# Foreword

This text was developed under the aegis of the American Society of Colon and Rectal Surgeons (ASCRS). It represents an attempt to cover the field of colon and rectal surgery with input from expert surgeons who have, in one way or another, shown special interest or expertise in specific areas of the specialty.

The book will hopefully serve as a source of useful information and perhaps even guidance to surgeons whose practice is confined to the specialty of colon and rectal surgery, and also to general surgeons, surgery residents, and medical students with an interest in surgery.

The finished product represents significant efforts from authors who have taken time from their busy schedules to set into writing their often unique perspectives. I know for certain that no author of any chapter in this book has a light schedule, but that fact validates each author's selection for authorship.

Special acknowledgment is due the editors, Bruce Wolff, David Beck, John Pemberton, and Steven Wexner. This project simply would not have come together without their efforts on many levels.

Finally, Jim Fleshman must be singled out for special recognition. The idea of an ASCRS-sponsored text began with Jim—an idea that he advocated, developed, nurtured, and forced until it became realized in the substance you now hold.

Professor of Surgery  
Chief, Division of Colon and Rectal Surgery  
The Hospital of the University of Pennsylvania

# Preface

The ASCRS Textbook was conceived as a means of providing state of the art information to residents in training and fully trained surgeons seeking recertification. The textbook also supports the mission of the American Society of Colon and Rectal Surgeons (ASCRS) to be the world's authority on colon and rectal disease. The combination of junior and senior authors selected from the membership of the ASCRS for each chapter will provide a comprehensive summary of each topic and allow the touch of experience to focus and temper the material. This approach should provide the reader with a very open-minded, evidence-based approach to all aspects of colorectal disease.

The Editorial Committee of the book has been designed to be a rotating group of experts selected by the ASCRS Executive Council. It has been my distinct pleasure and honor to work with this edition's editors and associate editors. They have sacrificed time and energy with patience to achieve what I believe to be the next gold standard in accumulated knowledge regarding the entire breadth of colorectal surgery. The idea for the book was originally Dr. Bruce Wolff's. The table of contents was intentionally based on the Core Curriculum established by the Association of Program Directors in Colon and Rectal Surgery. The Practice Parameters developed by the ASCRS Standards Committee have been incorporated into the appropriate chapters. The proceeds from the textbook and related publications will be utilized by the ASCRS Executive Council to sponsor the Research and Education Foundation of the society. This is truly an ASCRS effort.

As future editions continue the effort started with this first edition, I hope the fellows and members of ASCRS and trainees at all levels realize that this is the definitive source of knowledge in colon and rectal surgery. I am honored to have been a small part of such a monumental achievement. Dr. Robert Fry, as President of the ASCRS at the time of the textbook's inception, is to be congratulated for looking to the future and seeing the potential of such a project. I must also thank my wife Linda for her support during this effort and my administrative staff (Liz Nordike at Washington University and Beth Campbell, Laura Gillan D. Zerega, and Paula Callaghan at Springer) for all their effort toward completing the book.

*James W. Fleshman, MD, FASCRS*  
August 2006

# 1 Anatomy and Embryology of the Colon, Rectum, and Anus

José Marcio Neves Jorge and Angelita Habr-Gama

Although much of our fundamental understanding of the anatomy of the colon, rectum, and anus comes from the efforts of researchers of the 19th and early 20th centuries, comprehensive observations of this region had been made as early as 1543 by Andreas Vesalius through anatomic dissections.<sup>1</sup> However, anatomy of this region, especially that of the rectum and anal canal, is so intrinsically related to its physiology that much can be appreciated only in the living. Thus, it is a region in which the surgeon has an advantage over the anatomist through *in vivo* dissection, physiologic investigation, and endoscopic examination. However, anatomy of the pelvis is also challenging to the surgeon: the pelvis is a narrow space, packed with intestinal, urologic, gynecologic, vascular, and neural structures, all confined within a rigid and deep osseous-muscular cage. Therefore, detailed anatomy of this region is difficult to learn in the setting of an operating room and it demands not only observations *in vivo*, but historical reviews, anatomy laboratory studies, including dissections of humans and animals, with in-depth descriptions and drawings and sometimes associated with physiologic evaluation. Based on these studies, some controversial concepts of the anatomy, especially of the rectum and anal canal, have been actually changed.<sup>2-8</sup> In addition, virtual reality models have been designed to improve visualization of three-dimensional structures and more properly teach anatomy, pathology, and surgery of the anorectum and pelvic floor.<sup>9</sup>

## Anatomy

### Anus and Rectum

#### *Anal Canal Structure, Anus, and Anal Verge*

The anal canal is anatomically peculiar and has a complex physiology, which accounts for its crucial role in continence and, in addition, its susceptibility to a variety of diseases. The anus or anal orifice is an anteroposterior cutaneous slit, that along with the anal canal remains virtually closed at rest, as a result of tonic circumferential contraction of the sphincters

and the presence of anal cushions. The edge of the anal orifice, the anal verge or margin (anocutaneous line of Hilton), marks the lowermost edge of the anal canal and is sometimes the level of reference for measurements taken during sigmoidoscopy. Others favor the dentate line as a landmark because it is more precise. The difference between the anal verge and the dentate line is usually 1–2 cm. The epithelium distal to the anal verge acquires hair follicles, glands, including apocrine glands, and other features of normal skin, and is the source of perianal hidradenitis suppurativa, inflammation of the apocrine glands.

#### *Anatomic Versus Surgical Anal Canal*

Two definitions are found describing the anal canal (Figure 1-1). The “anatomic” or “embryologic” anal canal is only 2.0 cm long, extending from the anal verge to the dentate line, the level that corresponds to the proctodeal membrane. The “surgical” or “functional” anal canal is longer, extending for approximately 4.0 cm (in men) from the anal verge to the anorectal ring (levator ani). This “long anal canal” concept was first introduced by Milligan and Morgan<sup>10</sup> and has been considered, despite not being proximally marked by any apparent epithelial or developmental boundary, useful both as a physiologic and surgical parameter. The anorectal ring is at the level of the distal end of the ampullary part of the rectum and forms the anorectal angle, and the beginning of a region of higher intraluminal pressure. Therefore, this definition correlates with digital, manometric, and sonographic examinations.

#### *Anatomic Relations of the Anal Canal*

Posteriorly, the anal canal is related to the coccyx and anteriorly to the perineal body and the lowest part of the posterior vaginal wall in the female, and to the urethra in the male. The ischium and the ischiorectal fossa are situated on either side. The fossa ischiorectal contains fat and the inferior rectal vessels and nerves, which cross it to enter the wall of the anal canal.

FIGURE 1-1. Anal canal.

### *Muscles of the Anal Canal*

The muscular component of the mechanism of continence can be stratified into three functional groups: lateral compression from the pubococcygeus, circumferential closure from the internal and external anal sphincter, and angulation from the puborectalis (Figure 1-2). The internal and external anal sphincters, and the conjoined longitudinal are intrinsically related to the anal canal, and will be addressed here.

### *Internal Anal Sphincter*

The internal anal sphincter represents the distal 2.5- to 4.0-cm condensation of the circular muscle layer of the rectum. As a consequence of both intrinsic myogenic and extrinsic autonomic neurogenic properties, the internal anal sphincter is a smooth muscle in a state of continuous maximal contraction, and represents a natural barrier to the involuntary loss of stool and gas.

The lower rounded edge of the internal anal sphincter can be felt on physical examination, about 1.2 cm distal to the dentate line. The groove between the internal and external anal sphincter, the intersphincteric sulcus, can be visualized or easily palpated. Endosonographically, the internal anal sphincter is a 2- to 3-mm-thick circular band and shows a uniform hypoechoogenicity.

### *External Anal Sphincter*

The external anal sphincter is the elliptical cylinder of striated muscle that envelops the entire length of the inner tube of smooth muscle, but it ends slightly more distal than the internal anal sphincter. The external anal sphincter was initially described as encompassing three divisions: subcutaneous, superficial, and deep.<sup>10</sup> Goligher et al.<sup>11</sup> described the external anal sphincter as a simple, continuous sheet that forms, along with the puborectalis and levator ani, one funnel-shaped skeletal muscle. The deepest part of the external anal sphincter is intimately related to the puborectalis muscle, which can actually be considered a component of both the levator ani and the external anal sphincter muscle complexes. Others considered the external anal sphincter as being subdivided into two parts, deep (deep sphincter and puborectalis) and superficial (subcutaneous and superficial sphincter).<sup>6,12,13</sup> Shafik<sup>14</sup> proposed the three U-shaped loop system, but clinical experience has not supported this schema. The external anal sphincter is more likely to be one muscle unit, attached by the anococcygeal ligament posteriorly to the coccyx, and anteriorly to the perineal body, not divided into layers or laminae. Nevertheless, differences in the arrangement of the external anal sphincter have been described between the sexes.<sup>15</sup> In the male, the upper half of the external anal sphincter is enveloped anteriorly by the conjoined longitudinal muscle, whereas the lower half is crossed by it. In the female, the

FIGURE 1-2. Muscles of the anal canal.

entire external anal sphincter is encapsulated by a mixture of fibers derived from both longitudinal and internal anal sphincter muscles.

Endosonographically, the puborectalis and the external anal sphincter, despite their mixed linear echogenicity, are both predominantly hyperechogenic, with a mean thickness of 6 mm (range, 5–8 mm). Distinction is made by position, shape, and topography. Recently, both anal endosonography and endocoil magnetic resonance imaging have been used to detail the anal sphincter complex in living, healthy subjects.<sup>16–19</sup> These tests provide a three-dimensional mapping of the anal sphincter; they help to study the differences in the arrangement of the external anal sphincter between the sexes and uncover sphincter disruption or defect during vaginal deliveries. In addition, there is some degree of “anatomical asymmetry” of the external anal sphincter, which accounts for both radial and longitudinal “functional asymmetry” observed during anal manometry.<sup>20</sup>

The automatic continence mechanism is formed by the resting tone, maintained by the internal anal sphincter, magnified by voluntary, reflex, and resting external anal sphincter contractile activities. In response to conditions of threatened incontinence, such as increased intraabdominal pressure and rectal distension, the external anal sphincter and puborectalis reflexively and voluntarily contract further to prevent fecal leakage. Because of muscular fatigue, maximal voluntary

contraction of the external anal sphincter can be sustained for only 30–60 seconds. However, the external anal sphincter and the pelvic floor muscles, unlike other skeletal muscles, which are usually inactive at rest, maintain unconscious resting electrical tone through a reflex arc at the cauda equina level. Histologic studies have shown that the external anal sphincter, puborectalis, and levator ani muscles have a predominance of type I fibers, which are a peculiarity of skeletal muscles connecting tonic contractile activity.<sup>21</sup>

#### *Conjoined Longitudinal Muscle*

Whereas the inner circular layer of the rectum gives rise to the internal anal sphincter, the outer longitudinal layer, at the level of the anorectal ring, mixes with fibers of the levator ani muscle to form the conjoined longitudinal muscle. This muscle descends between the internal and external anal sphincter, and ultimately some of its fibers, referred to as the *corrugator cutis ani muscle*, traverse the lowermost part of the external anal sphincter to insert into the perianal skin. Some of these fibers may enter the fat of the ischioanal fossa.<sup>22</sup> Other sources for the striated component of the conjoined longitudinal muscle include the puborectalis and deep external anal sphincter, the pubococcygeus and top loop of the external anal sphincter, and the lower fibers of the puborectalis.<sup>7,23,24</sup> In its descending course, the conjoined longitudinal muscle may

give rise to medial extensions that cross the internal anal sphincter to contribute the smooth muscle of the submucosa (*musculus canalis ani*, *sustentator tunicae mucosae*, *Treitz muscle*, *musculus submucosae ani*).<sup>25</sup>

Possible functions of the conjoined longitudinal muscle include attaching the anorectum to the pelvis and acting as a skeleton that supports and binds the internal and external sphincter complex together.<sup>22</sup> Haas and Fox<sup>26</sup> consider that the meshwork formed by the conjoined longitudinal muscle may minimize functional deterioration of the sphincters after surgical division and act as a support to prevent hemorrhoidal and rectal prolapse. In addition, the conjoined longitudinal muscle and its extensions to the intersphincteric plane divide the adjacent tissues into subspaces and may actually have a role in the septation of thrombosed external hemorrhoids and containment of sepsis.<sup>7</sup> Finally, Shafik<sup>23</sup> ascribes to the conjoined longitudinal muscle the action of shortening and widening of the anal canal as well as eversion of the anal orifice, and proposed the term *evertor ani muscle*. This is controversial. In addition to this primary function during defecation, a limited role in anal continence, specifically a potentialization effect in maintaining an anal seal, has also been proposed.<sup>23</sup>

### *Epithelium of the Anal Canal*

The lining of the anal canal consists of an upper mucosal (endoderm) and a lower cutaneous (ectoderm) segment (Figure 1-1). The dentate (pectinate) line is the “saw-toothed” junction between these two distinct origins of venous and lymphatic drainage, nerve supply, and epithelial lining. Above this level, the intestine is innervated by the sympathetic and parasympathetic systems, with venous, arterial, and lymphatic drainage to and from the hypogastric vessels. Distal to the dentate line, the anal canal is innervated by the somatic nervous system, with blood supply and drainage from the inferior hemorrhoidal system. These differences are important when the classification and treatment of hemorrhoids are considered.

The pectinate or dentate line corresponds to a line of anal valves that represent remnants of the proctodeal membrane. Above each valve, there is a little pocket known as an anal sinus or crypt. These crypts are connected to a variable number of glands, in average 6 (range, 3–12).<sup>27,28</sup> The anal glands first described by Chiari<sup>29</sup> in 1878 are more concentrated in the posterior quadrants. More than one gland may open into the same crypt, whereas half the crypts have no communication. The anal gland ducts, in an outward and downward route, enter the submucosa; two-thirds enter the internal anal sphincter, and half of them terminate in the intersphincteric plane.<sup>28</sup> Obstruction of these ducts, presumably by accumulation of foreign material in the crypts, may lead to perianal abscesses and fistulas.<sup>30</sup> Cephalad to the dentate line, 8–14 longitudinal folds, known as the rectal columns (columns of Morgagni), have their bases connected in pairs to each valve at the dentate line. At the lower end of the columns are the

anal papillae. The mucosa in the area of the columns consists of several layers of cuboidal cells and has a deep purple color because of the underlying internal hemorrhoidal plexus. This 0.5- to 1.0-cm strip of mucosa above the dentate line is known as the anal transition or cloacogenic zone. Cephalad to this area, the epithelium changes to a single layer of columnar cells and macroscopically acquires the characteristic pink color of the rectal mucosa.

The cutaneous part of the anal canal consists of modified squamous epithelium that is thin, smooth, pale, stretched, and devoid of hair and glands. The terms pecten and pecten band have been used to define this segment.<sup>31</sup> However, as pointed out by Goligher, the round band of fibrous tissue called pecten band, which is divided in the case of anal fissure (pectenotomy), probably represents the spastic internal anal sphincter.<sup>11,32</sup>

### *Rectum*

Both proximal and distal limits of the rectum are controversial: the rectosigmoid junction is considered to be at the level of the third sacral vertebra by anatomists but at the sacral promontory by surgeons, and likewise, the distal limit is regarded to be the muscular anorectal ring by surgeons and the dentate line by anatomists. The rectum measures 12–15 cm in length and has three lateral curves: the upper and lower are convex to the right and the middle is convex to the left. These curves correspond intraluminally to the folds or valves of Houston. The two left-sided folds are usually noted at 7–8 cm and at 12–13 cm, respectively, and the one on the right is generally at 9–11 cm. The middle valve (Kohlrausch’s plica) is the most consistent in presence and location and corresponds to the level of the anterior peritoneal reflection. Although the rectal valves do not contain all muscle wall layers from a clinical point of view, they are a good location for performing a rectal biopsies, because they are readily accessible with minimal risk for perforation.<sup>13,33</sup> The valves of Houston must be negotiated during proctosigmoidoscopy; they are absent after mobilization of the rectum, and this is attributed to the 5-cm length gained after complete surgical dissection. The rectal mucosa is smooth, pink, and transparent, which allows visualization of small and large submucosal vessels. This characteristic “vascular pattern” disappears in inflammatory conditions and in melanosis coli.

The rectum is characterized by its wide, easily distensible lumen, and the absence of taeniae, epiploic appendices, haustra, or a well-defined mesentery. The prefix “meso,” in gross anatomy, refers to two layers of peritoneum that suspend an organ. Normally the rectum is not suspended but entirely extraperitoneal on its posterior aspect, and closely applied to the sacral hollow. Consequently, the term “mesorectum” is anatomically inaccurate. An exception, however, is that a peritonealized mesorectum may be noted in patients with procidentia. But, the word “mesorectum” has gained widespread popularity among surgeons to address the perirectal

areolar tissue, which is thicker posteriorly, containing terminal branches of the inferior mesenteric artery and enclosed by the fascia propria.<sup>34,35</sup> The “mesorectum” may be a metastatic site for a rectal cancer and is removed during surgery for rectal cancer without neurologic sequelae, because no functionally significant nerves pass through it.

The upper third of the rectum is anteriorly and laterally invested by peritoneum; the middle third is covered by peritoneum on its anterior aspect only. Finally, the lower third of the rectum is entirely extraperitoneal, because the anterior peritoneal reflection occurs at 9.0–7.0 cm from the anal verge in men and at 7.5–5.0 cm from the anal verge in women.

### Anatomic Relations of the Rectum

The rectum occupies the sacral concavity and ends 2–3 cm anteroinferiorly from the tip of the coccyx. At this point, it angulates backward sharply to pass through the levators and becomes the anal canal. Anteriorly, in women, the rectum is closely related to the uterine cervix and posterior vaginal wall; in men, it lies behind the bladder, vas deferens, seminal vesicles, and prostate. Posterior to the rectum lie the median sacral vessels and the roots of the sacral nerve plexus.

### Fascial Relationships of the Rectum

The parietal endopelvic fascia lines the walls and floor of the pelvis and continues on the internal organs as a visceral pelvic fascia (Figure 1-3A and B). Thus, the *fascia propria of the rectum* is an extension of the pelvic fascia, enclosing the rectum, fat, nerves, and the blood and lymphatic vessels. It is more evident in the posterior and lateral extraperitoneal aspects of the rectum.

The *lateral ligaments or stalks of the rectum* are distal condensations of the pelvic fascia that form a roughly triangular structure with a base on the lateral pelvic wall and an apex attached to the lateral aspect of the rectum.<sup>32</sup> Still a subject of misconception, the lateral stalks are comprised essentially of connective tissue and nerves, and the middle rectal artery does not traverse them. Branches, however, course through in approximately 25% of cases.<sup>36</sup> Consequently, division of the lateral stalks during rectal mobilization is associated with a 25% risk for bleeding. Although the lateral stalks do not contain important structures, the middle rectal artery and the pelvic plexus are both closely related, running, at different angles, underneath it.<sup>37</sup> One theoretical concern in ligation of the stalks is leaving behind lateral mesorectal tissue, which may limit adequate lateral or mesorectal margins during cancer surgery.<sup>34,35,38</sup>

The *presacral fascia* is a thickened part of the parietal endopelvic fascia that covers the concavity of the sacrum and coccyx, nerves, the middle sacral artery, and presacral veins. Operative dissection deep to the presacral fascia may cause troublesome bleeding from the underlying presacral veins. Presacral hemorrhage occurs as frequently as 4.6% to 7.0% of resections for rectal neoplasms, and despite its venous nature, can be life threatening.<sup>39–41</sup> This is a consequence of two factors: the difficulty in securing control because of retraction of the vascular stump into the sacral foramen and the high hydrostatic pressure of the presacral venous system. The presacral veins are avascular and communicate via basivertebral veins with the internal vertebral venous system. The adventitia of the basivertebral veins adheres firmly to the sacral periosteum at the level of the ostia of the sacral foramina,

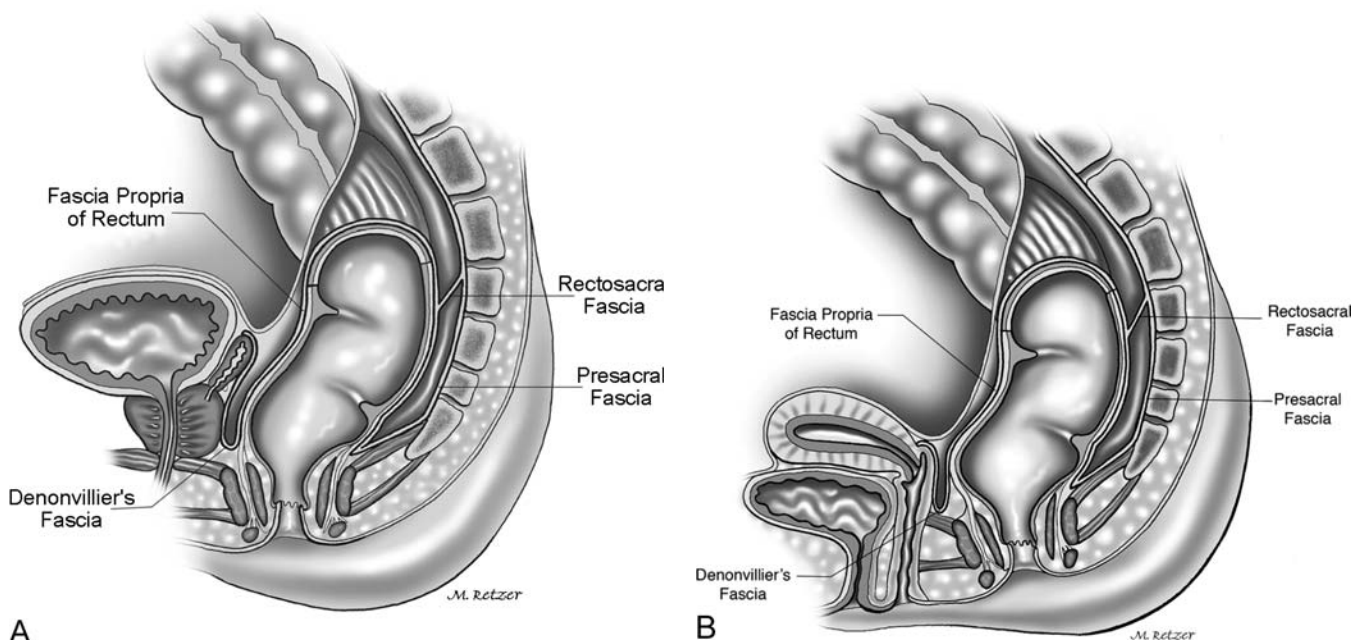

FIGURE 1-3. Fascial relationships of the rectum: **A** male, **B** female.

mainly at the level of S3-4. With the patient in the lithotomy position, the presacral veins can attain hydrostatic pressures of 17–23 cm H<sub>2</sub>O, two to three times the normal pressure of the inferior vena cava.<sup>40</sup>

The *rectosacral fascia* is an anteroinferiorly directed thick fascial reflection from the presacral fascia at the S-4 level to the fascia propria of the rectum just above the anorectal ring.<sup>42</sup> The rectosacral fascia, classically known as the fascia of Waldeyer, is an important landmark during posterior rectal dissection.<sup>2,42</sup>

The *visceral pelvic fascia of Denonvilliers* is a tough fascial investment that separates the extraperitoneal rectum anteriorly from the prostate and seminal vesicles or vagina.<sup>43</sup> Therefore, three structures lie between the anterior rectal wall and the seminal vesicles and prostate: anterior mesorectum, fascia propria of the rectum, and Denonvilliers' fascia. A consensus has generally been reached about the anatomy of the plane of posterior and lateral rectal dissection, but anteriorly, the matter is more controversial. The anterior plane of rectal dissection may not necessarily follow the same plane of posterior and lateral dissection, and the use of the terms close rectal, mesorectal, and extramesorectal have been recently suggested to describe the available anterior planes.<sup>44</sup> The close rectal or perimuscular plane lies inside the fascia propria of the rectum and therefore it is more difficult and bloody than the mesorectal plane. The mesorectal plane represents the continuation of the same plane of posterior and lateral dissection of the rectum. This is a natural anatomic plane and consequently more appropriate for most rectal cancers. Finally, the extramesorectal plane involves resection of the Denonvilliers' fascia, with exposure of prostate and seminal vesicles, and is associated with high risk of mixed parasympathetic and sympathetic injury because of damage of the periprostatic plexus.

### *Urogenital Considerations*

Identification of the ureters is advisable to avoid injury to their abdominal or pelvic portions during colorectal operations. On both sides, the ureters rest on the psoas muscle in their inferomedial course; they are crossed obliquely by the spermatic vessels anteriorly and the genitofemoral nerve posteriorly. In its pelvic portion, the ureter crosses the pelvic brim in front of or a little lateral to the bifurcation of the common iliac artery, and descends abruptly between the peritoneum and the internal iliac artery. Before entering the bladder in the male, the vas deferens crosses lateromedially on its superior aspect. In the female, as the ureter traverses the posterior layer of the broad ligament and the parametrium close to the side of the neck of the uterus and upper part of the vagina, it is enveloped by the vesical and vaginal venous plexuses and is crossed above and lateromedially by the uterine artery.

### *Arterial Supply of the Rectum and Anal Canal*

The superior hemorrhoidal artery is the continuation of the inferior mesenteric artery, once it crosses the left iliac vessels.

The artery descends in the sigmoid mesocolon to the level of S-3 and then to the posterior aspect of the rectum. In 80% of cases, it bifurcates into right, usually wider, and left terminal branches; multiple branches are present in 17%.<sup>45</sup> These divisions, once within the submucosa of the rectum, run straight downward to supply the lower rectum and the anal canal. Approximately five branches reach the level of the rectal columns, and condense in capillary plexuses, mostly at the right posterior, right anterior, and left lateral positions, corresponding to the location of the major internal hemorrhoidal groups.

The superior and inferior hemorrhoidal arteries represent the major blood supply to the anorectum. In addition, it is also supplied by the internal iliac arteries.

The contribution of the middle hemorrhoidal artery varies with the size of the superior hemorrhoidal artery; this may explain its controversial anatomy. Some authors report absence of the middle hemorrhoidal artery in 40% to 88%<sup>46,47</sup> whereas others identify it in 94% to 100% of specimens.<sup>45</sup> It originates more frequently from the anterior division of the internal iliac or the pudendal arteries, and reaches the rectum. The middle hemorrhoidal artery reaches the lower third of the rectum anterolaterally, close to the level of the pelvic floor and deep to the levator fascia. It therefore does not run in the lateral ligaments, which are inclined posterolaterally.<sup>2</sup> The middle hemorrhoidal artery is more prone to be injured during low anterior resection, when anterolateral dissection of the rectum is performed close to the pelvic floor and the prostate and seminal vesicles or upper part of the vagina are being separated.<sup>37</sup> The anorectum has a profuse intramural anastomotic network, which probably accounts for the fact that division of both superior and middle hemorrhoidal arteries does not result in necrosis of the rectum.

The paired inferior hemorrhoidal arteries are branches of the internal pudendal artery, which in turn is a branch of the internal iliac artery. The inferior hemorrhoidal artery arises within the pudendal canal and is throughout its course entirely extrapelvic. It traverses the obturator fascia, the ischioanal fossa, and the external anal sphincter to reach the submucosa of the anal canal, ultimately ascending in this plane. Klosterhalfen et al.<sup>4</sup> performed postmortem angiographic, manual, and histologic evaluations and demonstrated that in 85% of cases the posterior commissure was less well perfused than were the other sections of the anal canal. In addition, the blood supply could be jeopardized by contusion of the vessels passing vertically through the muscle fibers of the internal anal sphincter with increased sphincter tone. The resulting decreased blood supply could lead to ischemia at the posterior commissure, in a pathogenetic model of primary anal fissure.

### *Venous Drainage and Lymphatic Drainage of the Rectum and Anal Canal*

The anorectum also drains, via middle and inferior hemorrhoidal veins, to the internal iliac vein and then to the inferior

vena cava. Although it is still a controversial subject, the presence of communications among these three venous systems may explain the lack of correlation between portal hypertension and hemorrhoids.<sup>48</sup> The paired inferior and middle hemorrhoidal veins and the single superior hemorrhoidal vein originate from three anorectal arteriovenous plexuses. The external hemorrhoidal plexus, situated subcutaneously around the anal canal below the dentate line, constitutes when dilated the external hemorrhoids. The internal hemorrhoidal plexus is situated submucosally, around the upper anal canal and above the dentate line. The internal hemorrhoids originate from this plexus. The perirectal or perimuscular rectal plexus drains to the middle and inferior hemorrhoidal veins.

Lymph from the upper two-thirds of the rectum drains exclusively upward to the inferior mesenteric nodes and then to the paraaortic nodes. Lymphatic drainage from the lower third of the rectum occurs not only cephalad, along the superior hemorrhoidal and inferior mesentery arteries, but also laterally, along the middle hemorrhoidal vessels to the internal iliac nodes. Studies using lymphoscintigraphy have failed to demonstrate communications between inferior mesenteric and internal iliac lymphatics.<sup>49</sup> In the anal canal, the dentate line is the landmark for two different systems of lymphatic drainage: above, to the inferior mesenteric and internal iliac nodes, and below, along the inferior rectal lymphatics to the superficial inguinal nodes, or less frequently along the inferior hemorrhoidal artery. In the female, drainage at 5 cm above the anal verge in the lymphatic may also spread to the posterior vaginal wall, uterus, cervix, broad ligament, fallopian tubes, ovaries, and cul-de-sac, and at 10 cm above the anal verge, spread seems to occur only to the broad ligament and cul-de-sac.<sup>50</sup>

### *Innervation of the Rectum and Anal Canal*

#### Innervation of the Rectum

The sympathetic supply of the rectum and the left colon arises from L-1, L-2, and L-3 (Figure 1-4A and B). Preganglionic fibers, via lumbar sympathetic nerves, synapse in the preaortic plexus, and the postganglionic fibers follow the branches of the inferior mesenteric artery and superior rectal artery to the left colon and upper rectum. The lower rectum is innervated by the presacral nerves, which are formed by fusion of the aortic plexus and lumbar splanchnic nerves. Just below the sacral promontory, the presacral nerves form the hypogastric plexus (or superior hypogastric plexus). Two main hypogastric nerves, on either side of the rectum, carry sympathetic innervation from the hypogastric plexus to the pelvic plexus. The pelvic plexus lies on the lateral side of the pelvis at the level of the lower third of the rectum, adjacent to the lateral stalks.

The parasympathetic fibers to the rectum and anal canal emerge through the sacral foramen and are called the *nervi erigentes* (S-2, S-3, and S-4). They pass laterally, forward, and upward to join the sympathetic hypogastric nerves at the pelvic plexus. From the pelvic plexus, combined postgan-

glionic parasympathetic and sympathetic fibers are distributed to the left colon and upper rectum via the inferior mesenteric plexus, and directly to the lower rectum and upper anal canal. The periprostatic plexus, a subdivision of the pelvic plexus situated on Denonvilliers' fascia, supplies the prostate, seminal vesicles, corpora cavernosa, vas deferens, urethra, ejaculatory ducts, and bulbourethral glands. Sexual function is regulated by cerebrospinal, sympathetic, and parasympathetic components. Erection of the penis is mediated by both parasympathetic (arteriolar vasodilatation) and sympathetic inflow (inhibition of vasoconstriction).

All pelvic nerves lie in the plane between the peritoneum and the endopelvic fascia and are in danger of injury during rectal dissection. Permanent bladder paresis occurs in 7% to 59% of patients after abdominoperineal resection of the rectum<sup>51</sup>; the incidence of impotence is reported to range from 15% to 45%, and that of ejaculatory dysfunction from 32% to 42%.<sup>52</sup> The overall incidence of sexual dysfunction after proctectomy has been reported to reach 100% when wide dissection is performed for malignant disease<sup>53-55</sup>; however, this kind of procedure is unnecessary and these rates are much lower for benign conditions, such as inflammatory bowel disease (0% to 6%).<sup>53,54,56,57</sup> Dissections performed for benign conditions are undertaken closer to the bowel wall, thus reducing the possibility of nerve injury.<sup>58</sup>

Trauma to the autonomic nerves may occur at several points. During high ligation of the inferior mesenteric artery, close to the aorta, the sympathetic preaortic nerves may be injured. Division of both superior hypogastric plexus and hypogastric nerves may occur also during dissection at the level of the sacral promontory or in the presacral region. In such circumstances, sympathetic denervation with intact *nervi erigentes* results in retrograde ejaculation and bladder dysfunction. The *nervi erigentes* are located in the posterolateral aspect of the pelvis, and at the point of fusion with the sympathetic nerves are closely related to the middle hemorrhoidal artery. Injury to these nerves will completely abolish erectile function.<sup>56</sup> The pelvic plexus may be damaged either by excessive traction on the rectum, particularly laterally, or during division of the lateral stalks when this is performed close to the lateral pelvic wall. Finally, dissection near the seminal vesicles and prostate may damage the periprostatic plexus, leading to a mixed parasympathetic and sympathetic injury. This can result in erectile impotence as well as a flaccid, neurogenic bladder. Sexual complications after rectal surgery are readily evident in men but are probably underdiagnosed in women.<sup>59</sup>

#### Anal Canal

The internal anal sphincter is supplied by sympathetic (L-5) and parasympathetic nerves (S-2, S-3, and S-4) following the same route as the nerves to the rectum. The external anal sphincter is innervated on each side by the inferior rectal branch of the pudendal nerve (S-2 and S-3) and by the perineal branch of S-4. Despite the fact that the puborectalis and

FIGURE 1-4. **A, B** Innervation of the colon, rectum, and anal canal.

external anal sphincter have somewhat different innervations, these muscles seem to act as an indivisible unit.<sup>14</sup> After unilateral transection of a pudendal nerve, external anal sphincter function is still preserved because of the crossover of the fibers at the spinal cord level.

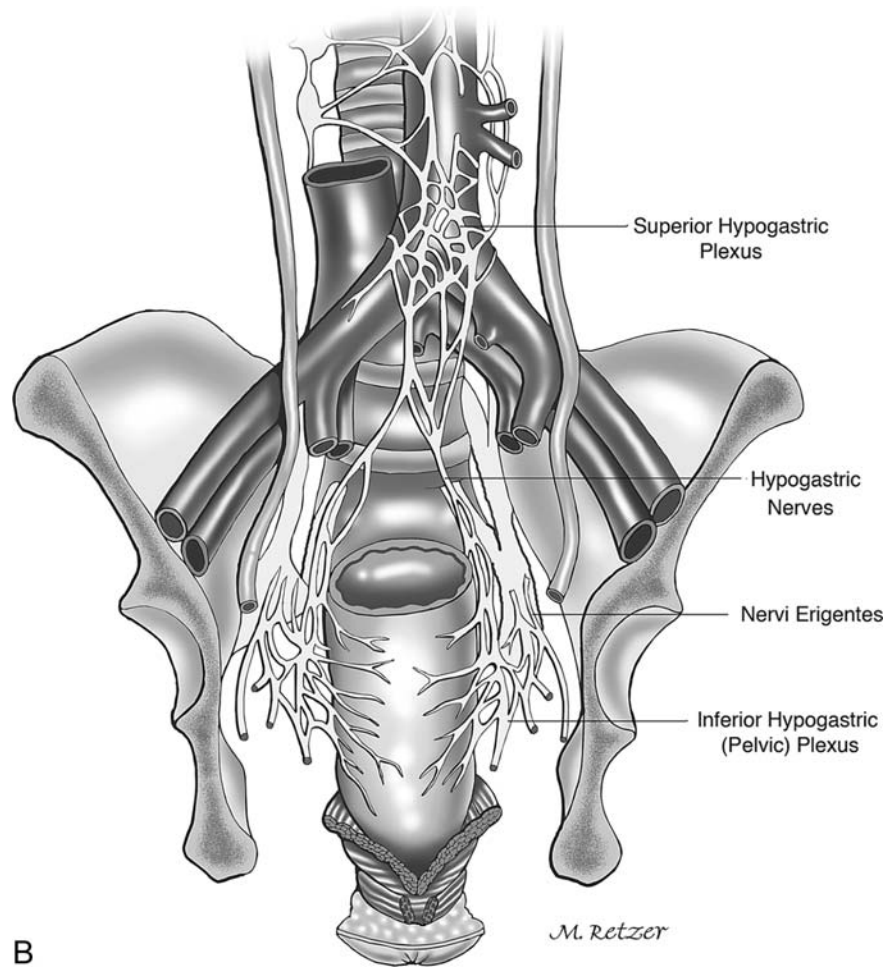

Anal sensation is carried in the inferior rectal branch of the pudendal nerve and is thought to have a role in maintenance of anal continence. The upper anal canal contains a rich profusion of both free and organized sensory nerve endings, especially in the vicinity of the anal valves.<sup>60</sup> Organized nerve endings include Meissner's corpuscles (touch), Krause's bulbs (cold), Golgi-Mazzoni bodies (pressure), and genital corpuscles (friction).

#### *Anorectal Spaces*

The potential spaces of clinical significance in close relation to the anal canal and rectum include: ischioanal, perianal, intersphincteric, submucosal, superficial postanal, deep postanal, supralelevator, and retrorectal spaces (Figure 1-5A and B).

The ischioanal fossa is subdivided by a thin horizontal fascia into two spaces: the perianal and ischioanal. The ischioanal space comprises the upper two-thirds of the ischioanal fossa. It is pyramid-shaped, situated on both sides between the anal canal and the lower part of the rectum medially, and the side wall of the pelvis laterally.<sup>61</sup> The apex is at the origin of the levator ani muscle from the obturator fascia; the base is the perianal space. Anteriorly, the fossa is bounded by the urogenital diaphragm and transversus perinei muscle. Posterior to the ischioanal fossa is the sacrotuberous ligament and the inferior border of the gluteus maximus. On the superolateral wall, the pudendal nerve and the internal pudendal vessels run in the pudendal canal (Alcock's canal). The ischioanal fossa contains fat and the inferior rectal vessels and nerves.

The perianal space surrounds the lower part of the anal canal and contains the external hemorrhoidal plexus, the subcutaneous part of the external anal sphincter, the lowest part of the internal anal sphincter, and fibers of the longitudinal muscle. This space is the typical site of anal hematomas,

FIGURE 1-4. **A, B** (Continued)

perianal abscesses, and anal fistula tracts. The perianal space is continuous with the subcutaneous fat of the buttocks laterally and extends into the intersphincteric space medially. The intersphincteric space is a potential space between the internal and external anal sphincters. It is important in the genesis of perianal abscess, because most of the anal glands end in this space. The submucous space is situated between the internal anal sphincter and the mucocutaneous lining of the anal canal. This space contains the internal hemorrhoidal plexus and the muscularis submucosae ani. Above, it is continuous with the submucous layer of the rectum, and, inferiorly, it ends at the level of the dentate line.

The superficial postanal space is interposed between the anococcygeal ligament and the skin. The deep postanal space, also known as the retro-sphincteric space of Courtney, is situated between the anococcygeal ligament and the anococcygeal raphe. Both postanal spaces communicate posteriorly with the ischioanal fossa and are the sites of horseshoe abscesses.

The supralelevator spaces are situated between the peritoneum superiorly and the levator ani inferiorly. Medially, these bilat-

eral spaces are limited by the rectum, and laterally by the obturator fascia. Supralelevator abscesses may occur as a result of upward extension of a cryptoglandular infection or develop from a pelvic origin. The retrorectal space is located between the fascia propria of the rectum anteriorly and the presacral fascia posteriorly. Laterally are the lateral rectal ligaments and inferiorly the rectosacral ligament, and above the space is continuous with the retroperitoneum. The retrorectal space is a site for embryologic remnants and rare presacral tumors.

#### *Pelvic floor musculature*

The muscles within the pelvis can be divided into three categories: 1) the anal sphincter complex; 2) pelvic floor muscles; and 3) muscles that line the sidewalls of the osseous pelvis.<sup>61</sup> Muscles in this last category form the external boundary of the pelvis and include the obturator internus and piriform. These muscles, compared with the other two groups, lack clinical relevance to anorectal diseases; however, they provide an open communication for pelvic infection to reach extrapelvic spaces. For example, infection from the deep

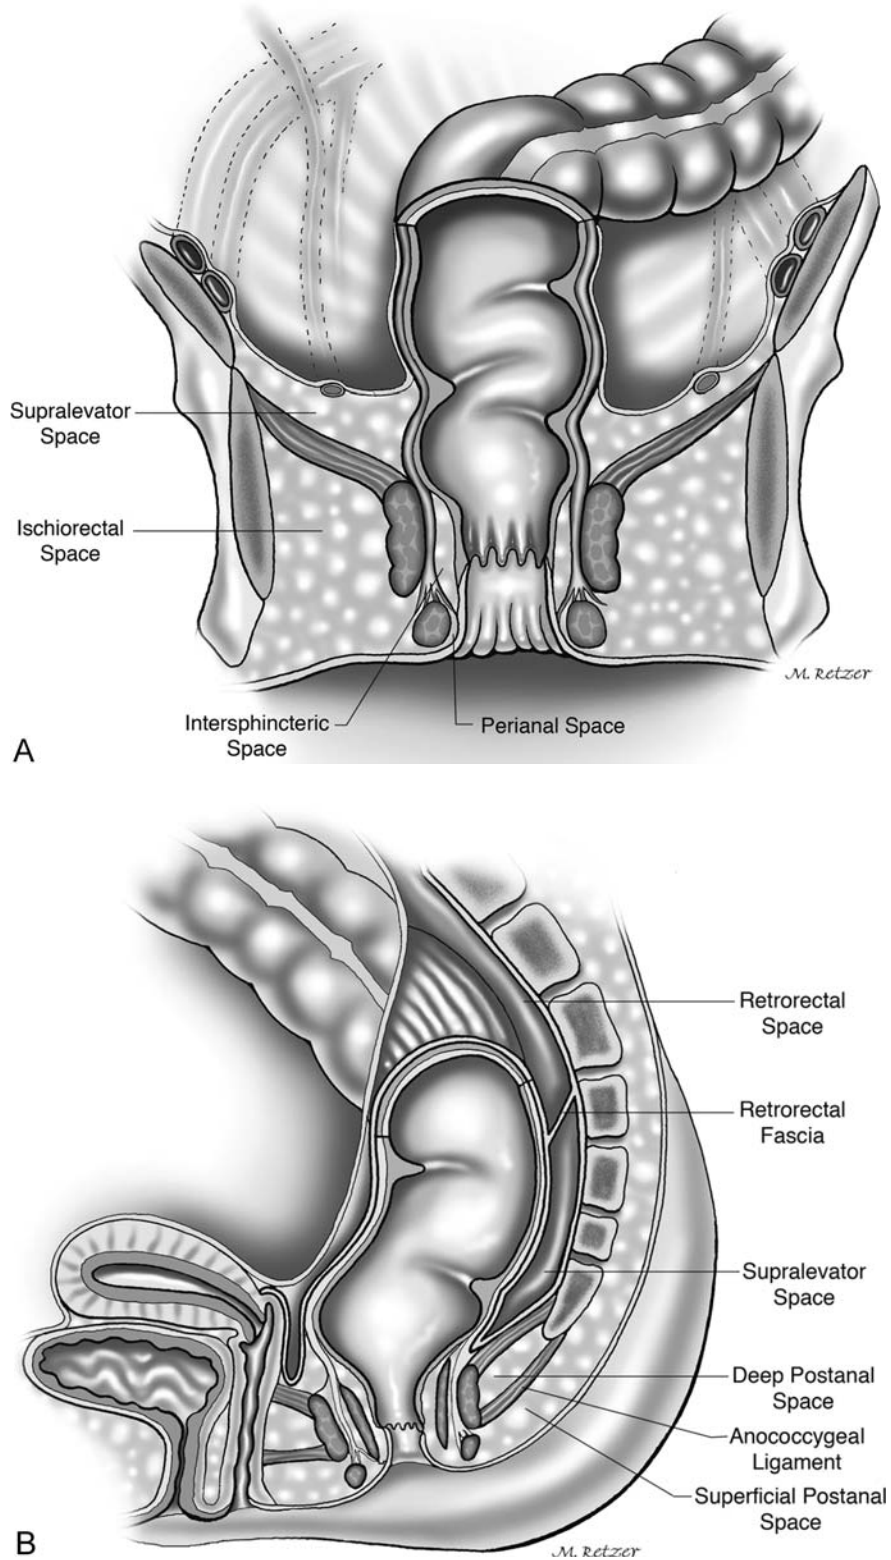

FIGURE 1-5. Para-anal and pararectal spaces. **A** Frontal view. **B** Lateral view.

postanal space, originated from posterior midline glands, can track along the obturator internus fascia and reach the ischioanal fossa.

