastase-derived fragments have also been investigated [350–352]. To date, only laminin-1 can be isolated in sufficient quantities to permit proteolytic fragmentation; hence, laminin-1 fragments are the best characterized and most widely employed in *in vitro* assays. However, because of conservation of domain structure in all laminin chains known to date, many of the structure-function relationships defined with laminin-1 fragments are thought to be conserved in other isoforms.

Elastase digestion of laminin-1 produces eight major fragments [350–353]. E8 represents the lower 35 nm of the long arm, comprising the C-terminal 226 residues of the β1 chain, the C-terminal 246 residues of the γ1 chain, and that portion of the α1-chain C-terminal to residue 1886, but lacking the C-terminal E3 fragment, of 55 kDa [132,353]. The fragment E1-4 (or E1-X) consists of the three short arms of laminin [132,353]. It is heterogeneous (hence 'X'), often lacking one or more arm-terminating globular domains. E1 is E1-4 but lacking all six short-arm globules. Fragments E4, E5, and E6 are globular preparations, possibly from the termini of the short arms. P1 is produced by peptic digestion of fragment E1-4 and lacks the terminal globular domains of the short arms (domains VI).

The most important functions of laminins in basement membranes involve their ability to self-assemble into a network structure and their ability to interconnect with other basement membrane components and cell-surface receptors. Studies involving laminin-1 fragments have identified the domain structures crucial for these different functions. Domains VI of the short arms of the molecule are necessary for self-assembly [354,355], and EGF-like repeats in domain III are crucial for laminin assembly into basement membranes via nidogen-1 binding, while the G domain (fragments E8 and E3) of the laminin α1 chain contains various cell-binding sites [356] as well as heparan sulfate proteoglycan-binding sites (fragment E3).

Laminin Self-Assembly and Incorporation into the Basement Membrane

Purified laminin-1 can polymerize in the presence of Ca^{2+} in a concentration- and temperature-dependent manner [354]. This self-assembly process requires the N-terminal globules of domains VI of the short arms of laminin-1 (Fig. 1D) because the inner cross-fragment, P1′, which lacks the α1, β1, and γ1 chain N-terminal globules, cannot bind to itself or to intact laminin-1 molecules, while both fragments E4 and E1′ can inhibit polymerization of laminin-1. Self-assembly of laminin-2 also requires the N-terminal globules of domains VI, as may be deduced from the dy^{2J}/dy^{2J} mouse, in which the laminin α2 chain lacks domains VI and assembly into the basement membrane is impaired [357], resulting in a mild muscular dystrophy. A similar condition has also been identified in humans [358]. In the case of laminin isoforms that have significantly truncated short arms, such as laminin-5, covalent linkage to laminins-6 and-7 allows cross-linking to the collagen type IV network and appropriate integration into the basement membrane [359].

The laminin network is thought to be interconnected to the collagen type IV lattice via nidogen-1, a sulfated glycoprotein of 150 kDa ubiquitously localized in basement membranes of embryonic and adult tissues. Rotary shadowing and electron microscopy (Fig. 2c) have revealed that nidogen-1 consists of three globular domains (G1–G3), with two of the globules (G2 and G3) connected by a rod-like segment containing four EGF-like domains and one thyroglobulin-like domain [360] (Fig. 3). The connection between G1 and G2 is both shorter and thinner (Fig. 1E) and presumably represents a flexible link which provides protease-sensitive sites that are readily cleaved by tissue proteinases such as thrombin, plasmin, leukocyte elastase, and matrix metalloproteinases [361]. This indicates a low conformational stability of the link and a prominent role in nidogen-1 catabolism, which may be of importance for basement membrane remodeling. Nidogen-1 binds with high affinity to the γ1 chain of laminin-1 (in a 1:1 molar ratio) via its C-terminal G3 domain [360,362], resulting in highly stable complexes. Although naturally occurring complexes of collagen type IV and nidogen-1 have not so far been identified, studies with recombinant nidogen-1 have identified possible interactions between the G2 domain of nidogen-1 and triple-helical binding sites in the C-terminal NC1 region of collagen type IV. However, other binding sites also appear to exist in nidogen-1 for collagen type IV, indicating a variability in this association.

A gene that codes for a second nidogen isoform, nidogen-2, has been cloned from a mouse osteoblast cell line [363]. Although deduction of the amino acid sequence of nidogen-2 revealed only 27.4% homology to nidogen-1, many structural similarities exist between the two proteins, and the domain structure of nidogen-1 is conserved. The distribution of nidogen-2 is also very similar to that of nidogen-1; however, its interaction with laminin-1 appears to be of lower affinity than that of nidogen-1 (R. Timpl, unpublished data). The data suggest that the functions of nidogen-1 and-2 are distinct, but this remains to be resolved.

Cellular Interactions

The first indication that laminins have a role in cell adhesion came in 1980 from work on the PAM212 mouse epithelial-derived cell line [364]. Since then, laminin-1 and its proteolytic fragments have been widely used in *in vitro* assays, and a wide range of cellular functions have been ascribed to laminin-1. It is important to keep in mind, however, that the *in vivo* distribution of laminin-1 is restricted (see Table 2), suggesting that many of the functions attributed to it are carried out by other isoforms *in vivo*. Despite some overall structural similarity between different laminin isoforms, their tissue-specific and developmentally regulated distribution patterns suggest that they have distinct functions. Apart from laminin-1, only laminins 2 [324], 5 [365] and 10/11 [335] can be purified, which has permitted their use in *in vitro* functional assays. However, difficulties in isolation procedures limit the number of experiments possible with these isoforms. Hence, the majority of the data discussed below are based on studies with laminin-1.

Laminin-1 supports the adhesion of many different types of cells; it also stimulates cell proliferation [155,366] and the migration of myoblasts and fibroblasts [155,348,367], is essential for neurite outgrowth [333] and epithelial cell development [368], can induce the differentiation of myoblasts to myotubes [369,370], and prevents apoptosis of cells [371]. Most of these functional activities of laminin-1 are located in the G-domain of the laminin α1 chain in fragments E8 or E3. Various cells have also been shown to attach to E1 and P1 in an RGDS-dependent manner [154,333,349,370,372–375] or to the E1-4 fragment in an RGDS-independent manner [154]. Which, if any, of these sites are used for cell attachment *in vivo* is as yet unknown, although it is believed from monoclonal antibody mapping studies that the orientation in native basement membranes is variable, with the E8 domain of laminin often being capable of pointing outward from the basement lamina toward the cells [376].

Growth and Differentiation

Laminin-1 has drastic effects on cell morphology, but it also affects cell growth. Myoblasts are spindle-shaped and polarized on laminins 1 and 2, while on fibronectin they are stellate [377]. Endothelial cells either on laminin-1 or within laminin-rich gels shut down division and form capillary-like structures; on other matrix molecules, such as fibronectin, they proliferate and flatten [378]. Laminin-1 stimulates an increase in cell numbers in a dose-dependent manner (compared to other matrix molecules) of fibroblasts [379], fibrosarcoma cells [380], Schwann cells [332,333,381–383], and epidermal cells [384–386] when offered as a substrate. Laminin-1 and its E1 fragment have been shown to move quiescent fibroblasts from the G_o phase into the cell cycle with kinetic and molar dose dependencies similar to those of EGF [366]. However, the EGF-like homologies in laminin-1 [362,387] evidently play no role in this process, and fibroblasts do not use E1 as an attachment substrate. Thus, the triggers for attachment and growth probably work through different receptors. The relationship between EGF-like cysteine-repeat motifs and growth promotion is not clear [377].

In accordance with its *in vivo* distribution, laminin-5 is more efficient than laminin-1 in promoting adhesion of primary keratinocytes and some other epithelial cells in *in vitro* assays [365]. Laminin-5 also has a different requirement for integrin receptor molecules (see below) as compared to laminin-1, suggesting distinct signaling pathways for these two laminin isoforms.

In vitro studies have identified both laminin-1 and laminin-2 as important factors in myogenesis, even though only laminin-2 is present in developing and mature muscle fiber basement membranes. Skeletal muscle precursor cells attach, proliferate, migrate, and differentiate to myotubes preferentially on these laminins as compared to collagen type I or fibronectin [155,348,370,377]. However, the addition of exogenous laminin-2, but not laminin-1, can restore the ability of laminin α2-deficient myoblasts to fuse into myotubes [388], and mouse myoblasts spread, differentiate, and form myotubes significantly faster on laminin-2 than on laminin-1 [370].

Preliminary data with mixtures of laminin-10/11 have shown that normal and malignant human epithelial cell lines [335,389] and a multipotent hematopoietic cell line (FDCP-mix cells) [390] bind preferentially to this isoform mix as compared to laminin-1. As laminins 10 and 1 are both expressed in epithelial cell basement membranes [318,391], the differential interaction of epithelial cells may reflect different intracellular signaling pathways for the two isoforms. However, this requires further investigation. The significance of multipotent hematopoietic FDCP-mix cell adhesion to laminin-10/11 remains to be established.

Locomotion

Laminin-1 stimulates the locomotion and associated rapid change in morphology of a number of cell types [348]. In particular, the E8 fragment of laminin-1 has been shown to be critical for the locomotion of primary skeletal muscle myoblasts, myoblast cell lines [367], and neural crest cells [392]. Similarly, laminin-2 has strong migration-promoting effects on myoblasts [393]. In marked contrast, fibronectin has no effect on myoblast locomotion but does promote myoblast adhesion [155,348,367,394], while the E1 fragment of laminin-1 promotes adhesion of neural crest cells but not their locomotion [392]. The E8 fragment does not stimulate locomotion when offered in suspension. Boyden chamber assays also show that laminin-1 [15], its E1 fragment, and the peptide YIGSR (Tyr–Ile–Gly–Ser–Arg) [395] will stimulate the movement of various transformed cell lines, compatible with laminin-1 exerting a haptotactic effect on the cells, as has been suggested for myoblasts [348].

Neurite Outgrowth

Sites in the E8 fragment of laminin-1 promote the outgrowth of neurites from peripheral ganglia [349,396]. Activity is detectable with coating in the 10 ng/mL range; cell attachment requires 10–50 times as much. Laminin-1 itself does not promote the adhesion of neurites, but the outgrowth is a laminin-1-stimulated motile phenomenon requiring a polyornithine-precoated adhesive substrate. Laminin-1, however, is not expressed by peripheral nerves and it has been shown that laminin-2 [370] has the same neurite-outgrowth-promoting activity as laminin-1 in *in vitro* assays [397]. Because laminin-2 is expressed by peripheral nerves, it is likely that *in vivo* the neurite outgrowth function is mediated by laminin-2. It has been shown that the laminin α4 chain is also strongly expressed by peripheral nerves [315,398]; however, no data are available yet on the neurite-outgrowth-promoting activity of isoforms containing this laminin chain because such isoforms have not been purified.

Epithelial Cell Polarization and Survival

Kidney epithelia polarize in coordination with the transient expression of laminin α1 chains within an α1/γ1 chain-rich and unpolarized background [368,399]. Inhibition of epithelial cell interactions with laminin-1, either using anti-laminin-1 antibodies or antibodies to known laminin-1 receptors (see "Matrix Receptors" below), in kidney and salivary gland organ cultures have identified two sites on the laminin-1 molecule that are important for early epithelial cell development [368,399–401]. A site within the E8 fragment of laminin-1 interacts with the α6β1 integrin, while the E3 fragment interacts with α-dystroglycan [402]. Further, the differentiation and survival of mammary epithelial cells grown on plastic or in collagen type I gels has been shown to require interactions with the E3 fragment of laminin-1, and inhibition of such interactions leads to apoptosis (reviewed in [371]).

Modern Methods for Identifying Laminin Functions

Data on inherited diseases involving laminin gene defects, and on laminin α2, β2, α5, and γ1 knockout mice, have provided some clues to the function of some of the laminin isoforms. In epidermolysis bullosa junctionalis, a blistering skin disease (see also Chapter 15, this volume), mutations in the human genes coding for laminin α3, γ2, and β3 chains, which comprise the laminin-5 isoform, have been described, demonstrating that this protein is essential for the attachment of keratinocytes to their basement membrane [403–408]. In the *dy/dy* mouse strain, a mutation has been described in the gene coding for laminin α2, resulting in significant reduction in expression of the protein and a marked muscular dystrophy [409,410]. When the laminin α2 chain gene is eliminated in mice, the muscular dystrophy is more severe and the animals die at 10 weeks of age [411]. In humans, various congenital muscular dystrophies have been shown to result from mutations in the laminin α2 chain gene similar to those identified in the mouse models. The data indicate that laminin α2 is necessary for the terminal differentiation and/or function of muscle fibers and also for the functioning of the peripheral nervous system. Eliminating the expression of the gene coding for laminin β2 has resulted in mice with impaired synapse formation and glomerular dysfunction [412], whereas laminin α5 [413] and γ1 [414] null mice die early in embryogenesis, suggesting that these chains are crucial for early embryogenesis. Due to the early manifestation of the phenotype of the γ1 and α5 null mice, it is not possible to identify sites of functional significance of laminins containing these chains at later stages of development or in the mature animal. Further experiments involving *in vitro* assays using the isolated laminin isoforms and *in vivo* elimination of laminin chains in particular tissues or at particular stages of development are therefore necessary to establish the functions of the different laminin isoforms.

COLLAGENS

With up to 25% (wt/wt) carbohydrate bound to their triple-helical structure, as in type VI collagen [415–417], and distinct cell-adhesive properties, collagens certainly represent the most abundant and ubiquitous class of adhesive glycoproteins in vertebrate tissues [5,7,418–420]. Although structural and pathological aspects of collagens are extensively reviewed in this volume, we feel that it is appropriate here to focus on their adhesive character and to compare structural and functional features of collagen-cell interactions with those of other adhesive glycoproteins.

Since it became clear from cell and organ culture studies using collagenous substrata that collagenous proteins serve not only as an inert structural support of connective tissue but also control multiple cellular parameters, such as adhesion, migration, cell shape, cytoskeletal architecture, and gene expression, efforts have been made in many laboratories to elucidate the biological significance and molecular basis of such interactions. The cell physiological activity of collagen was firmly established during the 1960s and 1970s; for example, fibroblasts were shown to exhibit a completely different, elongated morphology when cultured within hydrated collagen lattices as opposed to monolayer culture [421–423]. Not only is their morphology altered, but their metabolic activity in terms of collagen synthesis and matrix production is also reduced to physiological levels [424]. Denatured collagen (gelatin) has been shown to promote significantly the differentiation and fusion of skeletal myoblasts [425], to induce the differentiation of embryonic chick cornea epithelium [426], and to stimulate chondrogenic differentiation of somitic mesenchyme [427,428]. Three fundamentally different modes of collagen recognition are apparent: a conformation-independent way, with cells recognizing both triple-helical and denatured collagen, such as hepatocyte adhesion to collagen [429], a triple-helix-dependent mechanism, and a type of recognition requiring fibrillar structure, such as platelet aggregation [430]. Furthermore,

changes in cell shape, such as mesenchymal-epithelial transformations, capillary formation of endothelial cells [431], or the differentiation and polarization of mammary epithelial cells [432,433], require a three-dimensional lattice of collagen fibrils. Interestingly, such lattices are also able to induce the reverse phenomenon, namely the epithelial-mesenchymal transformation of lens epithelial cells associated with a fundamental change in gene expression from type IV to type I collagen synthesis [434].

The chain of molecular events involved in such complex phenomena, which begins with cell-collagen binding and transmembrane signaling and leads to changes in cytoskeletal arrangement and gene expression, remains to be elucidated. Progress in this direction has been achieved by dissecting complex organ culture systems into well-defined cell culture systems using purified collagens and by the identification of integrins and other collagen-binding cell-surface components. Yet collagens (particularly fibrillar collagens), as basic proteins, bind to numerous acidic glycoproteins and proteoglycans, raising questions about the physiological significance of *in vitro* interactions of cells or isolated cell-surface components with highly purified collagen molecules adsorbed to plastic dishes, as compared with interactions with native collagen fibers *in vivo*. Similarly, it will be difficult to establish finally whether, and which, cell-surface components binding to collagen *in vitro* are functionally involved in any of the cellular responses to extracellular collagen.

The analysis of the role of individual collagens has not kept pace with the identification of new collagen types, these having reached the respectable number of at least 20 genetically distinct proteins with triple-helical structures (for an overview, see Chapter 2, this volume, and [5,7,419,420]). Most significant information on the function of collagen has been obtained using collagen type I in the form of native or denatured molecules or as hydrated, three-dimensional gels consisting of native fibrils. More recently, cell interactions significantly different from those with type I collagen have been found with collagen types IV and VI [131,435,436]; for this reason, we will focus in the following on these three collagens.

Fibrillar Collagens

Collagen type I, as the most abundant collagen of the vertebrate organism, is not only the major component of connective tissue but, as a constituent of reticular fibers (together with collagen types III and V), pervades almost every tissue and thus is potentially in contact with most cell types [437]. Therefore, it is not unexpected that most cell types, including fibroblasts, skeletal and cardiac muscle cells [5], hepatocytes, osteosarcoma cells, and numerous other cell lines [2,3,8], should adhere to native, denatured, or fibrillar collagen *in vitro*. Because of its affinity for gelatin, fibronectin enhances cell adhesion to denatured collagen [44,438], but adhesion to native collagen can also occur in the absence of any serum adhesion factor [429,438,439].

It is now clear that not only do different cell types use different mechanisms for interaction with extracellular collagen, but also that the same cell may simultaneously use multiple mechanisms of collagen binding. For example, platelet aggregation and activation is stimulated only by native, fibrillar type I, II, or III collagens [430], whereas hepatocytes attach both to native collagen and to denatured collagen peptides [429,440].

Receptors for Fibrillar Collagens

The major collagen receptors are cell-surface heparan sulfate proteoglycans (syndecans and glypicans (for a review, see Chapter 4, this volume, and [122,441,442]) and integrins (see below). Syndecans and glypicans consist of an extracellular core protein domain carrying heparan sulfate side chains and a hydrophobic, transmembrane domain linked to the cytoskeleton [443]. At least four genetically distinct syndecans have been described; when incorporated into liposomes, these have been shown to bind specifically to fibronectin as well as to native collagen types I, III, and V (but not IV) [121] through their heparan sulfate side chains.

The major collagen-binding integrins are $\alpha1\beta1$, $\alpha2\beta1$, $\alpha3\beta1$, and $\alpha10\beta1$ [18,444–447]. $\alpha2\beta1$, or VLA-2 (very late antigen 2), the first defined collagen-binding integrin, was initially identified as the platelet receptor (GP Ia-IIa) for collagen. It binds to collagen types I, II, III, and IV [444,448]. The interaction of $\alpha2\beta1$ with collagen types I–III is Mg^{2+}-[321,338] but not RGD-dependent [448]. Although RGD is a frequent sequence in collagens, most of these sites are cryptic and do not interact with integrins unless exposed by denaturing procedures. Arg, Gly, and Asp residues are, however, recognized by $\alpha1\beta1$ when located on three different α chains in type IV collagen in adjacent positions [435,449]. Similarly, conformation-dependent binding sites for $\alpha1\beta1$ integrin are also present in the CB3 peptide of $\alpha1$(I) chains [450].

Reports indicating that the binding site for $\alpha2\beta1$ integrin in collagen types I and II includes a KDGEA (Lys–Asp–Gly–Glu–Ala) motif located in CNBr peptide CB3 or KDGET (Lys–Asp–Gly–Glu–Thr), respectively, [451] could not be verified [452,453]. Studies by Knight et al. [453] provide strong evidence for an integrin-binding sequence GFQGER (Gly–Phe–Gln–Gly–Glu–Arg) located within CNBr peptide CB3 of the $\alpha1$(I) chain in the vicinity of the KDGEA (Lys–Asp–Gly–Glu–Ala) sequence.

In previous attempts to identify collagen receptors, several collagen-binding membrane or membrane-associated proteins have been isolated by affinity chromatography on collagen adsorbents, yet, for many of them, their physiological role as receptors is still unclear. From platelet membranes, an $\alpha1$(I) collagen receptor of 68 kDa has been isolated and characterized [454]. Annexin V (or anchorin CII) was originally isolated from chondrocyte membranes as a collagen-binding protein that binds to native collagen types II and X after incorporation into liposomes [455,456]. Antibodies have located the protein on the chondrocyte surface [457,458] and inhibit chondrocyte adhesion to type II collagen. Annexin V is a major calcium channel of matrix vesicles [459] and, like other annexins (calpactins, lipocortins), has a strong affinity for phospholipids and calcium [456]. It is located preferentially in calcifying regions of cartilage and in bone, suggesting a role in matrix vesicle-nucleated calcification. As in most connective tissue cells, however, the main collagen receptors of chondrocytes belong to the integrins. Chondrocytes express $\alpha1\beta1$ and $\alpha2\beta1$ integrins [452], and more recently a new type II collagen-binding integrin, $\alpha10\beta1$, has been found in chondrocytes [446].

Type IV Collagen

In contrast to the fibril-forming collagen types I, II, III, and V, type IV collagen molecules assemble into a large network, cross-linked at their N- and C-termini and between triple-helical domains [23,460] (Fig. 2e); (see also

Chapters 2 and 25, this volume). As a constituent exclusively of basement membranes, type IV collagen is likely to undergo specific interactions with basement-membrane-associated cells, such as epithelial and endothelial cells, myoblasts, and adipocytes. In fact, *in vitro* cell-attachment assays have demonstrated a specific adhesion and spreading on type IV collagen of keratinocytes [461], hepatocytes [440], endothelial cells [462], myoblasts [369,463], and a number of tumor cells [464]. A cell-binding site recognized by integrins α1β1 and α2β1 has been localized in the central triple-helical domain, within cyanogen bromide-derived peptide CB15 [435,447,449]. It involves Arg, Gly, and Asp residues, which, however, are not aligned in a continuous sequence but located on three different chains in adjacent positions.

Type VI Collagen

Type VI collagen was originally identified as a major, cysteine-rich glycoprotein constituent of microfibrils [416, 417]. The collagenous portion obtained after pepsin extraction represents only about one-third of the molecular mass (see also Chapter 2, this volume, and [465]). The molecule consists of three different chains: the α1(VI) (110 kDa), the α2(VI) (140 kDa), and the α3(VI) (240 kDa) (Fig. 3). Each chain ends with a large N-terminal (235 residues) and C-terminal (430 residues) globular domain connected by a triple-helical region of 335 amino acid residues.

The protein is rich in carbohydrates: 90% of the hydroxylysine residues are glycosylated; the globular domains contain several N-glycosylation sites. Interestingly, the globular domains contain three homologous repeats of 180 (chick) or 200 (human) residues each, which show similarity to the collagen-binding sequences of von Willebrand factor and cartilage matrix protein [466–468]. It is possible that these collagen-binding motifs are responsible for the particular type of assembly of type VI collagen monomers into tetrads (Fig. 2F) through their interaction with the triple-helical domains of neighboring molecules [469].

A strong cell-adhesive character of type VI collagen has been observed using the isolated subunits GP 140 [α2(VI)] and GP 250 [α3 (VI)] [131]. Close interaction between cells and type VI collagen has also been concluded from the electron-microscopical localization of type VI collagen in microfibrils adjacent to fibroblasts [470] or chondrocytes [471]. *In vitro* a large number of normal fibroblasts and tumor cells, including fibrosarcoma, rhabdomyosarcoma, and astrocytoma cells, have been shown to attach and spread on type VI collagen substrates [131]. The cells also attach and spread on the isolated α2(VI) and α3(VI) chains but not on the α1(VI) chain. Adhesion to denatured chains can be impaired by fairly low concentrations of RGDS (Arg–Gly–Asp–Ser) or RGDT (Arg–Gly–Asp–Thr) peptide. This is consistent with the existence of a total of 11 RGD sequences in all three α chains of type VI collagen [466], although probably not all RGD motifs are involved in cell binding. For example, the α2(VI) chain of chick type VI collagen contains seven RGD sequences, in contrast to the three RGD sequences in human α2(VI).

MATRIX RECEPTORS: INTEGRINS AND THE DYSTROPHIN-GLYCOPROTEIN COMPLEX

All of the matrix proteins we have described can bind to specific transmembrane receptors from a superfamily of cell-surface proteins termed "integrins" [10,472]. The discovery of the integrins represents a watershed in the field, drawing together the cell exterior and interior and integrating several widely divergent fields of research. Many reviews address these molecules in greater detail than our space permits [447,473–477], but our chapter would be incomplete without a brief introduction to them.

Integrins are αβ, heterodimeric glycoproteins, both chains of which are transmembrane polypeptides, with a single α-helical transmembrane domain. Some eight β and seventeen α chains are known to date (Table 3). Mixing particular α and β chains confers a certain degree of ligand specificity on the complex. For example, by combining the β1 chain with any of 11 α chains, cells can produce receptors specific for laminins, the fibronectin RGDS domain, collagens I and IV, or vitronectin (among other matrix molecules). Both α and β subunits appear to be involved in both divalent cation (especially Ca^{2+} and Mg^{2+})-dependent ligand recognition and interaction with the cytoskeleton [447]. In addition, there is evidence that both the specificity [107,447,478,479] and the affinity of ligand binding [480] of integrins can be

TABLE 3. Integrin α and β Subunit Combinations and Their Ligands

Subunits		Ligands
β1	α1	collagen, laminin-1 (E1-X)
	α2	collagen, laminin-1 (E1-X)
	α3	laminins 1,5, and 10/11, fibronectin
	α4	VCAM-1, fibronectin, (CSIII and HepII)
	α5	fibronectin (RGD), denatured collagen
	α6	laminin-1 (E8)
	α7	laminin-1 (E8), laminin-2
	α8	fibronectin (RGD), vitronectin, tenascin-C, osteopontin
	α9	collagen, laminin-1, tenascin-C, VCAM-1
	α10	collagen
	α11	collagen, unknown ligands
	αv	vitronectin, fibronectin, osteopontin
β2	αm	C3bi, fibrinogen, factor X, ICAM-1, ICAM-2
	αL	ICAM-1,2, and 3
	αD	C3bi, ICAM-1 and 2
β3	αIIβ	fibrinogen, fibronectin (RGD), vitronectin, von Willebrand factor, thrombospondin
	αv	vitronectin, fibronectin, von Willebrand factor, thrombospondin, fibulin, fibrillin, denatured collagen, PECAM-1
β4	α6	laminin-1 and laminin-5
β5	αv	vitronectin, osteopontin
β6	αv	fibronectin
β7	α4	MAdCAM-1, VCAM-1, fibronectin (CSIII)
	αE	E-cadherin
β8	αv	vitronectin

modulated from within the cell to suit local conditions and so change the way that cells respond to their surroundings. In general, the β1 and αv integrins are principally involved with cell-matrix interactions, whereas the β2 integrins, which are found only on leukocytes, mediate cell-cell interactions.