The anal sphincter and pelvic floor muscles, based on phylogenetic studies, derive from two embryonic cloaca groups, respectively, sphincteric and lateral compressor.<sup>62</sup> The sphincteric group is present in almost all animals. In mammals, this group is divided into ventral (urogenital) and dorsal (anal) components.<sup>63</sup> In primates, the latter form the external anal sphincter. The lateral compressor or pelvicaudal group connects the rudimentary pelvis to the caudal end of the vertebral column. This group is more differentiated and subdivided into lateral and medial compartments only in reptiles and mammals. The homolog of the lateral compartment is the ischio-coccygeus, and of the medial, pelvicaudal compartment, the pubococcygeus and ileococcygeus. In addition, most primates possess a variably sized group of muscle fibers close to the inner border of the medial pelvicaudal muscle, which attaches the rectum to the pubis. In humans, the fibers are more distinct and known as the puborectalis muscle.

### *Levator Ani*

The levator ani muscle, or pelvic diaphragm, is the major component of the pelvic floor. It is a pair of broad, symmetric sheets composed of three striated muscles: ileococcygeus, pubococcygeus, and puborectalis (Figure 1-6A and B). A variable fourth component, the ischio-coccygeus or coccygeus, is rudimentary in humans and represented by only a few muscle fibers on the surface of the sacrospinous ligament. The levator ani is supplied by sacral roots on its pelvic surface (S-2, S-3, and S-4) and by the perineal branch of the pudendal nerve on its inferior surface. The puborectalis muscle receives additional innervation from the inferior rectal nerves.

The ileococcygeus muscles arise from the ischial spine and posterior part of the obturator fascia and course inferiorly and medially to insert into the lateral aspects of S-3 and S-4, the coccyx, and the anococcygeal raphe. The pubococcygeus arises from the posterior aspect of the pubis and the anterior part of the obturator fascia; it runs dorsally alongside the anorectal junction to decussate with fibers of the opposite side at the anococcygeal raphe and insert into the anterior surface of the fourth sacral and first coccygeal segments.

The pelvic floor is "incomplete" in the midline where the lower rectum, urethra, and either the dorsal vein of the penis in men, or the vagina in women, pass through it. This defect is called the levator hiatus and consists of an elliptic space situated between the two pubococcygeus muscles. The hiatal ligament, originating from the pelvic fascia, keeps the intrahiatal viscera together and prevents their constriction during contraction of the levator ani. A possible (but controversial) dilator function has been attributed to the anococcygeal raphe because of its crisscross arrangement.<sup>14</sup>

The puborectalis muscle is a strong, U-shaped loop of striated muscle that slings the anorectal junction to the posterior aspect of the pubis (Figure 1-7). The puborectalis is the most medial portion of the levator ani muscle. It is situated immediately cephalad to the deep component of the external sphincter. Because the junction between the two muscles is indistinct and they have similar innervation (pudendal nerve), the puborectalis has been regarded by some authors as a part of the external anal sphincter and not of the levator ani complex.<sup>14,15</sup> Anatomic and phylogenetic studies suggest that the puborectalis may be a part of the levator ani<sup>63</sup> or of the external anal sphincter.<sup>24,62</sup> Embryologically, the puborectalis has a common primordium with the ileococcygeus and pubococcygeus muscles, and it is never connected with the external anal sphincter during the different stages of development.<sup>6</sup> In addition, neurophysiologic studies have implied that the innervation of these muscles may not be the same, because stimulation of the sacral nerves results in electromyographic activity in the ipsilateral puborectalis muscle but not in the external anal sphincter.<sup>64</sup> Currently, because of this controversy, the puborectalis has been considered to belong to both muscular groups, the external anal sphincter and the levator ani.<sup>65</sup>

### *The Anorectal Ring and the Anorectal Angle*

Two anatomic structures of the junction of the rectum and anal canal are related to the puborectalis muscle: the anorectal ring and the anorectal angle. The anorectal ring, a term coined by Milligan and Morgan,<sup>10</sup> is a strong muscular ring that represents the upper end of the sphincter, more precisely the puborectalis, and the upper border of the internal anal sphincter, around the anorectal junction. Despite its lack of embryologic significance, it is an easily recognized boundary of the anal canal appreciated on physical examination, and it is of clinical relevance, because division of this structure during surgery for abscesses or fistula inevitably results in fecal incontinence.

The anorectal angle is thought to be the result of the anatomic configuration of the U-shaped sling of puborectalis muscle around the anorectal junction. Whereas the anal sphincters are responsible for closure of the anal canal to retain gas and liquid stool, the puborectalis muscle and the anorectal angle are designed to maintain gross fecal continence. Different theories have been postulated to explain the importance of the puborectalis and the anorectal angle in the maintenance of fecal continence. Parks et al.<sup>66</sup> opined that increasing intraabdominal pressure forces the anterior rectal wall down into the upper anal canal, occluding it by a type of flap valve mechanism that creates an effective seal. Subsequently, it has been demonstrated that the flap mechanism does not occur. Instead, a continuous sphincteric occlusion-like activity that is attributed to the puborectalis is noted.<sup>67,68</sup>

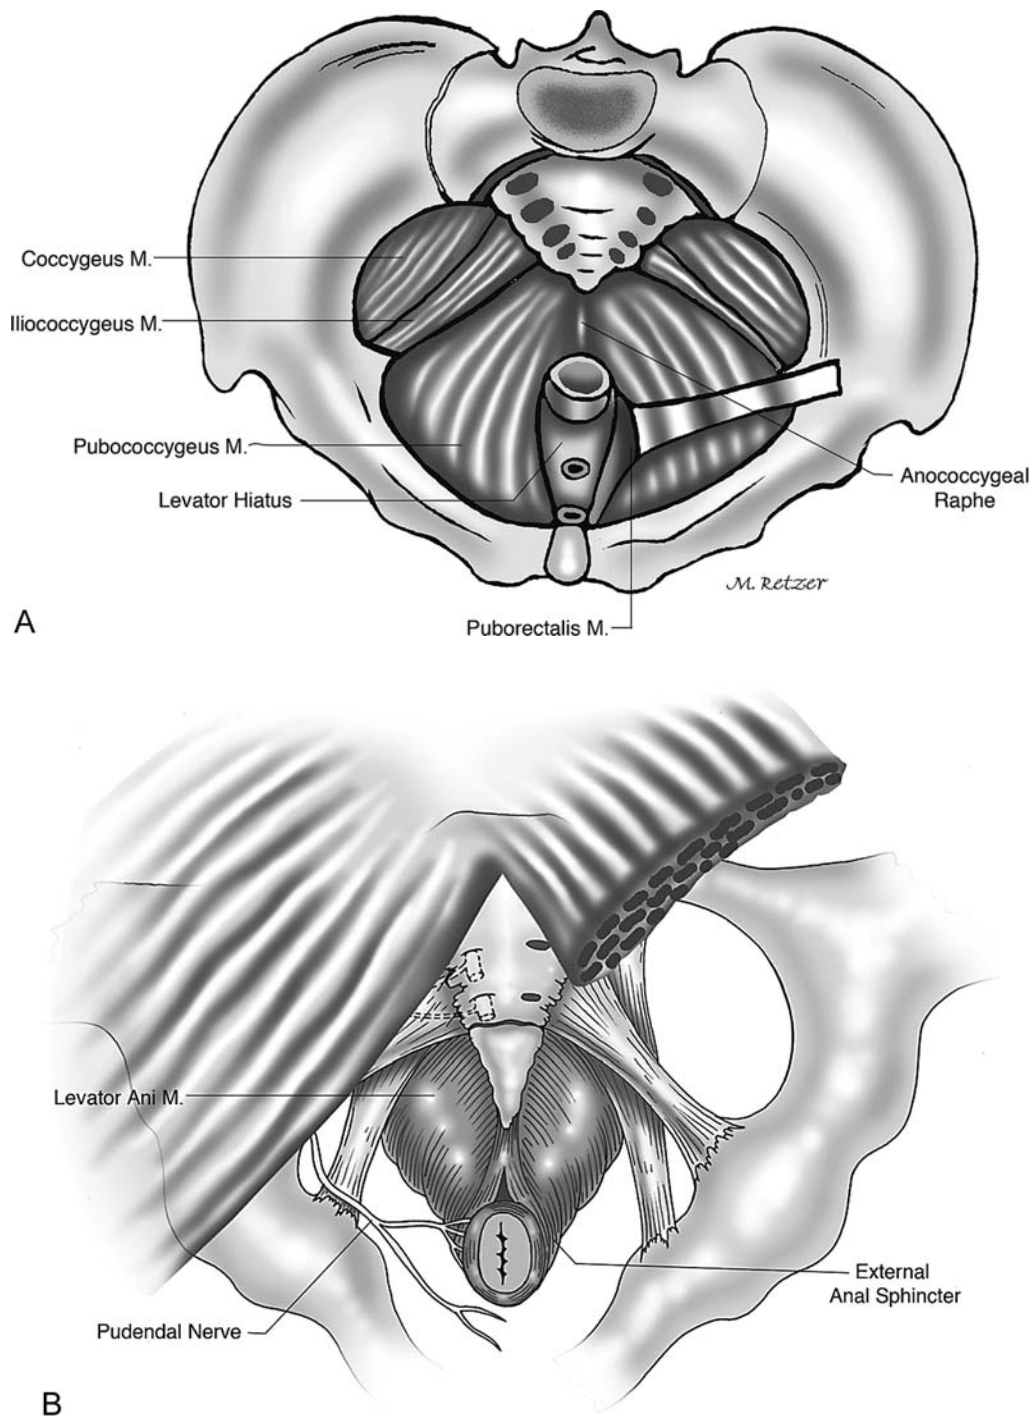

FIGURE 1-6. Levator ani muscle. **A** Superior. **B** Inferior surface.

## Colon

### *General Considerations*

The colon is a capacious tube that roughly surrounds the loops of small intestine as an arch. Named from the Greek *koluein* (“to retard”), the colon is variable in length, averaging

approximately 150 cm, which corresponds to one-quarter the length of the small intestine. Its diameter can be substantially augmented by distension, it gradually decreases from 7.5 cm at the cecum to 2.5 cm at the sigmoid. In humans, the colon is described to be somewhere between the short, straight type with a rudimentary cecum, such as that of the carnivores, and

FIGURE 1-7. The anteriorly directed pull of the puborectalis contributes to the angulation between the rectum and anal canal, the anorectal angle.

a long sacculated colon with a capacious cecum, such as that of the herbivores.

Anatomic differences between the small and large intestines include position, caliber, degree of fixation, and, in the colon, the presence of three distinct characteristics: the taeniae coli, the haustra, and the appendices epiploicae. The three taeniae coli, anterior (taenia libera), posteromedial (taenia mesocolica), and posterolateral (taenia omentalis), represent bands of the outer longitudinal coat of muscle that traverse the colon from the base of the appendix to the rectosigmoid junction, where they merge. The muscular longitudinal layer is actually a complete coat around the colon, although it is considerably thicker at the taeniae.<sup>69</sup> The haustra or haustral sacculations are outpouchings of bowel wall between the taeniae; they are caused by the relative shortness of the taeniae, about one-sixth shorter than the length of the bowel wall.<sup>13</sup> The haustra are separated by the plicae semilunares or crescentic folds of the bowel wall, which give the colon its characteristic radiographic appearance when filled with air or barium. The appendices epiploicae are small appendages of fat that protrude from the serosal aspect of the colon.

### Cecum

The cecum is the sacculated segment (Latin *caecus*, “blind”) of the large bowel that projects downward as a 6- to 8-cm

blind pouch below the entrance of the ileum. Usually situated in the right iliac fossa, the cecum is almost entirely, or at least in its lower half, invested with peritoneum. However, its mobility is usually limited by a small mesocecum. The ileum terminates in the posteromedial aspect of the cecum; the angulation between these two structures is maintained by the superior and inferior ileocecal ligaments. These ligaments, along with the mesentery of the appendix, form three pericecal recesses or fossae: superior ileocecal, inferior ileocecal, and retrocecal. Viewed from the cecal lumen, the ileocecal junction is represented by a narrow, transversely situated, slit-like opening known as the ileocecal valve or the valve de Bauhin. At either end, the two prominent semilunar lips of the valve fuse and continue as a single frenulum of mucosa. A circular sphincter, the ileocecal sphincter, originates from a slight thickening of the muscular layer of the terminal ileum. A competent ileocecal valve is related to the critical closed-loop type of colonic obstruction. However, ileocecal competence is not always demonstrated on barium enema studies. Instead of preventing reflux of colonic contents into the ileum, the ileocecal valve regulates ileal emptying. The ileocecal sphincter seems to relax in response to the entrance of food into the stomach.<sup>70</sup> As in the gastroesophageal junction, extrasphincteric factors such as the ileocecal angulation apparently have a role in the prevention of reflux from the colon to the ileum.<sup>71</sup>

## Appendix

The vermiform appendix is an elongated diverticulum that arises from the posteromedial aspect of the cecum about 3.0 cm below the ileocecal junction. Its length varies from 2 to 20 cm (mean, 8–10 cm), and it is approximately 5 mm in diameter. The appendix, because of its great mobility, may occupy a variety of positions, possibly at different times in the same individual. It has been estimated that in 85% to 95% of cases, the appendix lies posteromedial on the cecum toward the ileum, but other positions include retrocecal, pelvic, subcecal, pre-ileal and retroileal.<sup>72–74</sup> The confluence of the three taeniae is a useful guide in locating the base of the appendix. The mesoappendix, a triangular fold attached to the posterior leaf of the mesentery of the terminal ileum, usually contains the appendicular vessels close to its free edge.

### Ascending Colon

The ascending colon is approximately 15 cm long. It ascends, from the level of the ileocecal junction to the right colic or hepatic flexure, laterally to the psoas muscle and anteriorly to the iliopsoas, the quadratus lumborum, and the lower pole of the right kidney. The ascending colon is covered with peritoneum anteriorly and on both sides. In addition, fragile adhesions between the right abdominal wall and its anterior aspect, known as Jackson's membrane, may be present. Like the descending colon on its posterior surface, the ascending colon is devoid of peritoneum, which is instead replaced by an areolar tissue (fascia of Toldt) resulting from an embryologic process of fusion or coalescence of the mesentery to the posterior parietal peritoneum. In the lateral peritoneal reflection, this process is represented by the white line of Toldt, which is more evident at the descending-sigmoid junction. This line serves as a guide for the surgeon when the ascending, descending, or sigmoid colon is mobilized. At the visceral surface of the right lobe of the liver and lateral to the gallbladder, the ascending colon turns sharply medially and slightly caudad and ventrally to form the right colic (hepatic) flexure. This flexure is supported by the nephrocolic ligament and lies immediately ventral to the lower part of the right kidney and over the descending duodenum.

### Transverse Colon

The transverse colon is approximately 45 cm long, the longest segment of the large bowel. It crosses the abdomen, with an inferior curve immediately caudad to the greater curvature of the stomach. The transverse colon is relatively fixed at each flexure, and, in between, it is suspended by a 10- to 15-cm-wide area which provides variable mobility; the nadir of the transverse colon may reach the hypogastrium. The transverse colon is completely invested with peritoneum, but the greater omentum is fused on its anterosuperior aspect. The left colic or splenic flexure is situated beneath the lower

angle of the spleen and firmly attached to the diaphragm by the phrenocolic ligament, which also forms a shelf to support the spleen. Because of the risk for hemorrhage, mobilization of the splenic flexure should be approached with great care, preceded by dissection upward along the descending colon and medially to laterally along the transverse colon toward the splenic flexure. This flexure, when compared with the hepatic flexure, is more acute, higher, and more deeply situated.

### Descending Colon

The descending colon courses downward from the splenic flexure to the brim of the true pelvis, a distance of approximately 25 cm.<sup>32</sup> Similarly to the ascending colon, the descending colon is covered by peritoneum only on its anterior and lateral aspects. Posteriorly, it rests directly against the left kidney and the quadratus lumborum and transversus abdominis muscles. However, the descending colon is narrower and more dorsally situated than the ascending colon.

### Sigmoid Colon

The sigmoid colon is commonly a 35- to 40-cm-long, mobile, omega-shaped loop completely invested by peritoneum; however, it varies greatly in length and configuration. The mesosigmoid is attached to the pelvic walls in an inverted V shape, resting in a recess known as the intersigmoid fossa. The left ureter lies immediately underneath this fossa and is crossed on its anterior surface by the spermatic, left colic, and sigmoid vessels. Both the anatomy and function of the rectosigmoid junction have been matters of substantial controversy. As early as 1833, it was postulated that the sigmoid could have a role in continence as the fecal reservoir, based on the observation that the rectum is usually emptied and contracted.<sup>74</sup> Since then, a thickening of the circular muscular layer between the rectum and sigmoid has been described and diversely termed the sphincter ani tertius, rectosigmoid sphincter, and pylorus sigmoidorectalis, and it has probably been mistaken for one of the transverse folds of the rectum.<sup>75–79</sup> The rectosigmoid junction has been frequently regarded by surgeons as an indistinct zone, a region comprising the last 5–8 cm of sigmoid and the uppermost 5 cm of the rectum.<sup>32,80</sup> However, others have considered it a clearly defined segment, because it is the narrowest portion of the large intestine; in fact, it is usually characterized endoscopically as a narrow and sharply angulated segment.<sup>81</sup> According to a study in human cadavers, the rectosigmoid junction, macroscopically identified as the point where the taenia libera and the taenia omentalis fuse to form a single anterior taenia and where both haustra and mesocolon terminate, is situated 6–7 cm below the sacral promontory.<sup>5</sup> With microdissection, this segment is characterized by conspicuous strands of longitudinal muscle fibers and the presence of curved interconnecting fibers between the longitudinal and circular muscle

layers, resulting in a delicate syncytium of smooth muscle that allows synergistic interplay between the two layers. The rectosigmoid does not fit the anatomic definition of a sphincter as “a band of thickened circular muscle that closes the lumen by contraction and of a longitudinal muscle that dilates it”; however, this segment may be regarded as a functional sphincter because mechanisms of active dilation and passive “kinking” occlusion do exist.<sup>81</sup>

### *Blood Supply*

The superior and inferior mesenteric arteries nourish the entire large intestine, and the limit between the two territories is the junction between the proximal two-thirds and the distal third of the transverse colon. This represents the embryologic division between the midgut and the hindgut. The superior mesenteric artery originates from the aorta behind the superior border of the pancreas at L-1 and supplies the cecum, appendix, ascending colon, and most of the transverse colon. After passing behind the neck of the pancreas and anteromedial to the uncinate process, the superior mesenteric artery crosses the third part of the duodenum and continues downward and to the right along the base of the mesentery. From its left side arises a series of 12–20 jejunal and ileal branches. From its right side arises the colic branches: middle, right, and ileocolic arteries. The ileocolic, the most constant of these vessels, bifurcates into a superior or ascending branch, which communicates with the descending branch of the right colic artery, and an inferior or descending branch, which gives off the anterior cecal, posterior cecal, and appendicular and ileal divisions.<sup>82</sup> The right colic artery may also arise from the ileocolic or middle colic arteries and is absent in 2% to 18% of specimens.<sup>45,82,83</sup> It supplies the ascending colon and hepatic flexure through its ascending and descending branches, both of them joining with neighboring vessels to contribute to the marginal artery. The middle colic artery is the highest of the three colic branches of the superior mesenteric artery, arising close to the inferior border of the pancreas. Its right branch supplies the right transverse colon and hepatic flexure, anastomosing with the ascending branch of the right colic artery. Its left branch supplies the distal half of the transverse colon. Anatomic variations of this artery include absence in 4% to 20% of cases and the presence of an accessory middle colic artery in 10%; the middle colic artery can be the main supply to the splenic flexure in about 33% of cases.<sup>82,84</sup>

The inferior mesenteric artery originates from the left anterior surface of the aorta, 3–4 cm above its bifurcation at the level of L2-3, and runs downward and to the left to enter the pelvis. Within the abdomen, the inferior mesenteric artery branches into the left colic artery and two to six sigmoidal arteries. After crossing the left common iliac artery, it acquires the name superior hemorrhoidal artery (superior rectal artery). The left colic artery, the highest branch of the inferior mesenteric artery, bifurcates into an ascending branch, which runs upward to the splenic flexure to contribute to the arcade of

Riolan, and a descending branch, which supplies most of the descending colon. The sigmoidal arteries form arcades within the sigmoid mesocolon, resembling the small-bowel vasculature, and anastomose with branches of the left colic artery proximally, and with the superior hemorrhoidal artery distally. The marginal artery terminates within the arcade of sigmoidal arteries. The superior hemorrhoidal artery is the continuation of the inferior mesenteric artery, once it crosses the left iliac vessels. The artery descends in the sigmoid mesocolon to the level of S-3 and then to the posterior aspect of the rectum. In 80% of cases, it bifurcates into right and left terminal branches; multiple branches are present in 17%.<sup>45</sup> These divisions, once within the submucosa of the rectum, run straight downward to supply the lower rectum and the anal canal.

The venous drainage of the large intestine basically follows its arterial supply. Blood from the right colon, via the superior mesenteric vein, and from left colon and rectum, via the inferior mesenteric vein, reaches the intrahepatic capillary bed through the portal vein.

### *Collateral Circulation*

The anatomy of the mesenteric circulation is still a matter of controversy, and this may in part be related to the inherent confusion of the use of eponyms. The central anastomotic artery connecting all colonic mesenteric branches, first described by Haller<sup>85</sup> in 1786, later became known as the marginal artery of Drummond, because this author was the first to demonstrate its surgical significance (1913).<sup>86,87</sup> Subsequently, discontinuity of the marginal artery has been shown at the lower ascending colon, and especially at the left colic flexure and the sigmoid colon. This potential hypovascularity is a source of concern during colonic resection. The splenic flexure comprises the watershed between midgut and hindgut supplies (Griffiths' critical point); this anastomosis is of variable magnitude, and it may be absent in about 50% of cases.<sup>88</sup> For this reason, ischemic colitis usually affects or is most severe near the splenic flexure.<sup>89,90</sup> Another potential area of discontinuity of the marginal artery is the Sudeck's critical point, situated between the lowest sigmoid and the superior hemorrhoidal arteries; however, surgical experience and radiological studies have both demonstrated adequate communications between these vessels.<sup>91</sup> There is also a collateral network involving middle hemorrhoidal, internal iliac, and external iliac arteries which could potentially prevent gangrene of the pelvis and even the lower extremities in case of occlusion of the distal aorta.<sup>92,93</sup>

The term arc of Riolan was vaguely defined as the communication between superior and inferior mesenteric arteries in the author's original work. Later, the eponym marginal artery of Drummond confused the subject.<sup>94</sup> In 1964, Moskowitz et al.<sup>95</sup> proposed another term, meandering mesenteric artery, and differentiated it from the marginal artery of Drummond. The meandering mesenteric artery is a thick and tortuous vessel that makes a crucial communication between the middle

colic artery and the ascending branch of the left colic artery, especially in advanced atherosclerotic disease.<sup>94</sup> The presence of the meandering mesenteric artery indicates severe stenosis of either the superior mesenteric artery (retrograde flow) or inferior mesenteric artery (antegrade flow).

### *Lymphatic Drainage*

The submucous and subserous layers of the colon and rectum have a rich network of lymphatic plexuses, which drain into an extramural system of lymph channels and follow their vascular supply.<sup>50</sup> Colorectal lymph nodes are classically divided into four groups: epiploic, paracolic, intermediate, and principal.<sup>96</sup> The epiploic group lies on the bowel wall under the peritoneum and in the appendices epiploicae; they are more numerous in the sigmoid and are known in the rectum as the nodules of Gerota. The lymphatic drainage from all parts of the colon follows its vascular supply. The paracolic nodes are situated along the marginal artery and on the arcades; they are considered to have the most numerous filters. The intermediate nodes are situated on the primary colic vessels, and the main or principal nodes on the superior and inferior mesenteric vessels. The lymph then drains to the cisterna chyli via the paraaortic chain of nodes. Colorectal carcinoma staging systems are based on the neoplastic involvement of these various lymph node groups.

### *Innervation*

The sympathetic and parasympathetic components of the autonomic innervation of the large intestine closely follow the blood supply. The sympathetic supply of the right colon originates from the lower six thoracic segments. These thoracic splanchnic nerves reach the celiac, preaortic, and superior mesenteric ganglia, where they synapse. The postganglionic fibers then course along the superior mesenteric artery to the small bowel and right colon. The parasympathetic supply comes from the right (posterior) vagus nerve and celiac plexus. The fibers travel along the superior mesenteric artery, and finally synapse with cells in the autonomic plexuses within the bowel wall. The sympathetic supply of the left colon and rectum arises from L-1, L-2, and L-3. Preganglionic fibers, via lumbar sympathetic nerves, synapse in the preaortic plexus, and the postganglionic fibers follow the branches of the inferior mesenteric artery and superior rectal artery to the left colon and upper rectum.

## Embryology

### Anus and Rectum

The distal colon, rectum, and the anal canal above the dentate line are all derived from the hindgut. Therefore, this segment is supplied by the hindgut (inferior mesenteric) artery, with corresponding venous and lymphatic drainage. Its parasympathetic

outflow comes from S-2, S-3, and S-4 via splanchnic nerves.

The dentate line marks the fusion between endodermal and ectodermal tubes, where the terminal portion of the hindgut or cloaca fuses with the proctodeum, an ingrowth from the anal pit. The cloaca originates at the portion of the rectum below the pubococcygeal line, whereas the hindgut originates above it.

Before the fifth week of development, the intestinal and urogenital tracts terminate in conjunction with the cloaca. During the sixth to eighth weeks of fetal life, the urorectal septum or fold of Tourneux migrates caudally and divides the cloacal closing plate into an anterior urogenital plate and a posterior anal plate (Figure 1-8). Any slight posterior shift in the position of the septum during its descent will reduce the size of the anal opening, giving rise to anorectal defects.

The cloacal part of the anal canal, which has both endodermal and ectodermal elements, forms the anal transitional zone after breakdown of the anal membrane.<sup>73</sup> During the 10th week, the anal tubercles, a pair of ectodermal swellings around the proctodeal pit, fuse dorsally to form a horseshoe-shaped structure and anteriorly to create the perineal body. The cloacal sphincter is separated by the perineal body into urogenital and anal portions (external anal sphincter). The internal anal sphincter is formed later (6th to 12th week) from enlarging fibers of the circular layer of the rectum.<sup>6,97</sup>

In the female, the fused Müllerian ducts that will form the uterus and vagina move downward to reach the urogenital sinus about the sixteenth week. In the male, the site of the urogenital membrane will be obliterated by fusion of the genital folds and the sinus will become incorporated into the urethra. The sphincters apparently migrate during their development; the external sphincter grows cephalad and the internal sphincter moves caudally. Concomitantly, the longitudinal muscle descends into the intersphincteric plane.<sup>6</sup>

### Anorectal Malformations

The anorectal malformations can be traced to developmental arrest at various stages of normal maturation. The Duhamel's theory of "syndrome of caudal regression" is supported by the high incidence of spinal, sacral, and lower limb defects associated with these anomalies.<sup>98</sup> In fact, associated anomalies, most frequently skeleton and urinary defects, may occur in up to 70%.<sup>99</sup> Digestive tract, particularly tracheoesophageal fistula or esophageal stenosis, cardiac, and abdominal wall defects may also occur in patients with anorectal anomalies. There is evidence for familial occurrence of anorectal defects; the estimated risk in a family of a second occurrence of some form of imperforate anus is up to 50 times the normal chance.<sup>100</sup>

The proposed classification systems for the congenital malformations of the anorectal region are usually either incomplete or complex. The most comprehensive system has been proposed by Gough<sup>101</sup> and Santulli,<sup>102</sup> and takes into consideration whether the rectum terminates above (anorectal defects) or below (anal defects) the puborectalis sling (Table 1-1).

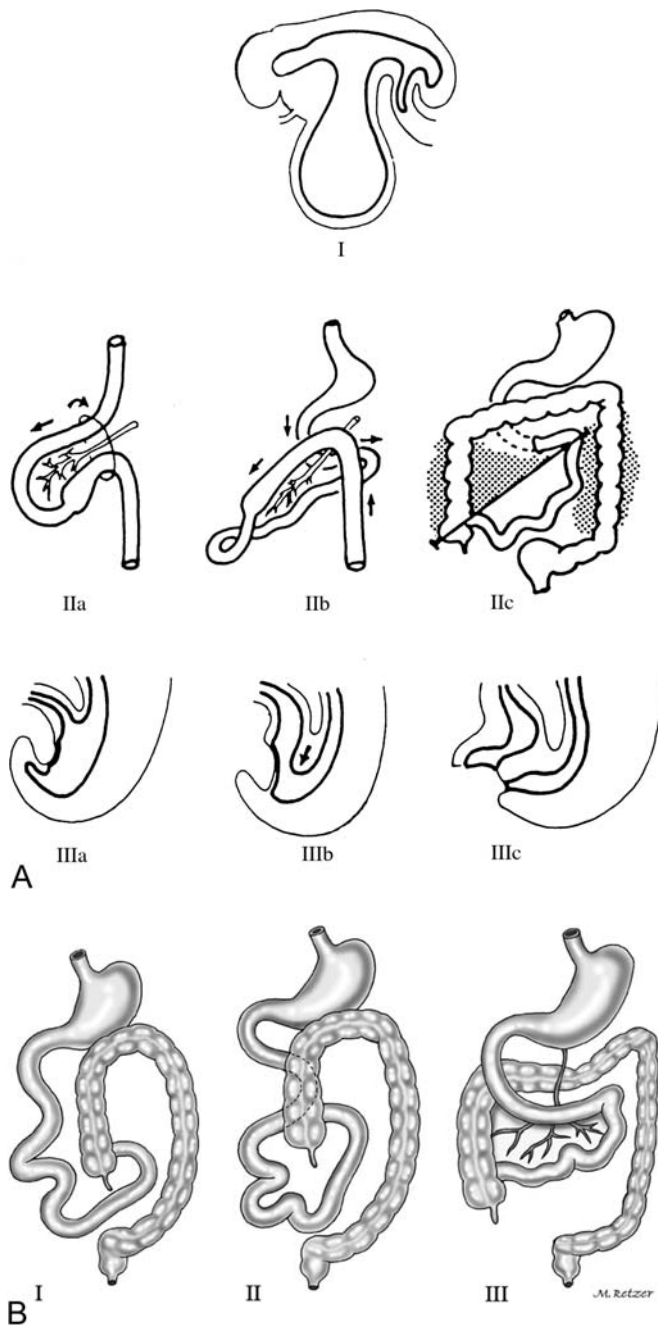

FIGURE 1-8. **A** Embryology of the large intestine. I. Sagittal section of early embryo with the primitive tube at the third week of development. II. Normal development of intestine. IIa: Midgut loop within the umbilical cord (physiologic herniation); IIb: midgut rotation and return to the abdomen; IIc: rotation complete with wide retroperitoneal fixation of small bowel mesentery as well as ascending and descending colon. III. Development of the anus and rectum. IIIa: The hindgut, tailgut, and the allantois form the cloaca; IIIb: at the sixth week, the urogenital septum grows to separate the hindgut posteriorly and the allantois anteriorly; IIIc: the rectum with the persistent anal membrane has been separated from the urogenital structures. **B** Malformations of the digestive systems. I, Nonrotation; II, incomplete rotation; III, reversed rotation.

TABLE 1-1. Classification of anorectal malformations

A. Anal defects (“low” defects)
1. Anal stenosis
2. Membranous atresia (rare)
3. Anal agenesis
a. Without fistula
b. With fistula (ectopic anus)
B. Anorectal defects (“high” defects)
1. Anorectal agenesis
a. Without fistula
b. With fistula
2. Rectal atresia (“high” atresia)
C. Persistent cloaca
1. Rectal duplication
2. Developmental cysts

**Anal Defects**

*Anal Stenosis*

Some degree of stricture of the rectum is present in 25% to 39% of infants, and only about 25% of these will show some degree of disordered evacuation, but spontaneous dilation occurs between 3 and 6 months of age in the vast majority of patients.<sup>103</sup> Although stenosis has been attributed to excessive fusion of the anal tubercles, probably the cause is a posterior shift in the position of the urorectal septum during its descent at the sixth week of fetal life.<sup>101</sup>

*Membranous Atresia*

This defect, also known as “covered anus” is very rare. It is characterized by presence of a thin membrane of skin between the blind end of the anal canal and the surface. Most cases occur in males and probably represent excessive posterior closure of the urogenital folds.<sup>101</sup>

*Anal Agenesis*

The rectum extends below the puborectalis and ends, either blindly, or more often, in an ectopic opening or fistula to the perineum anteriorly, to the vulva, or urethra. Regardless of the location of the ectopic orifice, the sphincter is present at the normal site.

**Anorectal Defects**

*Anorectal Agenesis*

Anorectal agenesis more often affects males and represents the most common type of “imperforate anus.” The rectum ends well above the surface, the anus is represented by a dimple, and the anal sphincter is usually normal. This malformation is the result of excessive obliteration of the embryonic tailgut and the adjacent dorsal portion of the cloaca. The descending urorectal septum reaches the dorsal wall of the diminished cloaca, leaving a blindly ending colon above and an isolated rectal membrane below.

In most cases, there is a fistula or fibrous remnant connecting the rectal ending to the urethra or vagina. Fistulae represent areas in the septum where the lateral ridges have joined but failed to unite, although the more caudal union is complete. High fistulae, vaginal and urethral, with anorectal agenesis originate as early as the sixth or seventh week, whereas low fistulae (perineal) of anal ectopia originate in the eighth or ninth week of fetal life.

### *Rectal Atresia or "High Atresia"*

Although considered clinically as an anorectal defect, embryologically this is the most caudal type of atresia of the large intestine. The rectum and anal canal are separated from each other by an atretic portion.

### *Persistent Cloaca*

This is a rare condition that occurs only in female infants. It results from the total failure of the urorectal septum to descend, and therefore occurs at a very early stage of development (10-mm stage).

## Colon and Small Bowel

The primitive gut tube develops from the endodermal roof of the yolk sac. At first, the primitive intestine is a straight tube suspended in a sagittal plane on a common mesentery. At the beginning of the third week of development, it can be divided into three regions: the foregut in the head fold, the hindgut with its ventral allantoic outgrowth in the smaller tail fold, and, between these two portions, the midgut, which at this stage opens ventrally into the yolk sac (Figure 1-8). The normal embryologic process of rotation of the intestinal tract includes three stages, as outlined below.

### *First Stage: Physiologic Herniation of the Primitive Digestive Tube*

The first stage of rotation begins between the sixth and eighth weeks of intrauterine life, when the primitive intestinal tube elongates on its mesenteric around the superior mesenteric artery and bulges through the umbilical cord as a temporary physiologic herniation. This intraumbilical loop moves, at the eighth week of embryologic development, counterclockwise 90° from the sagittal to the horizontal plane. The anomalies of this stage are rare and include situs inversus, inverted duodenum, and extroversion of the cloaca.

### *Second Stage: Return of the Midgut to the Abdomen*

The second stage of gut rotation occurs at the 10th week of intrauterine life. During this stage, the midgut loop returns to the peritoneal cavity from the umbilical herniation, and simultaneously rotates 180° counterclockwise around the pedicle formed by the mesenteric root. The prearterial segment of the midgut or duodenojejunal loop returns first to the abdomen,

as the gut rotates counterclockwise. The duodenum comes to lie behind the superior mesenteric artery. The postarterial segment or cecocolic loop also reduces and comes to lie in front of the superior mesenteric artery. Anomalies of the second stage are relatively more common than the ones originated from the first stage and include nonrotation, malrotation, reversed rotation, internal hernia, and omphalocele.

### *Third Stage: Fixation of the Midgut*

The third stage of gut rotation starts after return of the gut to the peritoneal cavity and ends at birth. The cecum, initially in the upper abdomen, descends, migrating to the right lower quadrant, as counterclockwise rotation continues to 270°. After completion of the sequential rotation of the gastrointestinal tract, in the latter weeks of the first trimester, the process of fixation initiates. Gradually, fusion of parts of the primitive mesentery occurs, with fixation of the duodenum, and the ascending and descending parts of the colon to the posterior abdominal wall in their final position. Anomalies of this stage are common and include mobile cecum, subhepatic or undescended cecum, hyperdescent of the cecum, and persistent colonic mesentery.

The midgut progresses below the major pancreatic papilla to form the small intestine, the ascending colon, and the proximal two-thirds of the transverse colon. This segment is supplied by the midgut (superior mesenteric) artery, with corresponding venous and lymphatic drainage.

The neuroenteric ganglion cells migrate from the neural crest to the upper end of the alimentary tract and then follow vagal fibers caudad. The sympathetic innervation of the midgut and likewise the hindgut originates from T-8 to L-2, via splanchnic nerves and the autonomic abdominopelvic plexuses. The parasympathetic outflow to the midgut is derived from the 10th cranial nerve (vagus) with preganglionic cell bodies in the brain stem.

The distal colon (distal third of the transverse colon), the rectum, and the anal canal above the dentate line are all derived from the hindgut. Therefore, this segment is supplied by the hindgut (inferior mesenteric) artery, with corresponding venous and lymphatic drainage. Its parasympathetic outflow comes from S-2, S-3, and S-4 via splanchnic nerves.

## Abnormalities of Rotation

### *Nonrotation*

In this condition, the midgut loop returns to the peritoneal cavity without the process of rotation, and, consequently, the entire small bowel locates on the right side of the abdomen, and the left colon is on the left side. This condition may be entirely asymptomatic and constitute a finding at laparotomies. However, it may complicate with volvulus affecting the entire small bowel. The twist of the entire midgut loop on its pedicle can occur, usually at the level of the duodenojejunal junction and the midtransverse colon, because of the defective fixation of the mesenteric root.

### *Malrotation*

In malrotation, the cecum fails to complete the 360° rotation around the superior mesenteric, and does not complete the migration process. As a result of this failure in the migration process, the malrotated cecum locates in the right upper quadrant and is fixed by lateral bands or adhesions. These bands can overlie the distal part of the duodenum and cause extrinsic compression.

### *Reversed Rotation*

In this condition, the midgut rotates clockwise instead of counterclockwise; consequently, the transverse colon locates posteriorly and the duodenum anteriorly, in relation to the mesenteric artery.

### *Omphalocele*

Omphalocele is the retention of the midgut in the umbilical sac as a result of failure of the gut to return to the peritoneal cavity.

### *Incomplete Attachment of Cecum and Mesentery*

In normal conditions, the cecum is almost entirely, or at least in its lower half, invested with peritoneum. However, its mobility is usually limited by a small mesocecum. In approximately 5% of individuals, the peritoneal covering is absent posteriorly; it then rests directly on the iliacus and psoas major muscles.<sup>32</sup> Alternatively, an abnormally mobile cecum-ascending colon, resulting from an anomaly of fixation, can be found in 10% to 22% of individuals.<sup>104</sup> In this case, a long mesentery is present, and the cecum may assume varied positions. This lack of fixation may predispose to the development of volvulus.

### *Internal Hernias Around Ligament of Treitz*

Both internal hernias and congenital obstructive bands or adhesions are causes of congenital bowel obstruction, and result from an anomaly during the process of fixation. This failure may occur when the fusion of mesothelial layers is incomplete or if it occurs between structures that are abnormally rotated. Retroperitoneal hernias can occur in any intraperitoneal fossae, particularly paraduodenal, paracecal, and intersigmoid. The most common internal hernias resulting from abnormal fixation of the colon are right and left paraduodenal hernias.<sup>103</sup>

## Other Congenital Malformations of the Colon and Small Intestine

### *Proximal Colon Duplications*

Duplication of the colon comprises three general groups of congenital abnormalities: mesenteric cysts, diverticula, and long colon duplication.<sup>105</sup>

Mesenteric cysts, similarly to the duplication cysts found at the retroperitoneum and the mediastinum, are lined by intes-

tinal epithelium and a variable amount of smooth muscle. These cysts lie in the mesentery of the colon or behind the rectum, may be separable or inseparable from the bowel wall, and usually present, as the size increases, either as a palpable mass or intestinal obstruction. Diverticula are blind ending pouches of variable lengths and arise either from the mesenteric or the antimesenteric border of the bowel. They may have heterotopic gastric mucosa or pancreatic-type tissue. Long colon duplication or tubular duplication of the colon is the rarest form of duplication. Almost invariably, the two parts lie parallel, sharing a common wall throughout most of their length; frequently it involves the entire colon and rectum. Often, there is an association of pelvic genitourinary anomalies.

### *Meckel's Diverticulum*

Meckel's diverticulum is a remnant of the vitelline or omphalomesenteric duct, arising from the antimesenteric border of the terminal ileum, usually within 50 cm of the ileocecal valve.<sup>73</sup> Associated abnormalities include persistence of a fibrous band connecting the diverticulum to the umbilicus or a patent omphalomesenteric duct, presence of ectopic mucosa or aberrant pancreatic tissue (in more than half of asymptomatic diverticula), and herniation of the diverticulum in an indirect inguinal hernia (Littre's hernia).

In most people, Meckel's diverticulum is asymptomatic, and according to autopsy series, it exists in 1% to 3% of the general population.<sup>106</sup> Surgical complications are more frequent in infants and children and include hemorrhage from ectopic gastric mucosa, intestinal obstruction resulting from associated congenital bands or ileocolic intussusception, diverticulitis, perforation, and umbilical discharge from a patent omphalomesenteric duct.

### *Atresia of the Colon*

Colonic atresia is a rare cause of intestinal obstruction; it represents only 5% of all forms of gastrointestinal atresia. It is probably caused by a vascular accident occurring during intrauterine life.<sup>104</sup> Colonic atresia can be classified in three basic types: 1) incomplete occlusion of the lumen by a membranous diaphragm; 2) proximal end distal colonic segments that end blindly and are joined by a cord-like remnant of the bowel; and 3) complete separation of the proximal anal distal blind segments with absence of a segment of megacolon.<sup>107</sup> Colonic atresia may be variable in length and can occur at any site in the colon, and its association with Hirschsprung's disease has been reported.<sup>104</sup>

### *Hirschsprung's Disease*

Congenital megacolon is one of the most distressing of non-lethal anomalies, and was promptly attached to Hirschsprung's name after his description of autopsies of two infants who died from this condition in 1888.<sup>108</sup> However, it was recognized as early as 1825 in adults, and, in 1829, in infants.<sup>109</sup> This disease results from the absence of ganglion cells in the myenteric

plexus of the colon caused by interruption of migration of neuroenteric cells from the neural crest before they reach the rectum. The physiologic obstruction, more insidious than an anatomic atresia, results in proximal dilation and hypertrophy of the colon above. The extent of the aganglionosis is variable. The internal anal sphincter is involved in all cases, and the entire rectum in most cases. The disease is more common in males and its severity is related to the length of the aganglionic segment. Although most patients reach surgery before they are a year old, many are older, and a few reach adulthood.

## Physiology: Colonic

Tracy L. Hull

The human colon is a dynamic organ that performs many functions including absorption of water and electrolytes, salvage of nutrients not absorbed in the small intestine, and transport of luminal contents. It is not an essential organ because life can be sustained after its removal. However, it has a major role in maintaining the health of the human body. Understanding the physiologic principles of its function is essential when treating diseases affecting it—both surgically and medically.