Fibronectin-Binding Integrins

One of the most studied adhesive receptors is the α5β1 integrin, which was successfully isolated and cloned as a fibronectin-specific receptor [481,482] following the identification of a major cell-binding site in fibronectin, in the RGDS sequence [50,483,484]. By passing detergent extracts of cells over a fibronectin affinity column and eluting with RGDS, M_r 140,000 membrane proteins were obtained that could be incorporated into liposomes and bound specifically and in an RGD- (but not RGE-[Arg–Gly–Glu]-) dependent manner to fibronectin-coated surfaces. Antibodies have localized α5β1 by immunofluorescence microscopy to focal adhesion plaques under cells in tissue culture and specifically block cell adhesion to fibronectin. Other integrins that bind to fibronectin belong either to the β1 (α3β1, α4β1, α8β1) or the αv (αIIbβ3, αvβ1, αvβ3, αvβ6) families [447]; however, unlike α5β1, these integrins also recognize other ligands (Table 3) [477,485,486]. Integrins α8β1, αvβ1, αvβ3, αvβ6, and αIIbβ3, which are structurally closely related to the α5β1 integrin, also use the RGD sequence in fibronectin for binding. Binding of α3β1 and α4β1 to fibronectin does not involve the RGD sequence. Various binding sites for the α4β1 integrin on the fibronectin molecule have been mapped within the IIICS region; two distinct sequences have been identified that mediate cell adhesion alone (REDV (Arg–Glu–Asp–Val) or RGDV (Arg–Gly–Asp–Val)) sequences in human and rat fibronectin, respectively) or adhesion and spreading (LDV [Leu–Asp–Val] sequence), while a third binding site (IDAPS [Ile–Asp–Ala–Pro–Ser]) is located in the second heparin-binding domain, termed Hep II [478].

Integrins Containing the αv Subunit and αIIbβ3

The αv subunit can associate with five different β subunits (Table 3) to form various receptors, all of which bind to their ligands in an RGD-dependent manner. Apart from αvβ6, which recognizes only fibronectin, all αv integrins recognize predominantly vitronectin. The αvβ5 and αvβ8 integrins selectively recognize vitronectin and not fibronectin, whereas αvβ1 recognizes both vitronectin and fibronectin, and both αvβ1 and αvβ5 also recognize osteopontin. Integrin αvβ3 has many different ligands, including vitronectin, fibronectin, fibrinogen, fibrin, von Willebrand factor, thrombospondin, tenascin-C, osteopontin, fibrillin, and denatured collagen. Furthermore, αvβ3 binds to the cellular receptor PECAM-1 (platelet endothelial cell-adhesion molecule-1) on endothelial cells, enabling αvβ3 to take part in cell-cell interactions between leukocytes and vascular endothelial cells [477]. The αv subunit has a widespread distribution *in vivo*, whereas its β subunit partners have spatially and temporally regulated expression patterns, conferring tissue specificity on the αv-series integrins.

The αIIbβ3 and αvβ3 integrins belong to a subset of integrins termed cytoadhesins. The αIIb subunit is restricted to megakaryocytes and platelets, in which it associates exclusively with the β3 subunit. On resting platelets, αIIbβ3 binds only fibrinogen, which triggers platelet activation and aggregation, finally resulting in clot formation. Activation of platelets by ligand binding or other stimuli also activates αIIbβ3, resulting in increased affinity for various RDG-containing ligands, including fibronectin, vitronectin, and von Willebrand factor (see Table 3).

Collagen-Binding Integrins

Integrins α1β1 and α2β1 have been shown to be the major receptors for native collagens and, depending on cell type, can also bind to laminins 1 and 2, but with low affinity (Table 3). More recently, α9β1 [194] and α10β1 have been reported as collagen receptors, while α11β1, which occurs principally on myogenic cells (D. Gullberg, personal communication), can also bind collagen among other yet to be defined ligands.

α1β1 binds collagen type IV with higher affinity than the fibrillar collagen types I, II, and III, whereas the opposite is true for α2β1 [449]. The two integrins recognize neighboring but distinct sites on collagen type IV [435]. Unfolding of the triple-helical collagen structure abolishes binding by α1β1 and α2β1 but exposes linear RGD sequences recognized by α5β1 and αvβ3. Integrin α2β1 is the major collagen receptor on platelets and, together with αIIbβ3, is a differentiation marker for platelets and plays an important role in platelet aggregation. α2β1 is further found on fibroblasts and various other cell lines and tissues. α1β1 is found on cells that are in close contact with the basement membrane, such as endothelial cells, smooth muscle cells, and hepatocytes, as well as astrocytes and neural crest cells and their derivatives.

Laminin-Binding Integrins

Several integrin receptors have been implicated in cell attachment to laminin isoforms, including α1β1, α2β1, α3β1, α6β1, α7β1, and α6β4 (Table 3). Some integrins, such as α6β1, α7β1, and α6β4, are specific for laminins, while the others behave as promiscuous receptors, binding other extracellular matrix components.

Integrins α6β1 and α7β1 appear to be the major receptors for the E8 fragment of laminin-1 on epithelial and myogenic cells, respectively [487–490]. In addition, α7β1 on myogenic cells binds to laminin-2, and elimination of this integrin in mice leads to a mild muscular dystrophy [491], suggesting interaction between α7β1 and laminin-2 *in vivo* [492,493]. More recently, α6β1 has also been shown to mediate the binding of normal and transformed epithelial cells [389] and multipotent hematopoietic cells [390] to laminin-10/11.

Integrin α6β4 is — besides α3β1 — the major laminin-5 binding integrin and occurs in association with hemidesmosomes in the skin and in other stratified epithelia. In epidermolysis bullosa junctionalis, a blistering skin disease (see Chapter 15, this volume), mutations in the human genes coding for laminin α3, γ2, and β3 chains, which comprise the laminin-5 isoform, have been described, demonstrating that this protein is essential for the attachment of keratinocytes to their basement membrane [403,408]. Mutations or deletion of the α6 or β4 subunits in mice result in a phenotype similar to that observed in epidermolysis bullosa junctionalis [476], suggesting that the endogenous ligand for α6β4 is indeed laminin-5.

Minor laminin receptors include α1β1, α2β1, and α3β1. The binding sites of α1β1 and α2β1 have been mapped to domain VI of the laminin α1 chain [494,495]. The α3β1 integrin was isolated by affinity chromatography using a human laminin preparation, which, at the time, was thought to be laminin-1 but is now known probably to have been laminin-10/11, as the ligand and Rugli rat cells as the integrin source. Further, α3β1 has been shown to interact with laminin-5 [365] and laminin-10 [335], and anti-α3β1 antibodies weakly affect cell attachment to laminin-1

fragments E8, E3, and P1 [479,496], suggesting that this receptor is promiscuous in its binding interactions.

Dystrophin-Glycoprotein Complex

α-Dystroglycan of the dystrophin glycoprotein complex, which was originally characterized in myogenic cells but is now known to be expressed on various cell types, is the major nonintegrin laminin-1 receptor that binds to the E3 fragment [497,498]. More recently, α-dystroglycan has also been shown to react with the equivalent of the E3 fragment (domains G4–G5) in the laminin α2 and α5 chains [498,499]. Apart from the laminins, α-dystroglycan interacts with perlecan, a basement membrane heparan sulfate proteoglycan [498], and with agrin at the neuromuscular junction [500]. The data suggest that this molecule plays a critical role in interconnecting the extracellular matrix to the cytoskeleton.

ACKNOWLEDGMENT

We wish to thank Drs. R. Chiquet-Ehrisman, J. Lawler, R. Timpl, H. Wiedemann, and K. Kühn for providing us with electron micrographs for Figure 1. We are very grateful to Dr. Simon Goodman, who wrote much of this chapter for the first edition and thus laid a solid base for the revised version. We are also very grateful to Mrs. Maire Rauber for her patience while typing the manuscript.

Chapter 6

Keratins

E. Birgitte Lane

CRC Cell Structure Research Group, Department of Anatomy and Physiology, University of Dundee, Dundee DD1 5EH, Scotland, United Kingdom

INTRODUCTION

Keratins are everywhere, from being the major components of household dust to common contaminants of laboratory protein analysis. Before being shed from the body surface, these proteins reach levels of 80% or more of the total cell protein in terminally differentiated keratinocytes of the skin. The skin is the largest organ of the human body, adapted to its barrier function with a "disposable" epidermal covering that naturally has a high turnover. Keratins are therefore likely to constitute a significant component in connective tissue sampling of the skin. The importance of keratins in skin derives from the physical pressures that keratinocyte cells of the epidermis are subjected to in normal everyday living. Keratins provide the reinforcement that keeps epithelial cells in the skin intact under pressure. A view is emerging that the family of proteins to which the keratins belong may have a broader function in stress resistance in many different tissues, and may be involved in the etiology of a number of disorders arising from cell fragility.

Keratins are the major filamentous proteins of epithelial cells, and occur at their greatest density and complexity in the keratinocytes of the epidermis. They make up a system of filaments that run through the cytoplasm of cells and connect at the cell periphery into cell-to-cell (desmosome) and cell-to-substrate (hemidesmosome) attachment plaques. Thus, the keratin-desmosome interaction creates a three-dimensional network through the epithelium, which must be of significant importance in the structural properties of the whole tissue. This chapter briefly outlines what is understood about the keratin intermediate filaments in relation to their tissue expression patterns, their structure and the consequences of faults in keratin proteins, and what can be deduced from all this about their function.

KERATINS AS INTERMEDIATE FILAMENTS

Keratins (often referred to as cytokeratins, and also sometimes as prekeratins or α-keratins) are members of the superfamily of intermediate filament proteins. These are cytoskeletal proteins that are expressed in one form or another in nearly every cell type of the vertebrate body. As a group of proteins they are widespread throughout the animal kingdom, ancient in evolutionary terms and substantially conserved in mammals. The whole human intermediate filament gene family is thought to consist of at least 50 members, expressed in different tissues (Fig. 1). All these proteins are intracellular; most are cytoplasmic like the keratins, and form long sinuous filaments of about 10 nm in diameter. Intermediate filaments fall into six classes (type I to type VI) on the basis of amino acid sequence data. Keratins make up the type I and type II groups which together account for about three-quarters of all the intermediate filaments known in human tissues.

Pairs of keratins are expressed together, a type I protein with a specific and (mostly) predictable type II partner, each pair being characteristic of a particular range of epithelial cell types. Intermediate filament protein types III–VI are found in non epithelial tissues. The type III filament proteins are expressed predominantly in mesenchymal cells, and include vimentin (present in many cell types including fibroblasts, endothelial and hemopoietic cells), desmin (in muscle cells), glial fibrillary acidic protein (or GFAP, in astroglia), and peripherin (in parts of the nervous system). Type IV intermediate filament proteins include the neurofilament proteins NF-L, NF-M, NF-H and α-internexin, expressed in neurons. The filament protein, nestin, is the largest intermediate filament protein known [1] and is also now grouped with the neurofilaments. The type V proteins are the intranuclear lamins, probably the oldest of the intermediate filament classes in evolutionary terms [2]. They consist of two groups, A- and B-type lamins, and have a broader range of tissue expression than any of the cytoplasmic intermediate filaments. Amongst the B-type lamins, lamins B_1 and B_2 are constitutive and B_3 lamin is found in germ cells. In contrast, the A-type lamins (lamins A and C, which are two alternatively spliced products of the lamin A gene) are absent from many undifferentiated or dedifferentiated cells [3,4]. Membership of the type VI group fluctuates from year to year as this category usually houses unusual or recently discovered intermediate filament proteins that do not easily fall into one of the other groups. Currently, this includes the lens intermediate filament proteins filensin and CP49 [5], and probably the large muscle intermediate filament proteins synemin and paranemin (See Fig. 1).

Keratins were initially identified by biochemical analysis using two-dimensional gel electrophoresis. They are classified individually by number after a system proposed by Moll et al. [6], which depends on their charge and molecular weight. Keratins 1–19 span the extremes (K20 is a later

Connective Tissue and Its Heritable Disorders, pages 329–341

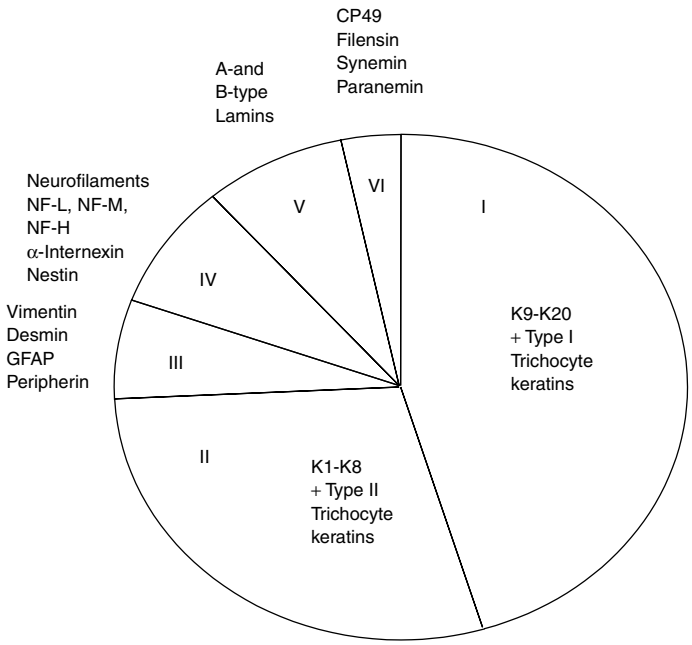

Figure 1. The six types of intermediate filament-like proteins identified in human tissues. This division is based on amino acid primary sequence data, but is supported by intron profiles observed in genomic DNA. Nearly three-quarters of these proteins are keratins, in the type I and type II classes. Types I and II are characteristic of epithelial cells, while type III are characteristic of various mesenchymal cells (vimentin occurs in many cell types, desmin in all muscle cells, GFAP [glial fibrillary acidic protein] in astroglial cells, and peripherin predominantly in peripheral neurons). Type IV filament proteins are all neuronal, type V (nuclear lamins) are in all tissues, and type VI currently includes two filament proteins identified in the eye lens, plus synemin and paranemin.

addition): K1 is the largest and most basic, and K19 the smallest and one of the more acidic. K9–K20 plus up to ten trichocyte keratins are in the type I group, and K1–K8 plus at least another ten trichocyte, or hair, keratins make up type II. The description of keratins by molecular weight is no longer used as a large number of related proteins coexist within a similar range of sizes and charges. The use of specific monoclonal antibodies has become an important way of distinguishing between different intermediate filament proteins and different keratins, both by immunoblotting and by *in situ* immunohistochemistry techniques. Today, nearly all of the human keratins have been sequenced at the DNA level, providing the ultimate identification. Among the latest members of this gene family to be characterized are the multiple genes encoding K6 proteins [7] and, most recently, several further genes for hair keratins [8]. The final count of intermediate filaments is probably still not complete.

KERATIN EXPRESSION IN SKIN

The major keratins show a characteristic tissue distribution (Fig. 2), even down to the resolution of subpopulations of cells within a tissue showing specific phenotypes. This must reflect physiological differences between these cell populations. Some keratin pairs, which can be described as *primary* or essential keratins, are constitutively expressed as the baseline keratin phenotype in appropriate tissues. These primary keratins are keratins 5 (K5) and 14 (K14) and keratins 8 (K8) and 18 (K18). The *secondary* keratins are differentiation-specific, and their expression can be modulated by a variety of external factors. Analysis of primary keratin distribution patterns confirms the existence of distinct categories of epithelial cells, *simple epithelial* cells, and *basal* or *stratifying epithelial* cells [9].

Simple epithelial cells. Simple epithelial cells retain contact with the basal lamina and also retain a free apical surface, and express K18 and K8, the primary simple epithelial keratins. In skin, such cell types are found in the secretory cells of the sweat gland. The other cell type found in skin which expresses these simple epithelial keratins is the Merkel cell, a type of solitary neuroendocrine cell found around the dermo-epidermal interface and thought to be involved in touch perception. K8 and K18 are the first keratins to be expressed in embryogenesis (Fig. 3) and persist as the only keratins in a small number of adult epithelia (e.g., hepatocytes). Occasionally, they have even been seen in some types of mesenchymal cells [10]. They appear to be the keratins expressed closest to the interface between epithelial and mesenchymal cells, and oscillations between expression of K8 and K18 and expression of vimentin are characteristic of epithelial-mesenchymal transitions in development and elsewhere. A switch to expression of simple epithelial keratins is commonly observed in metastatic non-melanoma skin cancers, although the significance of this is not yet clear. Keratins are very long-lived and stable proteins, and even these simple epithelial keratins, thought to be the most soluble and plastic of the keratins, have been calculated to have a half-life of around 100 h [13].

Basal epithelial cells. The basal cell type is seen in complex epithelial tissues from glandular epithelia to stratifying squamous epithelia. It is characterized by basal lamina contact in the absence of a free apical surface and is identified by a different keratin phenotype. Basal cells synthesize and

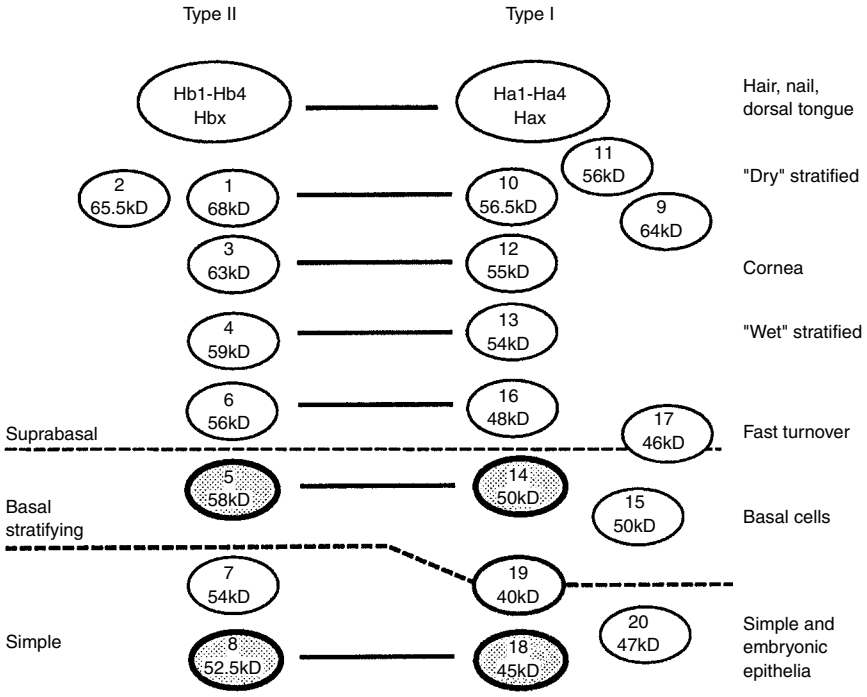

Figure 2. Summary of keratin classification, based on Moll et al. [6], giving the relative molecular weights observed on gel electrophoresis for each polypeptide. The major coexpressed keratin pairs are shown, based on Sun et al. [121], and their characteristic tissue distribution is indicated as deduced from many biochemical and immunohistochemical studies. Shaded keratins are the primary (essential) keratins for simple and stratified epithelia.

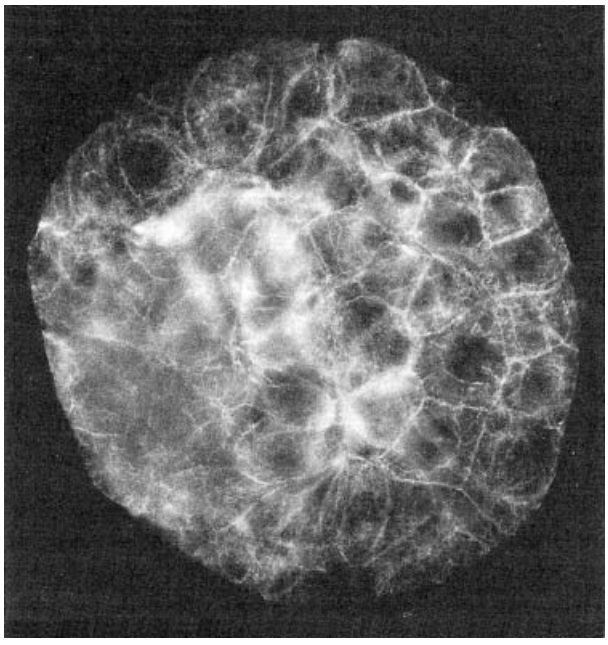

Figure 3. Simple epithelial or embryonic keratins K8 and K18 are the first to be expressed in the embryo. K8 and K18 persist into adult tissues in all simple epithelial cells, and even as the sole keratins in some tissues such as hepatocytes. They are shown here by immunofluorescence using an antibody to keratin 18 (LE65), in all cells of the preimplantation mouse blastocyst. (Unpublished material from collaborative experiments with Martin Johnson.)

express K14 and K5, the primary keratins of stratifying epithelia. Keratin filaments in this type of cell are shown in tissue culture in Figure 4. Basal cells appear to synthesize these keratins only while they are in contact with a basal lamina, although K5 and K14 persist in the tissue cells at biochemically detectable levels at least as far up as the stratum granulosum [9,12], corresponding to a transit time of 7–14 days.

Suprabasal cells. When basal cells begin to lose contact with the basal lamina and move upwards, as in the course of epidermal differentiation, a change occurs in keratin synthesis: production of keratins 5 and 14 slows or ceases [11] and secondary, or differentiation-specific, keratins are synthesized instead. Thus, a clear difference is usually seen in keratin expression between basal cells and the suprabasal cell layers. As a cell begins to leave the basal layer compartment there are several options for a particular cell type, depending on its body location and program of differentiation. Keratinocyte-like cells may begin to express keratins K1 and K10 in cornifying differentiation, as in skin and cornifying regions in the mouth, or K4 and K13 in non cornifying stratification such as occurs in mucosal epithelia of the eyes, ears, and nose, and in oral, urogenital and anal epithelia [14]. Corneal epithelial cells express K3 and K12 [15]. Areas of epithelium that are rapidly turning over express K6 and K16 (buccal epithelium, psoriatic lesions, cultured keratinocytes, hair follicles) [16], secondary keratins which can be simultaneously present with another keratin phenotype [17]. Trichocyte keratins are found in hair follicles and hair, nail bed and nail, Hassall's corpuscles in the thymus, and in filiform papillae on the dorsal surface of the tongue.

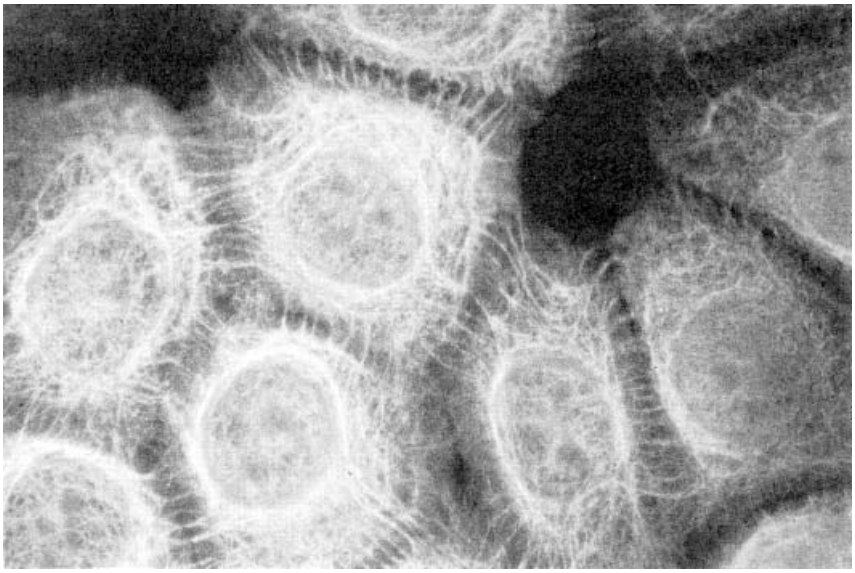

Figure 4. Keratinocytes express the greatest range of keratins at their highest organizational complexity. Keratin filaments are visualized here in tissue culture, by immunofluorescence of a squamous cell carcinoma-derived line, TR146 cells [122]. The position of the desmosomes is indicated, although they are unstained, by the symmetrical focussing of keratin filament bundles in neighbouring cells onto points around the cell periphery.

The precise localization of these keratins within tissues has come from the use of monospecific antibodies to individual keratins. As well as these major keratins, a number of other keratins are also expressed in these and other tissues: keratin 19 is present in a subset of cells in a wide range of simple and stratified epithelia [18], often at differentiation interfaces [19]. Keratin 15 is found in basal cells [20,21]. K17 is found in basal and suprabasal cells and is induced in response to stress, like K6/K16. There are now known to be two K6 genes, K6a and K6b, one of which appears to be strictly suprabasal while the other can be expressed in basal cells and may co-polymerize with K17 [22]. Keratin 20 is expressed by certain simple epithelia in the gastrointestinal tract [23] and in some neuroendocrine cells including Merkel cells in skin [24]. Keratins K2e (in epidermis) and K2p (in hard palate) occur in some cornifying epithelia [25]; keratin 7 occurs in a subset of glandular epithelia [26], and keratin 9 is expressed in regions of pressure or abrasion, such as palm and footsole skin [27,28].

Keratin expression in epithelia is therefore rather complex and the regulatory principles governing individual expression patterns are not yet fully worked out. It is possible that there are as many distinct keratin expression phenotypes among epithelial tissues as there are physically distinct epithelia and that these two parameters may be related.