### Embryology

To understand the colon, embryology is an important starting point. The midgut begins just distal to the entrance of the bile duct into the duodenum and ends at the junction of the proximal two-thirds of the transverse colon with its distal one-third. Over the entire length, the midgut is supplied by the superior mesenteric artery. The distal third of the transverse colon, the descending colon, the sigmoid, the rectum, and the upper part of the anal canal are derived from the hindgut. The inferior mesenteric artery supplies the hindgut.<sup>1</sup>

The epithelial lining (mucosa) is derived from endodermal tissue. The muscular and peritoneal components are of mesodermal origin surrounding the endoderm.<sup>1</sup> The primitive intestinal loops normally rotate 270 degrees counterclockwise around an axis formed by the superior mesenteric artery. Bowel loops are herniated outside the abdominal cavity. At the end of the third month, the loops return into the abdominal cavity and complete the rotation. The cecum normally rotates down to the right lower quadrant when the process is complete. The appendix begins as a bulge on the cecum at about the sixth week of intrauterine life. As the cecum grows, this bulge lags behind the elongation of the remaining portion of the cecum, forming the appendix.<sup>2</sup>

### Innervation

The innervation to the colon comes from two sources—one from outside (extrinsic) and the other inside (intrinsic). The

extrinsic component comes from the autonomic nervous system and affects both motor and sensory functions. Parasympathetic fibers reach the proximal colon through the posterior vagal trunk running with the arterial blood supply (along the ileocolic and middle colic branches of the superior mesenteric artery). The distal colon receives parasympathetic fibers from the sacral parasympathetic nerves (S2-4) through the pelvic plexus. These pelvic splanchnic (splanchnic means visceral) nerves give off discrete branches, which run under the peritoneum and into the sigmoid mesocolon toward the left colonic flexure.<sup>3</sup> The parasympathetic nerves are predominantly excitatory for the colon's motor component via the neurotransmitter acetylcholine and tachykinins, such as substance P. The parasympathetic nerves also convey visceral sensory function.<sup>4</sup>

Sympathetic input is inhibitory to colonic peristalsis (excitatory to sphincters and inhibitory to nonsphincteric muscle).<sup>4</sup> The effector cells originate from the thoracic and lumbar sections of the spinal cord. The thoracic splanchnic (visceral nerves) are divided into the greater (T4 to T10), lesser (T9 to T11), and least (T11 to L1). The lumbar input is L2-3.<sup>3,5</sup> As they emerge via anterior spinal nerve roots they merge into paired paravertebral ganglia, which are located along the medial margin of the psoas muscle in the retroperitoneum. The nerve fiber enters these ganglia as a white ramus and does one of the following: 1) travels up or down the trunk to synapse at another level and supply a segment without its own sympathetic input (i.e., above T1 and below L2); 2) synapses in the ganglion and exits as a gray ramus to supply viscera; 3) passes through the ganglion to a "prevertebral" ganglion such as the celiac plexus where it synapses; or 4) synapses in the ganglion and rejoins its own segmental nerve as a gray ramus.<sup>5</sup> Most preganglionic fibers serving the colon pass through to synapse in a prevertebral ganglia (number 3 above).<sup>6</sup> They form a plexus around the superior and inferior mesenteric arteries where there are perivascular ganglia. Here they synapse and follow the arteries which supply the gut.<sup>7</sup> The inhibition in tone to the colon from sympathetic input is believed to be mediated in part from alpha-2 adrenergic

receptors.<sup>8</sup> In one study in humans, alpha-2 agonists (clonidine) have been found to reduce colonic tone, whereas the alpha-2 antagonist (yohimbine) increased the tone.<sup>9</sup> Alpha-1 agonist and beta-2 agonist did not affect tone.<sup>9</sup> However, more research is needed. In other studies, beta-1, beta-2, and beta-3 adrenoceptors detected on the human colon were tested *in vitro*. Agonists relaxed the colon.<sup>10</sup>

The intrinsic innervation is called the enteric nervous system. The enteric nervous system has the unique ability to mediate reflex behavior independent of input from the brain or spinal cord.<sup>11</sup> It does this through an abundance of different types of neurons within the walls of the intestinal tract. It has neuronal plexuses in the myenteric and submucosal/mucosal layers. The myenteric plexus regulates smooth muscle function. The submucosal plexus modulates mucosal ion transport and absorptive functions. There is substantial diversity within the enteric nervous system and all the modulators and transmitters of the central nervous system are found in the enteric nervous system.<sup>11</sup> The amine and peptide neurotransmitters currently believed to be important are acetylcholine, opioids, norepinephrine, serotonin, somatostatin, cholecystokinin, substance P, vasoactive intestinal polypeptide, neuropeptide Y,<sup>4</sup> and nitric oxide.<sup>12</sup> Control of colonic motor function via the enteric nervous system remains poorly understood at this time.

## Colonic Function

### Salvage, Metabolism, and Storage

Even though the majority of our food undergoes digestion in the stomach and small intestine, the colon still has a major role in digestion. It processes certain starches and proteins, which are resistant to digestion and absorption in the foregut.<sup>13</sup> The large quantity of heterogeneous bacteria in the colon is responsible for fermentation—the process by which these starches and proteins are broken down and energy is produced. There are more than 400 different species of bacteria, the majority of which are anaerobes.<sup>14</sup> The bacteria feed upon mucous, residual proteins, and primarily complex carbohydrates that enter the colon.<sup>15</sup> During fermentation of complex carbohydrates, short-chain fatty acids (SCFAs) are produced. More than 95% of SCFAs are produced and absorbed within the colon.<sup>14,16</sup> The principle ones are acetate, propionate, and butyrate. This process for the most part occurs in the right and proximal transverse colon. Protein residue, which reaches the colon is also fermented by anaerobic bacteria.<sup>17</sup> Proteins are fermented in the left colon. Proteins are broken down into SCFAs, branched chain fatty acids, and ammonia, amines, phenols, and indoles. Part of these metabolites become a nitrogen source for bacterial growth.<sup>17,18</sup> These products are either passed in feces or absorbed. Thus, the colon salvages and actively processes carbohydrates and proteins that reach the cecum. Dietary fat is probably not absorbed to any degree in the colon.<sup>14</sup>

The colonic mucosa is unable to nourish itself from the bloodstream.<sup>19</sup> Therefore, the nutrient requirements are met from the luminal contents. Butyrate (produced in the least amount) is important as the primary energy source for the colonocyte.<sup>13</sup> Butyrate may also have a major role in cell proliferation and differentiation<sup>20,21</sup> as well as being important in absorption of water and salt from the colon. Regarding the other SCFAs produced, propionate combines with the other 3 carbon compounds in the liver for gluconeogenesis. Acetate is the most abundantly produced SCFA. It is used by the liver to synthesize longer-chain fatty acids<sup>13</sup> and as an energy source for muscle.<sup>15</sup>

The proximal colon differs from the distal colon in many functions. Besides being derived from different embryologic origins, the proximal colon is more saccular and the distal more tubular.<sup>22</sup> SCFAs are principally derived in the proximal colon and proteins degraded in the distal colon. When considering storage, the two parts also differ. The proximal colon acts as a reservoir and the distal colonic segments mainly act as a conduit.<sup>23</sup> When confronted with large amounts of fluid, the fluid seems to move quickly into the transverse colon with the solid material catching up later.<sup>24,25</sup> Even after right colon resection, the transverse colon can adapt to store colonic contents nearly as efficiently as the right colon.<sup>26</sup> In addition, the haustral segmentation of the colon facilitates mixing, retention of luminal material, and formation of solid stool.<sup>4</sup>

### Transport of Electrolytes

The colon is extremely efficient at conserving sodium and water.<sup>4</sup> Normally the colon is presented 1–2 L of water daily.<sup>15</sup> It efficiently absorbs 90% such that approximately 100–150 mL of fluid is eliminated in the stool. When challenged, it can increase the absorption to 5–6 L daily.<sup>27,28</sup> Therefore, when the ileal flow of fluid and electrolytes exceeds the capacity of the colon, diarrhea will result.

Additionally, the colon is important in the recovery of salts. Under normal conditions, the colon absorbs sodium and chloride and secretes bicarbonate and potassium. Sodium is actively absorbed against a concentration and electrical gradient. This concept is extremely important for the colon's ability to conserve sodium. The average concentration of sodium in the chyme which enters the colon is 130–140 mmol/L. Stool has approximately 40 mmol/L.<sup>17</sup> As long as the luminal sodium content is more than 25 mmol/L, there is a linear relationship between luminal concentration and the amount of sodium absorbed.<sup>29</sup> However, when the luminal concentration of sodium is less than 25 mmol/L, sodium is secreted.

Aldosterone is secreted by the adrenal gland in response to sodium depletion and dehydration. Aldosterone enhances fluid and sodium absorption in the colon. (This is in contrast to angiotensin, which also participates in fluid balance but via the small intestine.)<sup>29,30</sup> SCFAs produced in the colon are the principle anions. They also stimulate sodium absorption.<sup>15</sup>

Chloride is exchanged for bicarbonate, which is secreted into the lumen to neutralize organic acids that are produced.<sup>15</sup> This occurs at the luminal border of the mucosal cells.<sup>17</sup> Potassium movement, overall, is believed to be passive as a result of the active absorption of sodium. There is evidence that active potassium secretion occurs in the distal colon.<sup>31</sup> This secretion combined with potassium in bacteria and colonic mucous in stool may explain the relatively high concentration of potassium, 50–90 mmol/L, in stool.<sup>32,33</sup> Additionally, the colon secretes urea into the lumen. The urea is metabolized to ammonia. The majority is absorbed passively.<sup>17</sup>

Similar to differences in salvage of food components that enter the colon, there exist qualitative differences in several ion transport processes between different segments of colon.<sup>34,35</sup> Absorption of water and salt occurs primarily in the ascending and transverse colon.<sup>17,36</sup> Active transport of sodium creates an osmotic gradient and the water passively follows. Additionally, there is a difference in the functional nature of the mucosal cells. The surface cells in the colon seem to be responsible for absorption whereas the crypt cells are involved with fluid secretion.<sup>30</sup>

## Colonic Motility

### Methodology for Determining Motility

Even though altered motility is thought to have a major role in some gastrointestinal disorders, it is surprising how little is known about colonic motility. This is because of the difficulty and inaccessibility of the proximal colon for direct study. Interestingly, stool frequency has been shown to correlate poorly with colorectal transit time.<sup>37</sup> Early studies used barium but lacked the ability to give precise measurement of colonic motility.<sup>7</sup>

#### Marker

Radiopaque markers orally ingested and followed sequentially through the intestinal tract via plain X-rays is one of the first methods used to actually measure transit time.<sup>38</sup> This test is still used frequently to evaluate patients with severe constipation looking for slow transit through the colon. Variations in the protocol exist. Patients stop taking all laxatives 48 hours before the ingestion of the markers. One method calls for a capsule with 24 markers to be ingested and an X-ray obtained on day 5. This reflects the transit time of the entire gut. On day 5, 80% (17) of the markers should be expelled.

With sequential abdominal X-rays, markers can be localized to specific regions of the colon: right, left, and pelvis. One protocol asks patients to take one capsule with 20 markers and abdominal X-rays are taken every other day until all markers are passed. In an effort to decrease radiation exposure, patients ingest 84 markers on three successive days. (Some protocols call for markers to be different shapes on each of the 3 days.) Then one X-ray is obtained on day 4.<sup>39</sup>

Total colonic transit time is 30.7 (SD 3.0) hours for men and 38.3 (SD 2.9) hours for women.<sup>7</sup>

#### Scintigraphy

Some centers favor colonic scintigraphy to study colonic transit. Patients refrain from taking laxatives or opiates 24 hours before the test. They remain on their normal diet throughout the study. Typically, a capsule coated with pH-sensitive polymer containing <sup>111</sup>In-labeled radioisotope is ingested. The coating dissolves in the distal ileum and the radioactive material passes into the colon.<sup>23</sup> Alternately, the patient will ingest the <sup>111</sup>In-labeled material with water and serial images will be obtained with the gamma camera at specified hours (this varies but can be as frequent as twice daily or daily).<sup>40</sup> Segmental transit is usually calculated for the right, left, and rectosigmoid regions of the colon. Results are expressed as the percentage of the total amount of isotope ingested in each segment or the geometric center of the isotope mass at any given time point.<sup>40</sup> For clinical use, the total percentage retained compared with normal data seems to be the most convenient reporting system.

#### Recording Techniques of Colonic Motility

Most techniques that record colonic motility using some form of colonic manometry still remain in the researcher's domain and have not been assimilated into the clinical armamentarium for the caregiver. Difficulty in accessing the colon is the obvious obstacle. However, significant information is being obtained from these types of studies in the research domain. Typically, a flexible catheter is placed into the colon. It is either a solid-state manometry catheter or a water-perfused system. It is argued that the water-perfused system increases the amount of fluid in the colon and may alter results. However, solid-state manometry catheters are fragile, expensive, and sensitive to corrosive damage from colonic irritants.<sup>41</sup> The catheter is placed in the colon using one of several ways: it can be placed via the nasal-oral route and the position confirmed with fluoroscopy. The goal is to position the catheter so right colonic information can be obtained.

Alternately, it can be placed with a colonoscope using two methods. The catheter can be grasped with a biopsy forceps, which has been passed through the port of the colonoscope. It is then pulled along in a piggyback manner with the colonoscope. The scope is advanced via the anus and positioned in the colon usually as far as the transverse colon and then released. The colonoscope is carefully withdrawn in an effort to avoid displacing the catheter. The other method uses a guidewire threaded through a colonoscope. The guidewire remains as the scope is withdrawn. Then the catheter is threaded over the guidewire using fluoroscopic guidance. Initial studies asked patients to prep the entire colon. Because this is not physiologic, unprepped colons are more frequently used today (some still use enemas before colonoscopy). Retained stool can then hamper retrograde placement of the

catheter. Minimal air is insufflated via the colonoscope and as much air as possible is aspirated with removal of the colonoscope. Usually, the transverse colon is the most proximal point examined and fluoroscopy may be used to verify the proximal point. Using the direct placement technique, the proximal transverse colon is usually reached in all subjects and the probe remains in place in more than 80% of cases.<sup>41–44</sup>

Frequently, with prolonged data collection, the subject keeps a diary and has some method to mark events on the data (such as eating and passing flatus). In an effort to gain more data regarding colonic tone (which cannot be measured from manometry), a barostat was developed. It uses a compliant bag maintained at a constant pressure in contact with the colonic wall. Changes of volume in the bag reflect tone in the colonic segment, which can be measured.<sup>45,46</sup>

Myoelectrical signals from the colon are studied in the research setting by placing electrodes intraoperatively on the serosal surface of the colon, or intraluminally through scopes. This modality documents electrical signals in the colon, which initiate muscular activity.<sup>47,48</sup>

## Peristalsis

Peristalsis is the waves of alternate contraction and relaxation of the muscles of the intestinal tube, which propels contents. Using transit studies, scintigraphy, and especially ambulatory colonic manometry, information has been learned about motor and pressure activity in humans that leads to peristalsis. Unfortunately, it is difficult to precisely define colonic contractions, pressure waves, and electrical events because no standard terminology or definitions exist. There is also no standardized way that the measurements are obtained. It is also difficult to study the colon because of the inaccessibility of the proximal portion. In contrast to the small intestine where contents are quickly propelled forward, the colon needs prolonged observation to be correctly studied.

In an effort to standardize observations, Bassotti and colleagues<sup>49,50</sup> have proposed a classification system, which encompasses previous observations. Contractile events are divided as: 1) segmental contractions that are either single contractions or bursts of contractions, either rhythmic or arrhythmic contractions; 2) propagated contractions—low-amplitude propagated contraction (LAPC) (long spike bursts) and high-amplitude propagated contraction (HAPC) (migrating long spike bursts).<sup>50</sup>

HAPCs have also been referred to in the past as large bowel peristalsis, giant migrating contractions, and migrating long spike bursts.<sup>50</sup> HAPC is thought to be the equivalent of mass movement.<sup>42,51,52</sup> The main function of HAPCs is to move large amounts of colonic contents toward the anus.<sup>49,53</sup> They occur approximately five times daily. More than 95% of HAPCs propagate toward the anus (not retrograde).<sup>50</sup> They usually occur upon awakening, during the day, and after meals.<sup>50</sup> They are usually associated with abdominal sensation and defecatory stimulation (or defecation).<sup>50</sup>

Less is known regarding LAPCs. They occur in all normal volunteers and are strongly related to meals and sleep–wake cycles. They may also be related to the passage of flatus.<sup>54</sup> The mechanism regulating LAPCs and HAPCs remains unknown.

Single segmental contractions also have been referred to as electrical response activity, contractile electrical complex, and short-duration contractions. Bursts of segmental contractions have been referred to as long-duration contractions, continuous electrical response activity, and short spike bursts.<sup>50</sup> The majority of the colonic motility is represented by segmental contractions. This allows slow transit and the opportunity for the luminal contents to maximally come in contact with the mucosal surface.

The colon in humans differs from the small intestines and colons of other mammals in that there is no cyclic motility.<sup>49</sup> Combining what is seen with contrast fluoroscopy with what is known myoelectrically, haustra appear as ring-like segmenting contractions. They are static and partially occluding. With peristalsis, the haustra disappear as concentric waves of contraction spread distally along the now unsegmented colon. This seems to correspond to the descriptions of mass movement when contents in the right colon could be propelled distally into the left colon in seconds.<sup>23</sup>

## Cellular Basis for Motility

Cells important for movement in the colon include the circular muscle, longitudinal muscle, and interstitial cells of Cajal (ICC). Electrical activity is associated with mechanical activity. Electrical activity, which generates motility patterns in the human colon, is poorly understood.<sup>55</sup> All electrical activity in the human colon is dependent on stimulation by stretch or chemical mediation. Critical volumes of distention are needed for propulsion. Fiber may augment this degree of stretch.

ICC are the pacemaker cells of the gut that have a central role in regulation of intestinal motility.<sup>56</sup> These are mesenchymal cells, which form a three-dimensional network, placed between and in smooth muscle layers.<sup>57</sup> They are also in close association with elements of the enteric nervous system.<sup>58</sup> They are electrically active and create ion currents for pacemaker function. ICC in the submucosal layer (of the circular smooth muscle) initiate slow waves in the colon. There is also an additional pacemaker in the colon in the septa separating individual circular muscle bundles.<sup>55,57,59</sup> It is difficult to determine the exact role of ICC in spreading the waves, but slow waves appear to spread along the long axis and around the circumference of the colon with the ICC representing a basal pathway.<sup>57,60</sup> Slow waves of circular and longitudinal muscle cells are in phase, which indicates that a link must exist between these layers.<sup>57</sup>

## Characteristics of Colonic Motility in Health

Using 24-hour manometry, it has been found that the colon is continually active. There is a well-established circadian

rhythm with marked diminution of pressure activity at night.<sup>41,61</sup> Immediately after waking, there is a threefold increase in colonic pressure activity. This may account for bowel patterns in some individuals who move their bowels after awakening in the morning. Colonic pressure activity also increases after meals, which in one study lasted for up to 2 hours after a meal.<sup>41</sup> Propagating pressure waves (probably HAPCs) were seen intermittently throughout the day and especially after meals or after waking. There was also regional differences in pressure activity. During the day, the transverse to descending colon had more pressure activity than the rectosigmoid colon. Even though activity decreased at night, the rectosigmoid region was the most active. Women had less activity in the transverse/descending colon compared with men.<sup>41</sup> One other factor from this study was that even though scintigraphic studies have shown retrograde movement of radiotransducers, this type of wave occurred infrequently and usually after a meal or during the morning waking response.<sup>41</sup>

Stress can influence gut function. One study<sup>62</sup> found that psychological stress induced prolonged propagated contractions without appreciable autonomic response. These contractions propagated across several areas of the colon. The motor activity persisted after the stressor ceased. Physical stress induced simultaneous contractions defined as pressure waves occurring simultaneously in several areas of the colon. The motor activity ceased immediately after the activity stopped. In another study, it was found that acute physical exercise increased LAPCs and HAPCs.<sup>63</sup>

The right colon and transverse colon are major sites of storage of solid stool. Solid residue remains in the right colon for extended periods allowing for mixing.<sup>23</sup> There is also considerable variability among individuals as far as right colon transit.<sup>23</sup> After eating, the proximal colon has an immediate increase in tonic contraction.<sup>22,64</sup> There is also increased tone in the distal colon, but this is less pronounced than the one on the right.<sup>22,64</sup> Therefore, well before the ingested food reaches the colon, there is an increase in colonic motility and tone. This is known as the gastrocolic reflex.<sup>64</sup> The mediator of this response is unknown and neither a stomach nor intact nervous system is required for it to occur.<sup>65</sup> Cholecystokinin (CCK) is a well-known colonic stimulator increasing colonic spike activity in a dose-dependent manner. It has been postulated to be the mediator of this postprandial colonic activity.<sup>17</sup> However, CCK antagonists do not block the gastrocolic response<sup>66</sup> and CCK infusion that maximally stimulates the pancreatic exocrine secretion and gallbladder contraction has no effect on motor function or transit in a prepared colon.<sup>67</sup>

## Defecation and Colonic Sensation

The process of defecation seems to involve the entire colon. It has been shown to begin up to an hour before stool elimination—a preexpulsive phase. It is characterized by increased propagating and nonpropagating activity in the entire colon

and is largely unperceived.<sup>68</sup> This early component may result in stool contents being propelled into the distal colon and stimulating distal colonic afferent nerves. However, scintigraphic studies have also shown that the right colon can also be emptied during one episode of defecation. This could be associated with a total colonic propulsive activity that in some manner is associated with defecation.<sup>23,69–71</sup> A second component begins approximately 15 minutes before stool expulsion. Propagating sequences during this time are associated with an increasing sensation of an urge to defecate. Even though several studies have shown that caudally propagating HAPCs occur in close temporal association with defecation,<sup>72,73</sup> not all HAPCs end in defecation and defecation is not always preceded by HAPCs.<sup>49</sup> However, it does appear that usually at least one very high amplitude HAPC occurs with the sensation of the urge to defecate.<sup>68</sup>

Colonic sensation is complicated and poorly understood. The colon has no specialized sensory end organs. There are naked nerve endings within the wall and Pacinian corpuscles in the mesentery. Afferent fibers reach the central nervous system via sympathetic and parasympathetic pathways. Parasympathetic fibers convey nonconscious sensory information to the brainstem.<sup>4,64</sup> Pain from abdominal viscera is almost exclusively conducted through the sympathetic afferents to the spinal cord via the dorsal root ganglia. The afferent neuron can mediate conscious perception of visceral events by synapsing in the dorsal portion of the spinal cord and then exiting back to the viscera, ascending within the spinothalamic or spinoreticular tract toward the thalamus or reticular formation of the brain, or ascending directly to higher sensory centers of the brain.<sup>4</sup>

Modulation of visceral sensation occurs through several methods. The first allows for enteroenteric reflexes that are mediated in the spinal cord to alter smooth muscle tone thereby increasing or decreasing the activation of the nerve endings in the gut or mesentery.<sup>74</sup> Another method involves direct central modulation of pain. This can occur through the descending noradrenergic and serotonergic pathways from the brainstem. These project in the dorsal horn and can modify the actual afferent input.<sup>4</sup> This is the suspected mechanism by which wounded soldiers in the midst of battle will feel no pain.<sup>75</sup> A further method explains “referred pain.” To initially understand this phenomena, it is recognized that somatic afferent nerves enter the same dorsal portion of the spinal cord as the visceral nerves. There is a wide overlap over multiple spinal lamina and some changes may occur in the ascending projection of the visceral stimuli. The dorsal horn may function as a “gate” controlling central transmission or changing excitability of the neuron. When the overlap of input appears more recognized by higher central brain forces from somatic input, referred pain may occur. The input is actually occurring in the visceral structure, but is perceived to be from the somatic structure.<sup>4,75</sup> It is of note that when pain is referred it is usually to a structure that developed from the same embryonic dermatome.<sup>75</sup> And lastly, visceral sensation

can relay information via collaterals to the reticular formation and thalamus. This can induce changes in affect, appetite, pulse, and blood pressure through autonomic, hypothalamic, and limbic system connections.<sup>4,76</sup>

## Disturbances in Colonic Physiology

### Physiology of Constipation

Constipation refers to stools that are infrequent or hard to pass (or both). Arbitrary definitions have been used. Individuals with constipation are an incredibly heterogeneous group. Distinct subtypes of constipation occur and require different treatment modalities, but even within these subtypes there can be wide variability in the clinical presentation and pathophysiologic etiology. There may be dietary, pharmacologic, systemic, or local causes. Many people have constipation caused by dietary and lifestyle neglect. Two primary functions of the colon, solidifying chyme into stool and laxation, are interdependent on adequate dietary fiber. Dietary fiber “normalizes” large bowel function.<sup>77,78</sup> Recommendations for adequate fiber intake ranges from 20 to 35 g per day for adults.<sup>79</sup> Fiber is generally soluble or insoluble and seems to improve stool weight by different mechanisms. Oat bran, which is soluble, seems to increase stool weight by providing rapidly fermenting soluble fiber to the proximal colon. This allows for bacterial growth which is sustained until excretion. It seems that the increase in stool mass is from higher bacterial content and increased excretion of lipid and fat.<sup>80</sup> Insoluble fiber such as wheat bran increases stool weight by increasing dietary fiber (undigested plant material) in the stool. Wheat bran also increases fat excretion, but not to the extent of oat bran.<sup>80</sup> Interestingly, fiber intake in the United States is low. One explanation is that to achieve 15 g of fiber intake daily, 11 servings of refined grains and 5 servings of fruit and vegetables are needed for individuals consuming 1500–2000 kcal daily.<sup>77</sup>

Additionally, constipation may be seen more frequently in sedentary people. In fact, abdominal cramps and diarrhea are reported more frequently in runners.<sup>81,82</sup> Acute graded exercise has been shown to actually decrease phasic colonic motor activity. However, after the exercise, there was an increase in the number and amplitude of propagated pressure waves. It is believed that this post-exercise pattern may increase the propagating activity and propel stool.<sup>43</sup>

Idiopathic slow transit constipation involves a measurable delayed movement of material through the colon. These patients are not helped (in fact may be made worse) with increased dietary fiber. They seem to have altered colonic motor response to eating and impaired or decreased HAPCs of the colon.<sup>50,64</sup> This leads to reduced or absent colonic propulsive activity.<sup>83,84</sup> Abnormalities in the neuronal network are suspected and recently a pan-colonic decrease in the ICC has been shown.<sup>56</sup> As with other areas of colonic study, this one also needs much more investigation.

Irritable bowel syndrome (IBS) can manifest with multiple forms. It usually is characterized as altered bowel habits and pain directly related to the altered bowel habits. In one form, constipation can be the predominant feature. This may encompass about 30% of the IBS population and traditionally overwhelmingly affects women. This group of patients can show an overlap with those having slow transit constipation, but may have a normal transit study.<sup>85</sup> Pharmaceutical companies have targeted drugs that affect metabolism of serotonin, which seems to be involved in the regulation of motility, sensitivity, and intestinal secretions. The specific 5-hydroxytryptamine (5-HT)<sub>4</sub> receptor is involved in intrinsic sensory reflexes within the gut. Tegaserod is a 5-HT<sub>4</sub><sup>86</sup> agonist that has been approved by the Food and Drug Administration (FDA) (July 2002) for treatment of this group of patients.<sup>87</sup> Additionally, cholecystokinin-1 antagonists are in trials for treatment of patients with constipation-predominant IBS.<sup>87</sup>

### Obstructed Defecation

Obstructed defecation usually results from abnormalities in pelvic function versus colonic function. Typically this problem is associated with failure of the puborectalis to relax with defecation, rectocele, perineal descent, or other pelvic- and rectal-associated issues. Failure of the rectum to evacuate may lead to marker studies which also show marker collection in the left colon.<sup>88</sup> This may also be associated with colonic total inertia.<sup>89</sup>

A colonic source, which is a variant in obstructed defecation, is a sigmoidocele. Although rare, the sigmoid is seen to migrate into the pelvis with defecation and obstruct evacuation of stool. This form can be relieved and treated with a sigmoid resection, but the clinician should be aware of other pelvic floor abnormalities.

### Ogilvie's Syndrome

Ogilvie's syndrome was described initially in 1948. It is also known as acute colonic pseudoobstruction. The pathophysiology is not clearly understood. Based on evidence from pharmacologic studies, it seems that Ogilvie's original hypothesis is as correct as the current facts; namely, there seems to be an imbalance of autonomic innervation to the gut. The parasympathetic nerves, which are responsible for stimulating gut motility, have decreased function or input and the sympathetic nerves, which are inhibitory, increase their input.<sup>90</sup> Because of the law of Laplace, the cecum can be the site of extreme dilatation (it requires the smallest amount of pressure to increase in size and therefore increase the wall tension). Treatment has focused on ruling out a distal obstruction with a Gastrografin enema and if needed colonoscopic decompression. However, pharmacologic treatment with neostigmine has been successful.<sup>91</sup> This drug is a cholinesterase inhibitor that allows more available acetylcholine for neurotransmission in the parasympathetic system (excitatory) to promote contractility.<sup>92</sup>

## Irritable Bowel Syndrome

As stated above, IBS is characterized by altered bowel habits associated with pain. Besides the constipation-predominant type described above, there can be a diarrhea-predominant type and a mixed type. The pathophysiology of IBS has received extensive study, but it remains unclear. Abnormal motility, visceral hypersensitivity, inflammation, abnormalities in extrinsic autonomic innervation, abnormal brain–gut interaction, and the role of psychosocial factors have been investigated. If IBS is found in men it tends to be more diarrhea-predominant type. Treatment is based on the nature and severity of symptoms. Education, reassurance, and dietary modification (elimination of foods that aggravate the problem) are the first steps. For those who do not respond, medication is considered. Antispasmodics (anticholinergic) medication is considered for those with pain and bloating that is especially aggravated by meals. Usually, antispasmodics and anticholinergic agents are considered on an as-needed basis. Low-dose tricyclic antidepressants may be considered when the pain is more constant and perhaps disabling.<sup>86</sup>

Considering specific types, no good pharmacologic research is available for the mixed-type IBS patients. However, for the diarrhea prone, 5-HT<sub>3</sub> antagonists have been found to be effective. Alosetron was initially FDA approved (March 2000) only to be withdrawn after some patients suffered ischemic colitis and even death.<sup>87</sup> In June 2002, it was reapproved with restrictions that require the prescriber to demonstrate educational understanding regarding the drug. Additional drugs are also undergoing trials.<sup>87</sup>

## Implications of Colonic Physiology for the Surgeon

Why is colonic physiology important for the surgeon? Recognizing the innervation and differences in embryologic development may be important in colon resections when considering nerve preservation, blood flow, and resection margins. Colonic motility is poorly understood. However, as knowledge is gained through research, the surgeon will be asked to evaluate and use pharmaceutical products to reduce ileus and treat other conditions.

Resection of all or a portion of the colon can have profound ramifications for the patient. It is the surgeon's responsibility to understand the physiologic possibilities, recognize, and manage the outcome. For instance, this may be important for patients with a new ileostomy who may need counseling regarding fluids and increased salt intake to compensate for the colon, which has been resected.

Disorders of colonic motility are numerous in the human species. Surgeons will be consulted regarding surgical intervention. Knowledge of basic physiology will prepare the surgeon to make decisions regarding which patients are appropriate for medical treatment and the treatments

available. Surgical intervention will then be reserved for appropriate patients.

In the colon, many metabolic processes can be influenced by food components. Prebiotics are “non-digestible food ingredients that beneficially affect the host by selectively stimulating the growth and/or activity of one or a limited number of bacteria in the colon, that can improve the host health.”<sup>93</sup> The most common area has been stimulation of the growth of lactic acid-producing bacteria. This growth changes the colonic environment and may reduce the ability of carcinogens to form or lead to cancer.<sup>18</sup> Probiotics are “a live microbial feed supplement which beneficially affects the host by improving its intestinal microfloral balance.”<sup>94</sup> With increasing resistant bacteria in our hospitals, the World Health Organization has recommended trying to combat this problem by using microbial interference therapy or nonpathogens to eliminate pathogens.<sup>19</sup> Work is underway with probiotics in this manner in an effort to reduce potentially pathogenic microorganisms. Currently, probiotics may be used in cases of disturbed microbial balance, such as antibiotic-associated diarrhea, to lessen the risk and duration. In the future, pre- and probiotics may become important supplements administered to patients to promote health and prevent complications from illness.

## Conclusion

In conclusion, the colon is a mysterious organ. It salvages water and electrolytes, which have passed through the small intestine. It produces SCFAs, which nourish its mucosa and provide substrate for energy. It propels its contents slowly toward the anus, continuously mixing them and exposing them to the luminal surface. Its ultimate task is to store stool until it is socially acceptable to eliminate.

## Anal Physiology

Susan M. Parker and John A. Collier

Normal bowel continence is a complex process that involves the coordinated interaction between multiple different neuronal pathways and the pelvic and perineal musculature.<sup>1</sup> The importance of the anatomic relationships of the pelvic floor in maintaining normal continence has been suggested since the 1950s.<sup>2</sup> Yet the complex series of neural and behavioral-mediated interactions, combined with a lack of an ideal study to take all elements into account, makes complete understanding of anorectal anatomy and physiology's role in preserving continence difficult.<sup>3</sup> Complicating this are multiple other factors that have a role in normal regulation such as systemic disease, emotional effects, bowel motility, stool consistency, evacuation efficiency, pelvic floor stability, and sphincter integrity.<sup>4</sup>

Anorectal physiology testing allows evaluation of the patient with pelvic floor complaints using techniques such as manometry, endoanal ultrasound, electrophysiologic studies, and defecography, all of which help to elucidate anorectal structures and function. A physician with an in-depth knowledge of normal and abnormal anorectal physiology can apply the results in a meaningful way to diagnose and direct therapy. This chapter reviews the current knowledge regarding muscular, neurologic, and mechanical factors.

### Pelvic Floor Muscles

The pelvic floor consists of a striated muscular sheet through which viscera pass. This striated muscle, the paired levator ani muscles, is actually subdivided into four muscles defined by the area of attachment on the pubic bone. The attachments span from the pubic bone, along the arcus tendineus (a condensation of the obturator fascia), to the ischial spine. The components of the levator ani are therefore named the pubococcygeus, ileococcygeus, and ischiococcygeus. The pubococcygeus is further subdivided to include the puborectalis. Between the urogenital viscera and the anal canal lies the perineal body. The perineal body consists of the superficial and deep transverse perinei muscles and the

ventral extension of the external sphincter muscle to a tendinous intersection with the bulbocavernosus muscle.<sup>5</sup>

The fourth sacral nerve innervates the levator ani muscles. Controversy continues regarding the innervation and origin of the puborectalis muscle. Cadaver studies differ from in vivo stimulation studies as to whether the puborectalis muscle receives innervation only from the sacral nerve or also from the pudendal nerve. Comparative anatomy and histologic studies of fiber typing also support the inclusion of the puborectalis muscle with the sphincter complex and not as a pelvic floor muscle. In addition, electromyographic (EMG) studies of the external anal sphincter (EAS) and puborectalis muscle indicate that the muscles function together with cough and strain.<sup>6</sup>

The rectal smooth muscle consists of an outer muscularis mucosa, inner circular muscle, and outer longitudinal layer. The inner circular muscle forms the valves of Houston proximally and distally extends down into the anal canal becoming the internal anal sphincter (IAS). This is not a simple extension of muscle because there are histologic differences between the upper circular muscle and the IAS. For instance, the IAS is thicker than the circular muscle because of an increased number of smaller muscle cells. The outer longitudinal layer surrounds the sigmoid colon coalescing proximally into thicker bands called taenia coli. This same layer continues down to the anorectal junction where it forms the conjoined longitudinal muscle along with fibers from the pubococcygeus muscle. Distally, this muscle lies in the intersphincteric plane and fibers may fan out and cross both the IAS and EAS muscles. In an ultrasound view of the anal canal, the longitudinal muscle is seen as a narrow hyperechoic line in the intersphincteric space. The terminal fibers extend to skin as the corrugation cutaneous ani muscles.

### External Anal Sphincter

Anatomic and sonographic studies indicate that the EAS begins development, along with the puborectalis muscle, at 9–10 weeks' gestation. At 28–30 weeks, it is mature and the

anal sphincter then consists of three components: the striated puborectalis muscle, the smooth IAS muscle, and the smooth and striated EAS muscle.<sup>7</sup> Further differentiation of the EAS into two or three components is highly debated. In 1715, Cowper described it as a single muscle. Later, Milligan and Morgan promoted the naming of the components as subcutaneous, superficial, and deep. Recently, Dalley<sup>8</sup> made a convincing point that the three components can only be seen in the exceptionally dissected specimen and, in most cases, the muscle is one continuous mass and should be considered as such.

The EAS is innervated bilaterally by the pudendal nerve arising from S2-S4. Motor neurons arise in the dorsomedial and ventromedial divisions of Onuf's nucleus in the ventral horn of the spinal cord. Crossover of the pudendal innervation was first suggested in studies by Wunderlich and Swash<sup>9</sup> on rhesus monkeys. Hamdy and associates<sup>10</sup> evaluated corticoanal stimulation of humans and found variable crossover which was symmetric in some and either right- or left-sided dominant in others. This has been offered as one possible explanation for the inconsistent relationship between unilateral pudendal neuropathy and fecal incontinence.

## Internal Anal Sphincter

The IAS is an involuntary, smooth muscle. It is relatively hypoganglionic.<sup>11</sup> There are nerve fibers expected in an autonomic muscle—cholinergic, adrenergic, and nonadrenergic, noncholinergic fibers. It receives sympathetic innervation via the hypogastric and pelvic plexus. Parasympathetic innervation is from S1, S2, and S3 via the pelvic plexus. There is considerable evidence that the sympathetic innervation is excitatory but conflicting information regarding the parasympathetic effect.<sup>11</sup> The IAS contributes 55% to the anal resting pressure. The myogenic activity contributes 10%, and 45% is attributed to the sympathetic innervation. The remainder of the resting tone is from the hemorrhoidal plexus (15%) and the EAS (30%).<sup>12</sup> Spinal anesthesia decreases rectal tone by 50% and the decreased resting tone seen in diabetic patients may be attributable to an autonomic neuropathy.<sup>13</sup> The IAS has slow waves occurring 6–20 times each minute increasing in frequency toward the distal anal canal. Ultraslow waves occur less than 2 times a minute and are not present in all individuals, occurring in approximately 5%–10% of normal individuals. Ultraslow waves are associated with higher resting pressures, hemorrhoids, and anal fissures.<sup>11</sup> Ultrasound examination of the anal canal shows the hypoechoic IAS ending approximately 10 mm proximal to the most distal portion of the hyperechoic EAS.

The puborectalis muscle, EAS, and IAS muscles are easily viewed with endoanal ultrasound. In the hands of an experienced ultrasonographer, the technique is highly sensitive and specific in identifying internal and external sphincter defects.

## Sensory

Anal canal sensation to touch, pinprick, heat, and cold are present from the anal verge to 2.5–15 mm above the anal valves. This sensitive area is thought to help discriminate between flatus and stool but local anesthesia does not obliterate that ability. The rectum is only sensitive to distention. Rectal sensation may be attributable to receptors in the rectal wall but also in the pelvic fascia or surrounding muscle. The sensory pathway for rectal distention is the parasympathetic system via the pelvic plexus to S2, S3, and S4. Below 15 cm, rectal distention is perceived as flatus, but above 15 cm, air distention causes a sensation of abdominal discomfort. Anal canal sensation is via the inferior rectal branch of the pudendal nerve that arises from S2, S3, and S4. This is the first branch of the pudendal nerve and along with the second branch, the perineal nerve, arises from the pudendal nerve in the pudendal canal (Alcock's canal). The remainder of the pudendal nerve continues as the dorsal nerve of the penis or clitoris.<sup>14</sup>

## Reflexes

There are a great number of reflexes that end with the name “. . . anal reflex.” The reason for this is, in part, that the EAS is readily accessible and represents a convenient end point for recording during electrophysiologic study. Consequently, there are several ways that one can assess the integrity of neurologic connection through or around the spinal chord.<sup>15</sup>

### Cutaneous-anal Reflex

The cutaneous-anal reflex was first described by Rossolimo<sup>16</sup> in 1891 as a brief contraction of the anal sphincter in response to pricking or scratching the perianal skin. This is a spinal reflex that requires intact S4 sensory and motor nerve roots. Both afferent and efferent pathways travel within the pudendal nerve.<sup>16</sup> If a cauda equina lesion is present, this reflex will usually be absent. Henry et al.<sup>17</sup> recorded the latency of the anal reflex in 22 incontinent patients as compared with 33 control subjects. The mean latency was 13.0 versus 8.3 ms, respectively. The mean latency was within normal range in only 3 (14%) of the incontinent patients.<sup>17</sup> However, Bartolo et al.<sup>18</sup> have suggested that latency measurement of the cutaneous-anal reflex may be an inadequate means of demonstrating nerve damage in patients with fecal incontinence. From a practical standpoint, this is a sacral reflex that can be interrogated during physical examination by simply scratching the perianal skin with visualization of contraction of the subcutaneous anal sphincter. The response to perianal scratch fatigues rapidly so it is important to test this as the first part of the sphincter examination.

## Cough Reflex

Chan et al.,<sup>19</sup> using intercostal, rectus abdominis, and EAS electrodes, studied the latencies in response to voluntary cough and sniff stimulation. When compared with latencies from transcranial magnetic stimulation, it appeared that the EAS response was consistent with a polysynaptic reflex pathway.<sup>19</sup> The visible contraction of the subcutaneous EAS as a consequence to cough and sniff stimulation is a simple noninvasive validation of the pathways involved in the anal reflex. This response can also be displayed during anal sphincter manometry. Amarenco et al.<sup>20</sup> demonstrated that the greater the intensity of the cough, the greater was the electromyographic response within the anal sphincter. The reflex is preserved in paraplegic patients with lesions above the lumbar spine but it is lost if the trauma involves the lumbar spine or with cauda equine lesions. The mechanism of the cough–anal reflex contributes to the maintenance of urinary and fecal continence during sudden increases in intraabdominal pressure as might also be seen with laughing, shouting, or heavy lifting.

## Bulbocavernosus Reflex

The bulbocavernosus reflex was first described by Bors and Blinn<sup>21</sup> in 1959. The bulbocavernosus reflex is the sensation of pelvic floor contraction elicited by squeezing the glans penis or clitoris.<sup>22</sup> The EAS is used as the end point because it is easily accessed either for visual assessment or by concentric needle EMG recording. The bulbocavernosus reflex latency will be prolonged by various disorders affecting the S2–S4 segments of the spinal chord.

## Rectoanal Inhibitory Reflex

The rectoanal inhibitory reflex (RAIR) represents the relaxation of the IAS in response to distension of the rectum. This was first described by Gowers<sup>23</sup> in 1877 and documented by Denny-Brown and Robertson<sup>24</sup> in 1935. It is believed that this permits fecal material or flatus to come into contact with specialized sensory receptors in the upper anal canal.<sup>25</sup> This sampling process, the sampling reflex, creates an awareness of the presence of stool and a sense of the nature of the material present. It is believed that this process of IAS relaxation with content sampling is instrumental in the discrimination of gas from stool and the ability to pass them independently.<sup>25</sup> The degree to which IAS relaxation occurs seems to be related to the volume of rectal distension more so in incontinent patients than in constipated or healthy control patients.<sup>26</sup> Lower thresholds for the RAIR have been found to be associated with favorable response to biofeedback therapy in patients with fecal incontinence for formed stool.<sup>27</sup> The amplitude of sphincter inhibition is roughly proportional to the volume extent of rectal distension.

The RAIR is primarily dependent on intrinsic nerve innervation in that it is preserved even after the rectum has been isolated from extrinsic influences, following transection of

hypogastric nerves and the presence of spinal chord lesions. The inhibition response is in part controlled by nonadrenergic, noncholinergic mediators.<sup>28</sup> The reflex matures quite early in that it is generally present at birth and has been detected in 81% of premature infants older than 26 weeks postmenstrual age.<sup>29</sup> The reflex is destroyed in Hirschsprung's disease when myenteric ganglion are absent. In addition, the reflex is lost after circumferential myotomy and after generous lateral internal sphincterotomy.<sup>30</sup> Saigusa et al.<sup>31</sup> found that at an average of 23 months following closure of ileostomy after ileal pouch anal anastomosis, only 53% of patients maintained a positive RAIR as compared with 96% preoperatively. The incidence of nocturnal soiling was significantly greater: 72% in those who did not have preserved, or recovered RAIR as compared with 40% who had postoperative preserved RAIR.<sup>31</sup>

The RAIR seems to be nearly abolished in the early postoperative period after low anterior resection for cancer. In a study involving 46 patients, O'Riordain et al.<sup>32</sup> found that the RAIR that had been present in 93% of patients preoperatively was only present in 18% 10 days after low anterior resection. However, at 6–12 months, the RAIR was intact in 21% of patients and this increased to 85% after 2 years.<sup>32</sup> Similarly, van Duijvendijk et al.,<sup>25</sup> in a study of 11 patients, found RAIR present in only 36% of patients after undergoing total mesorectal excision for carcinoma at 4 months after operation. However, 81% of patients had a detectible RAIR at 12 months after surgery. The degree to which IAS relaxation occurs appears to be related to the volume of rectal distension more so in incontinent patients than in constipated or healthy control patients.<sup>33</sup>

Loss of RAIR is often a consequence of restorative proctocolectomy. Saigusa et al.<sup>31</sup> found that the RAIR was present in only 53% of double-stapled ileal pouch anal anastomosis patients at a mean of 23 months after closure of the ileostomy. Preservation of the RAIR correlated with less nocturnal soiling.

The RAIR in children can be elicited even when general anesthetic agents or neuromuscular blockers are used. Glycopyrrolate, an anticholinergic, seems to inhibit RAIR.<sup>34</sup>

Disturbances in the RAIR seem to be involved in the incontinence that is associated with systemic sclerosis. Heyt et al.<sup>35</sup> found that 25 of 35 patients (71.4%) with systemic sclerosis demonstrated an impaired or absent RAIR compared with none of 45 controls. Impaired RAIR was closely correlated with fecal incontinence in that 11 of 13 (84%) of incontinent systemic sclerosis patients exhibited an impaired RAIR.

## Rectoanal Excitatory Reflex

The rectoanal excitatory reflex (RAER), or inflation reflex, is the contraction of the EAS in response to rectal distension. Rectal distension sensation is likely transmitted along the S2, S3, and S4 parasympathetic fibers through the pelvic splanchnic nerves.<sup>36</sup> However, on the motor side, a pudendal nerve block abolishes the excitatory reflex suggesting that pudendal neuropathy may interfere with the RAER. Common methodologies

for assessing the integrity of the pudendal nerve involve both single fiber density (SFD) of the EAS and pudendal nerve terminal motor latency (PNTML). However, derangement of the distal RAER was shown by Sangwan et al.<sup>37</sup> to compare favorably with these more traditional and discomforting methodologies as an indicator of neuropathic injury to the EAS. It would seem that patients that have both an abnormal PNTML and an abnormal distal RAER do not require further study with SFD.

## Mechanical Factors of Continence and Defecation

### Anorectal Angle and Flap Valve

As a part of the pelvic floor musculature, the puborectalis arises from the pubic bone and passes horizontally and posteriorly around the rectum as the most medial portion of the levator ani muscle. This forms a U-shaped sling around the rectum near its anatomic junction with the anus, pulling the rectum anteriorly, and giving rise to the so-called anorectal angle. There are differences of opinion as to whether the puborectalis and anorectal angle are truly important in maintaining continence. Unlike the fine control of the external and internal sphincter muscles, the puborectalis sling is believed to be more involved with gross fecal continence.<sup>38</sup> Parks<sup>39</sup> postulated a mechanism by which this takes place. As intra-abdominal pressure is increased—such as with sneezing, coughing, or straining—and the force is transmitted across the anterior wall of the rectum at the anorectal angle. The underlying mucosa is opposed against the upper anal canal, creating a flap-valve mechanism that prevents stool from passing to the lower anal canal and preserving continence. Yet other authors have disputed this flap-valve mechanism and downplayed the role and reliability of measuring the anorectal angle. Bannister et al.,<sup>1</sup> in a study of 29 patients including 14 patients with incontinence, found no evidence of a flap valve in the normal subjects by using manometric measurements during increasing intraabdominal pressures. However, in the incontinent patients, the manometric pressures were consistent with a flap valve. Yet, subjects still had leakage of stool, questioning the contribution to overall continence. Bartolo and colleagues<sup>18</sup> also used manometric and EMG measurements in 13 subjects both at rest and during Valsalva, demonstrating a similar increase in rectal and sphincter pressures and puborectalis EMG recordings. Yet, with concomitant barium studies, the anterior rectal wall separated from the mucosa, allowing contrast to fill the rectum. The authors proposed that the puborectalis functions more like a sphincter rather than contributing to the flap-valve mechanism.

Furthermore, quantifying the anorectal angle and relating that to patient symptoms has resulted in mixed views. Jorgensen and colleagues<sup>40</sup> noted significant interobserver variation in anorectal angle measurements among three

interpreters but good intraobserver consistency, suggesting that variation in anorectal angle measurements may be attributable to subjective interpretation of the rectal axis along the curved rectal wall. The authors of another study, assessing the reproducibility of anorectal angle measurement in 43 defecating proctograms, found significant intra- and interobserver variations, and concluded that the anorectal angle is an inaccurate measurement. Jorge and associates<sup>41</sup> measured the anorectal angle during rest, squeeze, and push in 104 consecutive patients and also found highly significant differences in each measurement category.

### Reservoir

As an additional part of the continence mechanism, the rectum must be able to function as a temporary storage site for liquid and solid stool. With passage of the fecal stream into the rectum, the pliable rectal walls are able to distend and delay the defecation sequence until an appropriate time. This process relies both on rectal innervation to sense and tolerate the increasing volume of stool (capacity), as well as maintain a relatively low and constant pressure with increases in volume (compliance). Extremes of either of these components can lead to fecal incontinence through decreased accommodation or overflow states. Although decreased compliance has been demonstrated more often in patients with fecal incontinence, it has also been shown to occur as a normal consequence of aging.<sup>42</sup> In addition, Bharucha and associates,<sup>43</sup> in a study of 52 women with fecal incontinence, demonstrated that the rectal capacity was reduced in 25% of women, and these lower volume and pressure thresholds were significantly associated with rectal hypersensitivity and urge fecal incontinence. Furthermore, after low anterior resection for cancer, those patients with resultant lower rectal compliance and lower rectal volume tolerability (capacity) have been associated with higher rates of fecal incontinence.<sup>44</sup>

### Normal Defecation

The awareness of the need to defecate occurs in the superior frontal gyrus and anterior cingulate gyrus. The process begins with movement of gas, liquid, or solid contents into the rectum. Distention of the rectum leads to stimulation of pressure receptors located on the puborectalis muscle and in the pelvic floor muscles, which in turn stimulate the RAIR. The IAS relaxes allowing sampling of contents. If defecation is to be deferred, voluntary contraction of the EAS and levator ani muscles occurs and the rectum accommodates with relaxation after an initial increase in pressure. When the anal canal is deemed to have solid contents and a decision to defecate is made, the glottis closes, pelvic floor muscles contract, and diaphragm and abdominal wall muscles contract, all increasing abdominal pressure. The puborectalis muscle relaxes, resulting in straightening of the anorectal angle, and the pelvic floor descends slightly. The EAS relaxes and anal canal

contents are evacuated. Upon normal complete evacuation, the pelvic floor rises and sphincters contract once more in a “closing reflex.”

## Pathologic Conditions

### Incontinence

Incontinence is the inability to defer the passage of gas, liquid, or solid stool until a desired time. Numerous alterations in anorectal physiology can lead to incontinence and many patients have more than one deficit. Structural defects in the IAS or EAS muscles occur because of obstetric injury, trauma, or anorectal surgery. The keyhole deformity is a groove in the anal canal allowing the seepage of stool or mucus. Originally described as a complication after the posterior midline fissurectomy or fistulotomy, it can also occur with lateral IAS defects. Intact sphincter muscles with impaired neurologic function, because of pudendal nerve damage or systemic disorders such as diabetes, can also result in incontinence, especially if the impaired sphincter is further stressed by diarrhea or irritable bowel syndrome.

Abnormal rectal sensation can lead to incontinence in two ways. Conditions such as proctitis caused by inflammation or radiation can result in hyperacute sensation. The rectum fails to accommodate and the reservoir function is impaired leading to urgency and frequency stooling. Fragmentation of stools is often described by patients after low anterior resection, particularly if the pelvis has been radiated as in the case of adjuvant therapy for the treatment of rectal cancer. In the case of blunted sensation, because of a large rectocele, megarectum, or neurogenic disorders, the rectum becomes overdistended and overflow incontinence occurs.

The majority of patients with rectal prolapse are incontinent. Chronic stretching of the anal sphincters from full-thickness prolapse leads to a patulous anus through which gas and liquid stool easily leak. A reflex relaxation of the IAS may also occur as the rectal wall descends toward the anal canal. Patients with mucosal prolapse may have seepage of mucus or small amounts of liquid stool. Correction of the prolapse can resolve the incontinence if anal sphincter tone sufficiently returns. Age and duration of prolapse can affect this.

### Obstructed Defecation

#### *Suspected Enterocele or Rectocele (Obstructed Defecation)*

Patients with symptoms of enterocele or rectocele describe prolonged straining at defecation, with a sensation of partial or complete blockage (frequently a “closed trap door” preventing passage of stool). Defecography can demonstrate the presence of a rectocele or enterocele, suggest the presence of a peritoneocele, and clarify contributing disorders such as a

nonrelaxing pelvic floor, rectal intussusception or prolapse, and potentially uterovaginal prolapse.

### *Rectocele*

A rectocele is defined as greater than 2 cm of rectal wall out-pouching or bowing while straining, and can precede or accompany rectal intussusception. The rectocele can prevent passage of stool both by obstructing the anal orifice and by acting as a diverticulum to sequester stool. Patients with rectoceles often complain of the need for frequent sequential episodes of defecation, and even for manual compression or splinting of the anterior perineum or posterior vagina in order to completely evacuate. Additionally, patients may experience incontinence with relaxation, leading to reduction of the rectocele and return of the sequestered stool to the lower rectum.

Van Dam and associates<sup>45</sup> investigated the utility of defecography in predicting the outcome of rectocele repair. Rectocele size, barium trapping, intussusception, evacuation, and perineal descent were measured during defecography examinations of 74 consecutive patients with symptomatic rectoceles. The patients then underwent a transanal/transvaginal repair, followed by 6-month-postoperative defecography and reassessment of the five most common presenting symptoms (excessive straining, incomplete evacuation, manual assistance required, sense of fullness, bowel movement less than three times per week). No postoperative defecograms demonstrated a persistent or recurrent rectocele; however, one-third of patients had a poor result based on persistent symptoms. There was no association between defecography measurements and outcome of the repair. Still, the authors concluded that defecography serves three major purposes in the evaluation of a rectocele: preoperative evidence of its presence and size, documentation of additional pelvic floor abnormalities, and an objective assessment of postoperative changes.

An abnormal increase in perineal descent (typically greater than 2 cm) has been described among both incontinent patients and continent patients who strain during defecation.<sup>31,32</sup> These conflicting data underscore the poorly understood relationship between neuropathic pelvic floor damage and symptomatology.

Bartolo and associates<sup>46</sup> evaluated patients with perineal descent using manometric, radiographic, and neurophysiologic studies. When comparing 32 patients with incontinence and increased perineal descent with 21 patients with obstructed defecation and increased perineal descent, the authors found no significant difference in the extent of perineal descent or neuropathic damage to the EAS. Patients who were incontinent had lower manometric pressures (both resting and squeeze pressures) whereas those with obstructed defecation had normal manometric pressures. In a separate study, these authors also found that incontinent patients with increased perineal descent had severe denervation of both the puborectalis and the external sphincter compared with continent patients with increased perineal descent, who had

partial denervation of the external sphincter only.<sup>46</sup> Miller and colleagues<sup>47</sup> evaluated sensation in two similar patient groups. Patients who were frankly incontinent actually had less perineal descent than continent patients with descent, but had severely impaired anal sensation.

Berkelmans et al.<sup>48</sup> tried to determine whether women with increased perineal descent and straining at stool were at risk for future development of incontinence. The authors identified 46 women with perineal descent who strained during defecation but were continent. Twenty-four of the 46 were followed after 5 years and 13 of these (54%) had developed fecal incontinence, compared with 3 of 20 (15%) control patients. During their initial evaluation, the patients who previously strained and later developed incontinence had significantly greater perineal descent at rest and less elevation of the pelvic floor during maximal sphincter contraction than the women who strained but did not develop incontinence.

Thus, perineal descent may be a predictor of incontinence among patients with denervation of both the external sphincter and the puborectalis, and in patients with impaired anal sensation. Among patients with constipation, perineal descent and straining at stool may predict future fecal incontinence.

### *Dyskinetic Puborectalis*

Dyskinetic puborectalis, paradoxical puborectalis, nonrelaxing puborectalis, and anismus are terms that describe the absence of normal relaxation of pelvic floor muscles during defecation, resulting in rectal outlet obstruction.<sup>49</sup> Once diagnosed, dyskinetic puborectalis is usually treated with biofeedback and bowel management. Patients who fail conservative treatment have been offered botulism toxin injections into the puborectalis muscle with limited success.<sup>50</sup>

## Continence

The dynamic intention of all the aforementioned anatomy and physiology ensures continence. It does not follow that a deficit in any one area ensures incontinence. Continence achieved in patients with an ileoanal pouch is proof the rectum is not essential. An intact and functional puborectalis muscle can provide continence in the patient with pediatric imperforate anus, but incontinence can ensue during adulthood. Even profound deficits do not necessarily lead to incontinence if stool consistency is solid, whereas minor deficits can easily lead to incontinence and gas. To determine and treat abnormal fecal incontinence requires a systematic approach focusing on identifying the specific deficits present, applying appropriate testing to elucidate anal physiology and anatomy, and then directing therapy accordingly.

## Physiologic Testing

Lee E. Smith and Garnet J. Blatchford

Physiologic testing has been used to assess pelvic floor and anorectal disorders for the past 35 years, but only in the past two decades has this testing become of value for clinical use. These physiologic tests are performed in conjunction with a history, diary of the disorder, physical examination, endoscopy, and often imaging studies. Physiologic tests have provided or confirmed a diagnosis in 75% of patients with constipation, 66% of patients with incontinence, and 42% of patients with chronic anorectal pain according to one study.<sup>1</sup>

The original physiologic testing equipment was homemade, so that all of the studies were based on a specific unit, which was not available anywhere else; thus, the ability to compare studies was almost impossible. In the past two decades equipment has been commercially produced such that reproducible results are possible. Even now a major problem is lack of a good set of normal values for healthy patients of both sexes and of all ages. Physiologic testing includes several tests that complement each other, because there is not a single test that contributes the data necessary to analyze disorders of the pelvic floor. Unfortunately, many patients have diseases or disorders that are of multifactorial pathophysiologies that will give several abnormal results, which then are more difficult to interpret. These tests include manometry, defecography, anal ultrasound, magnetic resonance imaging (MRI), transit time, pudendal nerve terminal motor latency (PNTML), and electromyography (EMG). This chapter describes these tests and their usefulness in evaluating adult diseases and disorders.

### Manometry

Manometry is a technique for measuring pressures existing in the rectum and anus, and pressures and reflexes elicited by voluntary actions or by local stimuli. The equipment and techniques vary, but investigators are beginning to use more standardized equipment and methods so that our descriptions of the equipment and techniques can be focused on just a few. To be able to interpret the data, the range of normals by sex and

age is needed. These normal measurements may be obtained from sites using the same system, or studies of your own normal patients.

### Indications

First, manometry is used for evaluation of incontinence. A sphincter defect can be located and quantified. Second, constipation, mainly outlet obstruction type, is investigated to determine whether abnormal pressures exist. The loss of the rectoanal inhibitory reflex (RAIR) suggests Hirschsprung's disease. Third, some anorectal pain syndromes are associated with abnormal pressures within the sphincter mechanism. Fourth, the study is conducted to establish a baseline when an anorectal or pelvic floor procedure is contemplated. For example, if biofeedback or a surgical procedure is to be used for incontinence or constipation, a pre- and postprocedure study provides the means to quantify a change.

### Equipment

The equipment consists of several essential components: the probe, the transducers, the recorder, and the hydraulic pump for water infusion methods. There are two frequently used methods: the water-perfusion method and the solid-state method. The choice is based on cost and user experience.

### Probes

The probes may be water perfusion, solid state, small balloon, or large balloon; they may be either open-tipped or side-opening. The open-tipped and balloon probes have fallen into disfavor. The most popular type is the water-perfusion probe, which is relatively inexpensive, durable, and easy to use.

The water-perfusion catheter probe has side holes through which water is slowly perfused, and pressure resistance of the sphincter is exerted against the holes. The simplest catheters have four holes at the same level on the probe; this circumferential array will show asymmetry within the anal

canal. A balloon is attached to the tip, and a central channel in the tube opens into the balloon so that it can be inflated to elicit reflexes or elicit sensations in the rectum. Each of the side holes has an individual channel that can be connected to transducers. The mechanical water pressure is transmitted to the transducer.

The solid-state catheter is expensive and fragile, but it gives the most accurate, reproducible results. The sensors are located at the same level on the catheter, and a balloon, which is inflatable, is attached to the tip. One sensor is located at the tip within the balloon to measure the pressures within the rectum. The sensors are wired to a computer which gives a digital readout and a graph to show the pressure measurements. During this discussion, the terms probe and catheter will be used interchangeably.

### *Hydraulic Water-Perfusion Machines*

The water-perfusion machine is a key part of the water-perfusion method. The water is driven through each of the individual channels in the tube at a chosen rate; the water perfuses through the holes near the tip and thus is exposed to pressure changes.

### *Transducers*

Transducers are an essential part of the water-perfusion system. The water-perfusion catheter has individual channels as described above; each perfusion channel has a side channel that connects to a transducer. The side holes through which water is slowly perfused also transmits pressures back to individual transducers. The mechanical water pressure is changed to electrical signals in the transducer.

### *Amplifier/Recorder*

Many recording devices are available, but at present computerized systems with small amplifiers and recorders are preferable. Software has been designed to give chart, table, and graph printouts. An attached monitor is a useful way to observe the tracings as the procedure is in progress.

## Technique of Manometry

### *Initial Considerations*

Usually manometry is performed using either the water-perfusion method or the solid-state microtransducer method. In this section, reference to both will be made. In our laboratory, we first used homemade systems, later the water-perfusion method, and now the solid-state method. Most of the discussion will be based on the solid-state system, but mention of differences between systems will be made when appropriate.

The informed consent form is not necessary in many American and international institutions, but our institutional policy requires that we obtain a signed consent form. The study is performed with focus on the distal 5 cm, which is the

segment that contains the sphincter muscles. It is not possible to separate the puborectalis muscle from the external anal sphincter. However, the internal sphincter and the external sphincter may be analyzed based on the portions of pressure represented by the resting tone and the squeeze pressure.

### *Preparation*

The preparation is a simple small, tap-water enema or commercially prepared enema to empty stool from the rectum and anus before coming for the examination. The patient is placed in the left lateral position with the hips and knees flexed to 90 degrees. A digital examination with a well-lubricated glove is done first to verify that the rectum is empty, sense the direction of the rectal lumen, and recognize any abnormalities. Instructions about what the patient is to expect regarding relaxation, breathing normally, not talking, squeezing on command, and sensing the balloon will make the conduct of the examination quicker and easier for all.

### *Calibration*

Calibration is critical to obtain accurate, reproducible results. The calibration record should be saved with the actual procedure recording to validate the measurements. For the water-perfusion method, the reservoir is filled, and the hydraulic pump is set for a pressure of about 10 psi at a rate of less than 3 mL per minute. A large volume of water introduced may produce an error; so ideally the flow rate should be far less at a rate of 0.2–0.4 mL per minute. The transducers and the perfusion holes in the catheter should be at the same level during calibration and during the procedure, or the baseline must be zeroed again at the beginning. The transducers need to be inspected for the presence of air bubbles which produce error; the bubbles need to be removed.

The solid-state system does not need to be kept at the same level during the procedure. Following the vendors instructions, the zero atmospheric level is the baseline, and usually a high point on the scale of 100 mm Hg is measured.

### *Resting Pressure*

The probe is introduced higher than the 5-cm level and left in place for 5 minutes to permit the temperature to equalize to body temperature and the sphincter mechanism to relax to a baseline. The probe is oriented so that the posterior sensor corresponds to the recording of the posterior aspect of the anus. The recordings are made by either the station pull-through technique or the continuous pull-through technique. Most laboratories use the station pull-through method. The catheter is pulled through at 1-cm intervals, stopping to record the pressure at each increment for 10 seconds. As the sensors enter the sphincter mechanism, the pressure will be seen to increase over the baseline rectal pressure. There is usually a stepwise increase in pressure as the sensors progress distally (Figure 4-1). As the sensor leaves the sphincter mechanism, the pressure will drop to zero.

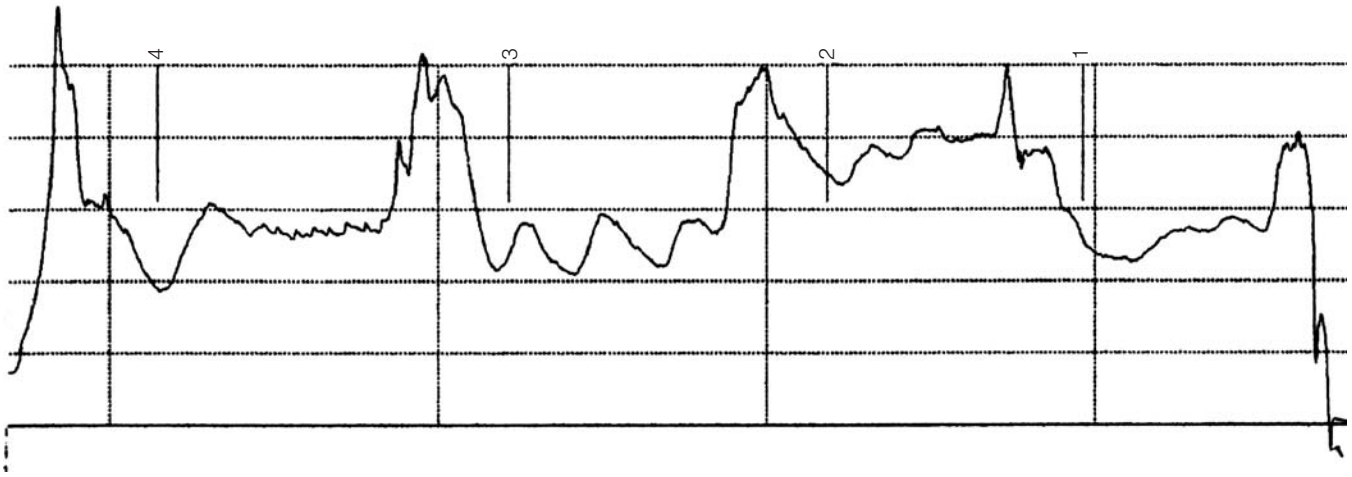

FIGURE 4-1. Normal tracing of resting tone in one quadrant on the manometry probe. The scale is 100 mm Hg. The pressure progressively increases from the 4-cm level to 2-cm level with a small decrease in pressure at the 1-cm level, and then to zero as the probe exits.

In the continuous pull-through method, the probe is pulled through with a small motor at a continuous rate. A curve reflecting the pressure zone is generated. The pressures generated by continuous pull through tend to be higher than those obtained from station pull through.

#### *Squeeze Pressure*

The probe is reinserted to at least the 6-cm level and reoriented. The probe is again removed at 1-cm increments. The patient is instructed to squeeze the sphincter muscles as if to stop a bowel movement and hold the squeeze for 3 seconds (Figure 4-2). The patient is also instructed to avoid using accessory muscles, especially the gluteals.

Using the continuous pull-through method, the patient is asked to squeeze and hold the squeeze as a motor pulls the catheter through the sphincter mechanism. The pull through can be performed several times and the results can be averaged.

FIGURE 4-2. Normal tracing of voluntary squeeze in one quadrant on the manometry probe. The scale is 100 mm Hg. The squeeze essentially doubles the resting pressure.

#### *Squeeze-Duration Study*

The probe is positioned in the site of the highest pressure in the anal canal. The high pressure zone is the length of the anal canal with resting pressures at least 30% higher than rectal pressure.<sup>2</sup> The patient is instructed to squeeze and hold the squeeze for 45 seconds as the recording is made (Figure 4-3). Some investigators perform this maneuver once and others do two or three runs and average the results. This study is also termed sphincter endurance.

#### *Reflexes*

The probe is again positioned in the high pressure zone in the anal canal to observe for the RAIR. Then 10 cc of air is injected into the balloon and the pressures are observed for 10 seconds. Then air is inflated into the balloon at 20-, 30-, 40-, 50-, and 60-cc increments (Figure 4-4). The recording normally shows a relaxation from the baseline, which verifies the intact reflex from the stimulated rectal wall to the internal sphincter.

The probe is positioned in the high pressure zone again, and the patient is asked to cough to elicit the "cough reflex." The squeeze pressure increases involuntarily to counteract the increased abdominal pressure. Unfortunately, the artificial situation in the laboratory while lying on the left side on a table interferes with the patient's willingness to make as good efforts as they would in the privacy of their own toilet.

#### *Strain Maneuver*

The probe is positioned in the high pressure zone. The patient is instructed to bear down as if to defecate for at least 5 seconds. The pressure is normally reduced for a few seconds similar to the RAIR (Figure 4-5). This maneuver is repeated after a 30-second rest. The result is obtained by averaging the total runs. To appreciate what is happening to the sphincter, the rectal

FIGURE 4-3. Normal squeeze duration study in one quadrant on the manometry probe positioned in the highest pressure zone.

FIGURE 4-4. Normal RAIR in one quadrant on the manometry probe. The scale is 100 mm Hg.

pressure is measured at the same time with the rectal balloon, which corresponds to the increased abdominal pressure.

*Rectal Sensation*

The balloon is inflated in 10-cc increments until the patient senses the balloon. The first sensation is normally at or before 20-cc inflation. The compliance test can be recorded by continuing the balloon inflation as detailed below.

*Compliance*

Having recorded the first rectal sensation, the balloon is inflated slowly in 50-cc increments. The patient will feel a point at which there is a strong urge to defecate. This is recorded. At a further point, the patient will experience a discomfort, which is recorded as the maximal tolerated volume. In the normal-sized rectum, this will be 200–250 cc (Figure 4-6).

FIGURE 4-5. Normal strain maneuver. A relaxation occurs.

FIGURE 4-6. Normal compliance in one quadrant on the manometry probe. The patient reports the insufflation causing the first sensation, the first urge, and the last tolerable volume.

## Other

### Ambulatory Anorectal Manometry

To record pressures over a long period of time, a sleeve catheter, which simply records the highest pressure in the anal canal, is fixed in place. The patient then carries a recorder during the decided upon time, perhaps 24 hours. This is generally a research tool at this time.

### Vector Manometry

This is best achieved with a probe that contains eight sensors in radial orientation. The probe is drawn through the anal canal, and the pressure profile shows the direction of abnormally decreased pressure. Vector manometry has been generally replaced by anal ultrasound.

## Interpretation

### Normals

In the anal canal there are subtle differences in the upper, middle, and distal segments.<sup>3</sup> In the upper anus the pressure anteriorly is lower; in the mid anus the pressures are about equal

circumferentially; and in the distal anus the pressure is slightly less posteriorly. Overall, men and young patients have higher pressures. However, there is overlap of normal measurements by sex and age.<sup>4</sup> The resting pressure has contributions from both the internal and external sphincters, with the internal sphincter providing 75%–80% of the total. The squeeze pressure is derived dominantly from the voluntary external sphincter.

Normal values are difficult to verify, because the literature sources are based on small numbers of patients. Some of the values vary, but by combining the totals from several authors, average numbers for practical purposes can be obtained.<sup>5,6</sup> These will be listed in the following sections.

### Interpretation of Resting Pressure

The resting pressure is the pressure in the high pressure zone at rest after a period of stabilization.<sup>2</sup> Seventy-five to 80% of the resting pressure is a measure of the internal sphincter tone.<sup>7</sup> For women, the resting pressure is approximately 52 mm Hg (range, 39–65). For men, the resting pressure is approximately 59 mm Hg (range, 47–71). Sometimes a normal patient may have low pressures, but does not have a

FIGURE 4-7. Low resting and voluntary squeeze pressures in an incontinent patient.

complaint if the stool is well formed. However, a patient may have “normal” pressures, but yet complains of incontinence. These measurements cannot be interpreted alone, but must be analyzed in the context of the history and other measurements. At times, slow waves of 8–12 cycles/minute can be seen on the tracings, but these are not associated with any specific pathology.

Low resting pressures are usually seen in patients who have the chief complaint of incontinence (Figure 4-7).<sup>6,8,9</sup> Patients who have low pressures may not be good candidates for a surgery that will leave them with a poorly formed or liquid stool, such as total colectomy with ileorectal anastomosis or proctocolectomy with ileal pouch to anal anastomosis; these patients might be better served with a permanent ileostomy.

High basal pressures may be associated with anorectal pain. Some patients have spastic sphincters, which may be associated with outlet obstruction. Also, patients with anal fissure have a spastic internal sphincter with high pressure measurements as part of the pathophysiology. These patients may be candidates for lateral internal sphincterotomy. Pharmacologic relaxation may be achieved in lieu of surgery. Relaxation of internal sphincter spasm can be achieved by 10 mg of sublingual nitroglycerine. Topical 0.2% nifedipine or 0.2% nitroglycerine applied to the anoderm relaxes the underlying muscle.<sup>10</sup>

Observation with a longer baseline tracing may show periods in which there is relaxation of the sphincter, even down to the zero level; incontinence might be expected to be a complaint from patients with this finding. However, the opposite can happen with episodes of spasms of high pressure. Some of these patients can be seen to have ultraslow wave activity of 1–2 cycles/minute.

#### *Interpretation of Squeeze Pressure*

The maximum voluntary pressure is the highest pressure recorded above the zero baseline at any level of the anal canal during maximum squeeze effort by the patient.<sup>2</sup> The squeeze pressure is the pressure increment above resting pressure after voluntary squeeze contraction and is a calculated value that is the difference between the maximum voluntary pressure and the resting pressure at the same level of the anal canal. The squeeze pressure is mainly a measure of the external sphincter.<sup>11</sup> For women, the squeeze pressure is approximately 128 mm Hg (range, 83–173). For men, the squeeze pressure is approximately 228 mm Hg (range, 190–266). The squeeze

pressure is examined as a total squeeze pressure, which includes the resting pressure plus the squeeze, and as a maximum squeeze pressure, which is the squeeze pressure minus the resting pressure.

A low squeeze pressure may be associated with sphincter injury or nerve damage from surgery, especially anal fistula surgery, obstetric trauma, or other anorectal trauma (Figure 4-7). Sometimes a patient will not cooperate during the test, often because of local pain. At this point, use of an anal ultrasound is appropriate to identify possible sphincter injury.

High squeeze pressure is found in those patients who have pelvic floor spasm (anismus), often associated with anorectal pain. These same patients are unable to relax the sphincter when asked to bear down as if to defecate.

#### *Interpretation of Squeeze Duration*

The sphincter duration is the length of time the patient can maintain a squeeze pressure above the resting pressure. The duration of squeeze should be >30 seconds at >50% of maximum squeeze pressure. When patients are unable to maintain a squeeze, they may be incontinent. In this case, there may be too few Type I motor nerves. There is a conversion from a dominantly Type I nerve to Type II nerves as patients grow older. The actual importance for this part of the manometry study is not clear.

#### *Interpretation of Reflex Studies*

The RAIR is the transient decrease in resting anal pressure by >25% of basal pressure in response to rapid inflation of a rectal balloon, with subsequent return to baseline.<sup>2</sup> The decrease in pressure during the RAIR test is a measure of the internal sphincter relaxation.<sup>12</sup> The reflex varies with the volume inflated into the balloon, the rate of inflation, and the rectal compliance. This reflex may be present even with central nervous system disorders; however, disease that interferes with the peripheral nerves or ganglion cells of the myenteric plexus or fibrosis of the internal anal sphincter may interfere with a measurable reflex relaxation. Likewise, a megarectum might be associated with a poor reflex, because the balloon does not touch the rectal wall to stimulate the reflex. The presence of a normal RAIR rules out Hirschsprung’s disease (Figure 4-8).<sup>13</sup> When the balloon is deflated, a rebound contraction may be seen in patients who have a hypertonicity of the sphincter mechanism. Patients with fissures may also manifest this rebound phenomenon.

FIGURE 4-8. Absent rectoanal reflex (RAIR), consistent with Hirschsprung's disease. Each spike is an insufflation, but no RAIR follows.

The cough reflex is the pressure increment above resting pressure after a cough, and is a calculated value that is the difference between the maximum pressure recorded during cough and the resting pressure at the same level in the anal canal.<sup>2</sup> The cough reflex, also equated with a Valsalva reflex, is a rectal reflex to counter a sudden abdominal pressure increase. This sacral reflex prevents soiling during abdominal pressure increases. This reflex may be abolished if there is a disruption of nerves in the cauda equina, sacral nerves, pudendal nerves, or peripheral nerves, but is maintained if nerves higher than the sacrum are injured.

#### *Interpretation of Strain Maneuver*

The ability to defecate requires both anal relaxation and abdominal compression. As mentioned previously, the patient

has difficulty straining and bearing down as if to defecate in this artificial environment. Embarrassment and fear of accidental passage of gas, liquid, or solid stool prevents complete cooperation.

Low abdominal pressures may be seen when there is central nervous system disruption or skeletal muscle disorders that prevent abdominal compression. Very high abdominal compression occurs when the anal sphincter does not relax, permitting high, recurrent pressures to be exerted on the pelvic floor.

The failure for the sphincter to relax appropriately is termed anismus or paradoxical pelvic floor contraction (Figure 4-9).<sup>14</sup> Such outlet obstruction may also interfere with interpretation of a transit time study. The failure to relax has been found in sexually abused patients and in neurologic disorders where inhibitory pathways are ablated.

FIGURE 4-9. Paradoxical increase in sphincter pressure during the strain maneuver, rather than a relaxation, is consistent with anismus.

### *Interpretation of Rectal Sensation*

The sensory threshold is the minimum rectal volume perceived by a patient.<sup>2</sup> A normal value for perception of rectal distention is approximately 15-mL (range, 9–25) inflation. Poor or absent sensation portends a poor response to biofeedback. The inability to sense suggests neural impairment, which may be related to a primary or secondary disorder, such as diabetes or amyloidosis. Constipated patients who have severe straining may progressively lose their ability to sense rectal fullness. Hypersensitivity may be evident in patients who have inflammatory bowel diseases, or have irritable bowel syndrome.

### *Interpretation of Compliance*

The urge sensation is the volume associated with the initial urge to defecate.<sup>2</sup> The rate of inflation, fast or slow, the balloon size and shape, and the distance up within the rectum may alter the result. Therefore, the laboratory must standardize their method. The maximum tolerated volume is the volume at which the patient experiences discomfort and an intense desire to defecate.<sup>2</sup> The maximal tolerable volume and pain threshold are reduced in patients who have a fixed, noncompliant rectal wall. For example, patients who have had proctectomy, fibrosis caused by ischemia, or fibrosis caused by inflammatory bowel disease will have lower maximal tolerable volumes and lower pain thresholds. A low tolerable volume may indicate rectal hypersensitivity and irritability. Increased compliance may be found in the megarectum. Decreased compliance caused by rectal reservoir reduction will result in fecal frequency and urgency with possible incontinence.

## Defecography

Defecography is a dynamic fluoroscopic examination performed with rectal contrast to study the anatomy and function of the anorectum and pelvic floor during defecation.<sup>2</sup> This procedure may be performed using standard radiology equipment and with relatively low radiation exposure. The specific points to be analyzed may be captured on still radiographs, but cineradiography provides a better look at the potential pathophysiologies that may influence and perhaps interfere with successful and normal evacuations.

### Indication

The use of defecography is indicated as part of the evaluation of a patient who has an outlet obstruction type of constipation. There are several mechanical obstructions that may be evident; however, these obstructions must fit symptoms associated, because normal patients have been found to have what appears to be an abnormal finding, which does not result in outlet constipation. This study may be used after a repair for outlet obstruction to compare the efficiency of the defecation process before and after the procedure.

## Equipment

The equipment is standard or inexpensive pieces that can be obtained from commercial surgical supply houses or hardware stores.

### *Table*

A standard fluoroscopic table capable of cineradiography, which can be used in the supine or erect positions, is used. Ideally, large radiograms are used, but fluorographic spot films might be substituted.

### *Videocassette Recorder*

Video recordings and spot films are helpful in analyzing the stages of defecation.

### *Chair and Cushion*

A defecography chair, which has a standard-shaped toilet seat, fits onto the footboard of the table. The seated position on a toilet is better accepted by the patient, because the act of defecation is easier, and the staff performing the study find it to be cleaner than defecation while the patient is lying on the radiologic table. For the person analyzing the study, the seated position is more physiologic. A cushion is placed on the toilet seat to raise the patient off the opaque seat, which interferes with imaging the anal area. Films can be made through the cushion filled with water, permitting the best images to the lowest point of perineal descent. If air is used in the cushion, it gives adequate images, and there is a slightly lower radiation dose.

### *Contrast System*

High density, barium paste (Anatrast E-Z-EM, Westbury, NY; or Evacupaste) is introduced into the rectum. These come prepackaged in a caulking tube. This tube fits into a standard caulking gun. Some radiologists place a thinner barium mixture into the rectum first and thus up into the sigmoid colon to better appreciate sigmoidocele. A thin, 240-cc barium contrast similar to that for a small bowel study may be given orally to better elucidate an enterocele. A tampon soaked in barium may be used to outline the vagina. Contrast in the bladder may be used to identify a suspected cystocele. Barium paste may be placed on the perineal skin to better see the lower limits of the perineal descent. More recently, the use of a water-soluble contrast in the peritoneal cavity outlines the depth of the cul-de-sac and structures within it.<sup>15</sup>

## Technique

### *Preparation*

The bowel may be studied with or without preparation. Our preference is to use a small enema an hour before the examination to minimize interference with sharp outlines of the

rectal wall. Friendly, clear explanations of what the patient is to expect and to do aids in conducting a rapid, complete examination.

### *Introduction of Contrast*

The clinician will have decided which sites require contrast based on the clinical history. The rectum, vagina, bladder, colon, small bowel, perineal skin, and/or peritoneum may be marked with contrast material.

If an enterocele is suspected, the patient should take 240 cc of diluted liquid barium orally 1 hour before the procedure. This use of barium must be used cautiously in the severely constipated, slow transit patient, because barium mixed with stool will harden to rock-like consistency during transit.

The patient is placed on a table with their left lateral side down. Tubing for injection of the contrast material is well lubricated and inserted through the anus into the rectum. The initial rectal contrast introduced is 50 cc of liquid barium to coat the rectal mucosa. To evaluate the sigmoid colon, additional barium may be injected, which will flow upwards. Air may be insufflated to better outline the mucosa. Then 250 cc of the thick barium paste in the caulking tube is inserted into the rectum using a caulking gun. If the bladder is to be evaluated, a urinary catheter is introduced into the bladder, and water-soluble contrast is injected.<sup>16</sup>

If the vagina needs to be seen, a tampon soaked in barium is inserted. If the cul-de-sac of the peritoneal cavity is to be seen, under sterile technique, a needle is inserted into the cavity, and 100 cc of water-soluble contrast is injected. When the patient

assumes an upright position, the contrast fluid will descend by gravity into the cul-de-sac. To see the perineal skin level, barium paste may be spread across the skin down the midline, anterior and posterior to the anus.

### *Imaging*

The patient is asked to be seated on the defecography chair (toilet), which is adjacent to the radiography table which has been erected to an upright 90-degree angle. The chair must have a water-filled cushion placed on the toilet seat to elevate the patient above the opaque seat. The patient is oriented so that lateral films can be taken. Video recording and fluoroscopy are begun. A baseline resting spot film is first (Figure 4-10). Second, the patient is asked to squeeze as if to hold a bowel movement tightly while the film is taken (Figure 4-11). Third, forceful straining without evacuating is urged for a spot film (Figure 4-12). Fourth, the patient evacuates as completely as possible with maximal straining. Ideally, this activity is captured on high-resolution videotape, plus a spot film near the end of evacuation. Last, a postevacuation film is taken. Anteroposterior filming may be done if there is a question of a lateral abnormality. The same procedures are performed with the patient facing the fluoroscope sitting in a semi-erect position in order to view the pelvic structures with the legs out of the image. It is important to remember that patients sometimes are quite embarrassed and intimidated by the mechanisms of this study; abnormal defecation dynamics may be nothing more than inability to defecate caused by embarrassment.

FIGURE 4-10. Defecography. The rectum at rest. R is rectum; A is the margin of the distal anus.

FIGURE 4-11. Defecography. The rectum with a voluntary squeeze. R is the rectum; A is the margin of the distal anus. The arrow shows the angle created by the puborectalis muscle pull.

FIGURE 4-12. Defecography. Rectum during bearing down. R is rectum; A is margin of the distal anus. The anorectal angle opens as the puborectalis muscle relaxes.

## Interpretation

Nonetheless, measurements and observations must be recorded on a data sheet which is designed to note all of the potential abnormalities. Having the study as cinedefecography allows repeated viewing of points where abnormality is suspected. The patient certainly does not want to do repeated studies. The findings include the anorectal angle, perineal descent, efficiency of emptying, and possibly rectocele, enterocele/sigmoidocele, anismus, and intussusception. There is an overlap of symptomatic and asymptomatic patients, so that the findings must be correlated with the clinical symptoms and signs. The patient at rest serves as the control, and the actions can then be observed. Future defecographies may be compared with this baseline study. This is important when a surgery is performed, and a change can be noted.

### *Anorectal Angle*

The anorectal angle is the proctographic angle between the mid-axial longitudinal axis of the rectum and the anal canal.<sup>2</sup> The videodefecography can be reviewed to see that the puborectalis muscle relaxes appropriately. The anorectal angle decreases during squeezing and increases during defecation and straining. This change shows that the puborectalis muscle is tightening and relaxing.<sup>17</sup> The resting anorectal angle ranges from 90 to 110 degrees.<sup>2</sup> During squeeze, the angle becomes more acute in the range of 75 to 90 degrees. On

evacuation, the angle becomes obtuse in the range of 110 to 180 degrees.

### *Perineal Descent*

Perineal descent is the caudad movement of the pelvic floor with straining.<sup>2</sup> A baseline is a line drawn from the tip of the coccyx to the underside of the pubis, the pubococcygeal line. The descent and ascent can be measured from this line. Normally the pelvic floor will rise during squeezing and lower during straining and evacuation.<sup>17-19</sup> The pelvic floor should not rise or fall more than 4 cm from the pubococcygeal line. If there is greater descent, it suggests a decreased muscle tone, which is most often the result of pudendal nerve injury. This finding is usually associated with other mechanical abnormalities.

### *Anal Canal Length*

During maximal evacuation, the length of the anal canal can be measured. The width of the anal canal can be noted to open and close adequately. During maximal strain to evacuate, the width of the anal canal should not exceed 2.5 cm. Wider openings suggest an incompetent muscle and possible incontinence.

### *Efficiency of Emptying*

Normally the rectum should empty completely, but 90% is the lower limit of normal. If an ileal pouch is being examined, 60% evacuation is the lower limit of normal.

### *Rectocele*

The rectocele is the most common finding in defecography. A rectocele is a bulging of the rectum into the posterior wall of the vagina (Figure 4-13).<sup>2</sup> A rectocele is much better defined by defecography than by clinical examination, giving better measurements of the size and adequacy of emptying.<sup>17-19</sup> Generally one that is <3 cm is not of consequence. Yet, even large rectoceles must be associated with outlet obstruction symptoms to be considered pathologic. Most of these patients have found that pressing upon the bulge of the rectocele aids them in evacuation. The best time to recognize a rectocele is during maximal straining to evacuate. The postevacuation film may show barium to be trapped in the rectocele. These bulges may be seen to be most often anterior, but occasionally posterior.