HOW KERATIN FILAMENTS ASSEMBLE

When a type I protein and a type II protein are present within the same environment under physiological conditions, polymerization takes place very rapidly in the absence of any cofactors or polymerization factors. It has, therefore, been difficult to study the process of sequential assembly of intermediate filaments. However, intermediate filaments all share the same general pattern of molecular structure — a central domain, which is a long, mostly α-helical region, flanked by non-helical amino-terminal (head) and carboxyl-terminal (tail) domains. Thus, although their precise amino acid sequences vary considerably and their encoding DNA sequences vary even more, information acquired about the assembly of one intermediate filament protein is often applicable to another. Analysis of the protein secondary and tertiary structure of keratins, and models for how these proteins pack into filaments, have therefore evolved from a wide variety of studies in many laboratories.

The keratins appear to be more complicated structurally than other intermediate filament classes as they only polymerize into filaments if both type I and type II proteins are present (Fig. 5b). This obligatory heterotypic polymerization superficially contrasts with other intermediate filament protein types that all appear to have at least some capacity for homotypic polymerization. It has been shown in many laboratories that single vertebrate keratins of either type are unstable, and are rapidly degraded in the absence of a copolymerizing complementary keratin of the other type [29–31].

The evolution of heteropolymerization in keratins may be associated with greater physical resilience of the filament network so formed, or with a greater insensitivity of the system to potentially damaging sequence changes, in tissues where these filaments are particularly important. This could also be one mechanism used to balance the quantities of two coexpressed keratins *in vivo*.

The Rod Domain

The earliest structural analysis of intermediate filaments came from studies on wool keratins [32] and suggested that the main components in these structures were α-helical proteins. This was reinforced by secondary structure predictions from amino acid sequences as they became available [33], initially for type III proteins and shortly after for a type I keratin (K14). Although intermediate filaments are indeed predominantly α-helical, their dimeric molecular structure is quite different from that of the trimeric collagen family (see Chapter 2, this volume).

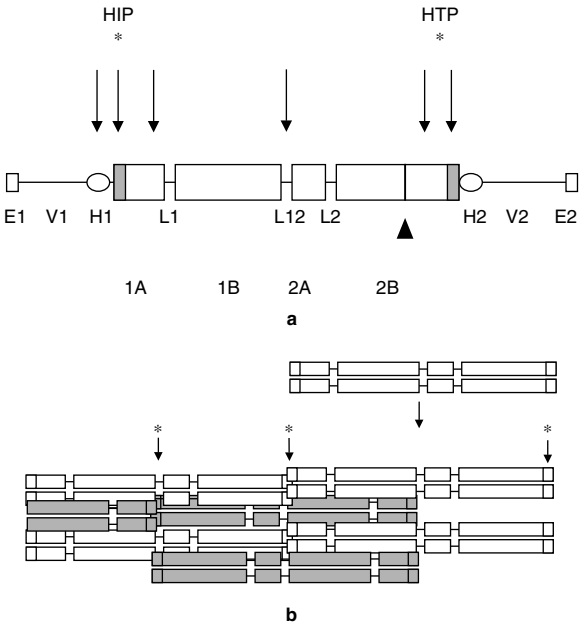

Figure 5. (**a**) Diagram of the basic structure of a keratin protein. In common with other types of intermediate filaments, keratin protein monomers consist of a central rod domain in four α-helical segments (1A, 1B, 2A, 2B) connected by nonhelical linker stretches (L1, L12, L2). The shaded triangle indicates the stutter, or helix polarity reversal feature, in helix 2B. The shaded blocks at either end of the rod domain are the conserved helix boundary peptides, the helix initiation peptide (HIP) and the helix termination peptide (HTP). This rod domain is flanked by nonhelical end domains, the amino-terminal head domain (E1, V1, H1) and the carboxyl-terminal tail domain (H2, V2, E2). Phosphorylation sites are predominantly in the H1 and H2 domains. See text for further description of the end domains. Arrows indicate the locations of mutation clusters seen in epidermolysis bullosa simplex (EBS) in K5 and K14; starred arrows (HIP, HTP) indicate the most frequent sites of mutations, especially in the HIP region, usually associated with severe Dowling-Meara EBS. The other four arrows are common mutation sites in the milder Weber-Cockayne EBS, especially the L12 site; (see also Chapter 15, Epidermolysis Bullosa, this volume). (**b**) Some features of current models of keratin assembly. The rod domain assembles in parallel in-register heterodimers (type I and type II) which then proceed by poorly-defined intermediate stages to a 10 nm thick intermediate filament consisting of about 32 polypeptide chains, or 16 dimeric strands. Whatever the order of assembly, the end result is that rod end overlaps occur within one strand and adjacent strands are anti-parallel, some with a half-length stagger alignment. This almost certainly brings 2–3 of the mutation cluster sites (starred arrows) into close proximity, identifying an important interaction within the polymer.

The basic structure of a keratin intermediate filament protein is shown in Figure 5a. A single polypeptide chain of an intermediate filament protein is unstable and once synthesized in the cell dimerizes rapidly to form a coiled-coil two-chain molecule. This will be a type I-type II heterodimer in the case of keratins [34,35]. This instability and dimerization is due to the presence of a curving strip of hydrophobic residues running down the length of the coiled α-helical cylinder. Formation of the coiled-coil sequesters the hydrophobic faces of two interacting polypeptides, with their hydrophobic side-chains interdigitating like the teeth of a zip, away from the aqueous environment of the cytoplasm. This tendency to form a coiled-coil is a characteristic that can be simply and confidently predicted from the amino acid sequence [36]. One can look for the presence of suitably hydrophobic residues (usually leucine, valine, isoleucine or methionine, or bulky residues such as phenylalanine or tryptophan: remembered in single letter code as "FAMILY VW") occupying the first and fourth positions of every seven residues over a stretch of sequence.

The α-helical conformation is the most common secondary structure seen in proteins [37], and the "leucine zipper" mode of dimerization is well known in many proteins. What makes the intermediate filament α-helical structure unusual is its great length. The rod domain extends for a fairly consistent minimum of 310 amino acids, starting and ending with two important conserved sequence motifs of about 15 amino acid residues, the helix boundary motifs, at either end of the rod. The rod domain also contains four interruptions of the helix. Three of these are unlikely to be α-helical in conformation and are referred to as linkers (L1, L12 and L2), dividing the rod domain into helical subdomains 1A, 1B, 2A and 2B (nomenclature of subdomains following Steinert [38]). The fourth interruption is also a highly conserved feature, or "stutter" (possibly a helix polarity reversal at which the handedness of the helical coil changes), in the middle of helix 2B. These features are all shown in Figure 5.

From a single polypeptide chain, a filament of around 8–10 nm in diameter is built up like rope by repeated coiled-coiling, forming dimers then tetramers, to protofilaments of 2–3 nm and then 4.5 nm, and then to the intermediate filament (around 10 nm in diameter). The final filament is composed of around 32 polypeptide chains assembled at any point as 16 dimeric strands forming coiled-coil protofilaments. Information on how the rod domains of these dimeric molecules pack to form a filament has come from a variety of sources. The smallest subunit of these proteins that can be identified is a tetramer formed of two antiparallel dimers, demonstrable by negative staining [39]. Herrmann et al. have shown that a "unit length" filament is formed as an early assembly stage by a variety of intermediate filament proteins, but that, if unchecked, keratin polymerization proceeds exceptionally rapidly from this stage to full-thickness long filaments [40]. Early binding studies [41] and transfection experiments [42,43] defined certain regions as essential for filament assembly, which substantially coincided with overlaps predicted from paracrystal analysis. Interactions between the rod domains are probably due primarily to numerous alternating charged patches on the surface of the helix [44], together with higher specificity "docking" sites at certain points. Sequence conservation in the helix boundary motifs, together with the dramatic effects on filament stability of deleting or mutating these motifs [45,46], highlights the importance of these rod ends. Analysis of near-neighbor fragments by sequencing dissociated peptides after cross-linking and partial proteolysis [47] suggests an overlap between the C-terminal end of one rod subunit and the N-terminal end of the next rod. These studies and earlier paracrystal analyses [48] suggest that the proteins assemble as alternate antiparallel strands, giving an overall apolar filament.

The nonhelical regions are also needed for correct filament assembly. It is not known why the diameter of intermediate filaments is so constant, but work from Aebi's laboratory [49] suggests that the end domains are involved in limiting the filament thickness, as removing them results in abnormally

thick structures. The linker regions that interrupt the α-helical rod domain (L1, L12, and L2) are highly conserved in their sizes and locations, and also show partial sequence conservation. Linkers may function as hinge regions to give the filament flexibility, since they are close to predicted boundaries or gaps between the staggered overlaps of the helical domains. A size restriction may be necessary to avoid steric hindrance of packing between the helical domains.

Head and Tail Domains

The nonhelical ends of the filament proteins can be divided into three subdomains (Fig. 5a). The extreme ends tend to be highly charged (the E1 and E2 domains on heads and tails respectively; [38]). Working inwards, there is then a section of high variability, V1 in the head and V2 in the tail. Secondary structure predictions here have suggested the presence of "omega loops" [50] or "glycine loops" [51] centered on the Phe- or Tyr- residues between runs of glycine-rich (in epidermal keratins) or serine-rich (in simple epithelial keratins) repeats. The abundance of glycines in the head and tail domains of epidermal keratins 1 and 10 argues for high flexibility in these domains. Immediately adjacent to the rod domains lie the H1 (head) and H2 (tail) domains, but these are not present in type I keratins. These shorter regions usually contain phosphorylation target sites within their sequences [52–54], suggesting that their net charge can be altered in response to signals from within the cell which could thus trigger cycles of polymerization/depolymerization and filament remodeling.

The end domains, at least the head domains, appear to play a significant part in regulating correct filament assembly [55,56]. Forced expression of keratins from which either head or tail domains had been deleted from one or both of the pair, suggested that tail domains were necessary for efficient filament network formation, and that at least one of the two interacting keratins needed both end domains intact in order to produce normal-looking filaments [31,57]. This suggests important functions for the head and tail domains within the filament itself, either as docking sites or spacers in setting up the initial polymer, or as regions that stabilize the forming filament by binding ahead or behind or sideways onto another strand or subunit. Sequence variation could result in different qualities of the final filament network, by altering for example the rigidity or flexibility of the filaments, or the ease with which the filaments could be dissociated or remodeled. For example, the large number of such repeat loops, as potential head-to-tail binding sites, on keratins 1 and 10 may result in a very strong bonding within the filaments, as opposed to the fewer repeats in simple epithelial keratins which are also easier to dissociate *in vitro*. The unusual presence of cysteine residues in the head and tail domains of trichocyte keratins [58,59] could allow for disulphide cross-linking to make a more rigid network in hair and nail cells.

It is very unclear where the head and tail domains lie in the polymerized filament. Several lines of evidence have suggested that the nonhelical domains of the head and tail may protrude outside the body of the polymerized filament. Light proteolysis of intact epidermal filaments was shown to yield fragments with the amino acid composition of terminal domains [60]. By immunoelectron microscopy the end domains can be seen, in neurofilaments at least, to protrude from the body of the filament: regular extensions at right angles to the filament are observed [61], and terminal-specific antibodies can be shown to bind to such extended protrusions [62]. Also, by immunohistochemistry of skin sections, K14 can be stained in the suprabasal layers of the epidermis when antibodies to the tip of the "tail" are used [9], but other sorts of K14 antibodies are often negative. It seems that parts of the molecule are no longer accessible outside the basal layer, possibly because of the laying down of secondary keratins over the top of them [63]. It seems possible, therefore, that the keratin end domains (and those of other intermediate filaments) could be in a good position to interact with other cellular components outside the filaments themselves, opening the way for a much wider range of potential functions.

Many intermediate filaments are known to be reversibly phosphorylated at sites within the head and tail domains. The H1 and H2 regions contain phosphorylation sites and regulation of filament assembly by modulation of H1 phosphorylation may be the reason that the head domains are so important. Hyperphosphorylation of the H1/H2 domains drives many intermediate filament proteins toward depolymerization [52–54], which may be necessary to allow cell separation during mitosis [64,65].

It appears, therefore, that the head and tail domains contain the key to the tissue specificity of intermediate filament expression. While the amino acid sequence of the α-helical rod domain is rather conserved, the head and tail domain sequences vary substantially, especially among the keratins. However, when terminal domains are compared between members of a coexpressed type I-type II keratin pair, a degree of relatedness in amino acid composition is seen. Thus, the end sequences are most closely related between members of a coexpressed pair, but the sequences in the rod domain are most similar between members of the same intermediate filament type class; it is in the end domains that we see the variability related to differentiation. The head and tail domains could primarily function to stabilize the filament itself or to modulate the physical qualities of the filament network, or to anchor the filament to other parts of the cytoskeleton. These domains could also function, alternatively or additionally, to detect and react to cell signals that require mobilization of the cytoskeleton. There is even evidence that selective keratin expression can influence the proliferative capacity of the keratinocyte [66–68]. As other possible binding sites are now emerging — such as the potential of a motif in the head domain of type II keratins to interact with desmoplakin [69] — the truth may be that they do all these things. As the analytical systems move from transfection of cultured cells into the complexity of transgenic mice, many of these ideas are being reinforced. A recent example is seen in a study in which the addition of the K14 tail made the behavior of an anomalous transgenic K16 substitute more like the K14 it was replacing [70].

HERITABLE DISORDERS OF KERATINS

The identification of a heritable disorder is usually very informative in understanding the true function of a protein and this has proven to be the case with keratins. The discovery of keratin mutations underlying a range of epidermal fragility disorders has made it very clear that a major function of these structural filament proteins is indeed to provide the tissue with the resilience it needs to withstand "wear and tear" in that particular body site. A number of fuller reviews of this field have been published recently [71–74] (see also Chapters 15 and 24, this volume).

Epidermolysis Bullosa Simplex

The inherited skin disorders in the epidermolysis bullosa group, in which skin blistering occurs upon minimal trauma, are divided clinically into three subgroups: junctional epidermolysis bullosa and dystrophic epidermolysis bullosa which arise from connective tissue abnormalities and result in sub epidermal blistering, and the epidermolysis bullosa simplex (EBS) forms which give rise to intra-epidermal tissue separation. Individuals with EBS have fragile skin that blisters on mild physical trauma, such as rubbing or scratching; the blistering is caused by breakdown of the basal cells of the epidermis leading to a fluid-filled blister under an intact blister roof of suprabasal cells. EBS of the Dowling-Meara form (EBS-DM, also known as EBS-herpetiformis; MIM 131760) is characterized at the electron microscopic level by the occurrence of cytoplasmic, non membrane-bound electron-dense bodies [75], composed of basal cell keratins K5 and K14 [76]. As these clumps of keratin protein are observed in both blistered skin [75,77] and non blistered skin of affected individuals [76], it was reasoned that they cannot be caused by the blistering but may predispose towards it. The keratin clumps are reminiscent of filament disruption induced in several other circumstances, such as the microinjection of antibodies [78], cold shock [79,80], and mitosis [64,81,82], or the transfection of cultured cells with aberrant keratins [42]. Tonofilament clumping was also seen following the introduction of a truncated keratin 14 gene into transgenic mice, in which skin loosening, reminiscent of human Dowling-Meara EBS, was produced [43]. When the molecular basis of EBS was first discovered, it was by three independent groups, producing convergent results from three different approaches. Epstein et al. identified a point mutation in helix 2 of keratin 14 (Leu384Pro) in one family [83], Coulombe et al. [84] identified two Dowling-Meara EBS patients with different point mutations in helix 1A (Arg125Cys in one, and Arg125His in the other), and our laboratory identified the mutation Glu475Gly in the helix termination peptide of keratin 5 [85]. These studies precipitated wide-scale investigations into other cases of EBS and other possible keratin disorders in which clinical phenotypes suggest epidermal fragility.

It is now clear that mutations are not randomly distributed along the protein but are clustered in particular regions. The rod ends are the most frequent locations of pathogenic mutations, particularly the helix initiation peptide of K14, and especially codon 125 encoding arginine (R125). Something like 70% of all mutations identified in cases of the severest form of EBS, the Dowling-Meara form, involve this codon. A closer look at the DNA sequence reveals a highly mutable CpG dinucleotide in this codon which would account for its high mutation rate, but this must also represent an extremely sensitive point in the protein structure at which there is little tolerance of variation. Such information is valuable in working out how subunits interact with one another during filament polymerization. The involvement of the rod ends in those mutations which most severely compromise the function of the keratin cytoskeleton fits very well with biochemical evidence for an overlap between the start of helix 1A and the end of helix 2B when protein subunits are packed together in a filament (see Fig. 5).

Nearly all of the mutations reported for Dowling-Meara EBS cases are dominant negative missense mutations. They can occur with equal effect in either K5 or K14, in either the helix initiation peptide or the helix termination peptide. What makes a difference to the clinical severity is when they are found outside the helix boundary motifs, in which case the phenotype is usually less severe and not usually diagnosed as the Dowling-Meara form. The severe Dowling-Meara form of EBS is only one clinical variant of the disorder. Weber-Cockayne EBS (EBS-WC; MIM 131800; also known as EBS localisata) is a milder form in which the skin fragility tends only to affect hands and feet. While Weber-Cockayne EBS is also caused by mutations in K5 and K14, and also is nearly always inherited as an autosomal dominant trait, the position of mutations within the protein sequence is more variable. Looking at data from many cases of Dowling-Meara and Weber-Cockayne EBS, it is apparent that the mutation clusters are non overlapping. While EBS-DM is associated with mutations in the two rod ends, the helix initiation motif and the helix termination motif, EBS-WC is linked to mutations in four regions elsewhere. These are (i) the H1 domain just before the helix initiation motif, (ii-iii) two regions in the rod domain which lie internal to the helix initiation motif and helix termination motif, and (iv) the non-helical linker domain, L12, that connects helix 1 to helix 2 [86]. All these mutation hotspots are shown in Figure 5.

Another variant of EBS is the Koebner form (MIM 131900; also known as EBS-generalisata), which is associated with generalized blistering all over the body. While the clinical presentation of Koebner EBS is the most variable and its diagnosis possibly the most subjective, some cases of Koebner EBS have turned out to be recessive forms in which K14 expression is lost altogether [87]. Recessive "knockout" forms of EBS seem to be quite variable in phenotype [87–90], and are the result of mutations causing premature termination of the mRNA, which usually leads to nonsense-mediated decay of the whole message and the lack of any detectable gene product. The survival of individuals completely lacking K14 has been a surprise, since this is one of the most widespread keratins, which occurs as a major protein in all basal cells, and in both stratified and complex epithelia. Interestingly, no K5 knockouts have been reported to date, suggesting that such a phenotype might be lethal.

There are other variants of EBS with different associated clinical hallmarks [91]. In a handful of EBS cases genes other than keratins have been implicated. The best understood of these is a rare disorder in which EBS is associated with muscular dystrophy (MIM 226670), which is caused by mutations in plectin [92-95], an intermediate filament-associated protein involved in hemidesmosome formation in the epidermis. In theory, any weak link in the structural chain of filament-cell junction could cause cell lysis resembling that in EBS. In our laboratory we have still been unable to identify keratin mutations in 20% of the apparently unequivocal EBS cases referred to us, so there probably are some other proteins involved in EBS-like skin disorders.

Bullous Congenital Ichthyosiform Erythroderma

Bullous congenital ichthyosiform erythroderma, or BCIE (MIM 113800; also sometimes loosely referred to as epidermolytic hyperkeratosis), is another skin fragility disorder caused by mutations in keratins, but in this case it is the suprabasal cells that are fragile. In sections of affected skin, the basal cell layer is intact while the suprabasal layers of cells are ruptured to varying degrees. The clinical picture, however, is very different from that of EBS: skin may blister in an infant, but in adults blistering is not often seen. Instead, the epidermis can become extremely thick and scaly, especially

in the flexure regions. This difference in phenotype is clearly due to the different cell population affected with fragility, and it is the striking thickening of the skin (hence the term *ichthyosiform*) arising from keratinocyte hyperproliferation that is the prevalent clinical feature, rather than the clusters of blisters seen when basal cells are very fragile, as in the severe forms of epidermolysis bullosa simplex. Prenatal diagnosis has been successfully carried out following the identification of mutations in K1 and K10 in this disorder [96,97].

The cause of the suprabasal cell fragility in BCIE is almost always a dominant negative mutation in either K1 or K10, i.e., the two major secondary keratins of cornifying stratified squamous epithelia [98–101]. Keratins 5 and 14 are never found to be affected — not surprisingly, since the basal cell layer is intact. The locations of the mutations within the protein structure are related to the mutation sites seen in cases of EBS, i.e., the helix boundary peptides, but it is interesting to note that mutations at the sites associated with milder forms of EBS are hardly ever seen in BCIE. The most likely explanation for this is the persistence of the K5/K14 filament substructure in the suprabasal cells of the epidermis, which may act as a template upon which the K1/K10 proteins polymerize, providing some reinforcement even to a filament weakened by a mutation in one of these secondary keratins. Thus, mutations at the "milder" sites would go undetected and only those mutations most severely disruptive to filament stability would have pathological consequences.

Thickening of the epidermis is a frequently observed phenomenon in many keratin disorders, but it is most usually seen on the palms and soles, which remains one of the unexplained features of these diseases. One possible mechanism may be that the breakdown of the keratinocytes may be chronically triggering a low-level wound response in the epidermis, since it is known that cytokines released by ruptured keratinocytes provide some of the signals that induce the epidermal response in wound healing.

Ichthyosis Bullosa of Siemens

Another genodermatosis now known to be caused by mutations in a keratin is ichthyosis bullosa of Siemens (MIM 146800). This is caused by mutations in keratin 2e [102–105], a late-expressed epidermal keratin [106] found in the upper layers of the epidermis. The histological phenotype of this disorder is cytolysis of the uppermost layers of the stratified epidermis only, which presents clinically as mild, very superficial blisters. The physical fragility of the cells fits exactly with the known expression pattern of the mutated keratin, but the clinical characteristics are sufficiently distinct to have given this form of keratin disorder a completely different classification.

All the above keratin disorders affecting skin keratinocytes dramatically demonstrate the critical structural role of keratins in reinforcing the epidermis, and adapting this epithelium to withstand one of the harshest environments to which cells are ever exposed.

Pachyonychia Congenita

The range of disorders associated with keratins is now very wide and not all of them strictly affect the epidermis, yet they all have their own story to tell and they all contribute a bit more to our understanding of how keratins work in cells. A rather bizarre group of genetic disorders associated with the epidermis is the spectrum of defects incorporating pachyonychia congenita and steatocystoma multiplex (MIM 18450).

As its name implies, pachyonychia congenita (PC) is characterized by abnormally thick nails on hands and feet. There are two clinical forms of PC: type 1, or Jadassohn-Lewandowsky type (MIM 167200), associated with thick nails, palmoplantar keratoderma and white plaques in the oral mucosa, and type 2, the Jackson-Lawler type (MIM 167210), with thick nails, pilosebaceous cysts, pili torti and, occasionally, natal teeth. The range of phenotypic characteristics was puzzling at first, but by extrapolating from the existing knowledge of keratin expression, the genes for the "stress" keratins K6, K16 and K17 were quickly identified as candidates that might be harboring detrimental mutations. The first mutations were found in keratin 16 for PC1 and keratin 17 for PC2, the expression range of these two genes fitting well with the places in which cellular weakening was indicated by the appendageal distortion [107]. Again, these mutations are dominant negative autosomal mutations, and are located in the helix boundary regions of the affected keratins.

These disorders are now shedding light on a number of other puzzles associated with keratins, one of which being the functional difference between the two (or more) K6 genes, K6a and K6b, and another being the identity of the polymerization partner of K17. K6a and K6b are indistinguishable at the protein level, but mutations found in K6a in PC1 [108,109] and K6b in a case of PC2 [22], led to the suggestion that K6b may be the partner for K17 [22] (and K6a possibly the partner of K16). The appearance of "K6" in basal cells (K6α in mouse [7]) would fit with the occasional appearance of K17 in basal cells also, while K16 is more cleanly restricted to the suprabasal layers.

Another contribution of these disorders may turn out to be in relation to the problem of phenotypic variation. Like the EBS phenotypes, the stress keratin mutation disorders also show a range of severity. However, unlike EBS, these variants appear not to be associated with the position of the mutation in the protein. Variation in severity is associated with quite different clinical markers. For example, in contrast to PC2, nail defects associated with K17 mutations in steatocystoma multiplex are minor [110,111], and hence the cysts influence the name of the disorder whereas they appear secondary to the nail defects in PC. In other cases the focal palmo-plantar keratoderma dominates. It seems likely that these disorders are part of the same spectrum and yet all the mutations have been found in the helix boundary motifs, not in the "milder" cluster regions associated in K5/K14 with EBS-WC. Maybe the lack of mutations in secondary sites is because, as with K1/K10, the cells are reinforced by an underlying framework of the primary keratins K5/K14, and so mild cluster sites do not result in any pathological abnormality. If this is the case, a mild phenotype must be due to the nature of a mutation rather than its position; i.e., substitutions that do not distort or loosen the tertiary structure of the protein, and therefore do not interfere too much with filament packing, produce a mild phenotype. The existence of multiple mutations at a single residue associated with phenotypes of quite widely differing severity [112] suggest that this is the only possible explanation.

Keratin Disorders in Tissues Other than Skin

As well as the disorders described above, there is a growing number of other disorders which have also been associated with mutations in keratins. Keratin disorders affecting stratified squamous epithelia but not manifested in skin include Meesmann corneal dystrophy (MIM 122100), in

which small blisters on the front of the cornea of the eye are associated with mutations in K3 and K12 [113], and white sponge nevus (MIM 193900), in which a type of benign oral leukoplakia is caused by mutations in keratins K4 and K13 [114,115].

All the extracutaneous keratin mutations identified to date have occurred in conserved regions of the α-helical domains, which would be predicted to be critical for filament structure. As with the first examples of pathological mutations in human keratin genes, the EBS disorders, the lack of an effective keratin cytoskeleton renders the epithelial cells susceptible to cytolysis on physical trauma; again, these are disorders of cell fragility.

The only significant group of keratins not yet associated with a type of genetic disorder is the group of simple epithelial keratins, K7, K8, K18 and K19. Since these are mostly expressed in internal tissues, it may be that we are not yet able to spot any such disorders before they escalate into clinical conditions with many other consequences and different overriding clinical characteristics.

Not surprisingly, disease-associated mutations are also now beginning to turn up in the non keratin intermediate filaments. These include desmin-derived myopathies in muscle tissues [116,117], lamin-associated disorders in Emery-Dreifuss autosomal dominant muscular dystrophy (MIM 181350) [118] and partial lipodystrophy (MIM 151660) [119], and possibly some neuropathies such as amyotrophic lateral sclerosis [120]. It is likely that several more such disorders are still waiting to be discovered.

CONCLUSIONS

All the observations described above indicate a fundamental structural role for the keratins, and one that is essential in tissue differentiation. The central question in intermediate filament biology is why is such heterogeneity necessary. Are we simply observing evolutionary redundancy?

Our inability to demonstrate, in a testable experimental context, a defined role for intermediate filaments in cells and tissues that requires such heterogeneity is probably because the essential function of intermediate filament proteins lies in the fully differentiated tissue, which we cannot adequately reproduce in a controlled tissue culture situation. From the structural integration of muscle cells to the maintenance of the attenuated axonal cytoplasm in a functional state in the neuron, a case for a supporting cytoskeleton can be seen, with distinctly different requirements in each tissue. The case is strongest of all for the keratins, since the structural role of epithelia as boundary tissues is unequivocal, and the association of keratin filaments with desmosomes gives a three-dimensional integrity across the whole tissue that helps it to resist deformation. Disorders are now being identified in which EBS-like phenotypes are associated with mutations not just in keratins but in keratin-associated proteins that link keratins to the cell-cell junctions [92,93].

This three-dimensional network also has the built-in potential to transduce mechanical signals over long distances. Across the wide variety of different situations in which an epithelial sheet has to perform a structural supporting role while contributing to optimal tissue shape compatible with function, the physical requirements of the component cells will vary substantially. Physical requirements such as plasticity or rigidity may or may not be accompanied by other functional demands, such as the production of specific secretory products as in glands. Biochemical properties of intermediate filament proteins observed *in vitro* are likely to reflect biological differences *in situ*. A more easily disruptable filament system (keratins 8 and 18) might be more appropriate in secretory cells, in which there is a lot of cytoplasmic vesicular traffic, and a less easily disruptable filament system (keratins 5 and 14) might be better fitted to the physically stressed epidermis [9].

There is no longer any doubt that different keratins make filaments with different physical properties. There is probably sufficient variability in the amino acid sequences of the head and tail domains to account for this variation. The coiled-coiling of the rod domains clearly forms the backbone of the keratin filament, although there are still many details to be worked out as to how this takes place. The tissue-specific modulation of the filament quality, and the remodeling of the filament network through the life of the cell, is probably effected by the head and tail domain sequences that are attached to and protrude from these long protein polymers. We hardly have any more information on the function of these end domains than we do on the rod domain, but at least we are learning where to look. The keratin filaments of the cytoskeleton must have tremendous strength and resilience, as they are the subcellular components that allow us, for example, to stand on the epithelium of our feet without bursting the keratinocytes. A closer study of these microscopical ropes and their role in cellular architecture and engineering might well have some valuable lessons for our larger scale human projects.

Chapter 7

Extracellular Matrix Degradation

Gillian Murphy and John J. Reynolds

School of Biological Sciences, University of East Anglia, Norwich, UK (G.M.); Department of Orthodontics and Paediatric Dentistry, King's College London, Guy's Campus, London, UK (J.J.R.)

INTRODUCTION

The degradation of connective tissue matrix is a normal event in the physiological remodeling associated with morphogenesis and growth, as well as in processes such as angiogenesis, cell migration, cervical softening, uterine involution, and wound healing. The resorption is brought about by both resident connective tissue and infiltrating cells and is tightly regulated by a complex interplay of cell–cell and cell–matrix interactions involving the production of enzymes, activators, inhibitors, and regulatory molecules such as growth factors. In recent years, the nature of these entities, as well as the modes of cellular degradation of matrix components, have become more clearly defined. It also seems that the accelerated breakdown of connective tissue occurring in pathological situations, such as the arthritides, periodontal diseases, and tumor invasion and metastasis, is mainly the result of a failure in the normal regulation of degradative processes. This chapter aims to present an overview of knowledge of the nature of the enzymes contributing to matrix turnover, their origin and role, and of the factors that control their production and function. The studies reviewed provide much of the foundations for future work that will be needed to define which disorders of the degradative processes are inheritable.

The endopeptidases (proteinases) are thought to be the key enzymes in degradative processes, because the protein components of most matrices are the predominant determinants of tissue structure and function: exopeptidases and glycosidases play a secondary role. In *in vitro* experiments matrix macromolecules can be degraded by endopeptidases from the four major classes (metallo, serine, cysteine, and aspartate active site residues; [1]; Tables 1 and 2). Their relative roles *in vivo* vary from situation to situation depending upon the tissue environment and the types of cells involved, particularly whether inflammatory cells are present. The current view is that the initial step in matrix degradation is an extracellular proteolytic process, which may range from fine modifications of glycoproteins associated with the cell to a clipping of the cross-linked insoluble collagen and elastin fibers that are the basis of the matrix (Fig. 1). This process may be supplemented by mechanical wear and tear, injury, and bacterial infection.

Of particular interest is the fact that connective tissue cells synthesize and secrete a group of MMPs, which can synergistically digest the major macromolecules of connective tissue matrices [2–5] (Table 2). Subsequent to such initial proteolytic attacks on the matrix, the fragments generated may be phagocytosed by local cells for intracellular degradation or degraded further extracellularly. Except in special circumstances, such as bone resorption or other situations where the cell is in close apposition to its matrix, extracellular degradation is thought to occur at neutral pH. Consequently, proteinases of the metallo- and serine families will be optimally functional and could be responsible for the initial phase of the degradative process. Their individual and synergistic actions on different types of matrix protein are discussed below. The cysteine proteinases, which are more active at acid pH values, are secreted in some situations and may act within local acidic environments extracellularly: their function, coupled with the other lysosomal hydrolases, appears to be confined to the subsequent degradative events within the phagosome into which they are incorporated with phagocytosed matrix fragments (Fig. 1). The extent of matrix turnover occurring extracellularly, relative to intracellularly, is extremely variable and often reflects differences in cell types present in the tissue. Interactions among cells, the effect of auto- and paracrine mediators, and the effect of the matrix on the production and activity of proteinases, are all discussed in detail in the sections below.

Abbreviations used: APMA, 4-aminophenylmercuric acetate; bFGF, basic fibroblast growth factor; cAMP, cyclic adenosine 3′,5′-monophosphate; EGF, epidermal growth factor; IGF, insulin-like growth factor; IL-1, interleukin 1; IL-6, interleukin 6; IL-8, interleukin 8; IL-10, interleukin 10; IL-18, interleukin 18; α_2-M, α_2-macroglobulin; MMP, matrix metalloproteinase; MT MMP, membrane-type matrix metalloproteinase; PTH, parathyroid hormone; PA, plasminogen activator; PAI, plasminogen activator inhibitor; PDGF, platelet-derived growth factor; PMN, polymorphonuclear leukocyte; PGE_2, prostaglandin E_2; α_1-PI, α_1-proteinase inhibitor; M_r, relative molecular mass; SFD, Sorsby's fundus dystrophy; TIMP, tissue inhibitor of metalloproteinases; t-PA, tissue plasminogen activator; TGF-β, transforming growth factor-β; TNFα, tumor necrosis factor α; u-PA, urokinase-like plasminogen activator; uPAR, urokinase-like plasminogen activator receptor.

Connective Tissue and Its Heritable Disorders, pages 343–384

TABLE 1. Proteolysis of the Extracellular Matrix

Proteinase Class	Matrix Substrates	pH Range
Serine:		
Plasmin	Fibrin, fibronectin, aggrecan, pro MMPs	Neutral
Tissue plasminogen activator	Plasminogen	"
Urokinase-type plasminogen activator	Plasminogen	"
Neutrophil elastase	Most ECM components, pro MMPs	"
Proteinase 3	Similar to elastase	"
Cathepsin G	Aggrecan, elastin, collagen II, pro MMPs	"
Plasma kallikrein	pro u-PA, pro MMP1, MMP3	"
Tissue kallikrein	pro MMP8	"
Tryptase	Collagen VI, fibronectin, pro MMP3	"
Chymase	Many ECM components, pro MMP1, MMP3	"
Granzymes	Aggrecan	"
Cysteine:		
Cathepsin B	Collagen telopeptides, collagen IX, XI, aggrecan	5.0–6.5
Cathepsin L	As cathepsin B, elastin	4.0–6.5
Cathepsin S	As cathepsin B, elastin	6.0–6.5
Cathepsin K	Collagen telopeptides, elastin	Neutral
Calpains	Proteoglycan, fibronectin, vitronectin	Neutral
Aspartate:		
Cathepsin D	Many phagocytosed ECM components	3.0–6.0

Abbreviations: ECM, extracellular matrix; pro MMPs, pro-matrix metalloproteinases.

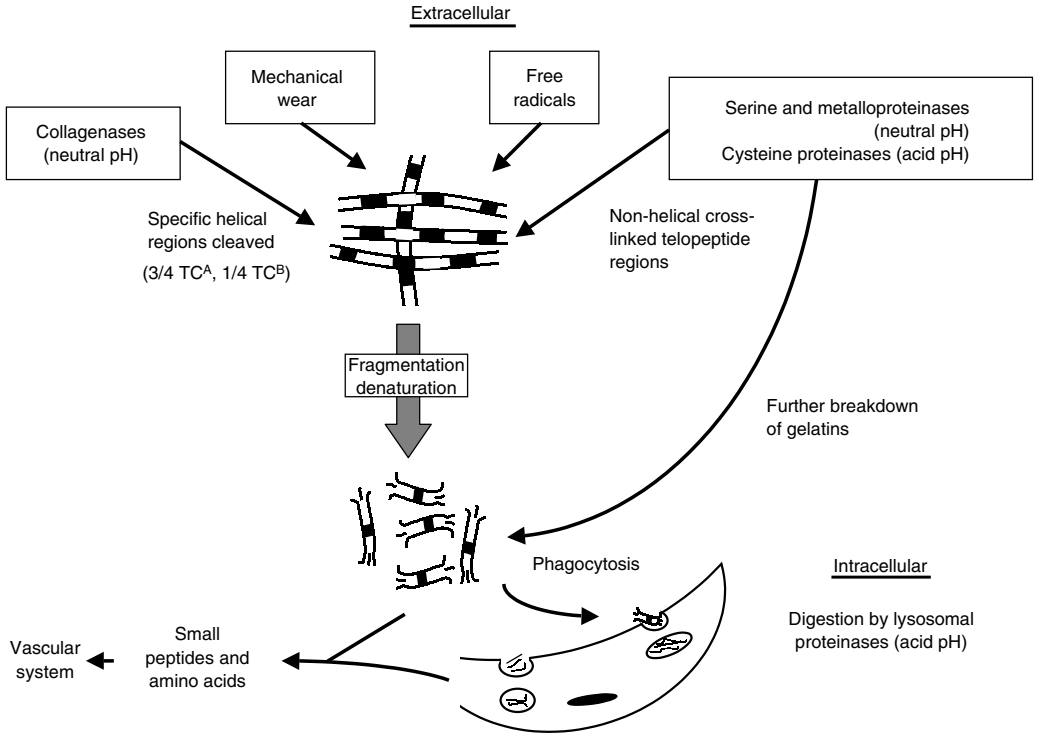

Figure 1. Pathways for the degradation of the collagenous components of connective tissues. Initial fragmentation of cross-linked insoluble collagen occurs extracellularly through proteinase cleavage, physical wear, and the action of free radicals in inflammatory situations. Telopeptidase activity, which weakens the cross-links, can result from the actions of metallo- or serine proteinases at neutral pH or cysteine proteinases at acid pH values. Cleavage within the fibrillar collagen triple helix has been attributed to specific collagenases only, resulting in TC^A and TC^B fragments (three-quarter- and one-quarter length fragments, respectively). In the case of fibrillar collagens, collagenase activity is more efficient against solubilized monomers generated by telopeptidase activity. The cleaved helix fragments (TC^A and TC^B) spontaneously denature at 37 °C and become susceptible to proteinases with gelatinolytic activity, including serine, metallo-, and cysteine proteinases. Collagen fragments, in some instances of very large size, are phagocytosed by cells and further processed by lysosomal enzymes, notably cysteine proteinases

TABLE 2. Proteolysis of the Extracellular Matrix

MMP No.	Enzyme Description	M_r Latent	M_r Active	Matrix Proteins Degraded
MMP1	Interstitial collagenase-1	55,000	45,000	Collagens I, II, III, VII, VIII, X; gelatin; aggrecan; versican; proteoglycan link protein; α_1-proteinase inhibitor; α_2-M; pregnancy zone protein; ovostatin; nidogen; myelin basic protein (MBP); pro TNF; L-selectin; MMP2; MMP9
MMP8	Neutrophil collagenase	75,000	58,000	Collagens I, II, III, V, VII, VIII, X; gelatin; aggrecan; α_1-proteinase inhibitor; α_2-antiplasmin; fibronectin
MMP13	Collagenase-3	60,000	48,000	Collagens I, II, III, IV; gelatin; plasminogen activator inhibitor 2; aggrecan; perlecan; tenascin
MMP3	Stromelysin-1	57,000	45,000	Collagens III, IV, IX, X; gelatin; aggrecan; versican; perlecan; proteoglycan link protein; nidogen; fibronectin; laminin; elastin; fibrinogen antithrombin-III; α_2-M; ovostatin; α_1-proteinase inhibitor; MBP; proTNF; MMP1; MMP7; MMP8; MMP9; MMP13
MMP7	Matrilysin	28,000	19,000	Collagens IV, X; gelatin; aggrecan; proteoglycan link protein; fibronectin; laminin; entactin; elastin; MBP; α_1-proteinase inhibitor; proTNF; MMP1; MMP2; MMP9
MMP10	Stromelysin-2	57,000	44,000	Collagens III, IV, V; gelatin; aggrecan; elastin; proteoglycan link protein; fibronectin; MMP1; MMP8
MMP11	Stromelysin-3	51,000	44,000	α_1-proteinase inhibitor
MMP12	Macrophage metalloelastase	54,000	45,000/ 22,000	Collagen IV; gelatin; elastin; α_1-proteinase inhibitor; fibronectin; vitronectin; laminin; proTNF; MBP
MMP19		56,000	48,000	Collagen IV; gelatin; aggrecan; laminin; fibronectin; COMP; tenascin
MMP20	Enamelysin			Amelogenin
MMP2	Gelatinase A	72,000	66,000	Collagens I, IV, V, VII, X, XI, XIV; gelatin; elastin; fibronectin; aggrecan; versican; proteoglycan link protein; MBP; proTNF; α_1-proteinase inhibitor; MMP9; MMP13
MMP9	Gelatinase B	92,000	86,000	Collagens IV, V, VII, X, XIV; gelatin; elastin; aggrecan; versican; proteoglycan link protein; fibronectin; nidogen; α_1-proteinase inhibitor; MBP; proTNF
MMP14	MT1 MMP	66,000	56,000	Collagens I, II, III; gelatin; elastin; fibronectin; laminin B chain; vitronectin; aggrecan; dermatan sulphate proteoglycan; fibrin(ogen); MMP2; MMP13; proTNF
MMP15	MT2 MMP	72,000	?	MMP2; gelatin; fibronectin; tenascin; nidogen; laminin
MMP16	MT3 MMP	64,000	52,000	MMP2
MMP17	MT4 MMP			proTNF; fibrin(ogen)
MMP24	MT5 MMP	63,000		MMP2
MMP23		44,000		Not known

Abbreviations: COMP, cartilage oligomeric matrix protein.

DEGRADATION OF EXTRACELLULAR MACROMOLECULES

Fibrillar Interstitial Collagens

The triple helical structure of the fibrillar collagens (e.g., types I, II, and III) is extremely resistant to the action of most proteinases and their durability is enhanced by being in tightly apposed fibrils, which can become heavily cross-linked in mature collagens. The presence of covalently bound carbohydrate and fibril interaction with glycoproteins of the surrounding matrix (ground substance) also make fibrillar collagens particularly difficult to degrade. The family of MMPs includes a number of enzymes that uniquely cleave the interstitial collagens at a single locus within the native helical structure at about three quarters of the distance from the N-terminal end (Fig. 1) [6]. These are the interstitial collagenases 1 and 3 (MMP1 and MMP13) and neutrophil collagenase 2 (MMP8). The membrane-associated metalloproteinase, MT1 MMP (MMP14), can also cleave collagen in this specific fashion. The collagenases show differing abilities to cleave the major forms of the fibrillar collagens, MMP1 favoring type III collagen, MMP8 type I, and MMP13 type II. Collagen I is slowly cleaved by gelatinase A (MMP2) and collagen III is susceptible to degradation by stromelysin 1 (MMP3) and gelatinase B (MMP9; Table 3). Cleaved portions of the helix quickly lose their triple helical

conformation and the denatured products are susceptible to the action of a number of less specific proteinases, such as the gelatinases. Gelatinase A is very widely distributed and is constitutively produced by many cell types in culture. Gelatinase B can also be produced by mesenchymal cells in culture after induction by cytokines and other agents and is a major product of monocytes and tumor cells: it is packaged in a granule fraction in PMNs. Recently, metal-dependent proteinases involved in the processing of the procollagen precursors of fibrillar collagens were fully identified [7]. These are members of families that are related to, but distinct from, the MMPs. The recessive disorder of animals and humans, dermatosparaxis, is due to a deficiency of the enzyme procollagen N-proteinase, resulting in the accumulation of collagen with N-propeptides in place and consequent skin fragility [8] (see also Chapter 9, this volume).

Serine proteinases such as elastase and cathepsin G from PMNs are very active against denatured collagens at neutral pH [9]. Lysosomal proteinases will degrade gelatin at acid pH [9] but there is no clear evidence for their generalized extracellular activity. The nonhelical telopeptide regions at the ends of the helical portions of interstitial collagens are important in both intra- and intermolecular cross-linking of the individual tropocollagen molecules, as well as of the aggregated fibrils. These nonhelical regions are susceptible to the action of a number of proteinases, particularly elastase and cathepsin G, as well as stromelysin 1 [10]. Similarly, at an appropriately acid pH, cathepsins B, L, K, and S may act against these regions [9,11–13].

Other Collagens

As described in Chapter 2, a plethora of collagens with specialized functions has now been characterized. The degradation of type IV collagen, which forms the basic network in basement membrane structures, is considered to be particularly significant, because this may be required for the intra- and extravasation of hemopoietic and tumor cells [14] and is central to capillary remodeling and growth during angiogenesis [15]. Type IV collagen consists of individual helical molecules with a large number of globular interruptions (Fig. 2) and is disulfide bonded into a network structure [16] (see also Chapter 2, this volume). It is quite susceptible to the action of a number of proteinases *in vitro*, including pepsin (Fig. 2) and plasmin [17]. The gelatinases A and B (MMP2 and MMP9, previously called type IV collagenases) derived from connective tissue cells and from PMNs and monocytes/macrophages have been shown to cleave isolated soluble type IV collagen within the helical portion of the molecule (Fig. 2), although there may be some doubt about the extent to which such type IV preparations are native and hence about the ability of these enzymes to cleave type IV collagen *in vivo* [18–20]. Collagen V is a component of hybrid fibrils in the extracellular matrix and is known to be cleaved by gelatinases A and B [21]. On the other hand, collagen VI is relatively resistant to MMP attack. Everts et al. [22] have shown that fibroblasts phagocytose type VI collagen prior to lysosomal degradation. Its extracellular degradation may be due to the action of collagenase 1, or of serine proteinases, as shown by Kielty et al. [23] for neutrophil elastase, cathepsin G, chymase, and tryptase.

Collagen VII, which forms anchoring fibrils in the skin, is susceptible to collagenase 1, gelatinase A, stromelysin 1, and gelatinase B [24]. Collagen IX, which aligns along the surface of collagen II fibrils, has a number of noncollagenous interruptions to the triple helix and is highly susceptible to proteolysis. The actions of collagenases 1 and 3 and stromelysin 1, against collagen IX have been documented [25,26]. Collagen X is cleaved by collagenases 1 and 3, stromelysin 1, and gelatinase A [26–28]. Collagen XI is cleaved by gelatinase A [29] and collagen XIV by gelatinase B [30]. It has recently been shown that type XVIII collagen can be proteolyzed at many sites adjacent to the NC1 domain but the enzymes involved were not identified. Such activity could generate the angiogenesis inhibitor, endostatin [31]. Other connective tissue cell MMPs, stromelysin 1 and

This table is not comprehensive in that not all MMP-collagen combinations have yet been analyzed.

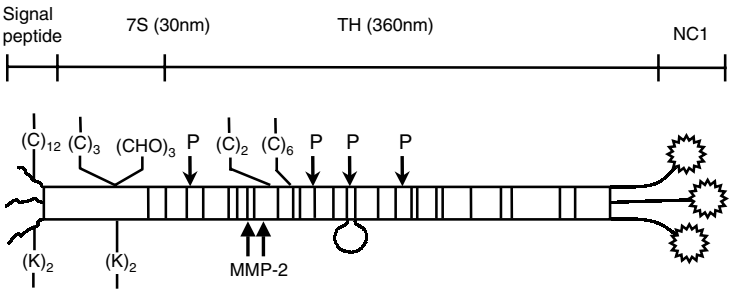

Figure 2. Type IV collagen structure and degradation. The type IV collagen molecule is most frequently composed of two α1(IV) and one α2(IV) chains that form a triple helix (TH) with an N-terminal domain that associates with other N-terminal domains to form the ''7S'' structure, and a C-terminal NC1 domain. The triple helix has many non-triple helical interruptions, indicated by black bars, which give the molecule great flexibility. However, there is substantial disulphide bonding with adjacent molecules that considerably modifies proteolytic susceptibility [20]. The major pepsin cleavage sites are indicated by arrows (P). The regions of gelatinase A cleavages within the molecule which are N-terminal to a disulfide-bonded region, are indicated by larger solid arrows (MMP-2). Type IV collagen is insoluble in basement membranes because of the formation of irregular polygonal networks of cross-linked supramolecular aggregates. Such structures are much more proteolytically resistant than soluble preparations. Cross-linking through cysteine is depicted by C and through lysine by K. CHO = carbohydrate binding site

matrilysin (MMP7), will efficiently degrade type IV collagen, apparently by attack at the nonhelical regions associated with cross-linking of the molecules [32,33], producing large but soluble fragments. The serine proteinases of PMNs, elastase and cathepsin G, can also degrade type IV collagen by attack on the nonhelical regions [34,35]. It is likely that the lysosomal cysteine proteinases act similarly at more acid pH values.

Proteoglycans

The protein cores of proteoglycans of differing types are generally susceptible to the action of many proteinases. The variation in cleavage patterns between types has not been systematically analyzed but most of the work carried out on chondroitin sulfate proteoglycan aggregates (e.g., cartilage aggrecan) seems likely to be generally applicable. Cleavages between the G1 and G2 globular domains, adjacent to the hyaluronate binding region are thought to be of the most significance, releasing a nonaggregating proteoglycan monomer, and various proteinases are now known to act in this region (Fig. 3). A predominant cleavage site is Glu373–Ala374, susceptible to the action of the metalloproteinase(s), ''aggrecanase'' [36], which is now thought to be a family of activities based on the soluble metalloproteinase disintegrins [37,38], termed ADAMTS [39], which contain thrombospondin 1 repeats (*a d*isintegrin *a*nd a *m*etalloproteinase: *t*hrombospondin). It should be noted that chondrocyte membrane aggrecanases have also been described [40]. Cleavage at Asn 341–Phe342, effected by many of the MMPs [41] and by cathepsin B [42] is also common. To compare the relative frequency of generation of these cleavages, antibodies to the neoepitopes have been used. Both types of digestion product could be isolated from osteoarthritic cartilage and were detectable by immunohistochemistry in rheumatoid, osteoarthritic, and normal cartilage. No specific distribution pattern could be defined and it was deduced that aggrecan turnover in all situations could be due to the classical MMPs or aggrecanase [43–45]. The topic is still under active investigation and it was recently shown that very early aggrecanase cleavages occur between G2 and G3 within the chondroitin sulfate-rich region (Fig. 3) [46]. The link protein that stabilizes the interaction of the aggrecan core protein with hyaluronan is also susceptible to proteolysis [47].

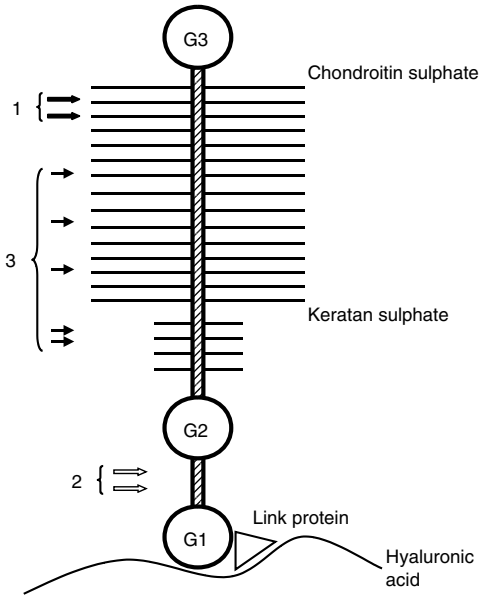

Figure 3. Proteinase degradation of proteoglycan core protein. The G3 domain is rapidly proteolyzed by an unknown mechanism, but early aggrecanase cleavage sites in the chondroitin sulphate-rich region have been identified (1). Major cleavage sites in the G1–G2 region (2) have been ascribed to either the aggrecanase or the MMP family, and generate large, nonhyaluronic acid-binding aggrecan monomers. Subsequent cleavages (3) can lead to further breakdown of both chondroitin sulfate and keratan sulfate-bearing regions of the core protein

Further cleavages between clusters of glycosaminoglycan side chains associated with extended regions of the core can occur, though these vary more widely. These cleavages generate small peptides with attached carbohydrate chains that are no longer trapped in the collagen network. In the case of aggregating cartilage proteoglycans, the fragment containing the hyaluronic acid binding region remains in the matrix, bound to hyaluronate. This may be due in part to protection of this region by link protein and hyaluronate [48].