### *Enterocele/Sigmoidocele*

Enterocele is a protrusion of the peritoneum between the rectum and vagina containing small intestine (Figure 4-14).<sup>2</sup> A sigmoidocele (pouch of Douglas descent) is a protrusion of the peritoneum between the rectum and vagina that contains sigmoid colon.<sup>2</sup> During straining is the best time to look for a loop of contrast-filled small bowel or sigmoid colon.<sup>17-19</sup>

FIGURE 4-13. Defecography. A rectocele. R is the rectocele; A is the margin of the distal anus.

Bowel can be seen to indent the upper rectum or, if a space is present in front of the rectum, to herniate down toward the perineum. It is abnormal for bowel to descend below the upper rectum, and it is abnormal for a space to be present of  $>2$  cm between the rectum and vagina. The postevacuation film may show the abnormal movement of bowel into the deep cul-de-sac. It is not necessary for viscera to enter the space to be abnormal. The best way to detect the depth of the pouch of Douglas is to introduce water-soluble contrast into the peritoneal cavity.<sup>20,21</sup> This finding is suspected in only half of the cases.

FIGURE 4-14. Defecography. An enterocele. V is the vagina; E is the enterocele descending between the vagina and rectum.

### *Anismus*

Anismus is a nonrelaxing puborectalis or levator muscle complex, which is seen as a fixed anorectal angle with a puborectalis indentation in the face of straining down or evacuation.<sup>17-19,22</sup> Normally the puborectalis relaxes, and the anorectal angle opens up. The patient with anismus complains of severe straining to evacuate, and sometimes pain. If the act of defecation is timed, patients with anismus take  $>30$  seconds to empty, starting when the anal canal begins to open. Normally evacuation takes 10 seconds after the anal canal starts to open. In addition, the anal canal width is narrow.

### *Intussusception/Prolapse*

The rectum may be seen to prolapse or intussuscept during straining or evacuation (Figure 4-15A-C).<sup>17-19</sup> The intussusception or prolapse can be characterized as upper, mid, or lower rectal, and the origin can be described as anterior or posterior. The intussusception usually begins at 6–8 cm above the anus. Generally the upper rectum should remain attached to the sacrum and the retrorectal (presacral) space should not vary. The distal part of the rectum may be in either a vertical or horizontal plane and still be normal. Radiologists have some difficulty deciding whether the enfolding is a full-thickness intussusception or a normal rectal fold. Measurement of the thickness of the enfolding rectal wall will be twice as thick as the rectal wall or a normal fold of the rectum, because it represents two adjacent layers of the wall.<sup>23</sup>

### *Megarectum*

This diagnosis is a combination of a large measurement of the diameter of the rectum and incomplete emptying. The measurement of the width of the rectum at the level of the distal sacrum  $>9$  cm suggests megarectum.

### *Incontinence*

During the procedure, incontinent patients may not be able to hold the barium in the rectum, and it can be seen to run out of the anal canal before the instruction to defecate is given. Incontinence is often associated with other pathology.

## Balloon Expulsion Test

The balloon expulsion test measures the ability of the patient to expel a balloon inflated with 50–60 mL of water.<sup>2</sup> Condoms and Foley catheter balloons have been used for this test.<sup>24</sup> Patients with outlet obstruction are not able to pass this balloon readily. The problem is that some patients may pass the balloon, but have undetected outlet obstruction. Conversely, patients with outlet obstruction may call upon compensatory mechanisms to pass the balloon.

FIGURE 4-15. A–C Defecography. Intussusception of the rectum. R is the rectum; A is the margin of the distal anus. The arrows show the progressive infolding of the rectum.

## Anal Ultrasound

Anal ultrasound is used to look for anatomic abnormality of the anal sphincters. See the chapter on Endoluminal Ultrasound, to see images of anal ultrasounds. Ultrasound has replaced EMG as the best means to define an injury.

## Indication

If a defect in the sphincter mechanism is suspected, ultrasound is the diagnostic technique of choice.<sup>25</sup> It is most useful in the work-up of incontinence. The obstetric injury is readily seen, and the ability to find the defect approaches 100%.

## Equipment

The most often used ultrasound machine displays a 360-degree image made possible by a mechanically rotating transducer on a hand probe. The 10-MHz transducer provides the clearest images. The transducer is covered by a plastic cap.<sup>25,26</sup>

## Technique

The only preparation is a small enema. Sedation is not necessary. The patient is placed in the left decubitus position. The ultrasound system is assembled, and water is introduced to fill the cap covering the transducer. Air bubbles must be removed, because they cause an artifact. A digital examination is performed to find abnormality, but also to define the direction for insertion of the probe. The probe is introduced blindly to the point where the transducer is in the rectum. Images are made in the upper, middle, and distal anus, which is the distal 4–5 cm.

## Interpretation

Bartram<sup>26,27</sup> describes six ultrasonographic layers in the anal canal: 1) a hyperechoic layer that is the interface of the cone with the tissues; 2) a hypoechoic layer that represents the mucosa; 3) a hyperechoic layer that represents the submucosa; 4) a hypoechoic layer that is the internal anal sphincter; 5) a hyperechoic layer that represents the intersphincteric plane and the longitudinal muscle; and 6) a layer of mixed echogenicity representing the external anal sphincter.

In the upper anal canal, the puborectalis muscle is seen to loop around the upper anus. In the middle anus, both the internal and external sphincters may be seen. In the distal anus, the subcutaneous portion of the external sphincter is visualized, but the internal sphincter does not extend this far. The thickness of the internal sphincter stands out in the middle of the anus. The normal adult sphincter is 2–3 mm thick. A neonate may have a sphincter of 1 mm, and in the elderly 3–4 mm thick.

## Incontinence

A thin muscle suggests primary degeneration of the internal sphincter. After lateral internal sphincterotomy, a distal defect can be seen in the internal sphincter. Obstetric trauma may extend into the transverse perineus muscle, the external sphincter, or completely down through the internal sphincter. The injury blurs out portions of the normal rings of tissue described above.<sup>28</sup>

## Magnetic Resonance Imaging

MRI of pelvic floor function is developing rapidly. Dynamic studies have yielded additional information compared with static examinations alone. Identification of the anal and rectal structures is fairly easy on MRI because the perirectal fat shows a high degree of contrast when compared with the musculature. Indications for MRI examination are primarily sepsis, trauma, congenital abnormalities, and tumor.

There is a significant change in T1 and T2 weighted imaging associated with infection. This change produces high soft tissue contrast and enables abscess and fistulous tracks to be demonstrated. Sensitivity of MRI using the body coil can be as high as 89% in identifying fistulas, but demonstration of site of internal opening and differentiation of various muscle layers is not always possible.<sup>29</sup> In this study, there was concordance between MRI and surgical findings for the primary tract and secondary tracts of 86% and 93%, respectively.

Muscular anatomy is seen so well that MRI has become useful in the evaluation of anal trauma. When compared with endorectal ultrasound, endoanal coil MRI is superior in identifying the outer aspect of the external sphincter muscle. Concordance between MRI and surgical findings has been shown with regard to location of sphincter tears after obstetric trauma.<sup>30</sup> Studies have shown endoanal MRI to be comparable to endoanal ultrasound for identifying defects and/or thinning of the internal sphincter. MRI, however, may also show thinning of the external sphincter and puborectalis, which are not easily seen on endoanal ultrasound. This may represent atrophy in the pelvic musculature. Atrophy may correlate with a poor result after sphincter repair. Determination of atrophy on endoanal MRI may help in predicting the outcome after sphincteroplasty.<sup>31</sup> Atrophy on MRI has been shown to correlate with single fiber needle EMG which confirms denervation at the level of the muscle.<sup>32</sup> However, PNTML may be normal even in the presence of external anal sphincter atrophy. Prolongation of the PNTML reflects damage to only the large heavily myelinated nerve fibers and does not reflect the nerve function at the muscle level.

Congenital abnormalities of the anus and rectum can be delineated by MRI examination.<sup>33</sup> MRI can be used to identify sphincter involvement by rectal tumors. Distance from the distal aspect of the tumor to the levator muscle can be accurately assessed before surgical planning. Because of the length of the endorectal coil, visualization of the musculature of the sphincter up to 2 cm above the levator ani only is seen.<sup>34</sup> Visualization of depth of invasion by tumor can be done by manipulation of contrast with the use of T2 weighted images.

Defecatory problems may also be evaluated by MRI. Dynamic pelvic MRI (or MRI proctography) is now possible since techniques for rapid MRI acquisition have been developed. This allows pelvic floor motion to be visualized in real time during defecation. Generally this does not require addition of contrast although some limitations with motion artifact can

be seen. It has been suggested that examination in the supine position (MRI) compared with the study in a seated position (balloon proctography) shows minimal and probably clinically insignificant differences in pelvic organ prolapse between these two techniques.<sup>35</sup> MRI is able to demonstrate peritoneoceles, cystoceles, perineal descent, and prolapse during evacuation. Evidence of obstruction defecation may be seen with the anorectal angle becoming more acute with straining, suggesting paradoxical contraction of the puborectalis.

## EMG of the Anal Sphincter

EMG is used primarily in evaluating fecal incontinence. EMG is a means of assessing the motor unit. The integrity of the muscle may be assessed as well as its nerve supply. The integrity of external anal sphincter innervation after sphincter injury can be demonstrated. Sphincter reinnervation secondary to pelvic neuropathy can be demonstrated. EMG may also be used to "map" specific anatomic sphincter defects. This mapping technique has largely been replaced by anal ultrasonography, which is simple, accurate, and painless. Anal EMG may also be used to demonstrate appropriate relaxation and contraction of the anal muscle and can be used in biofeedback therapy.

## Concentric Needle EMG

Concentric needle EMG focuses on different motor unit characteristics. A concentric needle electrode will record muscle contractions as motor unit potentials (MUPs). A single MUP is caused by depolarization of the muscle from a single motor unit. Three variables are noted within a MUP: amplitude, duration, and shape. Amplitude is dependent on the number of muscle fibers discharging. The larger the number of fibers, the greater is the amplitude of the MUP. Generally only the fibers lying within 1 mm of the electrode (typically less than 20) contribute to the spike of the MUP. Distance may also influence amplitude to some degree. Duration of the MUP is a result of dispersion of the action potentials originating from the different muscle fibers of a motor unit. Duration of MUPs increases with age. Denervation also causes a prolongation of duration and polyphasic potentials. Shape of the MUP results from summation of the single fiber action potentials in the motor unit. Most normal MUPs are bi- or triphasic. Polyphasic potentials (four or more phases) have been reported in up to 25% of normal external anal sphincter muscles. Polyphasic potentials of short duration occur in myopathic disorders and those with long duration correlate with histologic evidence of regeneration in denervated muscle. Concentric needle EMG can be of particular value in the diagnosis of specific neurologic problems, including conditions of the cone and cauda equina, sacral roots, pudendal nerve, and for differential diagnosis of the various types of multisystemic atrophy.<sup>36</sup> Normal amplitude of the MUP is <600  $\mu$ V and duration is <6 ms.<sup>37</sup>

## Single Fiber EMG

Single fiber EMG electrodes are used because the area of measurement is so small each fiber generates a single spike. In normal circumstances, only a few muscle fibers from a single motor unit are within the recording area of a single fiber electrode. In reinnervated muscle, the numbers of fibers belonging to a single motor unit increase, thereby increasing action potentials are recorded at the electrode. The number of spikes can be recorded from separate potentials and fiber density can be calculated. Fiber density is the measurement of the mean number of muscle fibers innervated by one alpha-motor unit. This is usually an average from numerous separate potentials. Technique of single fiber EMG involves placing a sterilized fine needle (single fiber electrode) with a recording surface of 25  $\mu\text{m}$  into the external anal sphincter just outside the anal verge. Readings are taken in both the left and right lateral areas with 20 needle positions or more done for calculation of fiber density. A value  $>1.7$  is considered abnormal.<sup>38</sup> Criteria for pudendal nerve damage in single fiber EMG are the presence of an increased fiber density, increase of MUP duration and amplitude at rest, decrease of the number of MUPs during maximum contraction, and presence of “jitter and blocking” phenomena.<sup>39</sup>

## Surface Electrodes

Surface EMG electrodes are generally used to document anal sphincter activity at rest, strain, and squeeze. Documentation of paradoxical sphincter contraction may improve assessment of patients with defecation disorders. When compared with proctography, both needle EMG and surface EMG have a low positive predictive value, but they have high negative predictive values.<sup>40</sup> Therefore, EMG alone is not optimal for diagnosing the presence of nonrelaxing puborectalis. Surface electrodes avoid the pain of needle EMG.

Biofeedback training is often done using surface electrodes. This may be done for fecal incontinence or for difficulties with evacuation, particularly if paradoxical sphincter contraction is present. A plug electrode may be used within the anal canal or surface electrodes may be placed near the anus in a lateral position. Surface electrodes are easy and painless to apply and therefore well tolerated by patients. They come with self-adhesive or can be secured with tape. They should be placed over the subcutaneous part of the external anal sphincter 1 cm from the anal verge in right and left lateral positions. A grounding electrode is then placed on the patient’s buttock. EMG recordings from the external anal sphincter during straining using surface electrodes applied to the skin correlate well with the result from needle electrodes inserted into the muscle.<sup>41</sup> Other studies have shown that the anal plug electrodes correlate well with anal manometry and with wire electrodes during rest, squeezing, and straining. Normal values for surface EMG show short contraction (3-second) amplitude from 8–10  $\mu\text{V}$ , 10-second contraction

amplitude from 8–10  $\mu\text{V}$ , endurance (maintenance of sustained contraction) of 30–40 seconds. Normal patients demonstrated no evidence of paradoxical activity.<sup>37</sup>

## Pudendal Nerve Terminal Motor Latency

The pudendal nerve originates from S2, S3, S4 nerve roots and travels along the lateral pelvic wall down to near the ischial spine where it exits the pelvis to supply the external anal sphincter and the periurethral muscles through its terminal perineal branch. Prolongation in the pudendal nerve conduction indicates injury to the pudendal nerve sheath that results in focal demyelination with resultant slowing of conduction. Testing is usually done with a St. Mark’s electrode with a stimulating electrode mounted at the fingertip portion and a recording electrode mounted at the finger base portion. The electrode has a constant distance of 50 mm between stimulation of the nerve and recording of the external anal sphincter response. Latency between stimulation and response can then be recorded (Figure 4-16). This latency reflects the myelin function of the peripheral nerve. Therefore, a normal PNTML does not exclude partial damage. However, when unilaterally or bilaterally severely prolonged, PNTML has been shown to affect results after sphincter repair.<sup>39,42,43</sup>

## Evaluation of Transit

The time it takes for food to travel through the digestive tract is known as bowel transit time. Gastric emptying, small bowel transit, and colonic transit may be studied. Transit is dependent on diet and varies greatly from person to person. For this reason, a dietary history and bowel evacuation history should be obtained in conjunction with any transit testing. Dietary history can be evaluated for fiber, fat, and calorie intake. Patients who believe they eat a high fiber diet may be shown to have a very modest fiber intake. Stool history will further delineate the extent of the patient’s problem. In patients complaining of chronic constipation who believed that they had less than or equal to three stools per week for more than 6 months, a 4-week stool diary revealed that only 49% actually met this criteria. The remaining 51% of patients had, on average, six stools per week.<sup>44</sup> This study also showed that a history of psychiatric illness was five times more frequent among those whose bowel symptoms correlated poorly with objective evidence of constipation.

## Colonic Transit

The rate at which fecal residue moves through the colon is important in determining whether the stool is liquid, semi-formed, or hard. Evaluation of constipation and pelvic problems may require determination of colonic transit times in order to assist in treatment. Transit may be measured by radiopaque markers or radionucleotide techniques.

FIGURE 4-16. NTML curves showing a latency of the right nerve of 2.0 msD and the left nerve of 2.4 msD.

Colonic transit is most easily measured by use of a marker test. The patient ingests a capsule containing radiopaque markers, which are then followed through the colon by abdominal radiographs. Markers consist of a capsule containing radiopaque markers, which are commercially available (Sitz-Mark, Konsyl Pharmaceuticals, Fort Worth, TX) or can be individually created by filling gel capsules with small circles cut from radiopaque tubing. In the most simplified colon transit technique, the patient takes one marker tablet which contains 24 markers on day 0. On day 5, a supine abdominal film is taken to determine the number and position of remaining markers. If five or fewer markers are remaining, the patient has normal colonic transit. If more than five markers are present, then the pattern of residual markers is noted. Diffuse scattering throughout the colon would suggest colonic inertia or decreased motility. If the markers are present in the rectosigmoid region, then the presence of pelvic outlet problems should be considered. Segmental transit may be calculated as described by Metcalf et al.<sup>45</sup> On day 0, day 1, and day 2, the patient takes one marker capsule for a total of three capsules. On day 4, an abdominal film is taken. If there are more than a total of 50 markers remaining, transit time is abnormal and an additional abdominal radiograph is taken on day 7 to determine the location and number of residual markers. The abdominal radiograph is divided into the following sections: right colon, left colon, and rectosigmoid. The number

of markers present in each section is counted on both the 4- and 7-day films. A table can then be made with the values (Table 4-1). Average normal transit is 11.3 hours, 11.3 hours, and 12.4 hours for the right, left, and rectosigmoid colon, respectively. Normal total transit averages 35 hours. Segmental colectomy is not indicated for constipation even in the face of markedly abnormal segmental transit time. Stool weight has been shown to correlate with transit time in constipated patients.<sup>44</sup>

### Radionuclide Transit

Transit may be measured by radionuclide gamma scintigraphic techniques.<sup>46</sup> Radiographic and scintigraphic methods correlate well. The major advantage of scintigraphy is that 24-48 hours of scanning is needed compared with 5-7 days for marker test completion.

TABLE 4-1. Results of a colon transit study

	Right colon	Left colon	Rectosigmoid	Total
Day-4 film	15	21	16	52
Day-7 film	0	4	14	18
Transit time (h)	15	25	30	70

The theoretical numbers of ingested markers by time and colonic segment. This example shows a right colon transit of 15 h, left colon of 25 h, rectosigmoid of 30 h, and a total colonic transit of 70 h.

## Small Bowel Transit

Small intestinal transit should be evaluated before surgical treatment of constipation because the patient may have a global motility problem. Small bowel transit may be measured by breath hydrogen analysis. Hydrogen breath analysis depends on the presence of bacteria in the large intestine to metabolize lactulose. Up to 25% of the population cannot metabolize the sugar because they lack certain bacterial strains in the colon.<sup>47</sup> A meal of lactulose and beans is ingested and hydrogen breath analysis is undertaken. Fermentation of the meal occurs when the substrate reaches the colon. The fermentation process releases hydrogen gas that is absorbed and excreted by the lungs. Time to a 20-ppm increase in hydrogen in the breath correlates with small bowel transit. Some conditions such as low colonic pH, bacterial overgrowth, or antibiotic administration may interfere with the use of this test for small bowel transit.

Small bowel transit may also be determined by scintigraphic techniques. These techniques have the advantage of also measuring gastric emptying. Scintigraphy has a tendency toward slightly shorter transit times, but this is probably not clinically significant. Radiation exposure with scintigraphy is highest for the colon and can be reduced by the administration of laxatives after the procedure. Radiation to the ovaries is less than in a plain abdominal X-ray.

## Diagnostic Evaluations—Endoscopy: Rigid, Flexible Complications

Santhat Nivatvongs and Kenneth A. Forde

The large intestine from cecum to anus can be effectively and accurately examined as part of a complete physical examination. An ultimate diagnosis of large bowel diseases can only be made by direct observation of the abnormalities and, if indicated, a biopsy. Different equipment is designed and used for different purposes.

### Anoscopy

Anoscopy is the examination of the anal canal. The lower part of the rectal mucosa, upper anal mucosa, anoderm, dentate line, internal and external hemorrhoids can be seen through this examination.

There are basically two types of anosscopes: beveled type such as the Buie or Hirschman scope (Figure 5-1) and the lighted Welch-Allen scope (Figure 5-2) that uses the same light source as the rigid proctosigmoidoscope. Another type is the side-opening Vernon-David scope with Hirschman handle (Figure 5-3). The Hinkel-James anoscope (Figure 5-4) is much longer than the Vernon-David scope and is suitable for patients with deep buttock cheeks.

### Indications

Any anal and perianal diseases or conditions require a full examination of the anal canal. These include anal fissures, anal fistulas, anal Crohn's disease, anal tumors, hemorrhoids, anal condyloma, bright red rectal bleeding, and pruritus ani.

Anoscopy is frequently used in conjunction with colonoscopy, flexible sigmoidoscopy, and rigid proctosigmoidoscopy as part of the examination.

### Contraindications

Patients who have severe anal pain such as an acute anal fissure or a perianal or intersphincteric abscess may not tolerate the examination. In general, if a patient can tolerate a digital examination, anoscopy can usually be done. A 2% lidocaine

jelly should be used in patients with anal pain. Anal stricture or severe anal stenosis is another contraindication.

### Preparation

No preparation is required.

### Positioning

A prone jackknife position gives the best exposure. An alternative is a left lateral recumbent position.

### Technique

The Vernon-David, which is a side-opening endoscope, gives the best examination. Inspection of the anal area should always precede any other examination and, for this, good lighting is essential. The cheeks of the buttock are gently spread to gain exposure. Skin tags, excoriation, and change in color or thickness of the anal verge and perianal skin can be detected quickly. A scarred, patulous, or irregularly shaped anus may give clues to the cause of anal incontinence. Particularly in multiparous women, the anal verge may be pushed down quite far during straining—a feature of the descending perineum syndrome. When the anal verge is pricked with a needle, the external sphincter visibly contracts because of the anal reflex. It is useful for testing the sensibility of the anal canal, which may be absent in areas of previous scar or defect, or in patients with an underlying neuropathy.

The next step is to do a digital examination. The index finger should be well lubricated with a lubricant jelly, and the finger pressed on the anal aperture to “warn” the patient. Then the finger should be gradually inserted and swept all around the anal canal to detect any mass or induration. In men, the prostate should be felt. In women, the posterior vaginal wall should be pushed anteriorly to detect any evidence of a rectocele. Anal tone, whether tight or loose, can be easily estimated. A stricture or narrowing from scarring or a defect in the internal or external sphincters from a previous

FIGURE 5-1. Buie anoscope.

operation can be felt. A fibrous cord or induration in the anal area and the anal canal may indicate a fistulous tract. The external sphincter, puborectalis, and levator ani muscles can also be appreciated by digital examination. When the puborectalis is pulled in the posterior quadrant, the anus will gape but will close immediately when the traction is released. Persistence of the gaping indicates an abnormal reflex pathway in the thoracolumbar region frequently seen in paraplegic patients. The finger should press gently on these muscles for signs of tenderness. When the person with good anal function is asked to contract the muscles, the examiner not only feels the squeeze of the muscle on the examining finger but also feels the finger pulled forward by the puborectalis muscle.

Insertion of the anoscope should always be done with the obturator in place. The obturator is removed during examination and reinserted to rotate the instrument to another area. However, if the beveled type of endoscope is used, the

FIGURE 5-2. Lighted Welch-AlLEN anoscope.

FIGURE 5-3. Vernon-David with Hirschman handle anoscope.

endoscope can be rotated all around without having to reinsert the obturator. If an inverted (jackknife) position is used, the examination table need not be tipped down more than 10–15 degrees. If a left lateral position is used, an assistant needs to pull up the right cheek of the buttock for exposure. During examination, the patient is asked to strain with the anoscope sliding out to detect any prolapse of the rectal mucosa and the anal cushion. Excoriation, metaplastic changes, and friable mucosa indicate a prolapsed hemorrhoid.

A biopsy via an anoscope is not advisable because of its poor exposure. If indicated, a biopsy via a rigid proctosigmoidoscope or a flexible sigmoidoscope is more appropriate.

## Complications

Anal tear, especially at the posterior midline, can occur in patients with anal stenosis.

FIGURE 5-4. Hinkel-James anoscope.

## Rigid Proctosigmoidoscope

Three sizes of rigid proctosigmoidoscope are available (Figure 5-5). A 19 mm × 25 cm scope is the standard size for a general examination and for polypectomy or electrocoagulation. A 15 mm × 25 cm endoscope is an ideal size for general examination. It is much better tolerated by the patient, causing less spasm of the rectum and, thus, minimal air insufflation, yet enables as adequate an examination as the standard-size endoscope. An 11 mm × 25 cm endoscope should be available for examining the patient who has anal or rectal stricture, such as Crohn's disease. Some physicians and surgeons prefer a disposable standard-size rigid proctosigmoidoscope for routine examination.

### Indications

Rigid proctosigmoidoscopy has largely been replaced by flexible sigmoidoscopy. However, rigid proctosigmoidoscopy is still useful in examination of the anorectum. One of its advantages is that any blood clots or stool can easily be washed out. In fact, in a patient who has massive gastrointestinal bleeding, a rigid proctosigmoidoscopy is the first line of examination to rule out the source of bleeding in the anorectum.

A rigid proctosigmoidoscopy is used when an abnormality of the anal canal and rectum is suspected such as nonspecific proctitis, radiation proctitis, anorectal ulcer, anorectal neoplasm, infectious proctitis, and anorectal Crohn's disease. Rigid proctosigmoidoscopy is also useful to identify the precise site and size of rectal neoplasm.

### Contraindications

Patients with severe anal pain from an acute fissure, thrombosed external hemorrhoids, and perianal abscess may not allow an examination. The examination should be postponed to some other date. Anal stricture that will not allow the passage of the smallest size rigid proctosigmoidoscope is a contraindication to its use.

FIGURE 5-5. Rigid proctosigmoidoscope. Top, 19 mm × 25 cm; middle, 15 mm × 25 cm; bottom, 11 mm × 25 cm.

Patients with acute abdomen of any cause, rectal and sigmoid anastomosis less than 2 weeks postoperatively should not have a rigid proctosigmoidoscopy.

### Preparation

Two phosphate enemas should be given within 2 hours of the examination. This is not necessary in a patient who has diarrhea or active bleeding. Sedation is unnecessary.

### Positioning

A prone jackknife is the position of choice. However, a left lateral position also gives an adequate examination and should be used in conditions such as pregnancy, severe hypertension, retinal detachment or postoperative eye surgery, and some apprehensive patients.

### Technique

Although a standard proctosigmoidoscope is 25 cm in length, the average distance that the scope can be passed is 20 cm. In men, the scope can be passed to 21–25 cm half of the time, and in women, it can be passed that distance one-third of the time.<sup>1</sup> Rigid proctosigmoidoscopy is suitable only to examine the rectum and, in some patients, the distal sigmoid colon. The pain experienced from proctosigmoidoscopy is from stretching the mesentery of the rectosigmoid colon when the scope is pushed against the rectal wall, and from the air insufflation. When properly performed, rigid proctosigmoidoscopy should produce no pain or only mild discomfort. Most patients are fearful of the examination because of past bad experience with the procedure or from what they have heard. A few words of reassurance will be helpful.

With the obturator in place and held steady with the right thumb, the well-lubricated rigid proctosigmoidoscope is gently inserted into the anal canal, aiming toward the umbilicus for a distance of about 4–5 cm. Then the endoscope is angled toward the sacrum and advanced another 4–5 cm into the rectum. The obturator is removed and the bowel lumen is negotiated under direct vision. Air insufflation is limited to the amount necessary to open the lumen. When an angle is encountered, the endoscope is withdrawn 3–4 cm and then readvanced. This may be repeated several times to straighten the angulation. If further advancement is unsuccessful, the procedure is terminated at this point. Careful examination is done as the instrument is withdrawn. It is usually necessary to insufflate a small amount of air for good visualization of the lumen. The instrument should be rotated on withdrawal to ensure examination of the entire circumference. The mucosal folds in the rectum (valves of Houston) can be flattened with the tip of the endoscope to see the area behind them.

The length of insertion should be measured from the anal verge without stretching the bowel wall. Some physicians measure it in relation to the dentate line. The appearance of the

mucosa and depth of insertion should be accurately described. If a lesion is seen, the size, appearance, location, and level must be recorded. If a biopsy is performed, the location, level, number of biopsies, and whether electrocoagulation is necessary should be noted. During the entire procedure, suction and water irrigation should be available.

## Complications

If not careful, the tip of the endoscope can tear the mucosa; a small or moderate amount of bleeding may occur. Abdominal pain and distention can occur from excessive air insufflation.

Perforation from diagnostic rigid proctosigmoidoscopy is extremely rare. Gilbertsen<sup>2</sup> reported an incidence of five perforations in 103,000 examinations. Nelson et al.<sup>3</sup> reported two perforations in more than 16,000 examinations.

## Flexible Sigmoidoscopy

The present-day flexible sigmoidoscope is no longer fiberoptic but contains a videochip at the tip of the endoscope. This videochip transmits the image through the processing unit to the monitor. The flexible videosigmoidoscope is 60 cm in functional length (Figure 5-6). The entire sigmoid colon can be reached by the flexible sigmoidoscope in 45%–85% of cases and, in a few, the splenic flexure can also be visualized.<sup>4,5</sup> The discrepancies in success depend on patient selection and the experience of the endoscopist. For selective screening examination, flexible sigmoidoscopy has a 3–6 times greater yield than does rigid proctosigmoidoscopy in detecting colonic and rectal abnormalities, especially neoplasms.<sup>6,7</sup> Because of this higher yield and better exposure, many physicians have discarded rigid proctosigmoidoscopy.

## Indications

The role of flexible sigmoidoscopy is difficult to define because it can examine only the sigmoid colon and rectum in

FIGURE 5-6. Flexible videosigmoidoscope.

most cases. However, it is more convenient to use, and in many cases the entire colon need not be examined.

In acute diarrhea, flexible sigmoidoscopy can be used to rule out *Clostridium difficile* colitis, acute bacterial colitis, amebic colitis, and ischemic colitis particularly after aortic aneurysm repair. Flexible sigmoidoscopy is also an excellent tool to examine bright red rectal bleeding to detect its cause such as nonspecific proctitis, radiation proctitis, anorectal Crohn's disease, rectal ulcer, and also anorectal neoplasm. Flexible sigmoidoscopy is also used for colorectal cancer screening in conjunction with tests for fecal occult blood and to complement a barium enema examination. In this situation, CO<sub>2</sub> may be used for air insufflation if a barium enema is to follow.

## Contraindications

Patients with severe anal pain from anal diseases may not tolerate the insertion of the scope. This also applies to anorectal stricture and colorectal anastomosis less than 2 weeks post-operatively. Other contraindications include acute sigmoid diverticulitis, toxic colitis, and patients with an acute abdomen.

## Preparation

Bowel preparation with two Fleet enemas given within 2 hours of examination is adequate. The patient may eat normally. Patients with diarrhea do not require the enemas.

## Positioning

Left lateral recumbent.

## Technique

Sedation is unnecessary. The anal canal is lubricated by digital examination. A well-lubricated flexible sigmoidoscope is then inserted. Advancement of the endoscope is performed under direct vision. Pushing the endoscope through a bend in the bowel is a poor technique. Instead, the endoscope should be withdrawn to straighten the bowel. The key of success is short withdrawal and advancement of the endoscope or a to-and-fro movement, together with rotating the instrument clockwise and/or counterclockwise as needed. Use of air insufflation should be kept to a minimum. The procedure should be completed within 5–10 minutes. If a lesion is detected and proved by biopsy to be a neoplasm, a complete colonic investigation is indicated, ideally by total colonoscopy at some other date. A polyp up to 8 mm in size can be sampled with coagulation (hot) biopsy forceps or biopsied and electrocoagulated. To prevent possible explosion, because of hydrogen or methane gas in the lumen, air should be exchanged in the colon and rectum with repeated insufflation and suction. A larger polyp should be reserved for colonoscopy and polypectomy.

## Complications

Excessive air insufflation can cause acute abdominal distention and abdominal pain. This is best corrected by reinsertion of the endoscope and aspiration of air. Too rough and improper technique can cause perforation and other injuries.

The most common site of perforation in flexible sigmoidoscopy is in the distal sigmoid colon where it is angulated from the relatively fixed rectum at promontory of the sacrum. Complications from flexible sigmoidoscopy are uncommon but can be serious. They can be immediately apparent or delayed. Gatto et al.<sup>8</sup> reported a large population-based cohort that consisted of a random sample of 5% of Medicare beneficiaries living in the region of the United States covered by the Surveillance, Epidemiology, and End Results (SEER) program registries between 1991 and 1998. There were 35,298 flexible sigmoidoscopies performed. The perforation rate within 7 days of the procedure was 0.9 per 1000. Anderson et al.<sup>9</sup> evaluated the 10-year experience between 1987 and 1996 at Mayo Clinic, Scottsdale, AZ. There were 49,501 flexible sigmoidoscopies performed. Two perforations occurred: one of the perforations was in the cecum, likely from excessive air. Another perforation was in the sigmoid colon but was not detected until 17 days later as a pelvic abscess. Both required operation. There was no mortality. Levin et al.<sup>10</sup> analyzed 107,704 individuals who underwent 109,534 flexible sigmoidoscopic screenings as part of Colorectal Cancer Prevention Program from 1994 to 1996 at North California Kaiser Permanente Medical Care Program. There were two perforations, two episodes of diverticulitis requiring operation, two cases of bleeding requiring blood transfusion, and one episode of unexplained colitis. In this study in multivariate models, complications were significantly more common in men than in women (odds ratio, 3.34; confidence interval, 95%).

## Ileoscopy

Examination of the small intestine via an ileostomy can be performed using a rigid proctosigmoidoscope or a flexible sigmoidoscope.

### Indications

Indications for endoscopic the terminal ileum are few. Most of the time it is to rule out recurrent Crohn's disease or to find an abnormality in patients with high ileostomy output.

### Contraindications

Stricture of the stoma.

### Preparation

Bowel preparation is not required, but it is helpful if the patient has been on a clear liquid diet for 1 day. Sedation is not required.

## Positioning

Supine.

## Technique

The examination starts with a digital examination to gently dilate the stoma, which is frequently slightly stenotic. The well-lubricated rigid scope is introduced directly into the ileostomy. The terminal ileum is quite active with frequent spasm. It requires more air insufflation than scoping the rectum. The distance traversed by the endoscope is usually limited to 12–15 cm. In patients with a large para-ileostomy hernia, the endoscope may usually not be passed beyond 10 cm.

Flexible sigmoidoscopy is much easier to perform. The angulation of the small bowel can be straightened by push, pull, and rotation of the scope. A moderate amount of air insufflation is usually required.

## Complications

The small bowel has thin walls and requires gentle maneuvering of the endoscope. Perforation can easily occur. If an angle cannot be straightened, the procedure should be terminated.

## Pouchoscopy

### Kock Pouch or Continent Ileostomy

#### *Indications*

Although the ileoanal pouch has almost completely replaced the Kock pouch, there are still many patients with a Kock pouch constructed more than 30 years ago. One of the most common problems that require endoscopy is the extrusion or slippage of the valve causing difficulty or impossibility of intubation to evacuate the stool. The examination is performed to help decompress the obstructed pouch and to place a draining tube. Other indications included Crohn's disease and complication of the pouch with fistulas and high output of the pouch. Both rigid and flexible endoscopes can be used. Church et al.<sup>11</sup> advised using a pediatric flexible endoscope.

#### *Contraindications*

Stricture of the stoma.

#### *Preparation*

Bowel preparation is unnecessary and sedation is not usually required. If possible, the pouch should be emptied or irrigated just before the examination. It is also preferable if the patient has been on a clear liquid diet for 1 day before the procedure.

### Positioning

Supine.

### Technique

The endoscope can usually be passed easily into the pouch with inspection of the stoma being performed on insertion or withdrawal. The pouch can be lavaged as necessary.

A general inspection of the pouch is performed noting the mucosal appearance, the pouch size, distensibility, and the status of suture lines. If possible, the afferent loop of ileum should be intubated, especially in patients presenting with pouch inflammation. The endoscope must be retroflexed within the pouch to check valve length and symmetry. A careful search for foreign material should be made, particularly around the base of the valve. If mesh was used to reinforce the nipple valve, a fistula may form at this area. In patients with extrusion of the valve, passing the endoscope will be difficult.

For an obstructed pouch from a slipped valve, Church et al.<sup>11</sup> used a flexible endoscope as an obturator to insert the rigid proctosigmoidoscope. The rigid endoscope is placed over the flexible endoscope, which is itself inserted into the pouch. The rigid endoscope is advanced over the flexible endoscope into the pouch. Now the flexible endoscope can be withdrawn and a drainage catheter inserted to temporarily relieve the obstruction. Surgical repair of the nipple valve is required.

### Complications

Perforation can occur, particularly when there is an obstruction of the pouch.

### Ileoanal Pouch

Examination of the ileoanal pouch is best performed using a flexible sigmoidoscope although a rigid proctoscope can also be used. Unless there is an anastomotic anal stricture, the examination is usually easy. The endoscope can be used to examine the entire pouch and usually the terminal ileum proximal to the pouch.

### Indications

Examination of the pouch is indicated for patients with bleeding from the pouch, diarrhea, recent onset of fecal incontinence, obstructive symptoms, pouchitis, for surveillance follow-up examination to exclude neoplastic changes, and to rule out Crohn's disease.

### Contraindications

Severe anal or anastomotic stricture.

### Preparation

The patient is prepared by taking clear liquids for 1 day or administered a small enema before the examination. Sedation is not required.

### Positioning

Left lateral recumbent.

### Technique

The examination starts with a digital examination to evaluate the anal canal and the anal anastomosis. If there is a stricture, it should first be dilated with a finger or with Hegar dilators.

The well-lubricated flexible sigmoidoscope or a colonoscope is introduced into the anal canal. The endoscope is advanced into the pouch. The terminal ileum proximal to the pouch can usually be intubated. The examiner should evaluate the mucosa of the pouch and anal canal for any edema of the mucosa, granularity, mucosal bleeding, contact bleeding, erosion, fibrin exudate, pattern of mucosal ulceration, plaque, and mass. Abnormal mucosa should be biopsied. Only cold biopsy should be performed.

### Complications

Tear of the anal canal can occur if there is stricture of the anus or anastomosis. Traumatic injury from the scope may cause moderate bleeding but it usually stops spontaneously. A perforation can occur from the instrumentation or a biopsy.

## Colonoscopy

With the many imaging methods available for evaluation and often therapy of colorectal disorders, colonoscopy has emerged as the gold standard for diagnosis. It is also, in some areas, an increasingly frequent option for therapy, be it definitive or palliative.

### Indications

Indications for diagnostic colonoscopy include: the evaluation of virtually all symptoms associated with potential benign or malignant, acute, or chronic diseases of the colorectum; for resolution of abnormalities seen on other imaging modalities; for investigating otherwise unexplained symptoms such as anemia; the evaluation of chronic and acute bleeding per annum; for screening and surveillance of patients at high risk for colon adenomas or carcinoma; and localization of nonpalpable lesions at open or laparoscopic operation. It is also increasingly possible to combine diagnostic colonoscopy and other imaging techniques such as ultrasound.

### Contraindications

Contraindications to diagnostic colonoscopy may be classified as *absolute* or *relative*. Although colonoscopy is appropriately considered a minimally invasive procedure, there are risks involved that may be avoided, or at least minimized, by

careful patient selection and certainly these risks should be discussed before the performance of the procedure.

*Absolute contraindications* are suspected bowel perforation or recent anastomosis, established peritonitis, and fulminant colitis.

*Relative contraindications* include suspected ischemia and acute colitis, in either of which instance an experienced examiner may safely perform a limited examination. Active bleeding is a relative contraindication unless the examiner has had significant experience with elective diagnostic colonoscopy and we believe the procedure should not be attempted if one is unprepared to provide, or for the patient to accept, treatment of complications of the procedure.

## Preparation

Preparation for colonoscopy, of necessity, should include preparation of the endoscopist, preparation of the patient in general, and of the colon specifically. Several organizations have prepared and published guidelines for credentialing the individual who is permitted to perform colonoscopy in an institutional setting<sup>12</sup> and, in some institutions, Credentials Committees have been established that grant privileges. Although there is some controversy involving required numbers of experiences in training, all recommendations include the following elements: background knowledge of anatomy, physiology, and pathology of the colon as well as familiarity with instruments and accessories used in endoscopy; some formal training; and quality assurance practices. The concept of proctoring has also been addressed by some.<sup>13</sup> Equipment for resuscitation should be available and individuals qualified to perform cardiopulmonary resuscitation should be present in the area where colonoscopy is performed. We cannot overstate the necessity for qualified assistance during the performance of the procedure and for monitoring the patient's condition.

Obtaining informed consent is an opportunity for discussing with the patient elements of the past and present medical history, especially medications and operative procedures, which may expose psychological concerns or the need to modify preparation, add prophylactic antibiotics, or change medication, timing, and dosage. In other words, taking an adequate history and performing pertinent physical examination are important. It is necessary to point out the potential hazards of colonoscopy, noting aspects of the process that might cause discomfort but it is also important to give reassurance that although the risk of complication is low the examiner is prepared for prompt management. The question of the need for antibiotic prophylaxis stems from concern that although diagnostic colonoscopy is a low risk procedure for bacteremia, infection of damaged cardiac valves or implanted prosthesis is a risk. The American Heart Association and the American Society of Colon and Rectal Surgeons have issued joint guidelines recommending antibiotic prophylaxis for patients with certain conditions associated with carditis.<sup>14</sup>

These recommendations include implanted prostheses, primarily orthopedic.

Thorough mechanical preparation of the colon is absolutely essential for efficient, safe, and complete endoscopic examination. In addition, should perforation occur, the empty colon certainly poses less risk of significant peritoneal contamination. There are various forms of mechanical preparation possible but the most thorough and safest current regimen involves the use of polyethylene glycol electrolyte lavage solutions. Other forms of preparation that are sometimes used involve ingestion of a saline cathartic (usually sodium phosphate or magnesium citrate) as well as enemas. With the latter, there is more concern about electrolyte imbalance especially in patients taking diuretic medications chronically or those with renal insufficiency. Some patients after gastrectomy may experience symptoms of dumping after saline cathartic administration.

## Monitoring

Although the use of pulse oximetry and intermittent monitoring of blood pressure as well as electrocardiography (if clinically indicated) have now become standard procedures, it is important for the assistant as well as the endoscopist to be aware of any changes in the patient's level of awareness, respiration, and abdominal distention.

## Bleeding Prophylaxis

Although bleeding is rarely associated with diagnostic colonoscopy, there are concerns about bleeding at or after colonoscopy, if biopsy or polypectomy are contemplated, and this has led to modification of anticoagulation regimens and cessation of drugs that might alter platelet function. There are no universally accepted guidelines for management of antiplatelet therapy in relation to endoscopy, especially because cessation of these agents may increase the risk of thromboembolism in some of these patients. If a particular patient has a known hematologic disorder (for example, factor V deficiency), precautions should be taken to optimize the coagulation potential by correcting missing or deficient factors as necessary before initiation of the endoscopic procedure.

## Technique

For successful passage of the colonoscope to the most proximal desired anatomic region (cecum or anastomosis), it is imperative that a few principles be understood.<sup>15</sup> The examiner must appreciate that the colon is of variable length, that respiratory and peristaltic activity is in progress during the examination, and that some areas of the colon are more fixed (by normal anatomy, previous inflammation, or postoperative change). It is dangerous to proceed with introduction of the endoscope without knowing at all times the location of the lumen.

Before starting the examination, the equipment should be checked to verify that it is in good working order. It should be verified that irrigation, suction, and air insufflation channels are open and that the directional controls are in the unlocked position.