The G3 domain appears to be very rapidly proteolyzed because as many as half of the aggrecan monomers in cartilage extracts have lost this domain. The lysosomal proteinases may be functional at pericellular sites, generating glycosaminoglycan peptides to be pinocytosed by the cell. It is possible that intact proteoglycan could be taken up by some connective tissue cells; some fibroblasts are able specifically to bind and internalize proteoglycans [49]. Dermatan sulfate proteoglycans appear to undergo pinocytosis more efficiently than heparan sulfate proteoglycans and via a different route. The internalized proteoglycan fragments are further degraded in the lysosomes, this involving the cathepsins, notably cathepsin D (reviewed by Heinegard and Paulsson [50]). There is sparse evidence for extracellular degradation of hyaluronic acid, although three hyaluronidase isozymes have been shown to be expressed by chondrocytes [51]. Pinocytosis through a specific receptor and intracellular degradation, and diffusion from the tissue and breakdown in the liver, have been described [52].

There is no evidence for cleavage of glycosaminoglycan side chains at extracellular sites, except in the case of heparan sulfate. Heparatinases and heparanases are known to be produced by platelets [53], activated T lymphocytes [54], neutrophils [55], and some tumor cells [56]. These enzymes are likely to be endoglucuronidases, similar to the well-studied platelet enzyme [53] and play an important role in the initiation of extracellular cleavage of this proteoglycan. Because heparan sulfate is involved in cell–cell and cell–matrix interactions, as well as binding to fibronectin, types I, III, and V collagens, and growth factors [57], its degradation may represent a significant part of the signaling mechanism of cells.

The intracellular digestion of glycosaminoglycan chains occurs through the initial action of lysosomal endoglycosidases, with further degradation by exoglycosidases and sulfatases that work from the nonreducing terminus (reviewed by Poole [58]). Our understanding of the degradation of glycosaminoglycans has been derived largely from studies of patients with genetic abnormalities, the mucopolysaccharidoses, resulting in either a deficiency or an absence of a specific enzyme in these pathways (reviewed by Neufeld and Muenzer [59] and in Chapter 22, this volume). Small leucine-rich proteoglycans, which interact with the surface of collagen fibrils, appear to be much more resistant to proteolytic degradation; it has been proposed that they help to stabilize the collagen network [60].

Elastin

As discussed in detail in Chapter 3, elastic fibers are comprised of two morphologically and chemically distinct components, predominantly an amorphous material (90%), which is the elastin, and fibrillin-containing microfibrils. This latter component is readily degraded by a variety of proteinases [61,62] but the amorphous elastin is susceptible to few enzymes. The serine proteinase elastase secreted by PMNs is a powerful general proteinase and degrades elastin moderately well by nonspecific electrostatic binding and attack of alanine rich regions [63]. This enzyme functions optimally at neutral to alkaline pH.

Metallo-elastase activities have been described in association with macrophages and some connective tissue cells [64–67]. It has also been shown that stromelysin 1 and gelatinases A and B produced by most connective tissue cells can degrade elastin, albeit slowly [66,68]. Whether their activity would be of significance *in vivo* is still difficult to judge, but a prominent role for MMPs in the degradation of elastin by human macrophages in the lung has been proposed [69]. The cysteine proteinase cathepsin L has been shown to have potent elastinolytic activity at pH 5.5, whereas cathepsin B has weak activity at this pH value [70,71]. Chapman and colleagues [65,72] have used a model system of macrophages growing on elastin substrates to demonstrate a major role for acid cysteine proteinases in elastin degradation. Their results also indicate that the action of the cysteine proteinases is dependent upon the action of neutral proteinases, notably plasmin, if the elastin substrate is associated with other glycoprotein matrix components. Their data suggest that matrix elastolysis mediated by cysteine proteinases occurs extracellularly and by analogy with bone resorption [73] they propose that acidification occurs at the cell-substratum interface.

In summary, the normal turnover of elastin in tissues is very slow and may be mediated by the MMPs produced by local cells. In situations of more rapid breakdown, notably pathological conditions such as emphysema, more potent proteinases may be involved, including cathepsin L from macrophages and leukocyte elastase from PMNs.

Fibronectin, Laminins and Other Extracellular Glycoproteins

Connective tissue cells produce many adhesive glycoproteins, some of which are specific to cell types while others, such as fibronectin, laminins, and vitronectin, have a widespread distribution (see Chapter 5, this volume). Characterization of these proteins and the definition of their roles have developed rapidly in recent years and detailed analyses of specific degradation patterns have been carried out. The majority of these glycoproteins are proteinase sensitive; they are susceptible to the action of many serine proteinases, such as PA [74,75] and PMN elastase and cathepsin G [76], MMPs including stromelysin [32,33], and the MT MMPs. A number of these molecules mediate cell–cell and cell–matrix interactions, and small changes in their levels, which could be effected by changes in their rates of degradation, may represent important signaling mechanisms *in vivo* [77]. Plasmin is thought to play a significant role in the removal of the glycoprotein components of the matrix. *In vitro* studies, including trophoblast and macrophage cultures on defined extracellular matrices, have shown that removal of glycoproteins by plasmin can be rate-limiting for the subsequent degradation of the collagen and elastin components [65,78,79].

PROTEINASE BIOCHEMISTRY

As outlined in the Introduction, members of the four major classes of proteinase are active in the degradation of connective tissue matrix macromolecules. This section briefly summarizes their biochemical properties in relation to their known roles in matrix turnover.

Matrix Metalloproteinases

Zinc dependent endopeptidases of the MMP (matrixin) family may be derived from many different cell types. At least 22 different human homologues have been identified and many are now well characterized, particularly in terms of their ability to degrade extracellular matrix proteins (reviewed in Nagase and Woessner [80]). The

MMPs have been classified into subgroups based on their structural similarity and substrate specificity. All the MMPs, apart from matrilysin (MMP7), have three common domains: the N-terminal propeptide, catalytic, and C-terminal domains [81]. The propeptide has the conserved sequence PRC V/N PD in which the cysteine residue plays a critical role in liganding to the active site zinc as part of the latency conferred by propeptide interactions with the catalytic domain [3]. The catalytic domain has the zinc binding motif HEXGHXXGXXH, in which the three histidine residues ligate the catalytic zinc. The C-terminal domain has a structure related to that of the hemopexin family and confers varying properties on different MMPs, including substrate, matrix and inhibitor binding. The two gelatinases (A, MMP2 and B, MMP9) have a fourth domain consisting of three fibronectin-like type II repeats with gelatin and collagen binding properties. The MT MMPs have a small C-terminal transmembrane domain and cytoplasmic domain such that the "traditional" MMP structure forms the ectodomain. Most recently, MMP23 was identified with cysteine-rich, proline-rich, and interleukin/receptor-like regions, which replace the hemopexin domain [80]. MMPs all require Ca^{2+} for stability and exhibit a preferred cleavage specificity for the N-terminal side of hydrophobic residues [82].

Collagenases and Gelatinases

MMPs with the ability to cleave fibrillar triple helical collagen [83,84] include collagenases 1 and 3 (MMP1 and MMP13), collagenase 2 (MMP8), and MT1-MMP (MMP14). Collagenase 2 is largely confined to neutrophils, although reports have been made of its expression in cartilage. The other collagenases are very widely distributed in most mammals; a definitive identification of MMP1 has yet to be made in rodent tissues, in which MMP13 is usually predominant. The collagenases have varying abilities to degrade other matrix components, but collagenase 3 seems to be particularly versatile [26]. Gelatinases A and B degrade denatured collagens or gelatins; they have been proposed to be of importance in the degradation of basement membrane type IV collagen, although this activity is confined to solubilized material [20]. Collagen V is also degraded [21] by gelatinases. They have activity on other matrix components including elastin [66,68], aggrecan [41], and cartilage link protein [47]. One of the most interesting recent observations is the cleavage of laminin 5 by gelatinase A, hence promoting epithelial cell migration [85]. Gelatinase A is very widely expressed, notably by mesenchymal cells in culture, and gelatinase B is found in neutrophils and macrophages. Mesenchymal cells may be stimulated to produce gelatinase B, which is constitutively produced by a number of tumor cell types.

Stromelysins, Matrilysin, Metalloelastase, and Membrane-Type Metalloproteinases

The stromelysins make up a subgroup of the MMP family, the archetypal members being stromelysin 1 and 2 (MMP3 and MMP10). They are biochemically similar with a broad ability to cleave matrix components including aggrecan, fibronectin, nidogen, laminin, and collagen IV [10,68]. Stromelysin 1 has also been shown to degrade collagens III, IX, and X as well as the telopeptides of collagens I, II, and XI. Stromelysin 3 (MMP11) is structurally much less related to stromelysins 1 and 2 but the mouse enzyme displays a very weak proteolytic capacity against similar substrates [86]. The human enzyme is only known to cleave α1-proteinase inhibitor [87] and specific synthetic peptides [88]; hence it is clear that its natural substrate(s) has not yet been identified. Stromelysin 3 is widely expressed in association with tissue repair [89] and tumor–fibroblast interactions. It is also expressed in atherosclerotic lesions [90] and co-localized with CD40 and it is suggested that MMP11 targets serpins that regulate cellular functions in atherosclerosis. Matrilysin (MMP7) has potent proteolytic activity, digesting a similarly wide range of matrix proteins as the stromelysins [68,91]. This is the only known MMP lacking the C-terminal domain, and therefore shows only weak interaction with TIMPs. Matrilysin is associated with ductal epithelia and may be secreted luminally by polarized cells [92].

Macrophage metalloelastase (MMP12) has been identified as an important MMP for the degradation of elastin [66] and has been implicated in destructive diseases such as abdominal aortic aneurysms [93]. However, it also has a broad matrix substrate specificity and is important in macrophage migration through tissues [94–97]. MMP12 has also been found in hepatocellular carcinoma [98], where it has been invoked as the enzyme responsible for the generation of angiostatin; lack of MMP12 and angiostatin correlated with poorer patient survival. The MT MMPs also exhibit a broad ability to cleave matrix proteins when studied in a soluble form. It is conceivable that their activity will be more limited at the cell surface. The catalytic domains of MT MMPs 1, 2, 3, and 5 are similar in substrate specificity, cleaving fibrin, fibronectin, tenascin, nidogen, aggrecan, and perlecan [84,99]. They all have the significant ability to initiate propeptide processing and activation of progelatinase A. MT1 MMP can be prepared with the C-terminal domain intact; in its soluble form it is able to cleave fibrillar collagen [84,99]. MT4 MMP appears to differ somewhat from the other MT MMPs and is not well characterized. MT MMPs 1-4 are widely expressed as evidenced by the detection of their corresponding mRNAs in many tissues, although MT5 MMP seems to be largely confined to the brain [100]. Correlation of MT1 MMP mRNA expression with that of gelatinase A and/or TIMP2 has been observed in some tissues [101,102]. Other MMPs, including MMP19 and 23, have been described, though they are not yet well characterized.

Activation of Latent Metalloproteinases

An important regulatory feature of the MMPs is that they are generally secreted in latent proforms and require activation. The activation of these precursors may be regarded as a critical step of matrix degradation as is subsequent inactivation by the action of endogenous inhibitors (see below). The other factor thought to modulate extracellular MMP activity is the ability to bind to specific extracellular matrix components, as discussed above, which increases the local concentration of the enzyme.

In vitro, the MMPs can be activated chemically by agents that modify cysteine residues, such as the organomercurial APMA. This acts to disrupt the cysteine-active site zinc interaction between the propeptide and the catalytic domain [21,103]. Disruption of cysteine-zinc binding can also occur when the conformation of the proenzyme is perturbed (e.g., the SDS activation of progelatinase A and progelatinase B during zymography). Most mechanisms involve a step-wise proteolytic processing of the propeptide [21]. These cleavages may be totally autolytic but often involve a second proteolytic activity that initiates the processing by cleavage of the propeptide in the N-terminal region, destabilizing the cysteine-zinc interaction.

Many of the MMPs share common activators that include other MMPs, leading to the concept of activation cascades (Fig. 4) [104]. The generation of plasmin by the action of PAs on plasminogen seems to be of particular importance for the activation of procollagenases 1 and 2, and prostromelysins 1 and 2. The u-PA is especially significant because it is functional in association with a specific cell surface receptor where activity can be focused (Fig. 4). The MT MMPs are also cell associated and appear to act as another focus for MMP activation cascades. MT MMPs 1–3 and 5 can all initiate the activation of progelatinase A and hence other pro MMPs (Fig. 4) [26,100,105].

Further regulation of the MMPs occurs by the action of the specific inhibitors, the TIMPs, which are described in more detail below. The tight regulation and relatively low activity of the MMPs may be a reflection of their physiological role in tissue turnover and remodeling. In disease states in which the control mechanisms become uncoordinated, the ubiquitous action and nature of MMP activities may be one of the factors leading to inexorable destruction of the extracellular matrix.

Mammalian Reprolysins and Astacins

Both of these groups of metalloproteinases fall within the metzincin superfamily with the MMPs. The mammalian reprolysins (or ADAMs) are proteins related to the snake venoms and contain *a d*isintegrin and *a m*etalloproteinase-like domain. They may be divided into two groups, membrane integrated, and soluble but cell-associated. The membrane-bound ADAMs frequently have fully fledged proteinase domains and are clearly implicated in the turnover of other cell surface proteins [106]. Some studies have suggested roles in the turnover of extracellular matrix but such a role is likely to be confined to cell bound molecules. A recent study suggests roles as fusion proteins for ADAMs 12 and 9 (meltrin-α and -β) in the formation of osteoclasts and multinucleated giant cells [107]. The major soluble ADAMs are the ADAMTS family that have C-terminal thrombospondin repeats, which may be involved in cell binding [39]. Two of these, ADAMTS-4 and ADAMTS-5, have been identified as aggrecanase and termed ADMP-1 and ADMP-2 respectively [37,38]. ADAMTS-3 is the procollagen N-proteinase involved in the processing of newly synthesized tropocollagen into fibrils (see Chapter 2, this volume).

The astacins are also multidomain proteinases and are still relatively understudied. The astacins discovered so far include procollagen C-proteinase (bone morphogenetic protein-1), which cleaves the carboxyl terminal propeptides of the fibrillar collagens during assembly [108] and others involved in cell differentiation and pattern formation during development. Meprin is an astacin expressed by intestinal epithelial cells and carcinomas and may have a role in the breakdown of basal lamina proteins [109,110]. It is a heterodimeric protein with α and β subunits and may be membrane anchored via the α subunit. Differential intracellular processing generates a soluble form that may be released into the lumen of the colon.

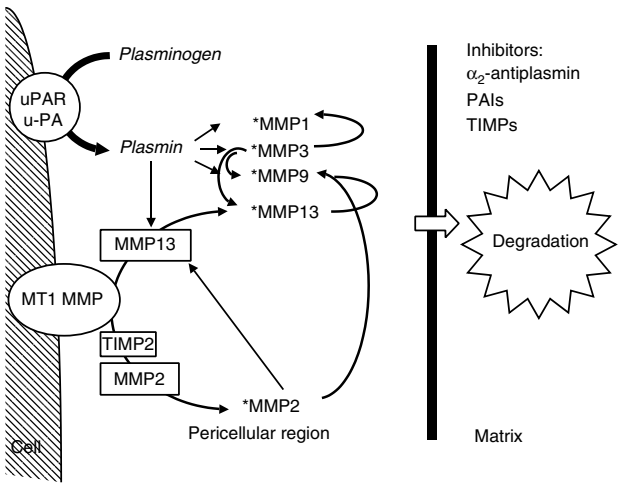

Figure 4. Cell surface-associated activation cascade for matrix metalloproteinases. The essential feature of this cascade is the production of proteinases and inhibitors by cells activated by cytokines, growth factors, and hormones. Whether or not matrix degradation occurs depends finally on the relative amounts of the metalloproteinases and inhibitors and also on the complex interplay with serum inhibitors. In many cases of tissue destruction, it is clear that plasminogen is essential for the cascade (see text): it is likely that u-PA plays a key role in the production of plasmin from plasminogen, which in turn is involved in the activation of collagenases and stromelysins. *indicates activated MMP. Solid lines denote activatory pathways

Serine Proteinases

Plasminogen Activators and Plasmin

The PAs specifically generate plasmin from its plasma zymogen plasminogen and are thought to be key regulators of connective tissue turnover [75]. Plasminogen is present in high concentrations in plasma [111] and binds to cells and components of the extracellular matrix [112]: thus its activation by PAs could be rate-limiting. Plasmin has activity against a number of connective tissue macromolecules including fibronectin, proteoglycan core proteins, other glycoproteins, and type IV collagen, as well as its major substrate, fibrin. Additionally, plasmin has been shown to initiate the autoactivation of many MMPs by a cleavage in the propeptide [21]. Both plasminogen and plasmin bind to extracellular matrix proteins that protect them from inactivation [113,114].

Two major PAs have been described, a t-PA and a u-PA. The single chain form of t-PA is an M_r 70,000 enzyme primarily associated with endothelial cells in tissues but variably expressed by other cell types, including fibroblasts, chondrocytes, and tumor cells. It binds specifically to fibrin and is thought to be the major generator of plasmin for fibrinolytic processes. u-PA is an M_r 55,000 enzyme, consisting of two disulfide-linked subunits, M_rs 30,000 and 24,000, and can be expressed by most cell types. It binds to a specific plasma membrane receptor on fibroblasts and some macrophage-like cells and may be more involved in generating plasmin for extracellular matrix remodeling processes [71,75,115]. Plasminogen (M_r 90,000) is cleaved by both PAs at an Arg–Val bond near the carboxyl terminus, resulting in an autocatalytic cleavage near the amino terminus of the enzyme. The PAs are chymotrypsin-like enzymes and are also initially secreted as proenzymes. Their activities are closely regulated by specific inhibitors, discussed below.

Elastase and Cathepsin G

The serine proteinases neutrophil elastase, proteinase 3, and cathepsin G are located in the azurophil granules of mature circulating PMNs. They are synthesized by premyelocytes during development in the bone marrow and packaged in the granules for future function in mature cells. These enzymes are potent nonspecific proteinases and

their roles are thought to be as bactericidal agents and in the degradation of immune complexes by intraphagosomal processes [116]. They may also be important in promoting inflammation, because the granule contents are frequently secreted into the extracellular environment. Elastase and cathepsin G can together degrade all the components of the tissue matrix. Both enzymes, however, are highly basic and bind tightly to the cell surface and the matrix, properties that may be important in determining the extent of their activity. Elastase, an M_r 29,000 glycoprotein, exists transiently in a proform and is then rapidly activated to the mature form [117]. It functions at neutral to alkaline pH, efficiently degrading not only elastin but also the nonhelical cross-linked regions of all collagens, including type IV [34,35]. Most glycoproteins of connective tissues are highly susceptible to elastase degradation. Proteinase 3 (myeloblastin) has a similar substrate specificity to elastase, degrading elastin, fibronectin, vitronectin, and type IV collagen [118]. Cathepsin G, M_r 22,000, is also active against collagens, solubilizing both insoluble types I and II, as well as degrading proteoglycan core protein and other matrix glycoproteins [119]. The activity of both enzymes is tightly regulated by a number of inhibitors, as discussed below.

Mast Cell Proteinases

Chymases are mast cell secretory proteinases with chymotrypsin-like specificity, and may have a role in matrix catabolism in some situations [120]. Chymase has a broad spectrum of activities, including activation of the proenzymes procollagenase 1, prostromelysin 1 [121], and progelatinase B [122], which can be synthesized by mast cells [123]. This group of proteinases varies to a large extent in its catalytic and physicochemical properties according to origin. Tryptase is a trypsin-like serine proteinase that is resistant to inactivation by circulating inhibitors and has been shown to be an activator of procollagenase 1 and prostromelysin 1 [21]. It has limited proteolytic activity toward type VI collagen, fibronectin, and fibrinogen [124]. Functional differences between tryptases from different tissues have been reported and the genetic heterogeneity of human tryptases documented [125]. Both chymase and tryptase as well as cathepsin G are stored in granules within the mast cell as inactive precursors and activation appears to occur during the secretory process.

Kallikreins

Plasma kallikrein, which consists of two disulfide-linked chains of M_r 36,000 and 52,000, acts on kininogens to generate bradykinin. It activates procollagenases 1 and 2 and prostromelysin 1 [21]. Tissue kallikrein (M_r 46,000) generates lys-bradykinin from kininogens [126] but is also an activator of procollagenase 2 [127] and progelatinase B [128].

Cysteine Proteinases

The cysteine proteinases that have been shown to degrade connective tissue proteins *in vitro* include cathepsins B, L, K, and S and the calpains. Although these enzymes function optimally at acid pH and have a major role in intracellular (lysosomal) digestion of phagocytosed material as well as in specific processing events, they may have extracellular activity in situations where the pH is acidic [71]. Both cathepsins B and L are secreted in significant amounts by stimulated connective tissue cells and macrophages, frequently in a proform that is stable at higher pH values [42,129,130]. With some cell types these enzymes have been shown to be associated with the outer surface of the plasma membrane, but it is not clear whether they are associated with specific receptors [131].

Cathepsins B and L have M_rs of about 28,000 and 25,000, respectively, in their active forms. They are related to the plant proteinase papain, all possessing an active site cysteine as well as an essential histidine residue, and cleave internal bonds in proteins and peptides. Cathepsin L is the most potent of the lysosomal endopeptidases, although the recently studied cathepsin S has a similar spectrum of activity and is more active at neutral pH values [132]. Cathepsin B is less active as an endopeptidase and can function as a peptidyl dipeptidase. It is likely that the normal physiological functions of cathepsins B and L are intracellular, with a major role in the lysosomal degradation of proteins in cells [133]. Although cathepsins B and L are generally stored in lysosomal granules, they can sometimes be found extracellularly and often in a latent form requiring activation. Both the active and latent extracellular forms of cathepsin B have higher M_rs than the lysosomal enzyme and are thought to be precursor forms that can be activated by proteolysis. They are stable at alkaline pH and some forms may be poorly inhibited by endogenous inhibitors such as the cystatins and α_2-M. Procathepsin L has been isolated from transformed mouse cells and activated human and mouse macrophages in culture, but is not active unless exposed to low pH. Both cathepsins B and L degrade cartilage proteoglycan and collagen [11]. Type I collagen is cleaved in the N-terminal telopeptide region causing depolymerization of the covalently cross-linked mature fibrils, thereby generating monomers [9]. Cartilage collagens, types II, IX, and XI, are also cleaved within the nonhelical domains. Cathepsin L is a particularly active matrix-degrading proteinase: it can degrade elastin and may have a role in elastin degradation in the lung, where macrophages are abundant [134]. Cathepsin S, M_r 24,000, has a similar substrate specificity to cathepsins B and L [132] but is more stable at pH values close to neutral. It has collagenolytic and elastolytic properties at neutral pH. It is less abundant than cathepsins B and L although it is still an important component of the lysosomal degradation mechanism. Cathepsin S maps to chromosome 1q21 and has been implicated in Alzheimer disease and Down syndrome [135].

Cathepsin K (previously O) has been isolated from cDNA libraries from osteoclasts and spleen [136] and has M_rs in the mature form of 43,000 and 29,000. It plays a key role in osteoclast-mediated bone resorption, efficiently degrading type I collagen at pH values of 4.5–6.0 as well as gelatin, elastin, and osteonectin. Strong evidence for the function of cathepsin K has been derived from the study of patients with the recessive autosomal disease pycnodysostosis (see Chapter 19, this volume). The disease is linked to chromosome 1q21 [137] and characterized by dwarfism, and severe bone abnormalities such as osteopetrosis. Collagen fibrils have been found to accumulate in cytoplasmic vacuoles in the osteoclasts of such patients [138]. Cathepsin K has subsequently been mapped to the pycnodysostosis location on chromosome 1q21 and has been shown to contain additional and altered stop codons in patients with the disease [139]. It was also shown that cathepsin K is localized at the ruffled border of osteoclasts and the collagen in resorption lacunae implying in part an extracellular localization and function [140]. Studies ablating the gene for cathepsin K in mice have resulted in a confirmatory osteopetrotic phenotype [141]. Osteoclast cathepsin K is

up-regulated by all-*trans* retinoic acid, a potent stimulator of osteoclastic activity [142] and may account for matrix degradation in other retinoid sensitive tissues. Specific extracellular inhibitors of the cysteine proteinases would further regulate their activity, as discussed below. To date, the only other cells reported to synthesize cathepsin K are bronchial and alveolar epithelial cells [143]; because cathepsin K is highly collagenolytic and elastinolytic, it is possible that this proteinase may be important in remodelling processes in the lung.

Calpains are cytosolic, Ca^{++}-dependent cysteine proteinases with neutral pH optima. μ-Calpain and m-calpain require micromolar and millimolar Ca^{++}, respectively, for activation [144]. These enzymes can degrade proteoglycan, fibronectin, and vitronectin [145]. Calpains have been shown to be raised in synovial fluids and tissues of patients with rheumatoid and osteoarthritis and in some animal models of arthritis. Calpastatin, a specific cellular inhibitor of calpains, has been identified as an auto antigen in some rheumatoid patients [146].

Aspartic Proteinases

Lysosomal cathepsin D is the major aspartic proteinase involved in matrix degradation. It is now accepted that its role is confined to the breakdown of phagocytosed material. Procathepsin D is sorted to lysosomes via the mannose-6-phosphate receptor and is stored in its M_r 34,000 mature form. Its optimal proteolytic activity against most substrates is at pH values as low as 3.5 and it is, therefore, most suited to a function within phagosomes [147].

PROTEINASE INHIBITORS

The abundance and diversity of proteinase inhibitors that function in connective tissue metabolism indicate the importance of efficient regulatory mechanisms for degradative events. The *in vivo* levels of proteinase inhibitors generally exceed the levels of their target proteinases. With the exception of α_2-M, the naturally occurring inhibitors act specifically against the individual classes of proteinases and are considered according to this classification.

α_2-Macroglobulin

This plasma inhibitor is unique in that it inactivates proteinases from all the major mechanistic classes [148]. α_2-M (M_r 780,000) consists of four identical polypeptide chains, which exist as two dimers covalently linked by S–S bonds, which can noncovalently associate to form a tetramer. Inhibition is effected by a "trap" mechanism in which a "bait" region of the molecule, containing preferred cleavage sites for all classes of endopeptidases, is cleaved. Upon cleavage of the bait region the conformation of the α_2-M tetramer is modified, trapping the enzyme within the molecule. The interaction of α_2-M with MMPs has been studied in detail and shows that the bond cleavage in the bait region is variable: collagenase preferentially cleaves in this region at the amino-terminal side of large hydrophobic residues [149]. Each subunit of α_2-M contains an intrachain β-cysteinyl-γ-glutamyl thioester which becomes reactive on proteolysis of the "bait" region and can form a covalent link with the proteinase. This is not essential for the inhibitory mechanism, however. α_2-M is thought to be largely confined to the blood supply since its large M_r usually precludes penetration within the tissue matrix. Consequently, it serves an important role as the humoral regulator of proteinase activity. The liver is the major site of synthesis, but there are reports of α_2-M synthesis by lung fibroblasts in culture [150] and by tissue. There is tissue penetration where capillaries are leaky, as in inflammatory situations, but the role of α_2-M, if any, within matrices is still not clear [148].

Inhibitors of Matrix Metalloproteinases

One major group of inhibitors of the connective tissue MMPs has been described in detail to date, the TIMPs. Four TIMPs have been described; TIMP1 is an M_r 28,000 glycosylated protein [151], TIMP2, an M_r 22,000 protein [152], TIMP3, an M_r 21,000–27,000 protein that binds to extracellular matrix components [153], and TIMP4, an M_r 22,000 protein that is related to TIMP2 [154]. The TIMPs have a similar basic structure of six disulfide-bonded loops that can be divided into two subdomains. All the TIMPs can inhibit all the MMPs, with a few rare exceptions, forming 1:1 complexes [155–157]. In addition to their ability to bind to active MMPs, complexes between specific TIMPs and pro MMPs have been identified, notably between TIMP2 and progelatinase A and TIMP1 and progelatinase B. These complexes are formed through interactions between the COOH subdomain of the TIMP and the C-terminal domain of the enzyme. The complex between TIMP2 and progelatinase A has been implicated in the cellular activation mechanism for progelatinase A, involving MT MMPs [104].

TIMP1 is produced by many cell types and can also be up-regulated by factors such as inflammatory cytokines, growth factors, retinoids, and progesterone. TIMP2 is constitutively produced by many cells in culture and little is known of its regulation. TIMP3 is induced by a number of growth factors and dexamethasone; its production appears to be cell cycle regulated [158]. Interestingly, point mutations have been identified in the TIMP3 gene that are associated with the hereditary macular degenerative disease, Sorsby's fundus dystrophy (see below). TIMP4 may have an important role in the proteolytic balance of the vasculature [159]; it is increased after vascular injury in rats.

Inhibitors of Serine Proteinases

Human plasma contains a superfamily of serine proteinase inhibitors, the serpins, which are synthesized in the liver [160]. They are generally glycoproteins (M_rs 40,000–60,000) with a single polypeptide chain, which act by presentation of a potential cleavage site for the target enzyme. These include α1-PI (previously called α1-antitrypsin), which is an important regulator of neutrophil elastase activity and may also act against plasmin. Indeed, α1-PI is the major serum inhibitor of PMN elastase and its deficiency is often associated with the early development of panacinar emphysema (see also Chapter 17, this volume). In emphysema, elastase-α1 proteinase inhibitor complexes can be detected in tissue fluids and the concept of protease:antiprotease imbalance has been invoked. Interestingly, mouse macrophage metallo-elastase (MMP12) can degrade native α1-PI at a single methionine residue [161] but does not degrade the oxidized form. This region of α1-PI has more recently been found to be sensitive to cleavage by many MMPs and other proteinases. Thus, it is possible that MMPs could disrupt the balance between serine proteinases and their inhibitors *in vivo*.

The major physiological plasmin inhibitor in plasma is α2-antiplasmin, an M_r 67,000 member of the serpin family that binds to both plasminogen and plasmin at lysine binding sites. α2-Antiplasmin subsequently complexes with the active site of plasmin at a second reactive site (reviewed in Lijnen and Collen [162]). The concentrations of such proteinase

inhibitors within connective tissue spaces are likely to be similar to those in plasma under normal conditions and they are thought to be effective in regulating plasmin activity. However, in inflammatory situations and other pathological processes, the free plasma inhibitor level may fall.

The PAIs are potentially some of the most important regulators of connective tissue degradation because of their control of the rate of plasmin generation in local extracellular environments. Although PAs do complex with other types of serine proteinase inhibitor, many may not be effective *in vivo*. Four specific PAIs have been described, all members of the serpin family (reviewed in Kruithof [163]; Andreasen et al., [164]). The endothelial-type, PAI1, originally isolated from cultured endothelial cells [165], is an M_r 54,000 glycoprotein produced by a number of cell types in culture; it inhibits both u-PA and t-PA but forms a more stable complex with the latter. It is present in platelets and is the primary inhibitor of PAs in plasma [166]. PAI2 is also present in plasma and has an M_r of 47,000 in the nonglycosylated form; an M_r 67,000 glycosylated form was originally described from placenta but is expressed by a number of cell types including macrophages [167]. The third inhibitor, PAI3, is identical to the inhibitor of activated protein C and is less well understood [163]. The fourth inhibitor, known as protease nexin I, was originally found in fibroblasts [168] but is produced by other cultured cells such as endothelial cells. Secreted PAI1 is initially deposited pericellularly and can be recovered from extracts of extracellular matrix [169]. This association maintains inhibitor stability, whereas the free form becomes rapidly inactive, suggesting that its major function is to regulate pericellular proteolysis. The precise function of PAI2 is not clear, although it may have a role in inflammatory reactions. It is more stable than PAI1, is more effective against u-PA than t-PA and is a plasmin inhibitor [163]. Reaction with PA leads to inhibitor inactivation with the loss of an M_r 15,000 peptide. Protease nexin I is a less specific inhibitor of both u-PA and t-PA; it has a broad spectrum of action and is more effective as a thrombin inhibitor. However, it has been shown to inhibit u-PA-mediated matrix degradation [170].

Acid-stable serine proteinase inhibitors have been isolated from mucus secretions, seminal plasma, and salivary glands and show a degree of immunological cross-reactivity. The inhibitor from human parotid secretions, mucus proteinase inhibitor or secretory leukocyte protease inhibitor, SLPI, has been isolated, characterized, and sequenced [171]. SLPI has an M_r of about 12,000 and is a potent inhibitor of the neutrophil proteinases, elastase, and cathepsin G. It is a two domain protein with the C-domain conferring proteinase inhibitory properties. SLPI is thought to play an important role in the defence of different tissues against these enzymes and it has been shown to inhibit proteolysis at the neutrophil-substrate interface [172]. An M_r 15,000 form of SLPI has been found in cartilage [173]. An inhibitor termed elafin has been isolated from human skin and is comprised of 57 residues with 38% similarity to the inhibitory domain of SLPI. It inhibits neutrophil elastase and proteinase 3, but not cathepsin G. Aprotinin, which is present in mast cells and cartilage is a kunitz-type pancreatic trypsin inhibitor that inhibits plasmin and kallikreins [174].

Inhibitors of Cysteine Proteinases

A super-family of cysteine proteinase inhibitors, the cystatins, is largely responsible for the extracellular regulation of the activity of these enzymes [175]. The members of the super-family have been placed into three groups. One comprises the type 1 cystatins (stefins), of low M_r (11,000) and containing no disulfide bonds or carbohydrate groups. They are synthesized without a signal sequence and are confined to the cell. Two species are known; type A, found in high concentrations in various epithelial cells and neutrophils, and type B, which is more widely distributed. Both type 1 cystatins have been found in extracellular fluids [176]. Type 2 cystatins are more complex, with two disulfide loops and an M_r of 13,000. Human cystatins C and S have been described [175]. Cystatin C has been found in cells [177] and is a major secretory product of human alveolar macrophages *in vitro* [178]. Type 3 cystatins (kininogens) are the most complex, containing three type 2-like domains. They are major plasma proteins functioning not only as cysteine proteinase inhibitors but also in vasodilation and coagulation events. Both types 2 and 3 cystatins are synthesized with signal peptides and are secreted products.

Barrett [175] has assessed and discussed the relative physiological roles of the cystatins. Cathepsins H and L are tightly bound by these inhibitors and their intra- or extracellular activities are likely to be adequately controlled. Cathepsin B, which is present in greater amounts, is more weakly inhibited, but cystatins C and S would probably be effective extracellularly.

PROTEOLYTIC MATRIX RESORPTION IN PHYSIOLOGICAL, PATHOLOGICAL AND EXPERIMENTAL SITUATIONS

Proteinase Cascade Model of Tissue Breakdown

It is clear that no one proteinase can be considered of overriding importance in matrix turnover. A complex cascade of proteolytic events best explains how matrix destruction takes place generally (Fig. 4); in each specific situation an interplay of proteinases will be seen. Overlapping specificities are clearly demonstrated by research showing that the phenotypes of MMP-mutant mice are generally mild with respect to development and physiology, but that the deletion of specific, abnormally expressed MMPs can alter disease onset [67,95]. It is also evident that proteolysis is usually localized and that extracellular matrix degradation takes place at or near the cell surface [4,77], often where activation of MMPs occurs. We envisage that in situations without invading cells, resorption is often initiated by specific attack on matrix macromolecules by activated MMPs synthesized by stimulated tissue cells. This initial attack on the integrity of extracellular macromolecules facilitates further extracellular degradation and also adds to any intracellular degradation by phagocytosis. These processes may be augmented by the infiltration of inflammatory cells, mechanical damage, free radicals, and bacterial infection.

In most situations there is a very substantial overlap between the various proteinases, in that one specific enzyme is not absolutely essential. With some cell types, such as human monocyte-derived macrophages, both MMPs and cysteine proteinases contribute to resorption [179], as they do in bone. However, there are instances where only one proteinase may be involved in specific roles, such as the central role of enamelysin (MMP20) in the process of tooth enamel formation [180] and the high elastase and general proteolytic activity of MMP12, which is produced essentially only by macrophages [94] and seems to be regulated differently than other MMPs [181]. Also, gelatinase B (MMP9) is found to be strongly expressed in invading trophoblasts, with no

expression of gelatinase A (MMP2). Many aspects of the individual actions of MMPs have been reviewed recently (see Parks and Mecham [182]). With regard to inhibitors, it seems that TIMP3 has a major role in the control of extracellular proteolysis associated with implantation in the early embryo, in which TIMPs 1 and 2 are not expressed [183], and in fetal development [184]. A protective effect against breakdown is suggested by the observation of extensive colocalization of TIMP2 with type IV and fibrillar collagen in the lung [185].

A second general theme is that an imbalance of proteinases over inhibitors seems to occur in rapid tissue degradation. Early evidence that tissue destruction in disease processes might result from an imbalance of MMPs over TIMPs came from a study showing a reduction in TIMP synthesis compared with that of MMPs in synovial explants from a rabbit model arthritis (reviewed in Murphy and Reynolds [186]). Studies with human joint tissues from normal individuals and patients with arthritis indicated close similarities with the rabbit model and supported the idea that resorption is closely linked to insufficient TIMPs to counteract increases in MMP production. Extracts from osteoarthritic cartilage have considerably elevated levels of MMPs and only moderately increased levels of TIMP activity, leading to an imbalance [187]. A detailed study of osteoarthritis and rheumatoid arthritis confirmed that an excess of MMPs over TIMP activity in the synovium and cartilage may make a significant contribution to cartilage loss [188]. Because active enzymes were found, it is clear that TIMP levels must be insufficient to counteract the enzymic activities. High levels of TIMP-MMP complexes have been found in the synovial fluid aspirated from patients with septic arthritis [189], with active MMPs present but no free proteinase inhibitory activity. It was suggested that MMPs are released from PMNs and complex all the available TIMP activity, thus leading to an imbalance with consequent rapid cartilage destruction.

Stromelysin 1 (MMP3) is very prominent in synovial biopsies from patients with rheumatoid arthritis and osteoarthritis [190] and, even if it is not the major enzyme concerned in cartilage destruction, it may be overpowering any TIMP activity. Such an imbalance is also likely to be true for periodontitis-related conditions. Pourtaghi et al. [191] showed that antimicrobial therapy raised TIMP levels and lowered MMP3 levels in gingival crevicular fluid. In other situations, members of the other classes of proteinases, such as cathepsin B, can contribute to TIMP destruction [192].

The balance between matrix deposition and turnover is fundamental in wound healing. Bullen et al. [193] found that TIMP1 levels were lower in fluids from chronic than from healing wounds, and MMP9 is probably involved in the early stages [193–196], although Moses et al. [197] suggested that MMP2 is the more important gelatinase. Berend et al. [198] found that a high ratio of MMP1 to TIMP1 in human chondrosarcoma may be indicative of a more invasive and aggressive tumor: the ratio could therefore be useful in diagnosis and therapy, and this area is explored in more detail below. MMP13 expression is also found in chondrosarcomas [199] and was detected along with bFGF in all specimens examined. Other pathological conditions, such as the matrix breakdown surrounding loose artificial hip joints [200,201] and the formation and stability of atherosclerotic plaque [202], may also be related to an imbalance of MMPs over TIMPs.

Although molecular and biochemical studies and *in vitro* studies have made substantial contributions to the understanding of matrix breakdown, our knowledge of the specific roles of proteinases and inhibitors *in vivo* is less extensive. A major problem is that there are few techniques available that can detect the often very low levels of these entities at the sites of resorption. Biochemical assays are too insensitive and *in situ* hybridization often lacks resolution. One approach has been to prepare specific antisera for use in immunolocalization studies on cells and tissues *ex vivo*, particularly using model systems of rapid matrix destruction. Even with specific antisera and an indirect second step for amplification it has often proved difficult to localize MMPs and TIMPs, and many early immunofluorescence localization studies on tissues showed low or no staining. Consequently, a method was developed for the accumulation of antigens by using short-term culturing of cells and tissues and inhibiting cellular secretion of the antigen with the ionophore monensin (e.g., the localization of TIMP1; [203]). Such treatment results in the intracellular accumulation of antigens in the Golgi apparatus and in secretory vesicles. With this technique, unique patterns of synthesis have been observed in many situations, consistent with specific roles for the individual MMPs and other data. For example, the results of immunolocalization studies on the rabbit growth plate [204] demonstrate a unique pattern in each developmental area, both spatially and temporally, of synthesis for each MMP and TIMP1. Most of the published work has concentrated on localization at the light microscope level but MMP1 has been immunolocalized to collagen fibrils by electron microscopy [205], and MMP3 to rheumatoid synovioblasts [206]; the fixation methods needed often cause problems with loss of antigenicity for MMPs and TIMPs [207].

Another interesting point is that in many instances of rapid resorption, active MMPs can be immunolocalized bound to extracellular components in tissue *ex vivo* [208–210]. A specific antibody to mammalian MMP1 was used to immunolocalize collagenase in a porcine synovial model system [209]. When synovial preparations were cultured with colchicine for 2 days, latent MMP1 could be detected within the cells and fluorescence was associated with the extracellular fibrils. It was concluded that this was active collagenase because latent collagenase does not bind to collagen. The addition of cortisol, an anti-inflammatory steroid, to cultures so treated, resulted in the abolition of the diffuse fluorescence of the active collagenase bound to collagen and a large reduction in the number of cells containing latent collagenase. MMP1 has also been immunolocalized on collagen fibrils in frozen sections of VX2 tumor taken *ex vivo* [210]. Such tumor cells, when transplanted into nude mice, were shown to contain MMP1, thereby demonstrating that the VX2 tumor cells synthesize it *in vivo*. Only recently have monoclonal antisera been prepared that will detect active MMPs and TIMPs specifically [211] and can be used in immunochemical studies [212]. Activated MMP9 was detected by immunohistochemistry in fixed, wax-embedded sections from a series of esophageal cancer cases known to contain the enzyme in tumors themselves [211].

In much recent work, *in situ* hybridization and *in situ* zymography [213] have become the norm for demonstrating expression, especially when no antisera are available. However, it must be pointed out that mRNA levels do not necessarily equate with protein expression. A study showing the expression of MT1 MMP in mouse tissue during embryogenesis, using *in situ* hybridization and immunolocalization

in combination with gelatin zymography, well illustrates the power of the present techniques [214]. Not only was the presence of MT1 MMP shown, but also its localization with respect to MMP2 and TIMP2. MMP7 was shown to be expressed by epithelial cells in a tissue-restricted pattern in the mouse very clearly by *in situ* hybridization using a riboprobe [215].

Modulators of the Synthesis of Matrix Metalloproteinases and Their Inhibitors

One of the striking features of the family of MMPs is that they are "inducible," i.e., their synthesis and secretion seem to be controlled by factors that alter gene expression. The expression of MMPs and TIMPs by connective tissue cells is regulated by complex interactions between a number of cytokines, growth factors and hormones [216], some of which are specific to cell type and others more ubiquitous. Many factors are the products of monocytes/macrophages and their production in inflammatory situations is a key step in initiating MMP synthesis and tissue degradation [217]. IL-1 [218,219] seems to be particularly important in the up-regulation of MMPs, and roles for TNF [220–222], growth factors such as bFGF [223–225] and PDGF [226,227], and prostaglandins as stimulators have been documented.

MMP2 production by human fibroblasts was found to be stimulated by TGF-β [228], whereas MMP1 synthesis was decreased by this factor [223,228]: TGF-β also increases TIMP1 production [223,228]. It is likely that MMP2 is controlled differently from the other MMPs, which may be related to the fact that it has a different chromosomal localization [229] to that of MMP1 and MMP3 [230] and is activated differently. In murine macrophages, it has been found that MMP2 and MMP9 are differentially regulated [231]. Different cell types show differential signalling pathways in response to TGF-β [232] and that there are cell-type activities of AP-1 components. TGF-β may be especially important because it can decrease the cytokine-induced synthesis of MMPs and increase that of TIMP1, and is probably physiologically important since many connective tissue cells make this factor and extracellular matrices can be large stores of it [233]. IL-10 can result in a decrease in MMPs and an increase in TIMPs [234], which may be mediated by the inhibition by IL-10 of prostaglandin production [235]. Interaction between multiple factors is important when considering cells in tissues *in vivo* rather than in artificial culture models. Inhibitory effects of IGF-I, IL-4, [236] and IL-13 [237] on MMP expression have also been found.

Studies with human gingival fibroblasts suggest that IL-1 may act to stimulate MMP1 by first stimulating nuclear factor (NF) κB proteins; these then interact with sites on the collagenase gene promoter. This pathway of activation may play a pivotal role in the pathogenesis of periodontitis [238] and IL-1α may be more important than IL-1β[239]. The MT MMPs can also be up-regulated by several growth factors [240]. IL-1α seems to be the mediator of other inducers of collagenase, such as phorbol 12-myristate 13-acetate [241].

MMPs are often synthesized coordinately in simple experimental situations but their expression in tissues *in vivo* is far more complex. From studies of the distribution of MMPs and TIMP1 in the development of the rabbit growth plate [204] and mandibular condyle [242] it is clear that each MMP has its own pattern of expression. Recent work suggests that MMP9 is particularly important in growth plate vascularization and ossification [243]. Not only are there unique patterns of MMP expression in normal situations but also, for example, in pathological tissues, such as rheumatoid synovium and tumors. These results are consistent with the idea of specific roles for the individual MMPs, and the role of TIMPs may be to tightly control MMP activity at both the level of activation and subsequent substrate degradation. As with other proteinase-inhibitor systems (notably the plasminogen activators) MMPs may be active only at specific locations where inhibitor concentrations are reduced compared with enzymes.

Corticosteroids are potent inhibitors of MMP synthesis [244–246] and many other agents have been tested for possible therapeutic use (in addition to TGF-β) to ascertain if they might either block MMP synthesis or increase TIMP activity. Retinoids can decrease MMP production and increase TIMP [244,246–248] and MMP synthesis can be down-regulated by interferon-γ [249] in fibroblasts, although opposite effects are found with cultured keratinocytes [250]. Interferon-γ and -β, but not -α, inhibit invasiveness and MMP2 production of renal carcinoma cells [251]; surprisingly the same workers found no effects on fibroblasts. Interferons α and γ up-regulated MMPs 2 and 9 in human melanoma cells [252] but only if treatment time was short.

Most cells, especially connective tissue cells and endothelial cells, synthesize TIMPs constitutively. Although activity is elevated by treating cells *in vitro* with phorbol esters [253], corticosteroids under some conditions, TGF-β bFGF [223], EGF, IL-6 family members and retinoids [246], less is known about the control of the basal levels of TIMPs *in vivo*. Many fibroblasts stimulated with IL-1 synthesize increased amounts of TIMP1 in parallel with MMPs, but with other cells, such as rabbit uterine cervical fibroblasts [254], IL-1 decreases TIMP synthesis. It has been reported that IL-6 can increase the synthesis of TIMP1 and can act synergistically with IL-1 [255], although Silacci et al. [256] found that IL-6 and its soluble receptor blocked IL-1-induced collagenolytic activity in parallel with the induction of TIMP1 in chondrocytes and synoviocytes; TIMP2 and TIMP3 levels were not affected. MMP9 seems to be involved in the HIV-induced invasiveness of monocytes and it was suggested that this enzyme has an important role in HIV pathogenesis [257]. IL-8 may play an atherogenic role by inhibiting local TIMP1 expression [202].

In murine embryonic development, TIMP1 is expressed at sites of osteogenesis in the limbs, ribs, digits, skull and vertebrae [258]. TIMP2 is often constitutively produced by cells and does not generally show a response to cytokines. However, where expression is regulated, it is often in the opposite direction to TIMPs 1 and 3; e.g., the expression of TIMP2 is repressed by TGF-β in various cell types. TIMP3 has been shown to be induced by factors such as EGF, PDGF, TGF-β, phorbol ester, and dexamethasone [258], and it has been shown that it is up-regulated in the G_1 phase of the cell cycle [259]. TIMP4 [154,260], the human form of which was cloned from a cDNA library and expressed as a 22-kDa recombinant protein, is more closely related to TIMPs 2 and 3 than to TIMP1.

TIMPs have growth-promoting activities [2,261] for many cells. Precisely how growth promotion is or is not related to MMP inhibitory activity is not known. The growth stimulatory activity of TIMP2 was shown to be cell type-specific and to require the presence of a cofactor, insulin [262]; tyrosine phosphorylation is crucial for growth signalling by TIMPs 1 and 2, and it has been suggested that MAP kinases are involved [263]. Also, an involvement of

a cAMP-dependent mechanism has been proposed [264], probably involving a cAMP-dependent protein kinase. Guedez et al. [265] have also shown that TIMP1, but not TIMP2 or a synthetic inhibitor of MMPs, suppresses apoptosis in B cells, suggesting a role in tissue homeostasis. A TIMP1 transgene rescued mammary epithelial cells from apoptosis when they were expressing an auto-activating MMP3, an effect which may be related to the cleavage of basement membrane entactin [266]. TIMP3 overexpression, however, can uniquely promote apoptosis in many cancer cell types [267]. Clark et al. [268] described yet another puzzle over the activities of TIMPs: they showed that TIMP1 applied to human fibroblasts could stimulate collagenase secretion but were unable to define any receptor-mediated event.

It has been reported that the expression of proteinases and proteinase inhibitors in human periodontal ligament cells can be modulated by fibronectin and fibronectin fragments, molecules found in the extracellular matrix. Kapila et al. [269] found an up-regulation of MMPs 1 and 3, and u-PA in these cells *in vitro*, and suggested that regions of the fibronectin molecule may modulate many functions of ligament cells and contribute to periodontal disease. The binding of fibroblasts to fibronectin involves integrins on the cell surface [270], and their precise role in signaling changes in MMP expression is still being defined [270–272]. α1 and α2 integrins mediate the invasive activity of mouse mammary carcinoma cells [273], principally through regulation of MMP3, whereas α6 integrins regulate cell motility. Integrins are important in signaling [273], and there is evidence that signal transduction through chondrocyte integrin receptors up-regulates MMP expression and that this may be mediated through induction of IL-1 [274]. Thus, binding of adhesion molecules may play a role in escalating the effects of IL-1 induction of MMPs. Tremble et al. [275] have found that one of the pathways that transduces signals activated by the $\alpha_5\beta_1$ fibronectin receptor acts through promoters that contain AP-1- and PEA3-responsive DNA sequences (see also below). Fibronectin and integrins induce a variety of downstream effects, including the altered expression of many proteins, and the signalling mechanisms involving kinases have been reviewed [276]. The role of the extracellular matrix in signaling and orchestrating cell behavior, especially in cancer, has also recently been reviewed [277].

The extracellular regulation of MMP activity is a key feature of their function, and TIMPs are not the only factors involved. The regulation of zymogen activation is a critical level of control of enzyme activity. The MMPs have latency conferred on them by their propeptide domains, which effectively block the active sites in their catalytic domains. *In vitro*, the MMPs can be activated by chemical agents that modify cysteine residues, such as the organo mercurial APMA. Activation may also occur when the conformation of the proenzyme is perturbed, as is evident from the SDS-activation of proMMP2 and proMMP9 during zymography. *In vivo*, activation probably takes place upon the enzymic cleavage of the propeptide. This cleavage may be an autolytic step, as occurs with proMMP2 at high concentrations *in vitro* [278], but more usually requires a second proteolytic activity. Many of the MMPs share common activators and many are activated by other MMPs. This has given rise to the concept that the MMPs are involved in many activation cascades [279]. An important cascade is initiated by the action of PAs on plasminogen, which results in active plasmin. This proteinase can activate several MMPs, although MMP2 is not involved in the plasmin cascade and is regulated differently to the plasmin-activated MMPs. Pro-MMP2 is not cleaved by trypsin, chymotrypsin, plasmin, thrombin, elastase, cathepsin G, plasma kallikrein, or MMP3 [280,281]. The mechanism involving MT MMPs (see above) appears to be the most likely pathway for MMP2 activation and can lead to the activation of MMP13 and MMP9 (see Fig. 4) [105]. MT1 MMP can itself be activated by the u-PA pathway extracellularly [282,283] and be found in a soluble form. However, MT1 MMP also seems to act as a pericellular fibrinolysin, even in PA- or plasminogen-deficient mice. Thus, in neovascularization there are multiple complex proteinase cascades in matrix resorption [284]. In inflammatory conditions it has been shown that a variety of bacterial proteinases can activate MMPs and thus increase tissue destruction [285].