With the patient in the left lateral recumbent position, the examination is initiated by thoroughly inspecting the perianal area for fissures, fistulae, hemorrhoids, condylomata, and rarer conditions such as melanoma, Bowen's disease, extramammary Paget's disease, squamous and anal gland carcinomas. Next, the lubricated gloved right index finger is inserted into the anus and a rectal examination carefully performed, giving especial attention to the surface of the prostate gland in the middle aged and older male patient. With the right index finger still in the rectum, the endoscopist then holds the tip of the instrument in the left hand, places it at right angles to the right index finger, and by effacing the sphincter with gentle pressure of the right index finger, the instrument tip can be gently inserted as the right index finger is withdrawn. The examiner then grasps the head of the instrument in the palm of the left hand, leaving the thumb and index finger free to manipulate the knobs for tip deflection with the former and the air and water insufflation as well as suction buttons with the other. The right hand is placed on the instrument shaft. With the instrument in the rectal ampulla, it is usually necessary to insufflate the lumen with a small amount of air in order to visualize the direction of the lumen.

The main objective on insertion of the instrument is to reach the most proximal point desired in as expeditiously a manner as possible, leaving detailed inspection until the process of withdrawal of the endoscope. However, detection of an abnormality on insertion may require a change in strategy. For example, it may be important to detect, localize, sometimes biopsy, or even remove a small lesion for fear of not being able to find it easily on withdrawal. In some circumstances, therefore, at least localization and biopsy should be performed, even on insertion.

One of the earliest challenges to insertion is advancing the instrument into the descending colon. The unprepared examiner, looking at the stylized cartoons of many an endoscopy record form and even many anatomic and surgical textbooks may not recognize how long the sigmoid colon can be and how easy it may be to insert a considerable length of the instrument into it. Because the sigmoid is usually not fixed, it accepts the instrument so readily that when the acute angle at the junction of the sigmoid and (fixed) descending colon is reached, the unprepared examiner may think that he/she has achieved insertion to the splenic flexure. Attempts at further insertion may be hindered then by the loop created in the sigmoid colon. Most of the time this frustrating situation may be entirely avoided by attempting to keep the sigmoid collapsed and shortened as early as possible. We have found that a clockwise turn with the right hand on the shaft of the instrument and with jiggling of the shaft as well as back and forth motion will often allow the bowel to fall over the instrument,

so to speak, allowing insertion with a less than one-to-one motion. It is this pleating or accordioning of the bowel over the instrument with alternating release that allows for efficient advancement and more than one-to-one motion. As a matter of fact, the recognition of this intermittent intussusception and reduction as part of the normal advancement of the instrument makes it understandable that, in estimating the extent of intubation or the location of a lesion, the least accurate determination is measuring on the shaft of the instrument.

Having entered the descending colon with the sigmoid shortened and "straight," it is usually quite easy to advance to and around the splenic flexure. Difficulty in intubation beyond the splenic flexure is, in our experience, more common when the patient has undergone previous operation within this area with adhesions in the left upper quadrant that may produce fixation. If the endoscopist recognizes the distal transverse colon by endoscopic anatomy or transmitted cardiac apical pulsation that one is in, it is to be recalled that, similar to the sigmoid, the transverse colon is on a long mesentery and is rarely fixed. The hepatic flexure can be more easily reached by keeping the transverse colon as collapsed as possible.

The hepatic is often a more complicated flexure than is the splenic and one may wander a while before entering the distal ascending colon. However, once the latter has been entered and there has been no prior right abdominal operation (for example, cholecystectomy, appendectomy), the cecum is often rapidly reached by application of suction to collapse the bowel over the instrument. It is important to be fully cognizant of the vagaries of endoscopic anatomy in order to confirm cecal intubation—by visualization of the appendiceal orifice and the ileocecal valve. Looking for translumination from the instrument tip through the abdominal wall in the right lower quadrant is, unfortunately, a trap for the unsophisticated endoscopist who uses it to verify cecal entry. It merely points out that the instrument tip is in the right lower quadrant but the endoscopic tip may be in any mobile part of the colon, for example, the transverse colon or even the sigmoid. In fact, the student of anatomy recognizes that the cecum is not always in the right lower quadrant.

There are aids to overcoming obstacles to cecal intubation. A common one is the attempt to keep the sigmoid in a straight position so that on further insertion the tip may progress proximally. Abdominal pressure by an assistant is often used in an attempt to keep the sigmoid from reforming a loop once it has already been straightened. We think it important not to expect or direct the assistant to reduce the loop by compression because this could theoretically lead to injury of the bowel wall. Rather, the sigmoid has to be straightened and then pressure may be used to keep the loop from being re-formed. If one reviews a series of barium enema films or has acquaintance with the position of the omega loop of the sigmoid at abdominal operation, it helps to understand these maneuvers. For those who have the capability of fluoroscopy in their endoscopy units, much can be learned and much assistance

provided in this maneuver, especially in the individual's early endoscopic experience. For one, it is humbling to recognize how inaccurate one can be of the extent of insertion or the shape of the bowel with the endoscope inserted. There are two recent developments in endoscopic and related instrumentation that may facilitate overcoming the difficult sigmoid loop, still the most challenging aspect of diagnostic colonoscopy.

One recent development in the design of some colonoscopies is the ability of the endoscopist to vary the stiffness of the endoscope to allow a previously shortened and straightened segment of bowel from re-forming a loop. The assumption is that the endoscopist knows with certainty that the loop has been adequately reduced and that it is safe to insert a now more rigid instrument. Those who have expertise with fluoroscopy know that this can be a fallible assumption. Another development is an extracorporeal magnetic device that can track the course and shape of the endoscope during insertion.<sup>16</sup> If proven accurate, this device could potentially obviate fluoroscopy for localization, reduction of difficult loops, and even allow for safer stiffening of the endoscope using either a variable-stiffness endoscope or the external splinting device introduced by Shinya in the early days of colonoscopy.

Certainly, the external splinting device should never be used without the benefit of fluoroscopic assistance because, with an angulated segment of bowel, it is possible to damage the bowel wall if the mucosa is caught in the space between the edge of the splinting device and the shaft of the instrument. When using the external splinting device, the fluoroscope is used to first verify that the tip of the instrument is just beyond the splenic flexure and acutely angled (Figure 5-7). The deflection knobs are then placed in the locked position and, as the instrument is withdrawn and the sigmoid loop

straightened under fluoroscopic control, the external splint is advanced over the endoscope up to, but not beyond, the proximal descending colon.<sup>14</sup> One does not wish to advance it to the splenic flexure where the lienocolic ligament may be vulnerable to avulsion. An assistant has to keep the splinting device fixed at the anus so that the examiner does not insert it further than desired during the remainder of the examination.

External manipulation may also be helpful in two other circumstances. Sometimes the transverse colon, having a long mesentery, may form a loop extending well into the pelvis. Reduction of this loop by withdrawing the instrument and using suction will usually achieve rapid progress into the ascending colon. But one can sometimes keep the loop from re-forming by having an assistant apply pressure from the right abdomen directed to the left upper quadrant (because the transverse colon mesentery is longer on the right and the loop is therefore more prominent in the right portion of the abdomen or pelvis). If the cecum is not fixed (as from prior operation, for example, appendectomy or pelvic surgery), it may be possible with gentle pressure on the abdominal wall to collapse it onto the tip of the instrument, remembering, however, that the cecum is not always in the right lower quadrant. Sometimes placing the patient in the prone position allows easier intubation of the cecum.

On withdrawal of the instrument, one has to be sure that the entire mucosa is visualized. As one withdraws the instrument and the bowel recedes, inspection is accomplished but it requires close attention because one can easily withdraw too rapidly as a previously accorioned segment escapes without the examiner's control. It may be necessary to go back over an area not adequately visualized initially. In this connection, adequate preparation is even more important at this time than on insertion. If liquid material is present but too thick to be aspirated by suction through the instrument channel, one may purposefully change the patient's position to allow the fluid to shift to another area. Withdrawal through the sigmoid colon perforce requires more time and attention because there are more folds and recesses. Although the experienced examiner can usually withdraw very slowly through the anal canal and thus visualize its entire circumference, this is sometimes better if complemented by retroflexing the tip of the instrument in the anal ampulla to visualize the region of the dentate line (if the rectal ampulla is readily distensible). As the endoscope is withdrawn through each segment of the colon, it is useful to decompress each examined segment with suction so that at the conclusion of the examination the abdomen is minimally distended.

### Normal Endoscopic Anatomy

Some segments of the colon are more readily recognized than others and one has to be careful not to be overconfident unless a classic appearance is present. On insertion it is important to first recognize the three rectal valves of Houston because the

FIGURE 5-7. Use of external splint.

relationship of a lesion to them will have great relevance if surgical intervention is to be contemplated. Diverticula may be seen throughout the intraperitoneal colon but rarely below the peritoneal reflection. The descending colon, being fixed along the white line of Toldt, will often present a long straight "tunnel view." Occasionally the splenic flexure is specifically recognized if there is an external bulging bluish mass indenting the colon, descending with respiration. More common in the sigmoid colon, diverticula may be seen throughout the length of the large intestine. Their orifices may be so wide that they may be mistaken for the bowel lumen. It is therefore safer to back away somewhat and have a longer view to be sure of the location of the lumen. In any one field of view, the diverticulum will of course be at right angles to the lumen (Figure 5-8).

The transverse colon, on insertion, being suspended by the three taenia coli presents the appearance of an equilateral triangle (the so-called "cathedral ceiling" appearance). Quite often, the distal transverse colon can be identified in relation to the proximal because the point of maximal impulse of the heart is transmitted through the diaphragm which overlies the distal transverse colon. Especially in thin patients, the liver casts a broad, flat, bluish-green cast outside the colon but because this may be seen for a variable distance from distal transverse colon to mid-ascending colon, it is not particularly helpful with localization of a lesion, from a surgeon's point of view. At the hepatic flexure, the colon often assumes a spiral configuration which can cause the taenia to so approximate each other as to make the novice assume the cecum has been reached (what one of us has called "the fool's cecum").

The interhaustral folds in the ascending colon are low in profile compared with those in the left colon. The ileocecal

valve is usually recognized as an eccentric bulge with a sometimes visible umbilication. Because there is more adipose tissue in it, the appearance is often a yellowish color compared with the pink of the rest of the colon. The ileocecal valve is rarely seen head on but is, of course, more easily recognizable when it is. It is important to intubate proximal to the valve because the true caput of the colon may be at a variable distance from the ileocecal valve. As the three taenia come together at the caput (often appearing like the branches of a tree or a crow's foot), the appendiceal orifice is usually recognized, even in the patient who has undergone previous appendectomy.

### Abnormal Findings

Exophytic lesions are the easiest to visualize and recognize at colonoscopy, the most common being adenocarcinoma. All polypoid lesions of the colon may be visualized at colonoscopy and virtually all have distinguishing characteristics. Several are submucosal (lymphoid hyperplasia, stromal tumors, lipomas, carcinoids, endometriomas, hemangiomas, neurofibromas, lymphoma). A few are metastatic from other organs (for example, prostate, pancreas, kidney). The diagnosis of most of these lesions can be made by endoscopic visualization or sampling. Some, being of no clinical consequence, require only recognition (lymphoid, hyperplasia, lipoma).

In addition to lesions that protrude, there are numerous inflammatory or degenerative conditions that have a recognizable endoscopic appearance and many can be safely sampled if necessary. These include the various colitides (bacterial, viral, ulcerative, granulomatous), ischemia, radiation proctopathy (formerly called "proctitis") and melanosis

FIGURE 5-8. Finding lumen in diverticulosis.

FIGURE 5-9. Cytology through stricture.

coli. Melanosis coli, when marked, may help in visualization of adenomatous tissue because the pigment is not deposited in only normal mucosa. Areas of angiodysplasia (vascular ectasias, arteriovenous malformations) can be recognized on diagnostic colonoscopy but must be distinguished from bruises created from instrumentation or even preparation. The endoscopist has to recognize colonic anatomy disturbed by previous operation and therefore has to be familiar with the variety of intestinal anastomoses performed.

Areas of stenosis and stricture may be encountered secondary to benign conditions (previous resection and anastomosis, diverticulitis, colitis, radiation injury) or malignancy. Other rare findings to be recognized include: colitis cystica profunda, pneumatosis, and Behçet's syndrome. The manner in which the nature of a lesion is established at diagnostic colonoscopy will vary. A tiny sessile lesion (for example, a diminutive polyp) may be removed in its entirety with the biopsy forceps for pathologic examination. A pedunculated lesion suspected of being a benign adenoma may be removed at the time of diagnostic examination by snare polypectomy. A sessile lesion suspected of being a carcinoma or villous adenoma may be biopsied at one or more sites or even partially removed with a snare and cautery to obtain a satisfactory specimen. A stricture may be sampled for possible malignant cells by advancing a cytology brush into the stricture ahead of the colonoscope (Figure 5-9). Malignant cells may thus be harvested even though the stricture cannot be traversed with the endoscope. A lesion that appears vascular and friable may be simply photographed. A submucosal lesion may be exposed by disrupting the overlying mucosa.

## Complications

Although colonoscopy is, in general, a safe procedure, it is invasive and adverse events do occur. The most common serious complication of diagnostic colonoscopy is perforation with the reported incidence of 0.03%–0.65% and the mortality of 0.01%–0.02%.<sup>17–19</sup> Other reported complications

include abdominal distension, dehydration, respiratory depression, vasovagal reaction, thrombophlebitis, incarcerated hernia, splenic capsular tear and subcutaneous and/or mediastinal emphysema, and equipment failure.

In diagnostic colonoscopy, perforation may be caused by the instrument itself, traction on a fixed segment of colon, or over-insufflation of a segment, especially a closed loop as may occur in patients with multiple strictures (inflammatory bowel disease) or as a consequence of prior radiation therapy and with hernia incarceration. Impaction of the instrument in a diverticulum with overdistention of the latter has also been a cause of perforation. Adequate training and experience should decrease adverse events to a minimum. Because perforation is related to the use of coagulation (“hot”) biopsy forceps and because of the low risk of bleeding from multiple forceps biopsies, use of the hot biopsy technique has declined. Perforation during diagnostic colonoscopy tends to be detected earlier when it is from instrumental causes, whereas perforation from therapeutic procedures is frequently related to thermal injury and is often delayed. Indeed, the management of perforation after colonoscopy is still controversial.<sup>20</sup> Whereas there is universal agreement that perforation with generalized peritonitis demands an operation, some believe that if the onset of symptoms is delayed, signs are localized, and the patient is not septic (even with the demonstration of pneumoperitoneum) that nonoperative management may be followed. An uncommon presentation of a contained perforation may be the presence of retroperitoneal or mediastinal air and even subcutaneous emphysema, which usually resolves without drainage.

Avoidance of perforation during diagnostic colonoscopy, related as it is to training, skill, and experience may be best achieved by the following: avoidance of dehydration and oversedation; discontinuation of the procedure if the preparation is poor; avoiding forceful instrument insertion; recognition of vulnerable bowel (inflammation, ischemia, narrowing, fixation); careful identification and avoidance of diverticular ostia; avoidance of bowing of the instrument; awareness of fixation from pelvic adhesions or tumor extending through and beyond the colon wall; ensuring that abdominal and inguinal hernias remain reduced; avoiding over-insufflation; and looping in the splenic flexure region. There should be constant identification of the location of the lumen with avoidance of “slide by” (sidewise passage of the instrument without direct visualization of the lumen), not attempting colonoscopy during acute bleeding if one has not had adequate experience with routine diagnostic colonoscopy.

If perforation occurs, early diagnosis will ensure more efficient management. Undue and sustained pain (especially shoulder discomfort), absence of liver dullness on percussion, demonstration of pneumoperitoneum on upright chest film, and subcutaneous emphysema all help in making the diagnosis. Signs and symptoms will in general be related to factors such as adequacy of bowel preparation, size of injury, and underlying pathologic state of the colon. For example, the

ischemic colon or one involved with active colitis will be more vulnerable to instrumental injury. Surgical intervention is favored by most surgeons for early recognized perforation at diagnostic colonoscopy. There are, however, some patients with either a delayed perforation or one that has remained localized without symptoms or signs of diffuse peritonitis. Nonoperative management but continuing observation of this subset of patients may be entirely satisfactory. With early surgical intervention of a mechanical perforation, if technically feasible, primary closure with or without protective proximal stoma is, of course, the most desirable and usually is feasible. However, the surgeon must use good judgment in assessment of such factors as adequacy of tissue perfusion, degree of spillage, and colon tissue free of inflammation.

## Diagnostic Evaluations—Radiology, Nuclear Scans, PET, CT Colography

Matthew G. Mutch, Elisa H. Birnbaum, and Christine O. Menias

The goal of this text is not to provide the definitive chapter on gastrointestinal (GI) radiology, but rather to provide a sturdy foundation for the techniques, indications, and interpretation of radiologic imaging studies used in everyday colon and rectal surgery practices. Diagnostic radiology is the application of data or image acquisition to our knowledge of anatomy and pathology. Advances in technology have allowed us to diagnose many common diseases at earlier stages as well as identify new pathology previously not detectable with radiologic studies.

### Plain Films

The information or picture provided by plain films is the result of differential absorption of the X-rays by the various components of the abdominal wall, bony skeleton, and the intraabdominal contents. In particular, it is the interfaces between the different anatomic planes created by the inherent contrast of the various tissues attributed to the relative fat content of each structure and intraluminal gas of the GI tract that gives the image seen on the film. It is these interfaces that allow for the delineation of the liver edge, renal shadow, psoas shadow and differentiation of the patterns of the stomach, small bowel, and colon. The typical flat plate X-ray uses 60–75 kV to expose each film. This varies depending on the equipment used and the size of the patient. A reciprocating grid and collimation are used to reduce scatter of the radiation and improve tissue contrast.

Controversy exists over the number of views or films needed to adequately examine the abdomen. Classical teaching recommends three views consisting of a supine abdomen, upright or lateral decubitus abdomen, and upright chest. The rationale for these films is as follows<sup>1</sup>: 1) the supine abdomen offers the most detail and contrast of the intraabdominal structures; 2) the upright or decubitus abdominal views allow for a change in intraluminal gas distribution and identification of extraluminal free-air; 3) the upright chest contributes diagnostic information in 20% of cases.<sup>2</sup> However, Mirvis et al.<sup>3</sup>

argued that the upright abdominal view was unnecessary. They reviewed 252 examinations and found that the supine abdominal and upright chest films alone provided the diagnosis 98% of the time. Whether two or three films are obtained is of secondary importance as long as the entire abdomen is viewed and the examination is able to address the clinical scenario in question.

Plain films clearly do not offer as much anatomic detail as the cross-sectional imaging modalities, but they remain highly sensitive and specific when there is suspicion of a bowel obstruction or a perforated viscus.<sup>4</sup> Other useful indications for plain films include longitudinal examination of megacolon, identification of foreign bodies, check positions of drains or catheters, and evaluation of associated skeletal diseases.

### Intestinal Obstruction

#### *Small Bowel Obstruction*

Investigation of intestinal obstruction, whether it is small versus large bowel or mechanical versus functional, is a common indication for abdominal plain films. The signs and symptoms of a small or large bowel obstruction depends on the location and extent of the obstruction and can include nausea, vomiting, abdominal pain, abdominal distention, and obstipation. Just as the clinical manifestations of the obstruction depend on its location so do its radiographic findings. Duration of symptoms, significant emesis, use of a nasogastric tube, and degree of obstruction also contribute to the radiographic appearance of a bowel obstruction. With regard to small bowel obstruction (SBO), the most common causes in descending order are adhesions, Crohn's disease, neoplasia, and hernia.<sup>5</sup> Abdominal plain films have been shown to be diagnostic in 50%–66% of cases with approximately 20% false-negative rate.<sup>4</sup>

The radiographic diagnosis of an SBO depends on the intraluminal gas pattern projected upon the plain film. A normal gas pattern is defined as small amounts of gas distributed

throughout the small and large bowel without bowel distention (<2.5 cm in diameter). An abnormal gas pattern is a variable amount of gas in the presence of one or more loops of dilated small bowel (>2.5 cm in diameter).<sup>6</sup> The mucosal markings of the small bowel, known as the plicae circularis, traverse the entire diameter of the lumen and help to distinguish it from the colon, which has haustral markings that project into the lumen but do not reach the opposite wall. The amount of intraluminal fluid or material also greatly affects the radiographic appearance of the intestinal gas pattern. Air-fluid levels, which are the dependent layering of fluid and air within a dilated loop of intestine when viewed in the upright position, are common radiographic findings of an SBO. A complete or high-grade SBO is characterized by dilated loops of small bowel, air-fluid levels, and absence of colonic gas (Figure 6-1A and B). There can be a single or multiple dilated loops of small bowel, and the dilated bowel loops may also be stacked on top of each other giving it a ladder-like appearance. Generally, the more dilated loops of intestine present, the more distal the obstruction is located. Several factors can confound the radiographic appearance of an SBO. First, a distal bowel obstruction may appear to be more proximal when the distal bowel is filled with fluid and not gas. If the obstruction has been longstanding or the patient has had excessive vomiting, the bowel may be completely filled with fluid and have a complete absence of gas. Clues that support the diagnosis of an SBO in a gasless abdomen are a ground-glass

appearance and loss of solid organ outlines such as the liver edge, renal shadow, and the psoas shadow. These findings are consistent with significant intraabdominal and intraluminal sequestration of fluid. Second, the presence of colonic gas in the setting of dilated small bowel and air-fluid levels is compatible with an early SBO without complete evacuation of distal gas, a partial SBO, or an adynamic ileus. If the diagnosis is uncertain clinically and radiographically, then a follow-up study with either computed tomography (CT) or small bowel contrast study is warranted.

Plain films are not able to reliably differentiate a simple obstruction from a strangulating obstruction. Findings that are considered to be high risk for vascular compromise include complete bowel obstruction, extensive mucosal thickening or edema, pneumatosis, portal venous gas, or a closed loop obstruction. A study of 51 patients with radiographic findings of a complete SBO found 29% of patients had infarcted bowel requiring resection.<sup>7</sup> This highlights the importance of interpreting the radiographic data in the context of the patient's clinical condition.

### *Large Bowel Obstruction*

Colonic obstructions typically present with the same signs and symptoms as an SBO. The most common causes of large bowel obstruction are carcinoma, volvulus, Ogilvie's syndrome, and fecal impaction. Other etiologies include Crohn's

FIGURE 6-1. **A** Plain film of SBO dilated loops, ladder. **B** SBO air-fluid levels.

disease, diverticulitis, ischemic stricture, anastomotic stricture, and endometriosis.

### Cancer

Typically the colon will be distended up to the point of obstruction with a paucity of distal gas. If the ileocecal valve (ICV) is competent, the cecum can be markedly dilated and there may be little dilation of the small bowel (Figure 6-2). With a competent ICV, the entire colon becomes dilated and the cecum has the greatest distensibility. Once the cecal diameter reaches >12 cm, it is generally agreed that the risk of impending perforation is high. However, if the ICV is incompetent, gas can reflux back into the small bowel. As a result, the colon may not be all that dilated and the small bowel may become dilated with air-fluid levels mimicking an SBO (Figure 6-3). In this case, careful review of clinical data is necessary to guide the next diagnostic evaluation.

If a colonic obstruction is suspected, the diagnosis can be confirmed with a water-soluble contrast enema. It is difficult to differentiate the etiology of the obstruction with plain films so a contrast enema can give significant information regarding the cause of the obstruction. Water-soluble contrast is preferred over barium in this situation for several reasons. First, this avoids the risk of barium peritonitis if there is any concern for perforation or compromise in the integrity of the colon wall. Second, by avoiding barium, subsequent radiologic studies are not compromised. Third, if the obstruction is the result of fecal impaction, water-soluble contrast is both diagnostic and therapeutic.

FIGURE 6-2. Large bowel obstruction secondary to sigmoid cancer. Competent ICV.

FIGURE 6-3. Large bowel obstruction secondary to sigmoid cancer. Incompetent ICV.

### Pseudoobstruction

Dr. Ogilvie first described acute colonic pseudoobstruction in 1948, which is a condition characterized by massive dilation of the colon with no evidence of mechanical obstruction.<sup>6</sup> Radiographically, it is characterized by marked dilation of the cecum, ascending colon, and transverse colon (Figure 6-4). The descending colon and rectum are infrequently dilated. If the diagnosis is in question, it can be confirmed by a water-soluble enema, where there should be free flow of contrast into the cecum with no evidence of obstruction. Once again, in the acute setting, barium should be avoided.

### Colonic Volvulus

Plain films are able to diagnose sigmoid volvulus in 75% of the cases. The classic plain film findings include a dilated, U-shaped loop of colon that is projected toward the right upper quadrant. This characteristic finding has also been called the “bent inner tube” sign (Figure 6-5A). The direction the volvulus points depends on the redundancy of the involved segment of sigmoid colon. In the middle of this loop is a vertically oriented white stripe that represents the two

FIGURE 6-4. Ogilvie's syndrome.

apposing walls of the obstructed loop of sigmoid colon. It is not uncommon to see dilated colon and even small bowel proximal to the volvulus because it does create a complete obstruction. If the diagnosis cannot be made with plain films, a water-soluble contrast enema will provide the diagnosis. Gentle instillation of contrast will demonstrate a smooth, tapered point of obstruction at the rectosigmoid junction known as a “bird’s beak” (Figure 6-5B). If the diagnosis is still in question a CT can be obtained.

The diagnosis of rotational cecal volvulus can be made with plain films 75% of the time. Classically, the medially placed ICV indents the dilated cecum giving it the characteristic “coffee bean” or “kidney” shape (Figure 6-6A). The dilated right colon folds into the left upper quadrant (opposite to sigmoid). Dilated proximal small bowel may obscure the diagnosis. A CT will demonstrate dilated small bowel and cecum centered around the “swirly” mesentery. The “bascule” type volvulus produces a sharp, flat cut off of retrograde contrast as the mobile, redundant cecum flips up medially into the upper abdomen, causing a dilated cecum and small bowel on plain films.

### Pneumoperitoneum

The plain film radiograph has been used since the early 1940s to diagnose free air within the peritoneal cavity.<sup>8</sup> The amount of air, patient position, direction of the X-ray projection, and phase of respiration contribute to the sensitivity of detecting pneumoperitoneum. In 1971, Miller and Nelson<sup>9</sup> demonstrated that as little as 1 cc of free air could be detected by upright chest plain film. The upright chest film is the most sensitive view for identifying free air under the diaphragm.<sup>10</sup>

A

B

FIGURE 6-5. **A** Plain film of sigmoid volvulus. **B** Contrast enema of sigmoid volvulus.

A

B

FIGURE 6-6. **A** Plain film of cecal volvulus. **B** CT of cecal volvulus.

In this position, the X-ray beam hits the diaphragm tangentially at its highest point and minimizes the collection of air being obscured by other organs. The left lateral decubitus film is also fairly sensitive for patients who are unable to be transported or stand. Some authors recommend keeping the patient in the left lateral position for 10–15 minutes before shooting the X-ray.<sup>10</sup> This allows adequate time for the air to rise above the lateral edge of the liver. When the plain film is performed during mid-expiration or mid-inspiration the ability to detect small amounts of air is increased.<sup>11</sup>

Intraperitoneal gas can be trapped in many locations such as under the diaphragm, in the lesser sac, under the liver,

between the liver and the anterior abdominal wall, between loops of bowel, within the peritoneal ligaments, and in Morison's pouch. The appearance and configuration of the air depends on the shape of the space in which it has accumulated. The most common plain film finding is the accumulation of air under the right hemidiaphragm (Figure 6-7A). The relatively dense liver offers a sharp contrast to the air and the diaphragm. The Rigler sign or double-wall sign, which has been found in 32% of cases of pneumoperitoneum, is created when gas accumulates on both sides of the intestinal wall.<sup>12</sup> Both sides of the wall are visualized as a thin, white stripe. Often, the air trapped between the loops of bowel or leafs of mesentery will appear in a triangular configuration. Gas that has entered the lesser sac appears as an ill-defined lucency just above the lesser curve of the stomach. When air has entered into Morison's pouch, the inferior edge of the liver becomes outlined (Figure 6-7B). If there is any question about the diagnosis, the films should be repeated in another position or a CT should be obtained, which is the most sensitive study to detect free air.

### Colitis

The diagnosis of colitis is typically a clinical one, but careful inspection of plain film radiographs can provide a wealth of valuable information. Plain films can give information regarding the condition of the mucosa, extent of colonic involvement, presence of perforation, evidence of bowel infarction, severity of colitis, and presence of associated ileus or obstruction.

When the colon is filled with gas, the gas/mucosa interface gives characteristic patterns associated with colitis. Thumbprinting is a sign for bowel wall and mucosal edema associated with most causes of acute colitis. Bowel wall edema results in thickening of the mucosal or haustral folds so that they appear as thick white lines projecting into the lumen. Also, the angle of the haustral folds becomes blunted and smooth versus the normal sharp angulation of the haustra. The edema also causes the bowel wall to become thick and stiff. As a result, the gas-filled loops tend to lie straight or gently curve and the gas distribution changes little when the patient is in different positions. When two edematous loops are adjacent to each other, the distance between the two lumens is greater than usual. An ominous sign is the presence of massively dilated segment of colon associated with bowel wall thickening and thumbprinting (Figure 6-8). This is diagnostic for toxic megacolon when associated with the clinical findings of leukocytosis, severe abdominal tenderness, and hemodynamic instability. All of these signs are suggestive of bowel wall edema, inflammation, and ischemia, but give little indication as to the underlying cause.

Examining five characteristics can provide considerable data regarding the severity and extent of the Crohn's or ulcerative colitis (UC).<sup>13</sup> First, the extent of solid colonic fecal material gives a general sense of the extent of disease. Solid

A

B

FIGURE 6-7. **A** Plain film of intraperitoneal free air under diaphragm. **B** Plain film of free air under liver edge.

FIGURE 6-8. Plain film of colitis with megacolon.

stool in the right and transverse colon indicates left-sided colitis, and absence of solid stool anywhere in the colon suggests pancolitis. Second, examining the mucosal contours can help determine which segments of the colon are involved. Normally, the mucosal edge is smooth with sharp, narrow haustral markings. In the presence of active or longstanding inflammatory bowel disease (IBD), the mucosal contours are altered. The mucosal edge becomes blurred and has a granular appearance because of inflammation and ulceration. Depending on the extent of ulceration, the haustral markings may appear thick or be absent all together. Third, the character of the haustral markings provides information regarding the severity of disease. The haustral clefts are normally narrow with sharp angulation from the mucosal edge and are closely spaced. As the colitis progresses, the haustra become thicker, the angulation with the mucosal edge becomes blunted, and they are spaced farther apart. The haustra begin to disappear as the mucosal ulcerations progress. Fourth, the diameter of the colon can indicate the severity and chronicity of the disease. A markedly dilated ( $>5$  cm) colon with thumbprinting and bowel wall edema is concerning for toxic megacolon. At the other end of the spectrum, a chronic, “burned out” colon takes on a tubular, narrowed appearance (Figure 6-9). This is more characteristic of UC than Crohn’s disease. Finally, the thickness of the wall becomes thicker

FIGURE 6-9. Plain film of chronic burned out colitis.

over time in patients with IBD. The distribution of the bowel wall thickening provides clues as to the extent of colonic involvement. Plain films are also able to provide information regarding the extraintestinal manifestations of IBD. Abnormalities of the skeletal system such as sacroiliitis, ankylosing spondylitis, and osteopenia secondary to chronic steroid use can be seen.

Another manifestation of colitis is pneumatosis where gas has accumulated within the wall of the intestine. This may be a relatively benign process such as pneumatosis cystoides intestinalis or it may represent the very grave situation of bowel infarction. Pneumatosis has two characteristic radiographic patterns. It may show a bubbly appearance where the gas accumulates within multiple cyst-like sacs in the colonic wall or the pneumatosis may dissect along the axis of the colon wall appearing as thin, linear streaks that are aligned along the axis of the bowel. Other associated findings that are concerning for vascular compromise of the colon include bowel dilatation, thumbprinting of the mucosa, and intraperitoneal free air. As the ischemia progresses to infarction, mucosal integrity is disrupted and gas may find its way into the mesenteric and portal venous systems. This is characterized by thin, branching lucencies within the liver, typically seen near the periphery. In the clinical setting of abdominal pain, known colitis, acidosis, or hemodynamic compromise, no further radiographic studies are needed to define the etiology of the pneumatosis or to indicate the severity of disease.

## Contrast Studies

### Contrast Enemas

Barium studies of the colon are designed for the detection of mucosal and intramural lesions. With the widespread use and availability of colonoscopy, the role of single or double contrast barium studies has diminished. Despite the direct competition with colonoscopy, barium studies continue to be an important player in the diagnosis of colonic pathology. The advantages of barium as a contrast medium are its ability to coat and adhere to the mucosa. This then allows for the instillation of air as second contrast medium. In air-contrast examinations, the colon is filled with barium. It is drained and then the colon is insufflated with air as a second contrast medium. The barium outlines the mucosal edges and the air distends the colon allowing for maximum visualization of mucosal detail. The indications for a barium study include screening and diagnosis of mucosal disease processes in the elective setting. Its disadvantages are the need for a colon preparation, the inherent characteristics of the medium, and the toxicity when exposed to the peritoneal cavity. The exposure of barium to the peritoneal cavity results in an intense inflammatory response that has a mortality rate of approximately 50%. Therefore, the use of barium should be avoided in urgent situations such as studying the integrity of an anastomosis, evaluating a large bowel obstruction, examining acute colitis, or when there is concern for bowel perforation. In these situations, a water-soluble contrast agent should be used. Water-soluble agents do not coat the mucosa. Instead, the bowel is visualized by passive filling of the lumen with the contrast as a single contrast study. As a result, water-soluble enemas do not provide as much detailed information as barium studies. Indications for a water-soluble study include evaluating the integrity of a colonic anastomosis, evaluating colonic obstruction, the preoperative evaluation of the colon for evidence of gross pathology, delineating colonic fistulas, and therapeutic enema for fecal impaction. The peritoneal cavity tolerates exposure of water-soluble contrast with very little reaction and, therefore, it is the contrast agent of choice in urgent situations.

### Cancer and Polyps

The most common reason for ordering an air contrast barium enema is for the screening and diagnosis of neoplastic lesions of the colon and rectum, especially when screening for colorectal cancer in conjunction with flexible sigmoidoscopy, when colonoscopy is not possible.<sup>14</sup> The sensitivity of air contrast barium enema depends on the quality of colonic preparation, the size of lesion, the ability to adequately distend the colon with air, and obtaining multiple views. There are many regimens available for cleansing the colon that range from oral agents such as magnesium citrate and polyethylene glycol to enemas and suppositories.<sup>15</sup> The cleaner the colon,

the better the barium is able to coat the mucosa and provide more detailed images.

A barium enema can detect up to 90% of polyps and cancers that are >1 cm in size, but sensitivity decreases to 50% for lesions <1 cm in size.<sup>16,17</sup> Lesions can appear sessile, pedunculated, flat, exophytic, and circumferential. The outline of the mucosal edge helps to differentiate benign versus malignant and intraluminal versus extraluminal processes. The configuration and the location of the lesion within the lumen dictate its radiographic appearance. Specifically, the profile in which the lesion is imaged and the location of the lesion within the lumen relative to retained pools of barium help to create its appearance on film. For example, lesions on the dependent portion of the lumen that sit in a puddle of barium will appear as filling defects. In contrast, lesions that are outlined in barium and are away from pools of barium appear as sessile, pedunculated, flat, or annular outlines that project into the lumen of the colon. When pedunculated lesions are viewed in profile, the stalk and head are easily identified.

Early cancers and polyps are very difficult to differentiate radiographically. The size of the lesion is the most helpful indicator of malignancy, with lesions >2 cm having a 50% chance of invasive cancer.<sup>18,19</sup> Also, the presence of an ulcer is highly suggestive of a malignant lesion. Polyps and early cancers can be sessile, flat, or pedunculated. Tubular adenomas tend to have a more regular, smooth mucosal surface. In contrast, villous lesions have many frondlike projections of the mucosa and barium gets trapped in these projections giving them a very irregular mucosal pattern. Sessile lesions when viewed in face take on a “bowlers hat” appearance that project into the lumen (Figure 6-10). The brim of the hat corresponds to the base of the lesion and the dome of the hat represents the head of the lesion. Depending on the size and complexity of a sessile lesion, the dome may be smooth or multi-lobulated. Pedunculated lesions are recognized by the appearance of their discrete stalk. When viewed obliquely or tangentially, the barium coats the stalk and it is easily identified. If viewed on end, it has the appearance of a “Mexican hat,” which consists of two concentric circles where the outer circle represents the head of the lesion and the inner circle corresponds to its base.<sup>20</sup>

As neoplastic lesions grow they tend to occupy greater portions of the circumference wall and lumen of the colon. As a result, it is easier to distinguish the lesions as malignant. The most common appearances of colon cancers found during an air contrast barium enema are annular or semiannular (53%), polypoid (38%), and flat (9%).<sup>21</sup> The size, complexity, and villous component of the lesion all contribute to its ability to retain barium and thus its radiographic appearance. Once again, its position within the lumen may require multiple views to accurately visualize the lesion. Lesions that straddle one-third to half of the circumference of the lumen are called semiannular or saddle lesion (Figure 6-11). When viewed in profile, semiannular cancers appear as convex lines with the margins etched in barium. The smooth outline of normal

FIGURE 6-10. ACE of polyp or early cancer.

mucosa abruptly transitions into a convexity with complex, irregular borders. Given this characteristic shape, these lesions are often described as saddle lesions. Annular lesions refer to cancers that encompass the entire circumference of the colon's lumen. They are usually found in the sigmoid colon, but can

FIGURE 6-11. ACE of semiannular cancer.

occur anywhere within the colon. Annular lesions are characterized as a circumferential narrowing of the lumen of the colon. Characteristic findings implicating a malignant lesion include destruction and irregularity of the overlying mucosa with shelf-like, overhanging borders, and there is a sharp transition from normal mucosa into the annular lesion. Benign strictures from ischemic colitis, diverticulitis, anastomotic strictures, or Crohn's disease, in contrast, tend to have smooth, tapering borders. Malignant strictures are best identified when viewed in profile. If a large bowel obstruction is suspected, barium should be avoided and a water-soluble contrast agent should be used, and only a single column contrast study is needed to define the pathology. Annular lesions in this setting can present as a completely obstructing lesion or a near obstructing lesion, where only a string of contrast may get past the lesion. A completely obstructing lesion will have an abrupt cutoff of contrast at the level of the lesion. There will be shouldering or evidence of mucosal destruction at the point of obstruction. If the lesion permits some contrast to flow past the lesion, a "string sign" may be seen (Figure 6-12). This will be seen as a thin line of contrast extending from the column of contrast at the level of the obstruction. There is an abrupt cutoff of normal mucosa to a shouldering, overhanging lesion. The "string" of contrast will show irregular, destroyed mucosa along the length of the lesion.

FIGURE 6-12. Contrast enema of apple-core cancer string sign.

### *Polyposis Syndromes—Familial Adenomatous Polyposis, Peutz-Jeghers, Juvenile Polyposis*

It is not possible to distinguish between the sporadic adenomatous polyps and these polyposis syndromes using contrast studies. Confirming the diagnosis of these polyposis syndromes requires histologic examination of the polyps. The polyps can be seen with contrast as previously described in the majority of instances, but contrast studies should only be used if endoscopy is not possible.<sup>22,23</sup>

### Ulcerative Colitis

Barium enema is used 1) to confirm the diagnosis of UC and differentiate it from Crohn's disease, 2) to assess the extent and severity of disease, and 3) for surveillance of the disease and its complications. The radiographic appearance of UC seen during barium enema examination depends on the state of the disease process. Changes consistent with acute colitis involve mucosal loss to varying degrees and bowel wall edema. The pattern by which the barium outlines the mucosa depends on the depth and size of ulceration. A granular mucosal pattern is one of the earliest changes seen, which corresponds to the accumulation of inflammatory cells and edema within the mucosa but the mucosa maintains its integrity. When the barium coats the swollen and edematous mucosal edge, it appears fuzzy and indistinct rather than the normal sharp edges. As the inflammatory process progresses, the integrity of the mucosa is broken, leading to the development of ulcers. These ulcerations are shallow, punctate lesions confined to the mucosal layer. They appear as small, dense collections of barium that are on the same plane as the rest of the mucosa. This pattern is known as mucosal stippling (Figure 6-13A). With continued inflammation, the crypt abscesses rupture, exposing the submucosa. The ulcers begin to extend laterally and undermine the adjacent mucosa. These are called collar button ulcers and are characterized by a narrow neck and wide base that extends below the level of the mucosal edge. As the ulcerations enlarge and coalesce, small islands of residual mucosa are left, and as these mucosal islands regenerate in the face of ongoing inflammation, they develop into inflammatory pseudopolyps. Pseudopolyps are irregular projections into the lumen of the bowel (Figure 6-13B). The projections can be round, linear, or have a complex branching pattern that represents mucosal bridging. The depth of ulcerations seen on air contrast enema has been found to correlate reliably with the depth and extent of ulceration seen on histopathologic examination.<sup>24</sup>

The chronic changes of UC are related to the effects of repeated ulceration and regeneration of the colonic mucosa. Over time, the persistent inflammation causes the muscular tone of tenia to relax and muscular hypertrophy of the muscularis mucosa. The changes of the musculature of the colon and the chronic scarring of the mucosa are what lead to the loss of all normal mucosal folds and haustra, narrowing of the bowel lumen, and foreshortening of the colon. Radiographically, this

A

B

FIGURE 6-13. **A** Contrast enema of UC showing stippling ulcers or early colitis. **B** Contrast enema of UC with pseudopolyps.

appears as blunting or complete loss of the haustral markings, a narrow tubular appearance to the colon, and loss of the redundant course of the sigmoid and transverse colon (Figure 6-14). The point of transition from narrowed and flat mucosa

FIGURE 6-14. Contrast enema of chronic UC.

to normal haustral configuration can help determine the extent of the colitis. There may be areas of the colon where the contraction of the bowel wall is worse giving rise to the appearance of symmetric, gentle narrowing resulting in a stricture. The presence of backwash ileitis is also a sign of chronic disease because the ICV has been scarred open. Barium contrast studies are also able to detect other colonic complications of UC such as adenomatous polyps and cancers. These appear as the neoplastic lesions previously described. However, it should be remembered that IBD-associated cancers tend to be more flat and infiltrating and do not always appear as typical neoplasms. Some authors argue that double contrast enemas are able to identify areas of dysplasia,<sup>25</sup> but contrast enemas are not recommended for routine surveillance.

#### Crohn's Disease

Contrast studies help differentiate Crohn's disease from UC, define the severity and extent of the colitis, and identify complications of the disease. Contrast enemas are better than colonoscopy at identifying and characterizing fistulas, strictures, and the distribution of disease.<sup>26</sup>

A

B

FIGURE 6-15. **A** Contrast enema of Crohn's disease showing ulcers. **B** Contrast enema of Crohn's with fissures, and long linear ulcers.

As with UC, the radiographic appearance of Crohn's disease depends on the acuity or chronicity of the disease. Aphthous ulcerations are the earliest mucosal lesions seen in Crohn's disease.<sup>22</sup> Barium accumulates within the lesions and they appear as small, shallow, or punctate collections with a surrounding radiolucent halo (Figure 6-15A). These lesions occur more frequently in the colon than the small intestine, and they help to distinguish Crohn's disease from UC. As the aphthous lesions progress, the ulcerations deepen, widen, and coalesce. The transmural nature of the inflammation allows the ulcerations to extend into the musculature of the bowel wall and even lead to fistulization. The result is deep longitudinal and transverse fissuring with edematous mucosa in between that gives the colon a cobblestone appearance. Barium deposits in the deep fissures and appear as multiple irregular white stripes (Figure 6-15B). The deepest portions of the fissures penetrate beyond the submucosa and the resulting image is one of "rose thorns" extending below the level of the mucosal edge. Once the ulcerations progress through the submucosa, the distinction of Crohn's disease can be made. Also, the identification of skip lesions or areas of normal mucosa in between areas of active colitis distinguish Crohn's disease from UC (Figure 6-16). Severe colitis leads to the development of long, deep linear ulcers typically along the mesenteric border of the colon. These long ulcers are known as "rake" or "bear claw" ulcers. If the ulcerations continue to burrow in the wall of the bowel, a fistula or sinus tract can result. Fistulas can be identified by early filling of the small bowel before opacification of the proximal colon or as irregular projections of contrast outside of the lumen. Another significant feature of Crohn's disease is the development of strictures. Crohn's strictures are a result of transmural fibrosis. Radiographically, the strictures are asymmetric, have irregular borders, and are not circumferential (they are centered on the mesenteric edge) (Figure 6-17). This is in contrast to the strictures associated with UC, which are symmetric, smooth, and circumferential.