Modulators of the Synthesis of Plasminogen Activators and Their Inhibitors

Those factors considered above for MMPs and TIMPs often have similar effects on the control of PAs and inhibitors, but there are some differences. Most published data indicate PA production is increased by IL-1, an effect that may be mediated, at least in part, by PGE_2 and cAMP [286]. The precise changes in t-PA and u-PA synthesis are different for different cell types and cytokine combinations (see, e.g., [287,288]). u-PA activity is suppressed by anti-inflammatory glucocorticoids [289] in several cell types, whereas PAI1 is increased substantially [290], as is also found with IL-6 [291]. PAI1 and PAI2 are members of the large superfamily of proteinase inhibitors named serpins; these serine proteinase inhibitors have roles far beyond the scope of this review [160]. It must be pointed out, however, that PAI2 is not required for either normal development or survival; mice that are deficient in PAI1 and PAI2 do not express any overlap of function between the two [292].

TGF-β increases PAI1 [228,293,294], and with this and a number of other agents there is often an inverse relationship between PAs and PAIs, as is often the case with MMPs and TIMPs. For example, PAIs 1 and 2 are TNF inducible [294a]: inhibitor levels go up as t-PA activity goes down in human fibrosarcoma cells. IL-1 can induce PA inhibitory activity by cultured endothelial cells [295].

Of considerable interest have been many studies on the regulation of plasminogen activation, especially the cloning of the cell receptor for u-PA and the work establishing that activation of plasminogen takes place via cell-associated u-PA [115,296]. Bound u-PA is less susceptible to inhibition. These studies have parallels with the activation of gelatinases and clearly proteolysis near the cell-surface is an important area of study. It is of interest that the binding of PAI1 to extracellular matrix has been demonstrated to be mediated by vitronectin [297].

Plasminogen added to chondrocyte cultures causes an increase in IL-1-induced matrix degradation, implicating PA in this process; indeed, IL-1 induces u-PA and PAI1 in these cells. Similarly, plasminogen added to IL-1-stimulated cartilage explants potentiates increased collagen and proteoglycan loss, and this can be blocked with PA inhibitors, or MMP inhibitors. Hence, there is a cascade of enzyme activation with PA activating plasminogen, and plasmin then activating MMPs [298,299]. Furthermore, intra-articular injection of protease nexin-1 blocks IL-1 or FGF-induced proteoglycan loss from rabbit knee, and tranexamic acid (TEA), another antiplasmin agent, used orally, has the same effect [300]. However, it is of interest

that loss of plasminogen gene function (t-PA and u-PA) in mice does not result in a lethal phenotype [301], although there is impaired wound healing [302], emphasizing that in the proteolytic cascades there must be redundancy of a high order.

In synovial fluid, u-PA, PAI1, and uPAR are all raised in rheumatoid arthritis (RA) compared with osteoarthritis (OA), and in OA compared with normal, but there is no direct association with clinical parameters [303]. There is also evidence for local production of u-PA and PAI1, with synovial fluid levels raised compared to plasma. At the invasive pannus front in RA synovium, u-PA, uPAR, PAI1, and PAI2 are all induced compared with normal tissue [304,305]. The *in vivo* role of the u-PA/plasmin system in the activation of MMPs during aneurysm formation has been well documented [306], along with the ancillary action of MT1 MMP in the activation of MMP2 and MMP13 [307].

Mechanisms of Induction of MMPs and TIMPs

The genes encoding MMPs 1,3,7,9, and 10 have a TATA box and a phorbol ester-responsive element (TRE), a sequence that binds to Fos and Jun (AP-1) and that is thought to mediate the induction of these MMPs by inflammatory cytokines such as IL-1 and TNF-α [308]. MMP2 seems to be constitutively produced by cells in culture and is not generally significantly modulated by cytokines. The 5′-flanking region has no TATA box or identifiable TRE sequence, but does contain a p53-sensitive sequence and an adenovirus ElA-responsive element resembling the AP-2 binding site and two "silencer" regions [309]. Glucocorticoids, retinoids, and TGF-β repress the expression of at least MMP1 and MMP3 in connective tissue fibroblasts [310,311]. Agents may induce the expression of one MMP, while repressing expression of another. Furthermore, the effect of any one agent may differ with cell type; this makes it difficult to predict the effects of blocking cytokine/growth factor action. In the case of gelatinase B (MMP9), a dual regulation of IL-1-mediated expression has been found in mesangial cells [312]. These workers demonstrated that both tyrosine kinase-mediated NFκB stimulation and c-Jun/AP-1 activation are essential for MMP9 induction; inhibition of either pathway blocks the cellular response. Stimulation of MMP9 promoter activity by *ras* oncogene requires multiple transcription factors including AP-1 sequences and closely spaced PEA3/ets sequences [313]. An src-related tyrosine kinase has been shown to be involved in transcription factor activation of the MMP1 gene by IL-1 [314]

The MMP3 gene has an AP-1 binding site, but Quinones et al. [315] found that other regions were involved. Recently Borghaei et al. [316] have attempted to identify the transcription factors and cis elements that might be involved in the IL-1 induction of MMP3. They found an upstream complex binding region that they termed the stromelysin IL-1 responsive element site, binding to which site is also induced by TNF. At least two DNA-binding proteins are involved; transfection experiments demonstrated that proteins binding to this site act as repressors of IL-1-induced expression of stromelysin. The suppression of SL expression by IFN-γ in human fibroblasts is mediated through the AP-1 element [317]. Recent work shows that both AP-1 and a cis-acting Cbfa1-like factor are required for the induction of MMP13 in mouse bone by parathyroid hormone (PTH) [318]; noteworthy is the fact that Cbfa1 is also a regulator of bone development [319]. TGF-β up-regulates MMP13 expression in fibroblasts in contrast to the down-regulation of MMP1 [320]. The signaling pathway involves protein kinase C and tyrosine kinase activities, and an AP-1 site. Protein kinase C is also involved in the regulation by vitamin D_3 of MMP3 expression by chondrocytes [321].

The promoter regions of TIMPs 1, 2, and 3 have potential Sp1-binding sites and share other features that are suggestive of housekeeping genes; however, TIMPs 1 and 3 are known to be highly stimulus-responsive [157]. The TIMP1 promoter has an AP-1 and a PEA3 motif in close proximity, reminiscent of the inducible MMP genes described above; this gene appears to have important regulatory sequences downstream of the transcription start sites. The murine TIMP3 gene has six upstream AP-1 sites that may be involved in basal expression of the gene. The data from the murine and human genes are in conflict here; the murine gene also has a putative p53 binding site that appears to be nonfunctional. The TIMP2 gene has a promoter proximal AP-1 motif [322], but this appears not to have a major role in basal expression of the gene [258]. Mertens et al. [323] have shown that gelatinase A expression at high levels is mediated by a unique interaction of two developmentally regulated transcription factors, AP-2 and YB-1, within a discrete 40-base pair enhancer element (RE-1) located in the 5′-flanking region of the gene. There is evidence for unique cell type-specific expression of MMP9; Fini et al. [324] found that although rabbit fibroblasts have AP-1-like elements, corneal epithelial cells also have the capacity for activation by the transcription factor AP-2.

Rat TIMP1 is expressed in rat hepatocytes and is up-regulated by IL-6. An IL-6/oncostatin M response element has been characterized [325] that has two functional binding sites for AP-1 and STAT3; binding to both sites is needed for full responsiveness. TIMP1 production is also stimulated by oncostatin M and other members of the IL-6 family in human articular cartilage [326]. Oncostatin M up-regulates TIMP3 gene expression in articular chondrocytes [327], and the involvement of tyrosine kinases and mitogen-activated kinase cascades are implicated in the signaling mechanism [328]. However, Gatsios et al. [329] found that oncostatin M preferentially up-regulates TIMP1 rather than TIMP3 in human synovial lining cells. Specific methylation events contribute to the transcriptional repression of the mouse TIMP3 gene in neoplastic cells [330].

SPECIFIC EXAMPLES OF PHYSIOLOGICAL MATRIX BREAKDOWN

Degradation of Bone Matrix

MMPs have been implicated in bone turnover, either via removal of osteoid by osteoblast-derived enzymes to allow osteoclastic bone resorption to take place, or more directly as osteoclast synthetic products. They have been found at sites of both endochondral and membranous bone formation [331], and appear obligatory for the migration of preosteoclasts to the sites of resorption [332]. Interstitial collagenase (MMP1) can be produced by both human osteoblasts and osteoclasts [333], although others have found that osteoclasts are not a source of high levels of it compared with osteoblasts and stromal cells [334]. In fetal rat calvarial osteoblasts, a variety of growth factors have been shown to alter expression of interstitial collagenase (MMP13 in rodents), and also to modulate bone resorption in calvarial explant assays; EGF and IL-1α have been shown as important up-regulators of rabbit MMPs, notably MMP1 [335]. Other inducing agents include PDGF [336], PTH, bFGF [337], and IL-6 [338]; suppressing factors include IGF-I and -II [339], TGF-β, and bone morphogenetic protein BMP-2. Some of these factors

(bFGF, TGF-β and BMP-2) also induce expression of TIMPs 1 and 3 [340]. Human osteoblasts have been reported to express at least MMPs 1,2, 3,9, 10,13, and 14 [341]; MMP14 has been identified in rabbit osteoclasts [342]. Synthetic MMP inhibitors suppress bone resorption *in vitro* [343] and TIMPs 1 and 2 can also do this [344].

In human development, MMP13 is expressed in mineralizing skeletal tissue, hypertrophic chondrocytes [345] and osteoblasts involved in ossification, rather than MMP1 [346]. In osteoblasts, MMPs 2 and 14 are colocalized with MMP13. In postnatal tissues, MMP13 is expressed at sites of remodeling such as bone cysts and ectopic bone and cartilage formation, while in rheumatoid arthritis patients strong expression is seen in cartilage. MMP13 has, therefore, been proposed to function in the degradation of type II collagen in primary ossification, skeletal remodeling, and joint disease [347]. Similar patterns of expression are seen in developing rat and mouse bone [348]. Rat osteoblasts possess a scavenger receptor that removes MMP13 from the extracellular space [340] and is a further control mechanism. The abundance and functioning of this receptor in rat bone and intracellular degradation are controlled by PTH [349]. In endochondral bone formation, it has been proposed that the complete degradation of type X collagen requires both the action of MMP13 from the chondrocyte and that of cathepsin B from the osteoclast [28].

Everts et al. [350] studied in detail the degradation of collagen in the bone-resorbing compartment underlying the osteoclast. This degradation clearly involves both MMPs and certain cysteine-proteinases and the work extended earlier studies showing that both classes of proteinase are important. Indeed, evidence continues to build that there are extracellular and intracellular pathways for collagen degradation, and bone resorption well illustrates the great complexity of degradative processes in specific tissues [351]. Specific inhibitors of a cysteine proteinase (cathepsin B) and metalloproteinases (collagenase and gelatinases A and B) can block bone resorption *in vitro* [352,353]. In bone resorption by osteoclasts in a murine calvarial assay, studies with specific inhibitors suggested that cathepsins L and S might act both intracellularly and extracellularly, but that cathepsin B only acts in the intracellular compartment, possibly via activation of other proteinases [352]. Gelatinase B has been implicated along with collagenase [351] as of importance in osteoclastic bone resorption [343,354]. Expression of MMPs has been noted in osteoclasts, particularly MMP9 [355,356], and also that of MMPs 1,2,3,13, and 14 [354]; indeed, some inhibition of bone resorption by MMP inhibitors has been shown even on osteoid-free bone [343]. Interestingly, stromelysin 2 (MMP10) has been found strongly associated with human osteoclasts in contrast to MMP3 [357]. In rat osteoclasts, cathepsin B and L immunostained along lacunae, with strong extracellular staining of both on collagen fibrils and the bone matrix under ruffled borders, and with a stronger signal for cathepsin L than cathepsin B [358]. A further ultrastructural study using specific inhibitors also suggested that cathepsin L plays a key role in bone resorption by cultured osteoclasts [359].

Recently a new cysteine proteinase, cathepsin K, has been discovered in osteoclasts. Cathepsin K has 56% sequence homology with cathepsin S; it has a pH optimum of 6–6.5 similar to cathepsin S, but has activity over a broader range, remaining largely active at neutral pH. It degrades elastin, collagen telopeptides, and gelatin better than the other cysteine proteinase cathepsins [13,360]. Uniquely, cathepsin K can act as a collagenase by attacking type I collagen in the helical region, reminiscent of the action of bacterial collagenase [361]. Inhibitors of cathepsin K have been shown to reduce bone resorption *in vivo* and *in vitro* [362], and an antisense approach blocked osteoclastic bone resorption *in vitro* [363]. It has been reported that only cathepsin K, and not cathepsins B, L, or S, is abundantly expressed in human osteoclasts, and that this enzyme is responsible for osteoclastic bone resorption [364]. Interestingly, an osteochondrodysplasia, pycnodysostosis (see Chapter 19, this volume), is caused by mutation in the cathepsin K gene [139]. Families with pycnodysostosis demonstrate a molecular heterogeneity of mutations, some of which seem to involve the active site binding to type I collagen [365]. Retinoic acid stimulates the expression of cathepsin K along with increased resorption when tested on rabbit bone cells from long bones, including osteoclasts [142]. Targeted disruption of the gene for this proteinase in mice leads to severe osteopetrosis [141].

Many of the seemingly disparate data on MMPs and cysteine proteinases have been resolved by the studies of Everts et al. [366]. These workers have documented site-specific differences in osteoclasts in calvaria (membranous bone) and long bones (endochondral bone). A major finding is that osteoclasts in long bones depend on cysteine proteinases (higher expression of cathepsins B and K) for resorption, whereas the activity of calvarial osteoclasts depends on MMPs and cysteine proteinases. These important findings may have wider implications since the site-specificity of cells has not often been considered.

Osteoblasts also produce u-PA, t-PA, PAI1, and uPAR, the synthesis of which is regulated by osteotropic hormones and PGE_2 [367,368]. In general, u-PA expression parallels that of MMPs. It has been proposed that PAs are involved in bone matrix degradation directly [369]; perhaps they could function as activators of proMMPs or latent growth factors in bone remodeling, or u-PA may be acting as a mitogen via its growth factor domain. The direct resorptive activity of osteoclasts does not require t-PA or u-PA [370], but the latter may be involved in migration of the preosteoclasts to the mineral surface [371]. In osteosarcoma cells there seems to be a u-PA/MMP cascade that leads to bone turnover [372], which is strongly stimulated by IL-1α.

The family of cysteine proteinase inhibitors, the cystatins, has been described in detail [175]. Their role in controlling the turnover of cartilage and bone is largely unknown, although cystatin C is reported to inhibit bone resorption in different *in vitro* systems through the inhibition of osteoclastic proteolytic enzymes and to be produced by bone cells [373].

Suture and Soft Tissue Remodeling

Orthodontic treatment is based upon the ability of fibrous joints and bone to undergo remodeling in response to mechanical forces. An organ culture system in which fibrous joints from the rabbit cranium can be deformed mechanically under controlled conditions showed that tension not only stimulates the synthesis of structural macromolecules but also MMPs [374]. By use of immunocytochemistry, localized areas of remodeling involving MMP1 and TIMP1 are seen to occur in response to mechanical force [375,376]. Sutural fibroblasts under tension synthesize significant quantities of type III collagen, as well as type I, suggesting an important role for the biomechanical environment in the expression of collagen phenotype.

Everts et al. [377] have highlighted the importance in many tissues of an intracellular route for fibrillar collagen digestion. Their research suggests that in situations where there is a high turnover of matrix (such as inflammation), the MMPs are especially important in a mainly extracellular pathway of degradation. Where turnover is low (normal remodeling), an intracellular pathway for resorption, particularly for collagens, is of major importance. In this case, they propose that membrane-bound gelatinases may be involved in partially digesting collagen fibrils prior to uptake into the lysosomal system and digestion by intracellular cysteine proteinases [378]. Evidence from experimental studies from these and other workers suggests that the normal turnover of collagen in the periodontal ligament may take place largely by this intracellular pathway (for review see Everts et al. [377]) and that cathepsin B, particularly, plays an important role [379]. Type VI collagen is present in most soft connective tissues, where it plays a role in the organization of the collagen meshwork. Everts et al. [22] have shown that type VI collagen degradation may be by way of the phagocytic route, with collagenase, serine proteinases, and lysosomal enzymes all involved.

Van der Zee et al. [380] have demonstrated that soft connective tissue can be a store of procollagenase, which can be activated under certain conditions. Thus, a collagenase-induced breakdown of collagen could take place without there necessarily being any *de novo* synthesis of this MMP. If these findings in an experimental system [380] were true for chronic inflammatory diseases in general, then an explanation would be available for the cyclic breakdown of tissues in active arthritis and periodontitis.

SPECIFIC EXAMPLES OF PATHOLOGICAL MATRIX BREAKDOWN

Periodontal Tissue Destruction

Many older studies focused on the action of proteinases released by bacteria, PMNs, and macrophages rather than tissue-derived proteinases. Evidence now suggests that invasion of the gingival tissues by intact bacteria occurs in more severe and advanced forms of periodontal disease, but many observations support the view that bacterial invasion is not a conspicuous feature of periodontitis. Periodontal pathogens could mediate connective tissue degradation in periodontal disease by the ability of antigens from their cell walls to stimulate cytokine production by circulating mononuclear phagocytes [381]. These cytokines and prostaglandins could in turn induce MMP synthesis by resident cells, thereby initiating degradation [382–384] of ligament attachment and an increase in bone resorption. Each of the major cell types of periodontal tissue is capable of expressing a unique complement of MMPs when stimulated [385]. Bacterial antigens also induce many arachidonic acid products that also can be involved in inducing proteolytic destruction of gingival tissues. Clearly the continued presence of bacteria is essential for the maintenance of inflammation and altering host defence.

Heath et al. [382] found that antigens from the walls of bacteria commonly present in dental plaque (both Gram negative and Gram positive) can induce matrix breakdown by a mechanism that involves a primary interaction with circulating mononuclear cells. Although human gingival fibroblasts *in vitro* responded directly to lipopolysaccharide (LPS) preparations in terms of PGE_2 production, they were only induced to synthesize collagenase in response to supernatants from mononuclear cells stimulated with either LPS or lipoteichoic acid. It was concluded that if a cytokine-mediated mechanism does play an important role in connective tissue destruction during periodontitis, then the disease can probably be triggered by a large variety of bacteria or by combinations of different bacteria. The particular cytokines responsible remain incompletely characterized but much circumstantial evidence and some direct evidence suggests that IL-1 is important (see below); cytokines, in turn, can stimulate PGE_2 production, although not all of the actions of the interleukins are mediated via prostaglandins. Indeed, there are many cytokine loops including one in which PGE_2 can stimulate osteoclast formation via endogenous IL-1β expressed through protein kinase A [386]. There is evidence from work with gingival fibroblasts that CD40 ligation can restrain up-regulated MMP production, and may be an important mechanism in restraining tissue damage [387]. An additional pathway for increased destruction is suggested by the observations of DeCarlo et al. [388] that quiescent mucosal epithelial cells and fibroblasts can be stimulated to degrade type I collagen by a thiol-proteinase released by *Porphyromonas gingivalis*.

A relationship has been established between latent and active forms of collagenase extracted from gingival tissues and the degree of inflammation [389]. Collagenase activity has been identified not only in gingival explant culture supernatants but also in gingival crevicular fluids at levels that correlate with disease activity. Collagenase activity can be found in the crevicular fluid of patients with periodontitis in much larger amounts than in control subjects [390,391]. This collagenase seems to be only partly tissue derived and mostly from PMNs [391] in the inflammatory infiltrate. More recent work has shown that although MMP8 from PMNs is the main collagenase in adult periodontitis, MMP1 is more prominent in localized juvenile periodontitis [392]. MMP9 from neutrophils is prominent in crevicular fluid and gingival tissue specimens from patients with periodontitis [393]. TIMP1 levels can be measured only in healthy individuals or in clinically healthy sites [390]. In clinical studies, Lee et al. [394] showed a good correlation between active MMP8 and disease activity, whereas Hayakawa et al. [395] found significantly lower TIMP1 levels in whole saliva in diseased subjects compared with healthy normals. Thus, it seems that periodontal disease activity does indicate an imbalance of proteinases over inhibitors. Hayakawa et al. [395] showed that reciprocal changes in TIMP1 and collagenase levels were observed after therapy. It has been suggested that a relative imbalance of MMP3 over TIMPs may be a significant marker of periodontitis-affected tissues [396], as it often is in arthritis [190], and an increased level of MMP3 does correlate moderately well with clinical indices [397]. MMPs from PMNs may also increase matrix destruction by inactivating α_1-proteinase inhibitor [398], which would normally control serine proteinase activities such as PMN elastase.

The first report of collagenase immunolocalization in human gingival biopsy specimens from patients with periodontitis showed that the enzyme was frequently associated with inflammatory cells, but its precise cellular origin was uncertain [399]. These studies were extended by identifying cells producing MMPs and TIMP1 in gingival biopsy specimens from patients with periodontitis [400]. MMPs 1,2, and 3 and TIMP1 were all immunolocalized in gingival tissues, both from patients with periodontitis and from patients undergoing crown-lengthening procedures. On histological and morphological grounds it was deduced

that the MMPs may be synthesized by both fibroblastic cells and macrophages. Cells secreting MMPs and TIMP1 were often observed at sites that histologically showed signs of connective tissue remodeling. A study using *in situ* hybridization [401] demonstrated that TIMP1 was broadly expressed in gingival tissue in periodontitis but that TIMP2 was predominantly expressed in tissue adjacent to the pocket epithelium. Pinchback et al. [402] found that much staining of proteolytic enzymes, particularly collagenases and inhibitors in advanced periodontitis is associated with vascular structures. Their results on biopsies from patients at a late stage of the disease suggested that an up-regulation related to the vasculature is an integral component of destructive periodontitis with chronic inflammation. An increase in mRNA for MMP1 was found in gingival biopsies from patients with inflamed gingiva, whereas only very low levels of message for MMP8 were measured [403].

Many data demonstrate the crucial importance of the inflammatory mediators IL-1 and TNF in connective tissue resorption. Thus, attention has particularly been given to these cytokines in periodontal diseases. IL-1 activity was early identified in gingival crevicular fluid samples from clinically inflamed sites in human subjects [404] and in peripheral blood monocyte culture supernatants from periodontitis patients [383]. It was found that there was an increased release of IL-1β and TNF-α by cultured peripheral blood mononuclear cells from patients with chronic periodontal disease, compared with controls [405]. These and many other studies amply demonstrate that in periodontal disease there is a stimulated release of cytokines, especially by circulating mononuclear cells, and that these modify the host response. This area of research has been well reviewed [406,407]. The cytokine-inducing components of periodontopathogenic bacteria are probably much wider than has hitherto been thought [408]. This area of research could give important clues to the most important agents for cytokine induction so that specific blocking agents could be aimed locally to block pro-inflammatory cytokine expression in the periodontium.

Already there is a considerable literature on the use of tetracycline analogues, such as doxycycline, in the treatment of periodontal disease and other inflammatory conditions [409,410]. Low doses prevented collagen breakdown and alveolar bone loss in animal studies and gave a reduction in pocket depth and attachment loss in human clinical trials [410,411]. Originally, it was thought that tetracycline antibiotics might primarily act as inhibitors of MMP8, but recent work suggests that doxycycline may act generally on latent MMPs by binding enzyme-associated Ca^{++}, rendering them more susceptible to proteolysis and loss of enzymic activity [412]. Also, it seems that MMP13 is much the most sensitive collagenase to inhibition by tetracyclines [413]. Another explanation for the mechanism of action of tetracyclines is that they might interfere with the cytokine induction of MMPs. Amin et al. [414] showed that they can inhibit the expression of inducible nitric oxide synthase; the overproduction of nitric oxide has been implicated in several inflammatory diseases, in which cytokines are in turn induced by this molecule. All the foregoing explanations support a mechanism of action at the post-translational level, but Jonat et al. [415] found a dose-dependent transcriptional inhibition by tetracycline on MMP3 expression by fibroblasts. The antimicrobial activity of tetracyclines is not needed for the efficacy of this group of compounds [410], but a major advantage is that tetracyclines have been used safely for many years. Other work indicates that gelatinases, especially MMP2, are important in tissue destruction in periodontitis [416]. Thus, the potential of specific MMP inhibitors that will become available could be investigated as therapeutic agents.

Synovial Tissue Breakdown, Joint Destruction, and Arthritis Models

As discussed above, there is now much evidence that cytokines, particularly IL-1 and TNF, are major stimuli for the production of MMPs in inflammatory conditions. Ghivizzani et al. [417] have shown that intra-articular expression of human IL-1β following gene transfer to rabbit synovium produces all the major pathological alterations associated with rheumatoid arthritis. Recently, it has also been shown that IL-18 (IFN-γ-inducing factor), which can be produced by human articular chondrocytes and has structural homology with IL-1, may also contribute to cartilage degradation, but it is less potent than IL-1 [418]. In cartilage breakdown, proteoglycan loss is rapid and reversible but, in contrast, collagen loss is essentially irreversible. Most *in vitro* studies have tended to correlate loss of proteoglycan with cytokine-induced cartilage destruction and fewer studies have been made on the extent of cartilage destruction as assessed by other parameters. Henderson and Pettipher [419] injected IL-1 and TNF into rabbit knees; in the case of IL-1 they found glycosaminoglycan release, but there was no such effect with TNF. The loss of glycosaminoglycans from cartilage *in vitro*, most often used as an assay of cartilage resorption, may be partly dependent on enzymes [420] but not entirely dependent on MMPs: it is not clear whether such experiments have physiological relevance. It is interesting, however, to note that the IL-1 stimulated loss of proteoglycans *in vitro* can be partially inhibited by TGF-β [421,422].

The enzyme responsible for proteoglycan release from cartilage was once thought to be MMP3, partly because of its abundance [190], but analysis of proteoglycan fragments released from resorbing cartilage implicates another enzyme, "aggrecanase," the identity of which, until recently, has been uncertain. A good correlation between inhibition of proteoglycan loss and inhibition of MMP3 has been reported, although high concentrations of MMP3 inhibitors were needed (approximately 1000 times greater concentration required to inhibit proteoglycan loss than inhibition of MMP3). A strong correlation was found between inhibition of collagenase activity and inhibition of collagen release from cartilage explants; no correlation was observed with inhibition of MMP3 or gelatinase activity [423]. Proteolysis of the aggrecan core protein occurs within the interglobular domain; amino-terminal sequencing of cleavage products has identified two main sites of proteolysis [36,424]. Cleavage at the Asn 341–Phe 342 bond has been attributed to the action of the MMPs [425]: cleavage at the Glu 373–Ala 374 bond appears to be predominant in rheumatoid arthritis and also in stimulated cartilage explants *in vitro*. MMP8 [425] and MMP13 [44] cleave aggrecan, and although MT1 MMP cleaves aggrecan it does not produce the fragments typical of arthritis [426]. Using a model system of cartilage degradation, Kozaci et al. [427] concluded that MMPs 3,8, and 13 are unlikely to contribute to proteoglycan degradation, but that collagenases and gelatinases have major roles in type II collagen breakdown. MT1 MMP is expressed in human articular cartilage; the level of its mRNA is not modulated by IL-1 [428], suggesting that regulation of MT1 MMP in the arthritides is not a significant factor. The

likely role of aggrecanase has already been discussed above. However, MT1 MMP expression by rheumatoid synovial fibroblasts is increased by TNF-α, resulting in secretion of active MMP2 [429]. Because MT1 MMP exhibits broad-spectrum proteolytic activity, it may itself be involved in matrix degradation as well as having a role as an MMP2 activator [430].

The identity of the collagenase responsible for cartilage collagen loss is currently not entirely clear. MMP1 and MMP13 can be made by human chondrocytes, with studies showing that MMP8 may also be expressed by these cells and be up-regulated by IL-1 [431]. There is some evidence that specific MMP13 inhibitors can block IL-1-induced collagen loss and an enhanced cleavage of type II collagen in osteoarthritic cartilage seems to be correlated with MMP13 activity [432]. Human chondrocytes synthesize MMP13, and this is strongly up-regulated by IL-1β and TNF-α [433,434]; its induction requires c-Fos, which binds to the AP-1 site. MMP3 can cleave collagen types II, IX, X, and XI of cartilage [25], and collagen type XI is also gelatinase susceptible [435]. MMP2, but not MMP9, can degrade human collagen type II almost as effectively as MMP8 [436], and MMP2 could be important in degradation at the pannus-hard tissue junction in rheumatoid arthritis.

Immunohistochemical studies of connective tissues have shown that gelatinase is frequently expressed in both normal and pathological situations and it has been demonstrated in stromal cells of the hyperproliferative synovium in an antigen-induced rabbit model arthritis [437]. MMP1 mRNA has been localized in synovium from patients with rheumatoid arthritis by use of *in situ* hybridization [438] and supporting evidence given that the collagenase was associated with the type A macrophage-like synovial lining cell. MMP3 has also been shown to be secreted by invasive synoviocytes in rheumatoid synovium [439] and is a marker of invasive arthritis in a rat model [440].

Using a collagen-induced arthritis model, Carmichael et al. [441] have shown that systemic administration of recombinant TIMP1 can suppress the pathology. These studies again suggest MMP inhibitors may be lacking in some diseases in which tissue breakdown is a feature and also that they may be potential therapeutic agents. TIMPs 1 and 2 have been shown to prevent collagen release in an *ex vivo* cartilage resorption model, suggesting the involvement of collagenase MMPs in this event; the same inhibitors were unable to prevent proteoglycan loss, again indicative of the nonMMP nature of aggrecanase activity. Synthetic MMP inhibitors can prevent both proteoglycan and collagen loss, but achieve the former only at high concentrations at which their specificity may be doubtful [442].

Considerable interest has been generated by the use of cysteine proteinase inhibitors in biological systems. Inhibition of IL-1-stimulated aggrecan degradation was found with a lipophilic inactivator of cysteine endopeptidases [443]. Inhibitors of cathepsins B and L were found to decrease the severity of joint destruction in a rat model of arthritis [444].

Tumor Invasion and Metastasis

The progression of tumors is driven by the expression of oncogenes and the loss of suppressor genes, leading to malignant traits such as the ability to invade into and grow in ectopic tissue environments. Although serine proteinases and MMPs have long been associated with tumor invasion and metastasis, much of the earlier work was centered on the role of proteinases in the destruction of extracellular matrices so that invasion could proceed [445]. There is now much evidence for a wider role of MMPs in tumor development, metastasis, and neovascularization [446]; they are crucial for creating and maintaining an environment that supports the initiation and growth of primary and metastatic tumors [447,448] and are involved in interactions with stromal cells. There are strong parallels between cancer invasion and tissue remodeling [449]. Many of the MMP activities expressed by tumor cells are similar, if not identical, to those produced by normal cells. Proteinases and their inhibitors can influence the bioavailability of growth factors and consequently modulate tumor growth, angiogenesis [450], which is a key step in the growth of large tumors, and apoptosis; they are involved in cell migration and the shedding of cell surface proteins. Also, there are many interactions between the proteinase classes and there are often cascades of proteolytic activities. Studies with proteinase-deficient mice do not define a phenotype, and support the idea that there are very considerable overlaps of proteinase activities. Thus, different tumors express different patterns of enzyme expression and complex cascades are a common theme.

Basement membranes constitute a reservoir of latent growth factors, such as bFGF, that can be released upon proteolysis of perlecan in the basement membrane [451], and could promote tumorigenicity [452]. MMPs and serine proteinases could be involved in their destruction and so influence their bioavailability in both positive and negative ways. Another illustration of the cooperation between MMPs and serine proteinases is the study of Montgomery et al. [453] showing that the degradation of matrix by melanoma cells is essentially a two-step process. The first stage involves the u-PA/plasmin system in the degradation of glycoproteins that cover collagen fibers; then, activated MMPs are involved in the destruction of the collagen network. There is also evidence that the u-PA system modulates invasive capacity and proliferation in prostatic tumor cells [454], with MMP activation being found. MT1 MMP correlates well with MMP2 activation potential after epithelial to mesenchymal transition in human breast carcinoma cells [455]. Other workers propose that MT1-MMP arises from stromal cells and that activation might be a perifibroblastic event [456]. It was postulated that MT1 MMP on the surface may mediate a paracrine loop for the utilization of stromally produced MMP2. Also, cell surface-associated MMP2 is more effective than soluble activated enzyme in remodeling of the matrix by tumor cells [457]. Invasion of interstitial matrix barriers by carcinoma cells seems more dependent on MMPs than the u-PA/plasmin system [458], in as much as MMP inhibitors are much more effective at reducing invasion than inhibitors directed against the plasminogen/plasmin axis.

The requirement for tumor cells to degrade basement membranes led to the characterization of MMP2 (originally named type IV collagenase) [459] and became the focus of many studies attempting to correlate proteinases with the various stages of invasion. The main component of basement membranes is type IV collagen, with laminin, entactin, and perlecan, and so proteinases that degrade these molecules have received most attention. With a number of tumors there is a moderate correlation between the expression of MMP2 and metastasis [460]. In breast cancer, MMP expression represents a tumor-induced host response [461],

with unique patterns of expression in different cell types. MT1 MMP is expressed in many tumor cells *in vitro*, but *in vivo* it is mainly localized in stromal cells [462]. It is therefore tempting to associate this proteinase with MMP2 activation and matrix breakdown as invasion proceeds. High levels of MT1 MMP expression were found to be associated with the degree of invasiveness of cervical cancer cells [463]. Polette et al. [462] observed that MT1 MMP was expressed in fibroblasts in focal areas in preinvasive lesions, and others have documented the proteolysis of matrix proteins being associated with plasma membrane protrusions, termed invadopodia [464]. Proteolysis of matrix by invadopodia facilitates breast cancer cell invasion by MMPs [465]. Nakahara et al. [466] showed that MT1 MMP is required for cell invasion and localizes to invadopodia in human melanoma cells overexpressing it. MMP13, along with MT1 MMP and MMP2, is associated with advanced local invasion in human squamous cell carcinomas of the larynx [467]. The other gelatinase, MMP9, is also often correlated with invasion (see also below) and is critical for breaching the vascular wall, a rate-limiting step for intravasation and consequently metastasis [468]. Cells with low surface u-PA are incapable of intravasation, even if MMP9 is abundant; thus intravasation needs the cooperation of u-PA/uPAR and MMP9 [468]. Bound u-PA is needed for the induction of brain tumor cell migration [469], independent of u-PA-mediated proteolysis. u-PA is expressed in stromal cells, in contrast to its receptor, which is found in cancer cells at invasive foci in human colon adenocarcinomas [470]. The mRNA for the inhibitor PAI1 is located in endothelial cells in the tumor stroma [471]. Such studies demonstrate the complex interaction between cell types as well as proteinase types. In some instances, it has been shown that there is a correlation between the metastatic potential of tumor cells and their secretion of MMP activities degrading type IV collagen [459].

There is evidence that MMPs have a role in the early stages of tumor progression. Stromelysin 3 (MMP11) expression promotes tumor "take" in nude mice, seemingly by favoring cancer cell survival in a tissue environment initially not permissive for tumor growth [472]. There is also evidence that it is involved in tumor implantation [473], seemingly by way of extracellular matrix-associated growth factors. Matrilysin (MMP7) production is increased in the early stages of colorectal tumorigenesis [474], which seems to be correlated with increased *in vivo* tumorigenicity. MMP7 expression in the mammary epithelium may contribute to early-stage mammary tumorigenesis [475]. Interestingly, synthetic inhibitors of MMPs cause a delay in human breast cancer regrowth, as well as reducing metastasis, in a nude mouse xenograft model [476]. In a model system it was shown that the expression of the *ras* oncogene up-regulated MMP3 and increased invasiveness and the degradation of collagen synthesized by vascular endothelial cells [477]. In other model systems, oncogenes (*fos*, *jun*, and *ets*) were shown to control the transcriptional regulation of MMP1 as well as MMP3 [478], and an Ets-related protein (E1A-F) was found to up-regulate MMPs [479].

It has now become clear that increased production of proteinases associated with malignant carcinomas often comes from the host stromal cells, induced by the tumor cells. Data from a study of invasive and noninvasive human meningiomas [480] first suggested this, and similar data were obtained with mouse fibrosarcoma cells [481] and with the Lewis lung tumor. All these data suggesting that tumor cells stimulate stromal cells to synthesize MMPs and aid cancer dissemination led Biswas and colleagues to characterize a factor that, in culture, stimulates fibroblasts to produce high levels of collagenase [482]. This factor was originally called TCSF (tumor cell-derived collagenase stimulatory factor) but is now named EMMPRIN (extracellular matrix metalloproteinase inducer). It is a glycoprotein and a member of the immunoglobulin superfamily that is located on the outer surface of many human tumor cells, but which is absent from most normal cells except keratinocytes [483]. Fibroblast MMPs 1,2, and 3 are all stimulated by it and it seems likely that it is acting via cell–cell interactions. EMMPRIN and MMP9 have been found to be strongly expressed in neoplastic melanocytes [484] and MMP9 may be involved in early invasion. Recent work demonstrates that EMMPRIN stimulates collagenase transcription specifically through MAPK p38 [485]

Other systems show that direct contact of tumor cells with stromal cells may lead to proteinase expression [486]. These workers found that even methanol-fixed metastatic rat embryo fibroblasts could induce MMP9 in normal cells. Co-culture of human breast adenocarcinoma MCF-7 cells with fibroblasts enhanced the production of MMPs, and soluble and membrane-bound factors were implicated [487]. Takahashi et al. [488] have characterized a gene *RECK*, which encodes a membrane-anchored glycoprotein with EGF-like repeats and serine proteinase inhibitor-like domains. *RECK* mRNA is expressed in human tissues but not in tumor-derived cell lines and transformed cells. Remarkably, restoring the expression of *RECK* in malignant cells suppresses invasive activity and decreases MMP9 secretion. This work suggests yet another pathway by which oncogenes act. Precisely how the suppression works is currently being investigated. Finally, in this context, it has been shown that MMP9 can bind to the cell surface hyaluronan receptor CD44 [489], thus providing a mechanism to explain how CD44 promotes tumor growth and metastasis by localizing proteolytic activity. CD44 cleavage seems to be mediated by MT MMPs [490], and thus is involved in a complex interaction between tumor cell and matrix that controls migration. CD44 is involved in the up-regulation of MMP2 in human melanoma cells [491], because binding of a monoclonal antibody uniquely increased expression of MMP2 and invasion in *in vitro* test systems.

Cathepsin B can facilitate tumor progression directly through degradation of components of the basement membrane and extracellular matrix [492]. Overexpression of cathepsin B mRNA, increased cathepsin B staining and elevated cathepsin B activity were found in different human cancers. These occurred especially at the invasive edges of cancers. Cathepsin B can also facilitate tumor progression indirectly through activation of other latent proteases and/or degradation of protein inhibitors of other proteases. Thus, cathepsin B may be an integral component of the proteolytic cascade linked to malignant progression of human tumors.

TIMPs may play an important role in the control of tumor MMP activity, since it has been shown with some experimental tumors that there is a marked decrease in TIMP1 production by malignant as compared to benign tumors. Khokha [493] showed that by transfecting B16-F10 melanoma cells to overexpress TIMP1 their tumorigenic and metastatic abilities were suppressed. This work built on earlier studies showing that anti-sense RNA to TIMP1 induced a reduction in murine TIMP1 levels and conferred

oncogenicity on Swiss 3T3 cells [494], and that TIMP1 inhibited B16-F10 cells from invading [495]. Overexpression of TIMP2 can also prevent local invasion and inhibit tumor growth [496]. TIMPs 1 and 2 can be up-regulated by activating cyclic adenylase activity with 8-bromo-cAMP [497] and this treatment suppresses the invasive phenotype of HT1080 cells. Recent work [498] suggests that with some tumors loss of TIMP3 is related to the acquisition of tumorigenesis and may be related to aberrant promoter-region methylation; the most frequent TIMP3-related methylation was found in renal cancers, which originate in the tissue that normally expresses the highest TIMP3 levels. However, there is some contrary evidence for the role of TIMPs since it has been observed that TIMP1 levels are higher in breast carcinomas than in fibroadenomas [499], and high levels of TIMP1 indicate a poor clinical outcome. High levels of TIMP2 expression in the tumor stroma are associated with a poor outcome in invasive bladder cancer [500]. In these situations, could it be that the TIMPs are acting as growth promoters? In a model system in which collagenase and gelatinase have been shown to be important, TIMP1 prevented the invasion of bovine capillary endothelial cells (stimulated with bFGF) into human amnion basement membrane [501]. TIMP1 has also been shown to inhibit the metastatic potential of a highly metastatic rat embryo cell line, transfected by c-Ha-ras1 in order to induce secretion of gelatinases [502]: high doses of TIMP1 injected intraperitoneally into nude mice prevented the metastasis to the lung of cells injected intravenously into the animals.

It has also been shown that collagen degradation and invasion by human melanoma cells can be reduced by transfection with an antisense RNA for MMP1 [503]. Durko et al. [503] found that, in addition to preventing degradation of type I collagen, there was inhibition of invasion through type IV collagen despite the presence of functional MMP2. Suppression of MMP7 inhibits colon cancer invasion *in vitro* [504]. Intestinal tumorigenesis is suppressed in mice lacking MMP7 [505], which is highly expressed in early-stage human colorectal tumors: it was postulated that MMP7 may function in a capacity independent of matrix degradation.

Fibrosis

The theme of matrix destruction based on an imbalance of proteinases over inhibitors has a mirror-image in the consideration that an excess of inhibitory activity could lead to accumulation of matrix. Evidence has been produced that cells from patients with scleroderma simultaneously produce less MMP3 but more TIMP1 than do normal fibroblasts [506] and a potential role for PN1 (protease nexin 1) overexpression in the pathogenesis of scleroderma has been suggested [507]. These abnormalities could play an important part in the molecular pathology of the disease, which is characterized by excessive matrix in skin and internal organs. It seems likely that TGF-β might be a major mediator. An excess of TIMP1 may be involved in the pathogenesis of liver fibrosis [508] and chronic asthma [509].

Interestingly, synthetic metalloproteinase inhibitors can result in the condition of "frozen" shoulder in patients treated with them [510]. There are many resemblances in this condition to Dupuytren's contracture, which is characterized by abnormal proliferation of fibrous tissue within the palmar fascia of the hand [511]. The localized nature of Dupuytren's contracture and the likely involvement of cytokines such as TGF, suggest that proteinases/inhibitors may be abnormal in this condition.

INHERITED DISORDERS LINKED TO MATRIX PROTEOLYSIS

Sorsby's Fundus Dystrophy

Sorsby's fundus dystrophy (SFD) (MIM 136900) is a rare autosomal dominantly inherited macular disorder. It is characterized by loss of central vision owing to subretinal neovascularization and degeneration; there is also a thickening of Bruch's membrane. The disease locus was mapped to chromosome 22q13-qter, the same region as the gene encoding TIMP3 [153,512]. Mutations were found to affect the C-terminal region (exon 5) of the mature TIMP3 protein [512–514]. All mutations result in an additional cysteine residue, suggesting strongly that mutations in *TIMP3* are causally responsible for the SFD phenotype and that there is a critical role for a free thiol group. The mutations in different families seem to have arisen independently [514], but all could lead to an altered regulation of proteolytic activity. TIMP3 is an inhibitor of angiogenesis [515] and mutations could disrupt the balance in the tissue. There are now five known different disease-associated mutations in the TIMP3 gene involving missense mutations and a splice site mutation with different clinical features [516].

Recent work [517] has shown that a mutant TIMP3 (Ser181Cys) [512,518], found in SFD, retained its ability to localize to the extracellular matrix and inhibit MMPs. It has been hypothesized that TIMP3 mutations contribute to disease progression by accumulation of mutant protein rather than by loss of functionality. This interpretation would fit with the late onset of symptoms, the absence of pathological features in other tissues with high TIMP3 expression, and immunolocalization studies showing that TIMP3 is a component of the increased extracellular matrix in Bruch's membrane in SFD [519,520]. It should be noted, however, that up-regulation of TIMP3 occurs in other degenerative diseases without mutations [521].

Promoter Polymorphisms

MMP3 gene expression was found in atherosclerotic plaques by *in situ* hybridization [522] and the involvement of MMPs in cardiovascular disease has been reviewed [523]. A common naturally occurring variant in the promoter of the *MMP3* gene has been identified [524], with one allele having a run of five adenosines (5A) and the other having six adenosines (6A), the latter having lower promoter activity. The 6A allele is associated with the progression of atherosclerosis and it was suggested that lower MMP3 activity might favor matrix deposition. In a clinical therapeutic study, it was confirmed that the 5A allele was associated with a beneficial effect on disease progression [525]; this raises the possibility that patients with coronary artery disease who are homozygous for the 6A allele (25–30% of the population) may be at particular risk of rapid disease progression. The same polymorphism has been associated with acute myocardial infarction [526].

A highly polymorphic marker has been found in the *CLG4B* gene [527], which encodes MMP9. This gene had been proposed as a candidate gene for abdominal aortic aneurysms, but, based on the reported results, this does not seem likely, even though macrophage-derived MMP9 levels are elevated in diseased aortic tissues [528]. Functional polymorphism in the regulatory region of MMP9 has recently been characterized in detail [529], but further work is still needed before it is clear that genetic variation does have a

profound influence on MMP9 expression and the severity of coronary atherosclerosis.

Of interest is a recent paper by Rutter et al. [530] showing that a single nucleotide polymorphism in the *MMP1* promoter creates an Ets binding site and augments transcription. Members of the Ets family of transcription factors are present within *MMP* promoters and are potent positive regulators. These workers [530] found that the polymorphism is not a mutation and that its frequency is increased in tumor lines. The data point to a mechanism for more aggressive matrix degradation and could have wide applicability.

Dawson et al. [531] found a common polymorphism in the promoter of *PAI1* and that the site might be of functional importance in regulating the expression of this inhibitor. There is also evidence that genetic polymorphism of cathepsin D is strongly associated with the risk of developing sporadic Alzheimer disease [532]; cathepsin D might be involved in the intracellular cleavage of amyloid protein and polymorphism could give rise to altered enzyme function.

CONCLUSIONS AND PROSPECTS FOR RESEARCH AND THERAPY

Clearly an exciting area for research is to use the information available to design therapeutic advances based on proteinase inhibition at multiple levels [533]. Proteinase inhibitors are now very attractive for a wide range of degradative diseases [534] and their possible use in cancer therapy has been reviewed by DeClerck and Imren [535]. The low-molecular-weight MMP inhibitors in clinical trials are mainly hydroxamic acid derivatives that do not fully mimic TIMP actions, and much more specific inhibitors are now being designed. Also, it is possible to think beyond MMP inhibitors working on active proteinases, to consider blocking agents that either prevent induction of MMPs and PAs or prevent the translation of messages or inhibit MMP activation. Also, we can consider the up-regulation of natural inhibitors such as TIMPs, and many combinations of inhibitors could also be useful. For example, although it has been shown that inhibitors of prostaglandins can reduce inflammation, no effort has yet been made to test therapy based on inhibitors of phospholipase, which controls a rate-limiting precursor, arachidonic acid. Combination therapies of nonsteroidal anti-inflammatory drugs with proteinase inhibitors might be effective, as has been proposed in periodontal disease [410]. Chemically modified tetracyclines (see also above) also show great promise in animal models of bone and gingival destruction [536].

Arner et al. [537] showed in a model system that a series of isothiazolones could inhibit cartilage proteoglycan degradation without decreasing synthesis: they concluded from their studies that the activation step for MMPs was the likely target of these drugs, without their having any activity against active enzymes. Thus, interfering with the activation of MMPs may offer a control point in many diseases involving the family of MMPs. Perhaps another good area for exploration would be to try to up-regulate TIMP production and restore a better balance in the tissue. A possible way that this might be done is suggested by the work of Fang et al. [538], who found that they could stimulate new bone formation *in vivo* by the technique of direct transfer of osteogenic plasmid genes. There seems every possibility that a similar approach could be used for agents that would up-regulate TIMPs. Another route is suggested by Cheng et al. [539], who used adenovirus-mediated gene transfer of TIMP2 to smooth muscle cells. Such cells expressed inhibitor and had reduced invasiveness *in vitro*, and the transfection delayed neointimal development *in vivo* after carotid injury. Fernandez et al. [540] have shown an inhibition of endothelial cell migration and invasion of extracellular matrix by gene transfer of TIMP1 using replication-deficient recombinant adenovirus technology. Also using a retroviral vector, Pelletier et al. [541] showed that a local increase in IL-1 receptor antagonist could reduce the progression of experimentally induced lesions in dogs.

Another recent advance should complement protease inhibitors. Human heparanase has been cloned by two groups [542,543]: the mRNA and the protein were shown to be preferentially expressed in metastatic cell lines and some human tumors. Transfection of low metastatic murine cells with heparanase cDNA gave rise to a highly metastatic phenotype *in vivo* [543], and mRNA for heparanase in rat tumor cells correlated well with metastatic potential [542]. Interestingly, both groups found that there was only one heparanase sequence, and so this enzyme must be the dominant endoglucuronidase in mammalian tissues. Specific inhibitors should soon be available that might suppress angiogenesis as well as halting the ability of metastatic cells to reach target organs.

RECENT DEVELOPMENTS

The field of proteases has developed apace and a number of new 'players' in the extracellular matrix degradation arena have been identified. These are comprehensively documented in the MEROPS database: *http//www.merops.co.uk*

In relation to extracellular matrix turnover, much new work has been achieved on the matrix metalloproteinases. Genetic manipulation of mice has yielded far more specific information about the significance of these enzymes [544].

There has been increased interest in the role of MMPs in tumor invasion and metastasis, especially whether inhibitors could be a powerful new therapy. It is now clear that membrane MMPs are involved in tumor cell adhesion and locomotion [545,546] and metastasis [547], as well as in normal cell migration [548] and angiogenesis [549]. Among the other families of MMPs it is clear that stromelysin is a powerful mammary tumor promoter [550,551].

The possibility of overexpressing TIMPs has been discussed in detail [552], and in an experimental nude mouse model, the intramuscular delivery of TIMP-4 DNA suppressed the growth of Wilms' tumor cells [553]. Tumor invasiveness can also be inhibited by the group of chemically modified tetracyclines [554]. New probes for imaging MMP activities in intact tumors have been developed, together with novel near-infrared fluorescence imaging technology [555].

The realization that peritumoral fibroblasts synthesize most of the MMPs in human tumors, rather than the cancer cells themselves, has increased interest in the role of extracellular MMP inducer (EMMPRIN) in tumor dissemination. Recent work on this glycoprotein, which is present on cancer cell plasma membranes, has demonstrated that it can enhance fibroblast synthesis of MMPs [556]. The authors concerned propose that EMMPRIN plays an important role in cancer progression by this pathway of increasing synthesis of MMPs.

Sorsby fundus dystrophy has continued to intrigue. Although a common molecular phenotype has been described for the TIMP-3 mutation [557], this condition has been found without any mutation in TIMP-3 [558]. It still seems

likely that Sorsby fundus dystrophy is connected to an overproduction of TIMP-3 and it will need further research to rule out whether the patients reported by Assink et al. [558] represent a related disease.

Of great interest has been the finding that the mutation of the *MMP2* gene in humans causes a multicentric osteolysis and arthritis syndrome [559]. The precise details of how MMP2 is involved remain unclear, but the results do demonstrate how disruption of matrix turnover can have dramatic effects on connective tissues. The inherited osteolyses, or "vanishing bone" syndromes, are a group of rare disorders (MIM 166300, 259600, 259610, 277950) of unknown etiology characterized by destruction and resorption of affected bones: clearly new insights will be forthcoming. It seems likely that gelatinase A (MMP2) is a key proteinase for controlling collagen turnover in many tissues [560].

It has also been suggested that a genetic variation of cathepsin D is a major risk factor for Alzheimer disease [561], backing up earlier work by the same authors.

Cathepsin K has been an intensively researched area, recently, since it is clear that this proteinase, produced by osteoclasts, is the dominant cysteine proteinase in bone. It has been clearly linked to osteopetrosis and pycnodysostosis (see Chapter 19, this volume) [562].

ACKNOWLEDGMENTS

The work of the authors is supported by funds from the Medical Research Council (U.K.), the Wellcome Trust, and the Arthritis and Rheumatism Campaign. We thank Jill Gorton for helping with the manuscript, Vera Knauper for help with the illustrations, and many colleagues for useful suggestions, especially Vera Knauper and Murray Meikle.