#### Diverticulitis

Air contrast barium enemas are more sensitive than single contrast studies at detecting diverticula because of better colonic distension and mucosal detail. The radiographic appearance of diverticula varies based on their size, number, angle at which they are viewed, amount of barium within the diverticula, and amount of colonic distention. When viewed in profile, they are flask-shaped with an associated neck that point away from the lumen. When filled with barium, they will appear as white projections or a white line outlining the mucosa when the barium has emptied from the diverticula. When viewed en face, they have the appearance of a bowler's hat projecting away from the lumen when they are empty of barium. If filled with barium, they will appear as a white spot or when partially filled, they will appear as a bowler's hat with a white meniscus. Diverticula can be distinguished from polyps and small cancers because they project away from the lumen as compared with neoplasms

FIGURE 6-16. Contrast enema of Crohn's disease showing skip lesions.

that project into the lumen. Other findings associated with diverticulosis include a shortened, narrowed, and spastic sigmoid colon. Hyperelastosis leads to a stiff, thickened, and nondistensible colon that is characteristic of extensive diverticulosis. The combination of a shortened, thickened colon and extensive diverticula can disrupt the symmetric appearance of the haustral clefts, giving the mucosal outline an irregular zigzag appearance (Figures 6-18A and B). This is best seen with single column contrast enemas.

In the acute setting, a water-soluble contrast agent should be used rather than barium to avoid the highly morbid case of barium peritonitis. In acute diverticulitis, the inflammation is pericolic and contrast studies are unable to directly demonstrate the inflammation. They are able to infer the effects of the pericolic inflammation on the mucosa. Findings such as narrowing of the sigmoid colon, extrinsic compression, mucosal edema, and spasm in the presence of diverticula are all suggestive of diverticulitis but they lack significant specificity. Contrast enemas are able to demonstrate complications of diverticulitis such as perforation, abscess, fistula, and strictures. Extraluminal leak of contrast is diagnostic of diverticulitis with free perforation, when associated with the appropriate clinical scenario. The contrast can flow freely into the peritoneal cavity, into a contained cavity, or a blind ending sinus. Contrast that flows into the bladder, vagina, or early filling of proximal loops of intestine are all findings consistent with a

FIGURE 6-17. Contrast enema of Crohn's disease showing a stricture.

fistula. A colovesical fistula is the most common diverticular-associated fistula, but contrast enemas are able to make the diagnosis only 20% of the time.<sup>23</sup> Therefore, a contrast enema should not be the first test used to confirm the diagnosis of a fistula. A pericolic abscess that impinges on the colon can be seen as a smooth contour defect along one wall of the colon that does not distend with the instillation of contrast material or air.

Stricture formation may occur after a single attack of diverticulitis but more frequently it is the result of recurrent episodes of inflammation. The site of the stricture is at the point of inflammation, which is typically within the sigmoid colon. Benign strictures have a smooth, gentle transition to the stricture with intact mucosa. The radiographic appearance of the stricture and adjacent colon along with the clinical scenario should help to elucidate the cause of the stricture.<sup>27</sup>

### *Submucosal and Extracolonic Lesions*

#### *Lipoma*

On double contrast barium enema, lipomas can appear as a submucosal mass or a polypoid lesion. The lesions can have an oval, lobulated, or pear shape and the overlying mucosa is smooth with sharp, well-demarcated borders. Lipomas are soft and pliable, so during fluoroscopic examination, com-

A

B

FIGURE 6-18. **A** Contrast enema single column showing severe diverticulosis with the sawtooth mucosa. **B** Air contrast enema of severe diverticulosis.

pression can change the configuration of the lesion; this is called the “pillow sign.”<sup>28</sup>

### Lymphoma

There are three basic radiographic morphologies that primary colonic lymphomas can demonstrate.<sup>29</sup> First, they can appear as discrete polypoid lesions. Typically occurring in the cecum, these lesions can range from 2 to 20 cm in size. In contrast, adenomatous polyps have mucosal irregularities because of their frond-like appendages. These are submucosal lesions, so the

overlying mucosa remains intact and smooth with the edges of the lesion being distinct (Figure 6-19). The involved segments tend to be long, with discrete proximal and distal edges, and the overlying mucosa remains intact. The barium may highlight nodular, irregular mucosal edges, but there is no ulceration. This is unlike annular carcinomas, which have short strictures with shouldering and ulcerated mucosa. Second, the mass can infiltrate the mesentery resulting in cavitation of the lesion into the mesentery. On barium enema, this appears similar to the annular lesions, but at some point within the affected segment, there is a nodular projection that is beyond the lumen of the colon. Finally, disseminated lymphoma appears as multiple, long segments of nodular, narrowed colon.

### Endometriosis

The findings on barium enema in the patient with endometriosis are consistent with an extracolonic process, because the mucosa remains smooth and intact.<sup>30</sup> Mild involvement will show a short, focal area with bunching of the mucosal folds, which has been termed mucosal pleating. This short segment will also show evidence of extraluminal narrowing. With more extensive involvement with scarring and contracture, stricturing can develop (Figure 6-20). Radiographically, this appears as a short, benign stricture with a sharp transition, mucosal pleating, and intact mucosa.

FIGURE 6-19. Contrast enema showing colonic lymphoma.

FIGURE 6-20. Contrast enema showing endometriosis.

FIGURE 6-21. Contrast enema showing colonic intussusception.

### *Colonic Intussusception*

Intussusception occurs when a proximal segment of bowel (intussusceptum) telescopes into the lumen of the distal bowel (intussusciens), much like turning a sock inside out. When viewed in cross-section, there are three rings or six layers across the diameter, which represent walls of the intestine—the outer wall is the distal lumen, the middle ring is the distal wall folded back onto itself, and the inner wall is the proximal intussuscepting wall. Plain films may reveal the pathognomonic “crescent sign.” As the intussusceptum telescopes into the intussusciens, the distal lumen folds into itself. At this transition, air can get trapped within the lumen, and this is seen as the “crescent sign.” Plain films may also show a dilated proximal colon that is decompressed distally. As a result, a contrast enema is often ordered to evaluate a large bowel obstruction. The classic appearance of an intussusception on contrast enema is the spring coil appearance or crescent sign (Figure 6-21). Contrast gets trapped between the lumens of the intussusciens and intussusceptum leaving a thin, circular line that encircles the intussusciens.

### *Anastomotic Assessment*

Contrast enema studies are frequently used postoperatively to examine a colocolic, colorectal, coloanal, or ileal-anal anastomosis. The studies are used to evaluate for anastomotic leak in a septic patient, before closure of a diverting stoma, or to rule out an anastomotic stricture in patients with defecation difficulties. When testing the integrity of an anastomosis,

a water-soluble contrast agent should be used. Contrast should be allowed to fill the colon under the weight of gravity, with the bag placed no higher than 1 m above the patient. Initially, the flow of contrast should be tightly controlled and increased as the examination permits. As previously mentioned, there is minimal peritoneal toxicity with water-soluble agents, and a single column study provides adequate detail to detect the majority of clinically significant leaks. The expected findings depend on the clinical scenario for ordering the examination. In the early postoperative period when evaluating for an anastomotic leak, water-soluble contrast enema is more sensitive than CT with rectal contrast.<sup>31</sup> Radiographic findings of an anastomotic dehiscence include the extravasation of contrast freely into the peritoneal cavity or into a contained cavity (Figures 6-22A and B). Key findings that influence the management of an early anastomotic leak are the size of the disruption, the containment of the leak, and how well it empties back into the lumen after evacuation. A leak identified before closure of a diverting stoma can be contained within a cavity or be a blind sinus. Typically, delaying the closure of the stoma will give the anastomotic disruption time to heal. There are several views that are important to see before a leak can be excluded. Obtaining anterior-posterior and lateral views of early filling of the lumen, full distention of the colon, and the postevacuation periods are necessary for an adequate study. Early filling may reveal subtle leaks that are either obscured by the distended rectum or empty readily when the bowel is decompressed. Distention of the bowel is necessary to unroll mucosal folds and provide some intraluminal pressure to test

A

B

FIGURE 6-22. **A** Contrast enema showing a contained anastomotic leak. **B** Contrast enema showing a free-flowing leak.

the anastomotic integrity. Finally, the postevacuation films are the most important because they identify any residual contrast outside of the lumen, which may be the only finding that a leak is present. The presence of smooth-bordered extraluminal compression at the level of the anastomosis is consistent

with an associated abscess. Anastomotic strictures are the result of ischemia or a septic complication of the surgery. Strictures typically occur remotely from surgery, therefore the concern for a leak is low and barium can be used as the contrast agent of choice. Radiographically, they have abrupt, short, symmetric narrowing with intact mucosa.

### Small Bowel Series and Enteroclysis

The small bowel represents 75% of the length and 90% of the mucosal surface of the entire GI tract, but the incidence of pathology is much less frequent than that of the upper and lower portions of the intestinal system. Consequently, radiologic studies of the small bowel are often used to finish an examination of the GI tract for the sake of completeness. Indications for small bowel studies include unexplained GI bleeding, evaluation for small bowel tumors, SBO, Crohn's disease, and malabsorption.<sup>32</sup> Examination of the small bowel is challenging for several reasons. First, with the enormous mucosal surface, it is difficult to adequately visualize all segments of the bowel. Second, the multiple overlapping loops of the small bowel can make visualization difficult. Finally, the flow of contrast through the small bowel cannot be controlled. As a result, findings may be missed if the physician is not paying close attention at all times. Nonetheless, small bowel contrast studies have a vital role in the practice of surgeons.

Barium follow-through and enteroclysis are the principle methods for examining the small bowel. During a small bowel follow through (SBFT), the patient drinks a large volume of dilute barium. The radiologist follows the flow of contrast through the small bowel with the use of fluoroscopy and spot films. The pylorus and gastric emptying limit the rate that the contrast enters the small bowel. Various techniques that apply pressure to the abdomen are used to manipulate and flatten out the loops of bowel to improve visualization. The major disadvantages are the inability to completely distend the bowel, and the time and attention required by the patient, radiologist, and radiology staff to perform an adequate examination.<sup>26</sup> During enteroclysis, the contrast and methylcellulose are administered through a small tube passed into the duodenum. This allows for rapid instillation of barium into the small bowel allowing for better distention and visualization. Advantages over SBFT include better filling and distention of the bowel and decreased study time. The major disadvantages are the placement of the nasoduodenal tube, the relatively high radiation dose, and hyperosmotic nature of the methylcellulose. When comparing the diagnostic results between SBFT and enteroclysis, the results are mixed. Regardless of the indication for the examination, the quality of the study depends on the radiologist's preferred technique and their attention to detail during the study.

The technical aspects of the SBFT begin with the oral administration of a 40%–50% barium suspension with a volume of 300–500 mL. The flow of barium, which is limited by pyloric emptying, is then followed under fluoroscopy. The

patient and bowel are manipulated and spot images are taken at points of interest or every 15 minutes. Normal transit time for the small bowel can vary widely but is generally defined as 90–120 minutes. Enteroclysis requires nasal or oral intubation of the pylorus so contrast may be rapidly administered to maximize the distention of the small intestine. The catheter is typically 12 French in caliber and can be passed with minimal discomfort to the patient. The catheter is passed under fluoroscopic guidance to ensure its postpyloric position. The contrast is then infused at an initial rate of 75 mL/minute and then is increased as needed and tolerated. Serial images are obtained in the same manner as the SBFT.

### *Crohn's Disease*

Barium studies of the small bowel are essential for staging the severity and extent of bowel involvement in patients with Crohn's disease. Indications for the studies include routine surveillance of known small bowel disease, assessing the severity of disease during a flare, defining the disease distribution for a new diagnosis, preoperative assessment, and to assist in the differentiation between Crohn's disease and UC. The radiographic appearance of Crohn's disease depends on the severity of disease and its distribution. Early or mild Crohn's disease is characterized by thickened, irregular mucosal folds, a coarse villous pattern of the mucosa, and aphthous ulcers (Figure 6-23A). The early edema and inflammation are typically confined to the mucosa, which can be seen as a fine nodularity of the mucosal edge. The edema also causes the villi to swell allowing barium to get trapped between them, producing a fuzzy, ground-glass, or coarse villous pattern. Aphthous ulcerations appear as shallow collections of barium surrounded by a radiolucent halo. As the disease progresses, more of the bowel wall becomes involved and the edema and inflammation extend into the submucosa and muscularis. The plicae circularis is made up of the mucosa and submucosa so submucosal involvement causes these folds to become even thicker and blunted producing the characteristic thumbprinting. Chronic or severe inflammation causes further distortion and disruption of the plicae circularis and enlargement, deepening, and coalescence of the aphthous ulcerations. The ulcers are classically located on the mesenteric border of the lumen, which is fairly specific to Crohn's disease. They enlarge and coalesce taking on various configurations such as stellate or rose thorn shapes and linear or crescent shapes. Continued progression leads to the characteristic deep linear ulcers of Crohn's disease.

Advanced disease is characterized by transmural inflammation that can be seen radiographically as deep, long linear ulcers, sawtoothed nodularity of the mucosa, cobblestoning, severe thickening of the bowel wall, luminal narrowing, and the complications of the disease. Inflammation of the submucosa and subserosa allows for the deep, knife-like clefts to burrow into the bowel wall. These clefts and fissures begin to merge into a longitudinal and transverse network of ulcerations.

A

B

FIGURE 6-23. **A** Small bowel series showing TI Crohn's disease strictures. **B** SBFT showing cobblestoning.

Between the ulcers remain pieces of relatively uninvolved mucosa. This produces a sharp, sawtooth nodularity of the mucosal edge, and ultimately develops a cobblestone pattern (Figure 6-23B). Barium fills the clefts and fissures and does not cling to the relatively spared mucosa in between, which is the basis for the cobblestone pattern. As these islands of residual mucosa attempt to regenerate, they heap up and branch giving rise to pseudopolyps. Once again, the barium does not adhere to these polyps so the cobblestoning becomes more irregular and complex. Transmural inflammation leads to fat creeping and bowel-wall thickening. The thickened bowel wall displaces adjacent loops of intestine so the distance between loops is

increased. During the barium study, these loops cannot be compressed or manipulated. The thickening also causes narrowing of the lumen. Radiographically, this can be seen as areas of nondistensible, ulceronodular bowel producing a string sign. The narrowing is caused by reversible edema, spasm, and inflammation or irreversible fibrosis.

Barium studies are more sensitive at identifying fistulas than endoscopy. The fistula tract may be visualized directly or indirectly. Early filling of the colon is highly suggestive of an enterocolic fistula. For example, an ileal-transverse colon fistula will show contrast entering the transverse colon before the right colon fills with contrast. An abscess may be seen as an extraluminal mass or compression of the adjacent loops of intestine.

### *Small Bowel Obstruction*

A complete bowel obstruction is readily apparent based on clinical grounds and easily supported by plain films of the abdomen. However, the diagnosis is not always clear in up to one-third of cases.<sup>33</sup> Subsequent delays in the diagnosis can lead to significant increases in morbidity and mortality. When the diagnosis is uncertain and the clinical circumstances support further testing, contrast studies of the small bowel can be very useful. Specific indications for either SBFT or enteroclysis include equivocal plain films, unclear etiology, early postoperative obstructions, or when preoperative localization of the site of obstruction is important. Dilute barium studies are the most useful because they provide the best mucosal detail and the barium typically does not become inspissated in the small bowel, therefore its use in the setting of a complete or partial SBO is not contraindicated. However, the use of water-soluble agents can be problematic in the setting of a complete SBO because of their hypertonicity, which draws water into the bowel lumen further exacerbating the fluid sequestration caused by the obstruction. Finally, traditional SBFT is the preferred technique for assessing the presence of partial SBO.

Findings consistent with an adhesive obstruction include a smooth, sharp transition point with a straight or curved line that stretches across the bowel (Figure 6-24). This is most apparent when the band is a single, thin adhesion. If multiple adhesions are present, the transition point is not as easily depicted. Typically, adhesions will fix the loop of intestine to the pelvis, retroperitoneum, or abdominal wall so that it does not move with manipulation or respiration. Peritoneal metastasis can also fix the affected loop of intestine to the peritoneal cavity. These two etiologies can often be differentiated. As mentioned, adhesions typically cause smooth transitions that stretch across the entire lumen and the surrounding mucosa appears normal. In contrast, metastasis will cause a desmoplastic reaction in the surrounding bowel so the mucosa at the transition point will appear irregular and tethered. Also, the tumor begins at one edge of lumen and either directly invades the lumen or infiltrates around the bowel circumference. This further exaggerates the mucosa irregularities and

FIGURE 6-24. SBFT showing a simple SBO.

may not completely obstruct the flow of barium into the distal, collapsed bowel. Metastasis can also cause obstruction by external compression of the bowel. This will be seen as an external mass effect and the overlying mucosa, in this case, will appear more normal.

Lesions intrinsic to the small bowel can also be elucidated. Primary adenocarcinomas of the small bowel are more common in the proximal bowel and occur with decreasing frequency more distal along the small intestine. Their findings are very similar to those seen for colon cancers on barium enema. There is mucosal destruction with sharp demarcation between normal mucosa and the lesion. The lesion may be semiannular or annular. Carcinoid tumors typically occur in the terminal ileum and start as submucosal lesions. As they grow, there may be mucosal destruction and tethering toward the center of the abdomen as the mesenteric desmoplastic reaction progresses.

## Computed Tomography

CT has become a routine examination to evaluate a wide range of disease processes because it is an easy, fast, and accurate test that provides cross-sectional imaging. The benefit of cross-sectional imaging is the detailed imaging and resolution of the hollow viscus and solid organs. Accurate interpretation requires optimal opacification of the GI tract and vascular structures. The bowel is opacified by administering a water-soluble oral contrast agent. The density of barium interferes with the acquisition of data during the scan and thus should be avoided as a contrast agent. The oral contrast is typically administered 45–60 minutes before scanning to

allow the contrast to opacify as much of the bowel as possible. If pelvic or rectal pathology is being evaluated, the contrast may also be administered per rectum at the time the scan is being performed. Intravenous (IV) contrast agents typically are iodinated so it is important to take a thorough history of allergies. It is administered as a bolus at the time of the examination. The reason for the examination dictates the exact timing between when the contrast is administered and when the CT images are acquired (i.e., venous versus arterial phase). The CT scan uses ionizing radiation to acquire the images with 5- to 10-mm collimation. Smaller collimation allows for sharper, more detailed images.

CT scans are usually ordered for the staging of colorectal cancer, evaluation of abdominal complaints, and evaluation of postoperative complications. Once again, having a specific question in mind when ordering the scan will allow the scan to be tailored to the appropriate parameters.

### Colorectal Cancer

An abdominal and pelvic CT is the most common method for staging colorectal cancer before definitive surgical resection. The aims of the CT scan are to 1) evaluate the liver for distant metastatic disease, 2) evaluate for regional lymphadenopathy, especially in rectal cancer, where nodes may have been missed during a transrectal ultrasound, and 3) assess for the presence of intraperitoneal disease. CT is also used to follow colorectal cancer patients longitudinally for the development of recurrent disease. It is most effective when used to evaluate patients who have symptoms concerning for recurrent disease or have a rising carcinoembryonic antigen (CEA) level. There are no strong data to support its use in routine surveillance for detecting metastasis in the absence of symptoms or rising CEA.<sup>34</sup>

There are several modalities, such as CT, ultrasound, and magnetic resonance imaging (MRI), available to assess the liver for metastatic disease. All of them have their advantages and disadvantages, but they all have equivalent diagnostic accuracy for the detection of liver metastasis.<sup>27,35</sup> CT images are typically obtained in two phases: the hepatic artery phase (20–25 seconds after the IV contrast is initiated) and the portal venous phase (65–70 seconds after the IV contrast is started). The majority of colorectal metastases are hypovascular and show up as hypodense lesions during the portal venous stage because the majority of metastatic lesions derive their blood supply from the arterial system. During the portal venous phase, contrast enhances the hepatic parenchyma and portal veins and the metastatic lesions do not enhance (Figure 6-25).

CT is able to differentiate many hepatic lesions based on their imaging characteristics and the dynamic effects of contrast on these lesions. Common liver lesions that need to be differentiated from colorectal metastasis include simple cysts, hepatic adenomas, primary liver tumors, hemangiomas, and focal nodular hyperplasia. Colorectal metastases typically are round, well-circumscribed lesions that are fairly homoge-

FIGURE 6-25. CT scan showing liver metastasis.

neous in density, which is consistent with solid tissue. As lesions grow they become more irregular in shape and their enhancement becomes more heterogeneous. Central necrosis and calcification may also be present. In contrast, simple cysts have a density consistent with fluid, which is more hypodense than solid tissue, and there is very little change in their enhancement during the various phases of imaging. Hemangiomas can be differentiated from metastatic lesions by the fact that they remain enhanced throughout the portal venous phase. The other hepatic lesions are typically hypervascular so they can be reliably differentiated from metastatic lesions during dual-phase CT imaging. The accuracy of CT for the detection and differentiation of liver lesions is greatest for lesions >1 cm.<sup>36,37</sup> Lesions <1 cm generally do not have the dynamic enhancing properties to be readily differentiated and, as a result, they are named indeterminate lesions.

Other advantages of the CT scans include the ability to detect regional adenopathy and to assess the relationship of the primary tumor to adjacent structures (Figure 6-26). Detecting regional adenopathy is most important for rectal cancer because the presence of adenopathy may influence the surgeon to give neoadjuvant chemoradiation therapy. The CT criteria for pathologic adenopathy are based on size only. Typically, nodes >1 cm in size are concerning for metastatic disease.

### Diverticulitis

The most common CT findings associated with diverticulitis are pericolic/mesenteric inflammation (98%), diverticula (84%), colonic wall thickening (70%), and abscess (47%).<sup>28</sup> Normally, the colonic mesentery and pericolic tissues are

FIGURE 6-26. CT scan showing primary lesion and adenopathy.

hypodense because of the high water content of the surrounding fat and sharp edges between adjacent structures. As the inflammatory process begins, the tissue becomes edematous and more vascular. This causes the pericolonic tissue to become more enhanced and the sharp contrasts between the various tissue plains become hazy, resulting in the so-called “dirty fat.” When the inflammatory response is centered on a portion of colon that is thickened (>5 mm), the diagnosis of diverticulitis is confirmed. Often, the inflammatory process can be extensive, producing a phlegmon in the absence of an organized abscess (Figure 6-27). Depending on the size of the perforation, there may be small flecks of extraluminal air within the mesentery or pericolonic tissue or in the upper abdomen above the liver. The inflammatory process is

FIGURE 6-27. CT scan showing uncomplicated diverticulitis.

typically localized around a short segment of the colon, thus if a long segment, several segments, or the entire colon is involved, a different diagnosis should be sought. The presence or absence of diverticula does not impact the radiographic diagnosis. The development of diverticula is associated with hyperelastosis of the colonic wall, which is evident by the thickening of the wall. This leads to decreased compliance and shortening of the involved segment of colon. When the thickness of the colon wall is >5 mm, it is considered abnormal. The wall thickening may be circumferential or just localized to the segment adjacent to the inflammation.

As mentioned, not only does CT allow for confirmation of the diagnosis of diverticulitis, but it can also identify associated complications. Abscess formation is the most common complication of diverticulitis. An abscess appears as a fluid collection typically near the area of diverticulitis (Figure 6-28). Often, oral and IV contrast are needed to distinguish an abscess from adjacent loops of intestine. When the surrounding loops of bowel are able to be opacified with oral contrast and the rim of the abscess is enhanced with IV contrast, the accuracy of diagnosing an abscess is maximized. The presence of air or an air-fluid level within the abscess cavity is also highly suggestive of an abscess.

A colovesical fistula is the most common fistula associated with diverticulitis, and a CT scan is the most sensitive for the detection of such a fistula.<sup>29</sup> Air within a bladder that has not been instrumented is diagnostic for an enterovesical fistula (Figure 6-29). When the wall of the bladder is thickened and in close proximity to the area of sigmoid colon that is thickened and contains diverticula, the etiology is likely related to diverticular disease. If the fistula is large enough, contrast, either administered orally or per rectum, may fill the bladder. Rectal contrast filling the bladder can help distinguish the source of fistula from a terminal ileal fistula associated with Crohn’s disease.

FIGURE 6-28. CT scan showing a diverticular abscess.

FIGURE 6-29. CT scan demonstrating a colovesical fistula.

### Crohn's Disease

The role of CT in the diagnosis and evaluation of Crohn's disease continues to evolve. A CT scan is used in two general situations during the management of Crohn's disease. First, a CT is obtained to evaluate a patient with new onset abdominal pain, and findings consistent with Crohn's disease are incidentally found. Second, a CT scan is obtained to evaluate for complications in a patient that is known to have Crohn's disease. The distribution of the disease greatly impacts the findings seen on CT. The most common findings associated with Crohn's disease are bowel wall thickening, peri-intestinal inflammation, and regional lymphadenopathy. The bowel wall can reach 11–13 mm in thickness, which can be either symmetric or asymmetric. The halo sign, which is a low-attenuation ring caused by submucosal deposition of fat between the enhancing mucosa and bowel musculature, is a common finding associated with Crohn's disease (Figure 6-30A). The transmural nature of the inflammatory process allows it to extend into the mesentery and adjacent structures so there is often an extensive inflammatory response centered on the affected bowel. There are many features that help to distinguish Crohn's disease from other inflammatory diseases of the GI tract. First, Crohn's disease is usually found to involve the terminal ileum and right colon. Second, there may be skip lesions. For example, multiple segments of small bowel and/or colon may be involved (Figure 6-30B). Third, the presence of mesenteric adenopathy suggests Crohn's or UC, but is not specific for IBD. Finally, the presence of complications such as abscess, fistula, or perforation points to a diagnosis of Crohn's disease. Abscesses can be located between intestinal loops, within the mesentery, in the psoas muscle, pelvic sidewall, and subcutaneous tissues (Figure 6-31). Fistulas

FIGURE 6-30. **A** CT scan showing Terminal Ileum (TI) Crohn's disease with abscess. **B** CT scan showing Crohn's colitis.

FIGURE 6-31. CT scan showing a psoas abscess related to Crohn's disease.

from the diseased segment of bowel to the bladder, skin, vagina, or normal bowel can also be delineated on CT.

### Small Bowel Obstruction

As mentioned above, SBO is a clinical diagnosis based on the signs, symptoms, and clinical condition of the patient. Radiologic studies are obtained to confirm the clinical diagnosis. Typically, the first line investigation is plain films of the abdomen, but their accuracy varies from 46% to 80%.<sup>30</sup> As a result, there is often a delay in the diagnosis, which can lead to an increase in morbidity and mortality. The use of CT in the evaluation of an SBO is expanding and in many cases can eliminate the delay in diagnosis. CT has the advantages of being able to identify the site of obstruction, cause of obstruction, and it can provide information regarding vascular compromise of the bowel. Indications when a CT scan is particularly helpful include 1) a patient with no prior surgery, 2) a patient with equivocal plain films and an uncertain diagnosis, and 3) a patient with known intraabdominal pathology such as Crohn's disease or cancer.

Oral contrast is not always necessary and should be avoided in patients with a high-grade or complete bowel obstruction. The intraluminal fluid often distends the bowel and acts as a natural contrast agent. The low-density intestinal fluid also extenuates the enhancement of the bowel wall after the administration of IV contrast, which can provide information regarding the flow of blood of the bowel.

The diagnostic criteria of an SBO by CT are based on the presence of dilated proximal small bowel (>2.5 cm) and collapsed distal bowel. When a transition between dilated and collapsed bowel is identified, then the diagnosis is confirmed (Figure 6-32). But when a transition point is not identified, it

is difficult to distinguish between an SBO and adynamic ileus. In such cases, one must search for other clues to differentiate the processes. For example, the presence of "small bowel feces," which is gas bubbles mixed within particulate matter, in the dilated bowel is a reliable indicator of an SBO. The presence of other intraabdominal pathology, particularly inflammatory processes, would generally indicate an adynamic ileus. This is a case in which oral contrast may be particularly helpful because if contrast reaches the colon, a complete SBO is not present.

CT can also provide significant information regarding the cause of the obstruction. Once again, the findings must be interpreted in context with the patient's clinical situation. When there is a sharp transition from dilated to decompressed bowel in the absence of other findings, this is highly suggestive of an SBO secondary to adhesions. CT does an excellent job identifying hernias such as inguinal, umbilical, incisional, or more of the atypical types. Often these hernias contain bowel but not all are obstructing. Clues indicating obstruction include dilate bowel going into the hernia and collapsed bowel exiting the hernia, oral contrast proximal to the hernia and no contrast distal to the hernia, and a localized inflammatory process surrounding the hernia, particularly in the subcutaneous tissues (Figure 6-33). Another common extrinsic cause of obstruction is recurrent cancer. A CT scan is often able to demonstrate a mass at the site of obstruction and may also provide evidence of more widespread peritoneal disease. Unexpected causes of obstruction may also be identified such as Crohn's disease, intussusception, or small bowel cancers.

When the affected bowel becomes strangulated, the morbidity and mortality associated with an SBO increase significantly. No test is able to provide definitive proof of strangulated bowel, but CT is able to provide a wealth of

FIGURE 6-32. CT scan showing a simple SBO.

FIGURE 6-33. CT scan showing an incarcerated hernia.

FIGURE 6-34. CT scan of SBO with evidence of ischemia.

information that can indicate concern for vascular compromise. Thickened, congested bowel with increased attenuation at the site of obstruction associated with engorgement of the mesenteric vasculature is concerning for strangulation (Figure 6-34). The mesentery may become hazy or the vasculature may be obliterated as the inflammation progresses and it becomes filled with fluid or even blood. Other findings of ischemia include lack of enhancement after IV contrast administration or the presence of ascites. The presence of pneumatosis and portal venous gas are the more ominous signs of intestinal ischemia. Finally, a spiral pattern of engorged mesenteric blood vessels may indicate an internal hernia or rotation of small intestine around fixed adhesions.

### Postoperative Evaluation

CT has greatly impacted the postoperative evaluation of the surgical patient. It is typically used to evaluate a patient with abdominal pain, fevers, leukocytosis, or persistent ileus in the postoperative period. The yield of a CT scan is greatest when it is obtained 5 days or more after surgery. Before postoperative day five, it is difficult to differentiate normal postoperative intraperitoneal free air or fluid from air or fluid that represents a leak from a hollow viscus or infected fluid. It usually takes more than 5 days for an abscess to organize into a walled-off, contained collection. Once again, the findings of the CT scan must be interpreted in the context of the clinical condition of the patient. Therefore, the yield will be greatest when the scan can address a specific question.

Findings highly suggestive of an anastomotic leak include an inappropriate volume of free air or fluid in the abdomen. The presence of extraluminal oral contrast

FIGURE 6-35. CT scan of colorectal anastomotic leak.

confirms a perforation of a hollow viscus. The presence of localized fluid and air around an anastomosis are concerning for a leak but must be taken in context to the postoperative period and the condition of the patient. As mentioned above, water-soluble enemas are more sensitive than a CT with rectal contrast at detecting a colorectal anastomotic leak. However, a CT is often more easily and readily obtained. An abscess is defined as an organized fluid collection with or without air that has an enhancing rim (Figure 6-35). As mentioned above, CT is very good at distinguishing between an ileus and a mechanical bowel obstruction, which is an important distinction in the perioperative period.

### Other Colitides

There are a handful of inflammatory processes that affect the colon that have not been addressed. The CT findings are very similar for all inflammatory processes of the colon. However, their clinical presentations are different, so combining the presenting signs and symptoms with the distribution of CT findings will usually lead to the correct diagnosis. This section will briefly address some these remaining processes.

Neutropenic enterocolitis or typhlitis typically occurs in patients who are neutropenic either from cytotoxic chemotherapy or severe immunosuppression. The terminal ileum, cecum, and right colon are most frequently affected. CT is the study of choice for the diagnosis. Circumferential thickening of the terminal ileum, cecum, and variably the right colon are the common CT findings consistent with typhlitis (Figure 6-36). The bowel wall may become so thickened because of edema that a hypodense ring develops between the mucosa and musculature. Complications such as pneumatosis or perforation can also be detected.

FIGURE 6-36. CT scan of neutropenic enterocolitis.

Ischemic colitis is the most common vascular abnormality of the colon. Presenting symptoms include abdominal pain associated with bloody diarrhea. The age of the patient and onset of symptoms will help to differentiate between IBD, infectious colitis, and ischemic colitis. Endoscopy is the gold standard for diagnosing ischemic colitis. CT is much more readily available so it is often the first test ordered. The colitis may be segmental or diffuse, typically occurring in the watershed areas of the right colon, splenic flexure, and rectosigmoid. CT findings consist of thickened, edematous colon in these areas (Figure 6-37). The typical “thumbprinting” in the colonic mucosa can be seen on CT scan as well as plain films. There may be a halo sign of either low attenuation caused by edema or high attenuation caused by hemorrhage within the bowel wall. A pericolic inflammatory response is often present as well. Thrombus within the colonic

FIGURE 6-37. CT scan of ischemic colitis.

FIGURE 6-38. CT scan of pseudomembranous colitis.

mesenteric vessels may also be seen. Finally, pneumatosis or portal venous gas may be present indicating bowel infarction.

Pseudomembranous colitis resulting from the toxins produced by *Clostridium difficile* can cause profound inflammation of the colon. Computed tomographic findings include nonspecific thickening and edema of the colon and pericolic inflammation. Generally, the edema and thickening of the colon is greater than that seen with infectious colitis or other inflammatory processes. The presence of pancolitis also tends to suggest pseudomembranous colitis versus other colitides (Figure 6-38). Once again, the CT results must be interpreted in the clinical context of the patient.

## Radionuclide Imaging

Radionuclide imaging studies base their imaging on physiology rather than anatomy, and have a wide spectrum of use in clinical medicine. Radiopharmaceuticals and gamma cameras are the mainstay of radionuclide imaging. The specific radionuclides are chosen based on either the biologic properties of the element (i.e., iodine has an affinity for thyroid tissue) or the physical and chemical properties that allow linkage to appropriate compounds. These radiolabeled compounds are given to a patient to localize within a specific organ system (such as the thyroid) or identify the sight of an ongoing physiologic process (as in GI bleeding). The quality of a scan depends on how well the agent targets the organ or the physiologic process. A gamma camera is used to acquire images once the agent is given to the patient. Gamma and X-ray photons are absorbed and converted into flashes of light.<sup>38</sup> The location and intensity of these scintillation events are determined and recorded. Spot images are generally taken in 10-minute intervals and the completed image reflects the

distribution of scintillation events (counts) detected during the acquisition phase. Image quality improves as the number of counts increases.

Radionuclide imaging studies are widely used in the diagnosis of lower GI bleeding. The principle is that the intravascular tracer will be extravasated into the bowel lumen during active bleeding. Concentration of the tracer on the acquired images allows identification of the bleeding sight. Technetium  $^{99m}\text{Tc}$  is the radionuclide used in bleeding scans. This radiopharmaceutical can label colloid or red blood cells for scanning purposes. Radiolabeled colloid is readily available, but is metabolized rapidly. Red blood cells take longer to label but clearance of the tagged cells is prolonged and the tracer can remain active up to 24 hours after injection. Most centers prefer to use tagged red blood cells because lower GI bleeds are characteristically intermittent and the opportunity to identify the active bleeding sight lasts only a few minutes with labeled colloid. The preparation for a tagged red blood cell scan requires an aliquot of the patient's blood to be labeled with  $^{99m}\text{Tc}$ . Once labeled,  $^{99m}\text{Tc}$  red blood cells are injected back into the patient and the patient is imaged with 10-minute acquisition intervals for approximately 60–120 minutes. Focal areas of increased activity identified within the lumen of the bowel indicate that active bleeding occurred during this acquisition period (Figure 6-39). A positive scan may localize the region of bowel that contains the bleeding site, but may not accurately localize the specific site, if the bleeding is slow or intermittent. The labeled red blood cells remain in circulation as long as the cells are viable and the limiting factor to imaging is the half-life of the  $^{99m}\text{Tc}$ . If no bleeding occurs during the initial acquisition phase, then delayed views can be obtained up to 24 hours later to determine whether active bleeding has occurred. Bleeding scans have greater prognostic value than diagnostic value when the tracer is only seen on delayed images.<sup>39,40</sup> The location of activity seen on delayed images does not reflect the exact bleeding sight but does indicate that active bleeding occurred during this observation period. The accuracy for localizing the actual bleeding site increases if the extravasation of tracer is identified within the first 15–30 minutes.<sup>36</sup> The longer it takes the tracer to accumulate, the less likely the bleeding site will be accurately

identified by angiography. Backwash and washout of blood caused by peristalsis account for some of this inaccuracy.

Bleeding scans are more sensitive than angiograms in the detection of lower GI bleeding. The required rates of bleeding for detection are lower for bleeding scans (0.1–0.2 mL per minute) than for angiograms (0.5 mL per minute).<sup>37,41</sup> The early (within 3 minutes) detection of intraluminal tracer indicates a high likelihood of successful arteriographic localization of the bleeding site. For this reason, some interventional radiologists require a positive scan before performing angiography. The addition of early colonoscopy to the diagnostic algorithm requires a bowel preparation. Cathartics will remove any intraluminal tracer making delayed images worthless. If the patient is hemodynamically unstable and rapidly bleeding, some centers may prefer to go directly to arteriograms because the time involved in pretest preparation for tagged red blood scans may be too lengthy.

A Meckel's scan, although not used as often as the tagged red blood scan, can be useful in the evaluation of patients with occult bleeding with no identifiable colonic source. These scans are generally limited to the evaluation of children and young adults who have complaints of abdominal pain and intestinal bleeding. The abnormal bleeding from a Meckel's diverticulum is caused by the aberrant gastric mucosa that lines the diverticulum.  $^{99}\text{Tc}$  pertechnetate is actively extracted by mucous secreting cells in gastric mucosa.<sup>42,43</sup> Meckel's scans are performed with  $^{99m}\text{Tc}$  per pertechnetate as a radiolabel for the detection of ectopic gastric mucosa. Imaging is usually done for approximately 30–60 minutes after injection of the tracer. All views should be obtained early because the tracer is extracted into the stomach and then into lumen of the GI tract. Rapid transit of the tracer through the GI tract will obscure extravasation on later images.

A focus of increased radioactivity outside of the stomach indicates ectopic gastric mucosa (Figure 6-40). Typically, the collection of activity is identified in the right lower quadrant within 10–20 minutes. The sensitivity of the Meckel's scan is 85% and the specificity is 95%.<sup>43</sup>

## Arteriography

Arteriography is an invasive procedure performed by specially trained physicians and is used in the diagnosis and treatment of a variety of colorectal diseases. The arteriogram is performed through a percutaneous approach under sterile conditions. The femoral artery is a preferred puncture sight although axillary and brachial arteries may be used. A guidewire is introduced through the needle and a catheter is introduced over the guidewire. Various catheters and guide wires allow the interventional radiologist to access the vessels in question.

Arteriography is an invasive procedure with an overall mortality of one in 40,000.<sup>44</sup> Complications from the performance of the procedure and manipulation of the wires and catheters

FIGURE 6-39.  $^{99m}\text{Tc}$ -tagged red blood cell study shows early blood pool activity within the ascending colon in this patient with bleeding after a recent polypectomy.

FIGURE 6-40.  $^{99m}\text{Tc}$ -pertechnetate scan (Meckel's) shows a discrete focus of increased uptake in the right lower quadrant, with approximately the same intensity as the stomach indicating gastric mucosa is present within this Meckel's diverticulum.

are more common than reactions to the contrast itself.<sup>45</sup> The most common complications are related to hematomas or pseudoaneurysms at the puncture sight, dissection or embolization secondary to catheter manipulation. Contrast reactions and contrast toxicity (renal failure) occur in <1% of studies done. Experience and technique can minimize many of the complications. Hydration and IV mannitol can reduce the nephrotoxicity. If the patient has allergies to iodine or has had a prior contrast reaction, premedication with methyl prednisolone is done 12 and 2 hours before arteriography.

The arteriogram is a useful diagnostic and therapeutic modality in the treatment of active lower GI bleeding. If a radionuclide scan is performed and localizes the site of bleeding, a selective angiogram can then be performed. For bleeding localized to the left colon on tagged RBC study, the inferior mesenteric artery is selected first. The superior mesenteric artery is selected first for those bleeds that occur in the right colon. If the bleeding site is not identified after injection of both the superior and inferior mesenteric arteries, a celiac run is performed looking for an upper intestinal bleeding source. Active bleeding can be diagnosed by the accumulation of contrast in the arterial phase that persists through the venous phase (Figure 6-41). Bleeding needs to occur at a higher rate for a positive angiogram (0.5 mL per minute) than for nuclear imaging (0.1–0.2 mL per minute). Because lower GI bleeding can be intermittent, the bleeding site is sometimes not identified at the time of the angiogram.

Diverticulosis and vascular ectasias are presumed to be the leading cause of lower GI bleeding in most patients.

FIGURE 6-41. Mesenteric angiogram shows pooling of contrast in the sigmoid colon in this patient with surgically proven diverticular bleeding.

Diverticular bleeds appear as a blush of contrast contained within a diverticulum. Vascular ectasias often occur in the right colon and appear as small vascular clusters, a blush in the wall of the colon and early opacification of a draining vein.<sup>46</sup> Arteriovenous malformations are developmental in origin and are often seen in the small bowel. They appear as tortuous, dilated arteries and early prominent veins. Capillary telangiectasias (common in Osler Weber Rendu syndrome) appear as multiple, tiny areas of blush and no arteriovenous shunting. Postpolypectomy bleeding has been diagnosed and treated with angiography. A rapid blush of dye occurs at the site of bleeding and often stops with direct infusion of vasopressin or embolization (Figure 6-42).

Acute mesenteric ischemia is one of the most common intestinal disease processes for which arteriography is used for diagnosis and treatment. Acute mesenteric ischemia can be either nonocclusive or occlusive. Nonocclusive mesenteric ischemia arises from a “low flow” state typically secondary to reduction in mesenteric blood flow from cardiac failure or hypotensive shock. This diagnosis can frequently be made with clinical symptoms and computer tomography images. The typical early angiographic images show diffuse vasoconstriction of mesenteric arterial branches and decreased parenchymal vascularity (Figure 6-43). In the late stage there is increased accumulation of contrast in the bowel wall. Treatment includes volume resuscitation and cardiac support. The diagnostic percutaneous catheter can be used to treat the mesenteric phase of constriction with IV glucagon or intraarterial infusion of the papaverine in an intensive care unit setting.

Occlusive acute mesenteric ischemia is a medical emergency, thus early diagnosis and treatment may prevent bowel

A

FIGURE 6-42. Mesenteric angiogram shows extravasation of contrast **A** indicating an acute bleed that was successfully treated after infusion of pitressin **B**.

FIGURE 6-43. Mesenteric angiogram shows vasoconstriction and pruning of the superior mesenteric artery and its branches in this patient who presented with mesenteric ischemia secondary to severe hypotension.

necrosis and perforation. These patients typically have severe abdominal pain with nonspecific physical findings.<sup>47</sup> An arteriogram is the most useful diagnostic examination for patients in whom one has a high clinical suspicion of acute occlusive mesenteric ischemia.<sup>48</sup> A catheter is inserted into the aorta and an aortogram is obtained. The celiac and superior mesenteric arteries are catheterized and injected with contrast in order to identify the level of occlusion and document collateral circulation. A superior mesenteric artery embolus typically lodges just proximal or distal to the take off of the middle colic artery and is seen as a meniscus at the site of occlusion and blockage of contrast (Figure 6-44). Atherosclerotic occlusion will often involve the origin of the superior mesenteric artery seen as stenosis or plaque with a trickle of glow beyond (Figure 6-45). Collaterals will develop from the inferior mesenteric artery through the marginal artery. If the inferior mesenteric artery is occluded or absent, the collaterals will develop from the middle or inferior hemorrhoidal arterial branches of the internal iliac artery.<sup>48,49</sup>

## CT Colonography

CT colonography is rapidly developing as a noninvasive total colonic examination for the detection of colon polyps and cancers. This technique uses volumetric data acquired by helical CT scanners and workstations which use two- and three-dimensional images to evaluate data. Since 1994, there have been technical improvements in the CT hardware and software allowing better visualization and discrimination of the reconstituted images. The three-dimensional endoluminal imaging is better at evaluation of surface morphology and discriminating between polyps and haustral folds (Figure 6-46).<sup>50</sup> The

FIGURE 6-44. Mesenteric angiogram shows a large filling defect within the proximal superior mesenteric artery consistent with an embolism in this patient with ischemic bowel.

FIGURE 6-46. Three-dimensional image confirms the presence of the polyp in Figure 6-45.

two-dimensional images help in the correlation of images seen on the three-dimensional fly-through.

Image processing and interpretation has improved with newer software and an experienced radiologist can generally complete the examination in <15 minutes.

Although the colon is evaluated in a noninvasive way, a bowel preparation is still required the day before the examination to eliminate formed fecal matter. Air insufflation is done via a small tube placed within the rectum to distend the bowel and to minimize folds within the colonic wall. Insufflation with a handheld bulb, or with a CO<sub>2</sub> insufflator is performed. A CT tomogram is obtained to confirm adequate insufflation in both the prone and supine positions and further air is insufflated as needed. Unlike colonoscopy, IV sedation is not required. Patient satisfaction after colonoscopy and CT colonography are similar because bowel preparation is needed for both tests.<sup>51</sup>

Rapid scanning can be done in a single breath hold. Volumetric data are acquired twice, once with the patient prone and once with the patient supine. The change in position allows any fluid within the bowel lumen to shift, revealing abnormalities within the contralateral wall. Most tests can be completed in <15 minutes. Once the images are acquired, a trained radiologist reviews them at the workstation and the images are recreated in such a way as to give an endoluminal view of the colon similar to that seen on colonoscopy. Several studies have compared CT colonography to colonoscopy for high- and low-risk patients. The sensitivity of this technique per individual patient ranges from 75% to 100% and the specificity ranges from 72% to 100%.<sup>50-54</sup> Both the sensitivity and specificity are dependent on the polyp size. In randomized,

FIGURE 6-45. Axial two-dimensional image from a CT colon study shows a well-defined 6-mm polyp in the sigmoid colon.

FIGURE 6-47. Axial attenuation corrected PET image **A** and fusion PET CT image **B** show an area of intense FDG uptake in the right hepatic lobe consistent with hepatic metastatic disease in this patient with cecal adenocarcinoma.

controlled trials, the specificity is greater for polyps larger than 1 cm than for polyps larger than 5 mm.<sup>53</sup> The detection of small (< 5 mm) polyps is poor in most studies with sensitivities as low as 11.5%.<sup>54,55</sup> The importance of these small lesions continues to be debated by the medical community. A recent nonrandomized multicenter blinded study comparing CT colonography with colonoscopy found that the sensitivity for CT colonography detecting polyps  $\geq 6$  mm was 39% and those  $\geq 10$  mm was 55%.<sup>56</sup> This study acknowledged that the accuracy of CT colonography varied between centers and with the experience of the radiologists. Interobserver variability can be significant and is evidence of the steep learning curve.<sup>57</sup>

The main limitation of CT colonography has been distinguishing polypoid tissue from fecal matter and the detection

of flat lesions.<sup>55</sup> Acquiring images after a change from the prone to the supine position can frequently unmask hidden polyps and tagging residual stool with subsequent digital subtraction is being evaluated.<sup>58</sup> An added benefit of the technique is the potential for the discovery of incidental extracolonic findings. The dose of radiation used for CT colonography is less than for conventional CT with the result that the scanned images are not the same. Nonetheless, the incidence of clinically important extracolonic findings is approximately 11%.<sup>59</sup>

Whether CT colonography can be used for mass screening of average-risk patients has yet to be determined. Currently, most centers are using CT colonography for those patients who have had incomplete colonoscopies or who cannot undergo colonoscopy for medical reasons. Clinical trials are ongoing as educational efforts and technical improvements are made in an attempt to improve this potential screening technique.

## Positron Emission Tomography

Whole body positron emission tomography (PET) was originally developed as a research technique in the 1970s. The clinical use of this technique has evolved over the past several decades. This technique uses [<sup>18</sup>F] 2-fluoro-2-deoxy-D-glucose (FDG) which is a radiopharmaceutical glucose analog to measure increased glucose uptake and metabolism in rapidly dividing cells. Malignant and other rapidly dividing cells that have a high metabolic rate will take up FDG for use as a glucose substrate. The first metabolite of FDG is FDG-6-phosphate which is not a substrate for glucosephosphate isomerase because of the configuration of FDG. FDG-6-phosphate has a low membrane permeability and thus the labeled substrate accumulates intracellularly.<sup>60</sup> The imaging technique of PET utilizes differences in uptake of FDG in malignant versus benign cells. The intracellular accumulation concentrates the radiopharmaceutical analog, which appears “bright” upon imaging (Figure 6-47).

The performance of a PET scan requires that the patient fast for 4–6 hours before the injection of FDG. A urinary catheter is placed to minimize the effect of the accumulation of tracer in the bladder. Emission scans are then performed with the patient motionless shifting the table between scans to alter the field of view. Older techniques required that a patient remain motionless for approximately 1–2 hours. Newer techniques have reduced the scan per bed position to approximately 2 minutes. Scans are then enhanced through a segmentation calibration and the scattered events outside the body are removed. Attenuation in each area is altered depending on tissue within the region.<sup>61</sup>

FDG PET has been used to evaluate metastatic disease and to improve staging accuracy (Figure 6-48). This technique images the whole body and is more sensitive than CT for the detection of hepatic and extrahepatic colorectal cancer

A

B

FIGURE 6-48. CT scan in a patient who had prior rectal resection for carcinoma shows soft tissue mass in the surgical bed of the perirectal fat **A**. Follow-up PET examination **B** shows intense FDG uptake within this soft tissue mass consistent with recurrence.

metastases and the detection of local recurrence. The reported sensitivities for PET detection of liver metastases range from 89% to 95% and for extrahepatic metastases 87% to 92%.<sup>62-66</sup> The use of FDG PET versus CT or MRI is based on the premise that functional differences in tumor appear before size changes. Postoperative changes, particularly for rectal cancers, are difficult to evaluate using standard modalities. The distinction between tumor and scar is not easily defined with the

current CT and MRI scans. FDG PET is extremely useful in this arena because a positive FDG PET scan in the setting of no inflammation would indicate a local recurrence of a rectal cancer. Furthermore, detection of small extrapelvic metastases is more accurate using FDG PET than CT or MRI. Thus, the use of FDG PET for staging or recurrent cancers may help plan or avoid expensive and possibly more morbid surgical procedures.

False-positive and false-negative tests have been reported to occur in several distinct situations. FDG is not a tumor-specific substance and increased FDG activity is seen in the normal urinary and GI tracts. The cellular glucose metabolism is also increased in inflammation as the increased uptake of FDG can be seen in leukocytes and macrophages. Inflammatory processes such as diverticulitis and pneumonia can lead to false-positive readings thus making it imperative to correlate positive PET findings with the clinical picture and conventional radiologic evaluation.<sup>67,68</sup>

Detection of metastatic disease is dependent on the size and degree of metabolic activity. Limited spatial resolution may lead to false-negative readings for small, <1-cm lesions.<sup>69</sup> Adenocarcinomas with a high mucinous content may result in false-negative readings because of the low cellularity of these cancers. Sensitivity can be as low as 59% for mucinous carcinomas.<sup>70</sup> The combination of CT and FDG PET imaging has reduced some of the inaccuracies and makes the study more readily correlated anatomically.

The routine use of FDG PET for primary cancers is more problematic. Although the risks and radiation doses are low and the technique is noninvasive, the cost per scan is very high. Thus, for primary cancers in which the information would not alter the planned surgical procedure, it is probably not indicated. However, in patients that are poor surgical risk, the findings in FDG PET may help avoid or alter the surgical procedure and might change the goal from a curative to palliative intent. Current CMS (HCFA) recommendations for reimbursed PET imaging in colorectal cancer include 1) evaluation of patients with a question of recurrent disease as indicated by rising CEA, 2) evaluation of resectability, and 3) evaluation of patients with locally advanced disease to determine unresectability on the basis of metastasis when the operation is a large otherwise debilitating procedure.

MRI is a continually evolving field of radiology. The technique was developed in the early 1980s and currently there is a wide range of MRI systems in use. This technique relies on the difference in tissue contrast or signal intensity. High signal intensity appears white on the image whereas low signal intensity is dark. T<sup>1</sup> and T<sup>2</sup> refer to specific tissue properties that describe the way protons behave after being excited by a radiofrequency pulse in a strong magnetic field.<sup>71,72</sup> The specific parameters chosen to acquire an image on an MR magnetic system determine whether an image is T<sup>1</sup> or T<sup>2</sup> weighted. T<sup>1</sup> refers to the longitudinal relaxation rate and T<sup>2</sup> refers to the transverse relaxation rate. Structures containing water appear black on T<sup>1</sup>-rated images and structures containing fluid (cysts or gallbladder) are white on T<sup>2</sup>-weighted

images. Unlike CT scans, iodinated contrast is not used for the performance of these scans. The contrast agents that have been developed can be used in patients with renal insufficiencies, and those with iodinated contrast allergic reaction. The risk from MRI is attributed to the interaction between the strong magnetic field and certain implantable devices such as cardiac pacemakers, cerebral aneurysms clips, and cochlear implants.

The use of MR for intraabdominal bowel anatomy is limited because of the peristaltic action of the bowel wall and motion of the abdominal cavity caused by respirations. MRI has evolved to be better than CT for tissue characterization and evaluation of tissues planes within the pelvis. The layers of the bowel wall can be visualized easily for evaluation of rectal cancers. The muscularis propria is low signal intensity and the submucosa has higher signal intensity.<sup>73,74</sup> The accuracy of MRI for preoperative staging for rectal carcinoma continues to be evaluated. Contrast enhancement improves the correlation with histologic stage.<sup>75</sup> Endorectal MRI is similar to endoluminal ultrasound for determination of tumor depth and nodal staging although some studies have shown ultrasound to be more accurate in determining local invasion.<sup>76,77</sup> Overstaging and interobserver variation make reliable preoperative staging difficult.<sup>75,78</sup> MRI more accurately predicts the circumferential resection margin (Figure 6-49).<sup>79</sup> Several parameters help distinguish pathologic tissues. After pelvic irradiation, the radiation edema or fibrosis can be differentiated from tumor on T<sup>2</sup>-weighted images. The fibrosis appears low signal in the T<sup>2</sup> images and enhances slowly. Recurrent tumors have a higher signal and enhance quickly during dynamic gadolinium-enhanced scanning.<sup>80,81</sup> Changes in postradiation normal tissue result in slow tissue enhancement with gadolinium.<sup>80</sup>

FIGURE 6-49. Endorectal MRI examination shows an ulcerated plaque-like cancer arising from the mucosa and extending to the first muscular layer of the muscularis propria.

FIGURE 6-50. Endoanal MRI image demonstrates a nondisrupted (normal) signal of the internal and external sphincter.

The anal sphincter and pelvic anatomy have been imaged with MR using an internal coil (Figure 6-50). The internal sphincter has higher signal intensity than the external sphincter. Pelvic muscle morphology, sphincter injuries, and abscesses can be identified. Clinical experience with MR has not been as extensive as with endoluminal ultrasound but comparative studies have been favorable. MRI of the puborectalis is better than endorectal ultrasound and capable of showing atrophy.<sup>82</sup> It remains to be seen what the role of MR will be in the evaluation of fecal incontinence because of variability of scanner capabilities among institutions and limited access to high-performance scanners.

## Endoluminal Ultrasound

Donald G. Kim and W. Douglas Wong

Evaluation of the anal canal and rectum has traditionally relied on digital examination, anoscopy, and rigid or flexible proctosigmoidoscopy. The introduction of imaging methods, particularly endoluminal ultrasonography has brought a greater degree of objectivity to the evaluation of the anorectum.

Endoluminal ultrasound has become the diagnostic procedure of choice in the evaluation of many anorectal disorders. Endorectal ultrasound (ERUS) has evolved into the best imaging modality for accurate staging of rectal neoplasms. The accurate determination of tumor penetration depth and regional lymph node status has become critical to guiding subsequent treatment of rectal malignancies. In addition, endoanal ultrasound (EAUS) has become invaluable in the diagnostic workup of fecal incontinence and anorectal suppurative conditions. This chapter will focus on the use of endoluminal ultrasound in the evaluation of patients with benign and malignant conditions of the anorectum.

### History

Endoluminal ultrasound of the rectum was first introduced by Wild and Reid<sup>1</sup> in 1952. They were the first to develop an “echoendo probe,” but it was never used clinically. Because of limitations in technology, it was not until 1983 that this type of imaging was introduced into clinical practice by Dragsted and Gammelgaard.<sup>2</sup> They used a Bruel and Kjaer (Type 8901) ultrasound probe with a rigid rotating endosonic probe with 4.5-MHz transducer initially designed for prostatic ultrasound. Thirteen primary rectal cancers were evaluated and invasion was correctly predicted in 11 cases when compared with the final histopathology. Two patients could not be adequately imaged because of stricture. Although successful, they did not define their reporting criteria. In 1985, Hildebrandt and Feifel<sup>3</sup> found that ultrasonography correlated with pathologic finding in 23 of 25 rectal cancers. They proposed a modification of the tumor-node-metastasis (TNM) classification<sup>4</sup> for ultrasound tumor staging (uTNM).<sup>3</sup> The

prefix “u” indicated ultrasound staging as opposed to the prefix “p” representing pathologic staging. Similar to Dragsted and Gammelgaard, they also made no reference to the reporting criteria used for degree of invasion. Further refinements of the technique and improvement in the ultrasound equipment have made endoluminal ultrasound routine in the evaluation of patients with anorectal disorders.

### Endorectal Ultrasound

As the treatment for rectal cancer has evolved, the importance of accurate preoperative staging of the lesion has become paramount in determining the patient’s treatment regimen. Radical surgery, either low anterior or abdominoperineal resection is not always the initial or only therapy available for patients diagnosed with rectal carcinoma. With the development of preoperative neoadjuvant therapies for rectal cancer, accurate staging of these patients’ lesions has become increasingly important. In addition, local excision has become an option in highly selected early-stage rectal cancers necessitating accurate preoperative staging.

The goal of preoperatively staging the rectal lesion is an accurate evaluation of the primary tumor, which includes the depth of tumor penetration and an evaluation of regional lymph node disease. ERUS accomplishes these goals using an intraluminal high-frequency sonographic transducer via a handheld rotating probe to accurately image the rectal wall and adjacent structures. For this reason, ERUS has become the preferred method used to stage the patient with rectal cancer.

### Equipment and Technique

Equipment used for endoluminal ultrasonography includes a handheld endocavitary probe with rotating transducer which acquires a 360-degree image. Most investigators use a B-K Medical scanner with a rigid handheld Type 1850 rotating probe and a 7- or 10-MHz transducer (B-K Medical,

Wilmington, MA). Transducers of 7 and 10 MHz provide a focal length of 2–5 and 1–4 cm, respectively, rotating a 90-degree scanning plane at four to six cycles per second to obtain a 360-degree radial scan of the rectal wall and surrounding structures. Because of its superior near-image clarity, the 10-MHz transducer is preferred. Rectal imaging requires a latex balloon covering the transducer for acoustic contact. The balloon is instilled with water allowing the ultrasound signals to easily pass through the water to image the rectum. The water instilled distends the rectum allowing the balloon to maintain contact with the rectal wall without separation, preventing any distortion of the image by the interposition of nonconductive air between the probe and the rectal wall.

Patients receive one or two phosphosoda enemas to cleanse the rectum before examination. The procedure is performed with the patient in the left lateral decubitus position without sedation. A digital rectal and proctoscopic examination is performed to assess the tumor size, appearance, location, and distance from the anal verge. Any residual stool or enema effluent that might interfere with the ultrasound is removed. A wide-bore ESI proctoscope (Electrosurgical Instrument Company, Rochester, NY) is inserted into the rectum to examine the rectum and lesion of interest. Optimally, the proctoscope is advanced proximal to the lesion to facilitate complete examination of the tumor by the transducer. The wide-bore ESI proctoscope permits passage of the ultrasound probe through the proctoscope to facilitate positioning of the probe above the lesion. This facilitates complete imaging of the lesion from its most proximal to distal extent as well as the proximal mesorectum, which may harbor involved lymph nodes. This approach is preferred to blind insertion of the ultrasound probe into the rectum. With blind insertion, distortion of the image can occur and the proximal areas of a lesion as well as the adjacent mesorectum will often be missed.

After correct positioning of the wide-bore ESI proctoscope, the ultrasound probe with latex balloon is lubricated and passed through the proctoscope to its full extent. The ultrasound probe is oriented with the stopcock and syringe positioned upright to the patient's right. The proctoscope is slightly withdrawn keeping the ultrasound probe in place to expose the transducer protruding beyond the end of the proctoscope, above the rectal lesion. The latex balloon is filled with 30–60 mL of water providing an optimal acoustic environment surrounding the rotating transducer. Initial preparation of the ultrasound probe includes careful removal of all air bubbles within the latex balloon to minimize acoustic interference. The probe and attached proctoscope are slowly withdrawn together carefully scanning the rectum from proximal to distal. The ultrasonographer observes for alterations of the rectal wall and perirectal tissues to assess depth of invasion and perirectal lymph node involvement. Optimal evaluation often requires several passes back and forth across a lesion. The evaluation of the lesion occurs on the basis of real-time imaging intermittently capturing still images that are representative of the lesion being studied. With the patient and ultrasound posi-

tioned as above, the images obtained are oriented radially similar to a computed tomography scan, looking up from the patient's feet. The patient's right side is oriented to the left of the image, anterior is up, and posterior is down. The studies can also be videotaped for further review.

## Image Interpretation

On most ERUS images, a series of five distinct layers can be identified in the rectal wall. They consist of three hyperechoic (white) layers separated by two hypoechoic (black) layers. Beynon and colleagues<sup>5</sup> proposed a five-layer model based on an anatomic study, demonstrating that the five basic layers seen on an ultrasonographic scan of the rectal wall correspond directly to the anatomic layers present in the rectal wall. It is this five-layer model that we continue to use today (Figure 7-1). The five layers from the center to the periphery consist of the following:

- First hyperechoic layer: Interface between the balloon and the rectal mucosal surface
- Second hypoechoic layer: Mucosa and muscularis mucosa
- Third hyperechoic layer: Submucosa
- Fourth hypoechoic layer: Muscularis propria
- Fifth hyperechoic layer: Interface between the muscularis propria and perirectal fat

Occasionally, a seven-ring model may be visualized when the muscularis propria is observed as two black rings separated by a white ring (Figure 7-2). This model represents the inner circular and outer longitudinal muscle layers as hyperechoic (black) rings separated by a hypoechoic (white) interface.

## Assessment of Rectal Neoplasms

### Depth of Invasion

As discussed above, ultrasound classification of rectal tumor stage was initially proposed by Hildebrandt and Feifel<sup>3</sup> as a modification of the TNM classification. Ultrasound staging

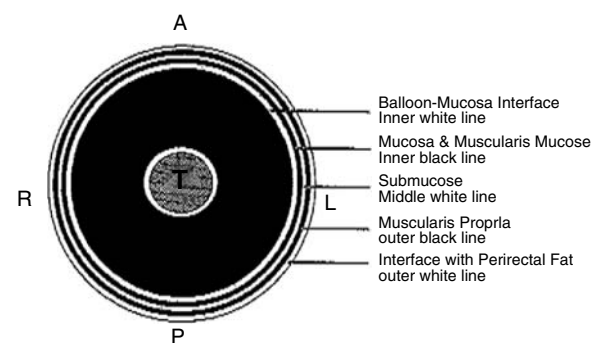

FIGURE 7-1. Five-layer anatomic model of an ERUS scan. Three hyperechoic (white) layers and two hypoechoic (black) layers are visualized. A, anterior; L, left; P, posterior; R, right; T, transducer.

FIGURE 7-2. This endorectal ultrasonography image depicts the typical five layers of the rectal wall. Seven layers are depicted anteriorly, where an interface can be seen between the inner circular (A) and outer longitudinal (B) muscle layers of the muscularis propria.

classification (uTNM) is presented in Table 7-1. The depth of invasion is classified as follows: uT0 lesions are benign, non-invasive lesions confined to the mucosa; uT1 lesions indicate an invasive lesion confined to the mucosa and submucosa; uT2 lesions penetrate but are confined to the muscularis propria; uT3 lesions penetrate the entire bowel wall and invade the perirectal fat; and a uT4 lesions penetrate a contiguous organ (i.e., uterus, vagina, cervix, bladder, prostate, seminal vesicles) or the pelvic sidewall or sacrum.

#### uT0 Lesions

uT0 lesions are benign, noninvasive lesions confined to the rectal mucosa. Sonographically, the mucosal layer (inner black band) is expanded with an intact submucosa (middle white, hyperechoic line) (Figure 7-3). Benign rectal villous adenomas are classified as uT0 lesions and may be treated with local excision with excellent results. Important in this decision is to accurately exclude any focus of invasion. The accuracy of ERUS is probably highest for T0 lesions. In an

TABLE 7-1. Ultrasound staging classification (uTNM) for rectal cancer

uT0	Noninvasive lesion confined to the mucosa
uT1	Tumor confined to the mucosa and submucosa
uT2	Tumor penetrates into but not through the muscularis propria
uT3	Tumor extends into the perirectal fat
uT4	Tumor involves an adjacent organ
uN0	No evidence of lymph node metastasis
uN1	Evidence of lymph node metastasis

FIGURE 7-3. This image demonstrates a benign uT0 lesion in the left posterolateral aspect of the rectum. There is an expansion of the inner black line that represents the mucosa (A), but the submucosa (B) is seen to be completely intact.

initial study by Deen and colleagues<sup>6</sup> from the University of Minnesota, 47 of 53 lesions (89%) were correctly staged preoperatively. A more recent update reported 129 of 148 patients (87%) were correctly staged preoperatively from that same institution.<sup>7</sup> Pikarsky et al.<sup>8</sup> reported that 25 of 27 patients (96%) were accurately staged a benign lesion when compared with pathologic results. Because of the frequent misdiagnosis of rectal adenomas by biopsy and the subsequent finding of invasive cancer in the final pathologic specimen after transanal excision, Worrell et al.<sup>9</sup> conducted a systematic literature review to assess the utility of ERUS in the assessment of rectal villous adenomas comparing the diagnosis by biopsy alone with diagnosis by a combination of biopsy and ERUS. This metaanalysis revealed that, of 258 biopsy-negative rectal adenomas, 24% had focal carcinoma on final histopathology and that ERUS correctly detected the cancer in 81%.

#### uT1 Lesions

uT1 lesions are early invasive cancers. uT1 lesions have invaded the mucosa and submucosa without penetrating into the muscularis propria. Sonographically this is characterized by an irregular middle white line (submucosa) without alteration of the outer black line (muscularis propria) (Figure 7-4). Irregularities are indicated by a thickening or stippling of the submucosal layer but there must not be a distinct break in the submucosal layer. A distinct break in the submucosal (middle white line) layer indicates invasion of the muscularis propria, hence a T2 lesion.

Local transanal excision is an acceptable treatment method for selected T1 lesions highlighting the need for accurate staging of these cancers. Criteria for the use of local therapies

FIGURE 7-4. This image depicts a uT1 cancer in the left lateral wall of the rectum. The middle white line or submucosa is irregular and somewhat thickened (A), but not completely disrupted.

to treat early rectal cancers have been described<sup>10</sup> and include tumor size less than 4 cm, involvement less than one-third of the rectal circumference, location less than 8 cm from the anal verge, well- to moderately well-differentiated histology, absence of lymphatic or vascular invasion, and no involvement of perirectal lymph nodes.

#### uT2 Lesions

uT2 lesions penetrate into the muscularis propria (second hypoechoic, black line) but are confined to the rectal wall. Sonographically the hallmark finding is a distinct break in the submucosal layer. Characteristically, there is an expansion of the muscularis propria (outer black line) but the interface between the muscularis propria and the perirectal fat (the outermost white line) remains intact. The expansion of the muscularis propria may be variable depending on the degree or invasion. “Early” uT2 lesions may just invade the muscularis propria with minimal expansion of the layer. “Deep” uT2 lesions have significant expansion of the muscularis propria (outer black line) and may appear to scallop the outer aspect of the muscularis propria but preserve the interface with the perirectal fat. An example of a uT2 lesion is illustrated in Figure 7-5.

#### uT3 Lesions

uT3 lesions penetrate the full thickness of the muscularis propria and into the perirectal fat. Continuous structures are not involved. The sonographic appearance reveals disruption of the submucosa, thickening of the muscularis propria, and disruption of the outer hyperechoic, white line indicating penetration into the perirectal fat (Figure 7-6). The recognition of

FIGURE 7-5. A uT2 lesion is identified in this image, in the right anterior location. The hallmark of a uT2 lesion, as seen on endorectal ultrasonography, is the distinct break (A) in the submucosa (the middle white line) as seen in this image.

perirectal fat invasion is an important determinant in the preoperative evaluation of the rectal cancer patient. Because of the high incidence of lymph node metastases (30%–50%), local therapy cannot be recommended for these patients, who are usually candidates for preoperative radiation and chemotherapy followed by surgery. ERUS obviously has an important role in selecting those patients who will undergo preoperative radiation and chemotherapy.

FIGURE 7-6. This image demonstrates a uT3N1 lesion. The tumor disrupts all layers of the rectal wall, with extensions evident into the perirectal fat (A). A lymph node (B) is identified in the left posterior location within the mesorectum.

### uT4 Lesions

uT4 lesions are locally invasive into contiguous structures such as the uterus, vagina, cervix, bladder, prostate and seminal vesicles, or involve the pelvic sidewall or sacrum. They are clinically fixed and tethered. Sonographically, there is loss of the normal hyperechoic interface between the tumor and adjacent organ (Figure 7-7). Therapy of a T4 lesion usually requires preoperative radiation and chemotherapy followed by surgical resection of the rectal cancer and involved adjacent organ. The overall prognosis is poor, with less than half of patients resected for cure. Preoperative radiation and chemoradiation therapy can shrink the tumor for increased resectability and decreased local recurrence. ERUS provides the means to preoperatively identify those lesions with T4 involvement to adequately plan the patient's treatment.

### Nodal Involvement

Lymph node involvement in rectal cancer is associated with decreased survival rates and increased local recurrence rates. ERUS is able to detect metastatic lymph nodes in the mesorectum. Unfortunately, the accuracy of detecting involved lymph nodes is less than the accuracy in determining the depth of invasion. The accuracy of ERUS in detecting lymph node metastases ranges from 50% to 88%.<sup>11-13</sup> ERUS determination of metastatic lymph nodes is certainly more accurate than clinical (digital) evaluation<sup>14</sup> as well as other imaging modalities including CT<sup>11,15</sup> and conventional mag-

netic resonance imaging (MRI).<sup>16</sup> However, phased array MRI and endorectal coil MRI are comparable to ERUS in lymph node assessment.

As indicated in Table 7-1, lymph node staging parallels pathologic TNM staging classifying tumors with (uN1) or without (uN0) lymph node involvement. Undetectable or benign-appearing lymph nodes are classified as uN0. Malignant-appearing lymph nodes are classified as uN1. Normal, nonenlarged lymph nodes are usually not detectable by ERUS. Inflamed, enlarged lymph nodes appear hyperechoic with irregular borders. Lymph nodes suspicious for malignancy include larger, round, hypoechoic lymph nodes with an irregular contour. ERUS findings consistent with metastatic lymph nodes are demonstrated in Figure 7-8. Hypoechoic lymph nodes greater than 5 mm are highly suspicious for metastases. Involved lymph nodes are usually found adjacent to the primary tumor or within the proximal mesorectum.

The echogenic pattern and size of imaged lymph nodes have been suggested to be indicators of metastatic nodal disease. Tio and Tytgat<sup>17</sup> were the first to recognize the hypoechoic pattern of malignant lymph nodes using ERUS. Hildebrandt et al.<sup>18</sup> differentiated two main groups of lymph nodes: hypoechoic and hyperechoic lymph nodes. Compared with pathologic findings, hypoechoic lymph nodes represent metastases, whereas hyperechoic lymph nodes are visualized because of nonspecific inflammation. There is no definitive size threshold to determine if an identified lymph node is malignant. Lymph nodes smaller than 5 mm can harbor metastatic disease.<sup>19-21</sup> In a pathology-based study, Herrera-Ornelas et al.<sup>19</sup> found that two-thirds of metastatic lymph nodes from colorectal cancer were smaller than 5 mm in diameter. Katsura and associates<sup>20</sup> found that 18% of nodes

FIGURE 7-7. This image identifies a T4 lesion in the distal rectum and upper anal canal extending to the vagina. The curved white line (A) seen anteriorly represents the examiner's finger in the vagina, and the hypoechoic anterior tumor (B) can be seen to extend into the vagina.

FIGURE 7-8. This image demonstrates a typical metastatic lymph node (A), which is round and hypoechoic.

measuring 4 mm or less on ERUS were involved with metastatic disease. Similarly, Akasu et al.<sup>21</sup> found that approximately 50% of cases of lymph nodes measuring 3–5 mm on ERUS harbored metastases. Sunouchi et al.<sup>22</sup> described a “small spot sign” for lesions at the margin of rectal carcinomas on ERUS measuring 1–3 mm in diameter. The small hypoechoic “spots” correlated with massive venous or lymphatic invasion histologically.

Nodes larger than 5 mm harbored metastatic disease 54% of the time. Sunouchi et al.<sup>23</sup> studying hypoechoic lesions larger than 5 mm on ERUS demonstrated that 68% were metastatic lymph nodes and 20% were tumor deposits. Statistically, the incidence of metastatic disease increases as lymph node size increases.

Overall, four nodal patterns are seen with differing probabilities of being involved with metastatic disease. Nonvisible lymph nodes on ultrasound have a low probability of harboring lymph node metastases. Hyperechoic lymph nodes with nonsharply delineated boundaries are more often benign resulting from inflammatory changes. Hypoechoic lymph nodes larger than 5 mm are highly suggestive of lymph node metastases. Mixed echogenic lymph nodes larger than 5 mm are difficult to classify but should be considered malignant.

Accurate lymph node staging of rectal cancers by ERUS relies on the experience of the examiner. False-positive results may occur because of inflammatory lymph nodes or confusing the cross-sectional appearance of perirectal blood vessels for metastatic lymph nodes. Scanning longitudinally will distinguish between blood vessels and lymph nodes because blood vessels will extend longitudinally, change direction, and/or branch. The sonographic continuity of the hypoechoic vessel over a distance greater than the cross-sectional area is the criterion used to distinguish the two. Three-dimensional imaging can help in making this distinction.

False-negative results are also problematic in interpreting nodal involvement on ERUS. Lymph nodes harboring micrometastases are difficult to detect. Grossly malignant lymph nodes may be present outside the range of the ultrasound probe and remain undetectable. This may be the case of lateral pelvic lymph nodes such as the obturator nodes as well as those within the mesorectum beyond the proximal extent of the rigid probe.

### Accuracy of Ultrasound in the Diagnosis of Rectal Cancer

The success of any imaging modality is the result of its diagnostic accuracy. Preoperative therapy for rectal cancer depends on the accurate staging of the primary lesion. The determination of the lesion’s depth of invasion (T stage) and lymph node involvement (N stage) are important factors dictating the therapeutic options. ERUS has the ability to determine the depth of tumor invasion and lymph node involvement of rectal cancers. ERUS has been found to be accurate in determining the tumor’s depth of invasion within the bowel wall, although

ERUS is only moderately accurate in the assessment of lymph node involvement.

The accuracy of ERUS for the staging of rectal cancer has been established from studies comparing preoperative ultrasound staging with the pathologic staging from the operative specimens. The accuracy of ERUS for tumor depth of invasion has been reported in the range of 69%–94% (Table 7-2). Overstaging has been reported in approximately 10% of patients and is believed to be the result of peritumoral inflammation beyond the leading edge of the tumor. Understaging for depth of wall invasion has been reported to be approximately 5% and is considerably more serious than overstaging because inadequate management may result. With overstaging, potentially more aggressive management is recommended than might be required.

Detection of lymph node metastases with ERUS has been less accurate, ranging from 61% to 83% in reported series (Table 7-2). Solomon and McLeod<sup>24</sup> reviewed the literature and pooled raw data were collected from eight published cross-sectional surveys assessing the degree of tumor penetration in 873 patients and lymph node involvement in 571 patients with primary rectal cancer. As previously noted, ERUS was very accurate in determining tumor penetration ( $\kappa = 0.85$ ), but only a moderate correlation was found between ERUS and histopathology for detecting lymph node involvement ( $\kappa = 0.58$ ). Furthermore, the positive predictive value was 74% with a negative predictive value of 84%, indicating only moderate accuracy among the included series.

There is a significant learning curve associated with the performance and interpretation of ERUS. Accuracy rates have been demonstrated to improve significantly with experience.<sup>13</sup> ERUS is highly operator dependent and thus accuracy is dependent on the experience and expertise of the examiner.<sup>7,25</sup>

Several factors can lead to the misinterpretation of ERUS images.<sup>26</sup> These factors include a lesion in close proximity to the anal verge, improper balloon inflation with associated balloon-wall separation, a nonperpendicular imaging plane, shadowing artifacts caused by air or stool, reverberation artifacts, refraction artifacts, and a transducer gain setting that is too high. Postbiopsy and postsurgical changes, hemorrhage, and bulky or pedunculated tumors can cause changes in the ultrasound image significantly affecting the accuracy of the ERUS interpretation.

The accuracy of ERUS after neoadjuvant therapy is decreased.<sup>27–31</sup> Radiation therapy can significantly downstage tumors and may in fact leave no residual tumor within the pathologic specimen. In fact, up to 24% of patients treated with preoperative radiation therapy have a complete pathologic response with no evidence of residual tumor.<sup>32</sup> Radiation therapy can cause tissue edema and fibrosis of the rectal lesion making ERUS interpretation difficult. One cannot accurately distinguish radiation-induced changes from residual tumor. For these reasons, reevaluation of rectal lesions with ERUS after radiation therapy is inaccurate, unreliable, and not recommended.

### Postoperative Follow-up

Local recurrence continues to be a difficult problem in the treatment of rectal cancer. Overall, local recurrence rates have been reported between 4% and 30% after curative rectal cancer surgery. More than 50% of patients will have local recurrence only at the surgical site without distant metastases.<sup>33,34</sup> Even with newer adjuvant therapies available, surgical resection remains the best chance of cure for the patient with isolated local recurrence. Clearly, early detection of local recurrence is important and follow-up programs should be directed at this goal in order to be successful. ERUS may be used in a variety of settings for surveillance purposes after surgery for rectal cancer. When used in combination with a digital rectal examination and endoscopic surveillance, ERUS may significantly improve the sensitivity of detecting recurrent lesions.<sup>35–37</sup> ERUS may improve the ability to diagnose recurrent neoplasm by as much as 30%.<sup>38</sup> In a series studying ERUS as a means to identify local recurrence, overall local recurrence ranged from 11% to 20% with the proportion of local recurrences diagnosed exclusively by ERUS varying from 18% to 35%.<sup>37–39</sup> These ERUS-only recurrences represent only 3.2%–5% of the entire group of patients. The University of Minnesota group presented similar results although the impact on overall survival is unclear.<sup>36</sup>

Although local recurrence occurs intraluminally at the anastomosis, locally recurrent tumor usually occurs from extrarectal tumor that invades through the rectum, often at the level of an anastomosis. Extrarectal tumor not involving the mucosa may be undetectable endoscopically, but can be identified at an early stage with ERUS. Recurrent tumor appears as a circumscribed hypoechoic lesion in the para-anastomotic tissues with all or a portion of the rectal wall

FIGURE 7-9. This image demonstrates a recurrent rectal cancer. It is located in the left lateral rectal wall. Note the intact inner three lines (A) on the ultrasound image, indicating no involvement of the mucosa or submucosa but an obvious abnormality at the level of the muscularis propria (B), representing the recurrence.

intact on the inner, luminal aspect (Figure 7-9). Early postoperative changes, particularly adjacent to the anastomosis, can make the interpretation of the ERUS difficult. Interpretation is aided if a “baseline” ultrasound is obtained soon (3 months) after surgery and compared with subsequent surveillance images. A baseline examination is useful to document postoperative scarring and to evaluate that area for potential changes on serial examinations. Lesions that increase in size on subsequent examinations are more likely to represent recurrent tumor. Because ERUS cannot establish that a lesion is malignant with absolute certainty, a biopsy of suspicious lesions is recommended to confirm recurrent disease. Biopsies may be performed by ultrasound-guided biopsy or computed tomography scan-guided biopsy.

The optimal interval and length of time for serial follow-up ERUS examinations have not been determined. Because most recurrences present within the first 2 years after surgery, more intensive follow-up is justified during this period. Imaging every 3–4 months for the first 2–3 years may be appropriate with less frequent, every 6-month evaluations until 5 years.

### Endoanal Ultrasound

EAUS is useful in the evaluation of the anal canal in both benign and malignant disease. The anal sphincter anatomy can be clearly identified detecting abnormalities in the external and/or internal sphincter. EAUS is routinely used in the evaluation of fecal incontinence and may be particularly

useful in the evaluation of complex perianal abscesses and fistulas. EAUS is also useful in the evaluation of anal canal neoplasms accurately staging these lesions.

### Equipment and Technique

The equipment used for EAUS is similar to that used for ERUS. The same B-K scanner is used with the 1850 rotating probe and 10-MHz transducer (B-K Medical). In place of the latex balloon, a translucent plastic cap (B-K type WA0453) is placed over the transducer to maintain contact with the anal canal. The plastic cap is again filled with water to provide the acoustic medium. There is a pinhole in the apex of the plastic cap that permits the escape of any air through displacement of the space with water.

The examination technique for EAUS is similar to that of ERUS. Patients are examined in the left lateral decubitus position, again usually without sedation. A careful external examination of the perianal area followed by a digital rectal examination is performed. The probe is lubricated with a water-soluble gel and gently inserted into the anal canal until the plastic cap is no longer visible. This will usually ensure that the transducer is at the level of the upper anal canal. The probe is slowly withdrawn to image the full length of the anal canal. Images are typically obtained in the upper, mid, and distal anal canal. In most instances, patients can be reassured that the examination should cause no more discomfort than a digital rectal examination. Certain instances of complex anorectal sepsis may be painful and require examination under anesthesia to adequately image the patient with EAUS.

### Image Interpretation

Normal anal canal anatomy is well visualized with EAUS. As with the rectum, the interpretation of these images must be based on a precise definition of normal endosonographic anatomy of the anal canal that correlates well with anatomy. EAUS of the anal canal and pelvic floor have been correlated with cadaveric anatomic dissections.<sup>40</sup> The ultrasonographic anatomy of the anal canal is generally divided into three levels: the upper, mid, and distal anal canal. Each level has a different appearance on EAUS. The upper anal canal is illustrated in Figure 7-10. The puborectalis is an important landmark delineating the upper anal canal. The puborectalis is imaged as a horseshoe-shaped mixed-echogenic structure forming the lateral and posterior portion of the upper anal canal.

The mid anal canal is illustrated in Figure 7-11. Within the mid anal canal, the internal anal sphincter is represented by a hypoechoic band surrounded by the hyperechoic external anal sphincter. Between the transducer and the internal anal sphincter is an additional hyperechoic ring of variable thickness representing the epithelial, hemorrhoidal, and submucosal tissues. Perineal body measurements can be made at the level of the mid anal canal (Figure 7-12). With the probe positioned within the mid anal canal, the right index finger is

FIGURE 7-10. This image represents the ultrasound appearance of the upper anal canal at the level of the puborectalis, which can be seen as the hyperechoic U-shaped structure seen posteriorly and laterally (arrows) in this image.

placed within the vagina against the rectovaginal septum and ultrasound probe. The distance between the hyperechoic ultrasound reflection of the finger and the inner aspect of the internal anal sphincter may be measured and represents the perineal body thickness. Normal measurements for perineal body thickness range from 10 to 15 mm, with a lower limit of

FIGURE 7-11. This image depicts the characteristic appearance of the mid anal canal. The circular hypoechoic structure represents the internal anal sphincter (A), surrounded by the thicker hyperechoic circumferential external anal sphincter (B).

FIGURE 7-12. This image depicts the technique used to measure the anterior perineal body in a female patient. The examiner's finger is placed in the vagina, and the hyperechoic curvilinear structure (A) seen anteriorly delineates the examiner's finger. The two cross-hatches between the examiner's finger and the transducer measure the thickness of the perineal body in this intact sphincter at the mid anal canal level.

normal considered to be approximately 8 mm. This measurement is useful in the evaluation of women with fecal incontinence from anterior sphincter defects. The examining index finger not only better defines the perineal body, but may accentuate an anterior sphincter defect that may otherwise appear intact.

The distal anal canal is illustrated in Figure 7-13. The distal anal canal is defined as the point where the internal anal sphincter is no longer seen. Only the hyperechoic external anal sphincter and surrounding soft tissues are visualized.

### Evaluation of Fecal Incontinence

EAUS has an important role in the evaluation of fecal incontinence, accurately delineating anal sphincter anatomy.<sup>41-43</sup> Causes of anal sphincter defects include obstetric injuries, anorectal surgeries, traumatic injuries, and congenital abnormalities.

Fecal incontinence is eight times more frequent in women,<sup>44</sup> the most common cause being obstetric trauma leading to injury of the anal sphincter muscles or traction neuropathy involving the pudendal nerve.<sup>44-46</sup> Although anal sphincter injury identified during delivery does not lead to significant deterioration in sphincter function immediately, it is suspected to lead to fecal incontinence in approximately 40% of women in long-term follow-up despite primary sphincter repair.<sup>47-49</sup> Anal incontinence is not restricted to patients with recognized third- or fourth-degree obstetric tears. Patients may also develop delayed symptoms of incontinence several years after an unrecognized sphincter injury.<sup>50</sup> The introduction of EAUS

FIGURE 7-13. This image represents the distal anal canal below the inferior level of the internal sphincter, where only the hyperechoic circumferential fibers of the superficial external anal sphincter (A) are imaged.

has led to the recognition of unsuspected sphincter defects in asymptomatic, continent women thought to have normal perineums.<sup>51-54</sup> Traumatic sphincter disruption can frequently be associated with a subsequent rectovaginal fistula. These patients may be anally continent but have symptoms of fecal incontinence associated with the fistula. Because these patients may have an unrecognized anal sphincter defect, all patients with rectovaginal fistula should undergo preoperative evaluation for occult sphincter defects by EAUS.<sup>55</sup> Local tissues are inadequate for endorectal advancement flap repairs in patients with anal sphincter defects and these patients should be treated by sphincteroplasty with levatoroplasty.<sup>55</sup> EAUS has become an accurate method to image the anal sphincters identifying anal sphincter defects that result in fecal incontinence.<sup>46,56-58</sup>

EAUS has become the best modality to accurately demonstrate the anatomy of the anal canal as well as anal sphincter defects that contribute to fecal incontinence.<sup>43</sup> Defects in the external anal sphincter usually appear hypoechoic, although some may appear hyperechoic or demonstrate mixed echogenicity. Defects of the internal anal sphincter are represented by the lack of segment of the hypoechoic band of internal sphincter muscle. There is usually associated contralateral thickening of the hypoechoic internal anal sphincter. With complete sphincter disruption, EAUS demonstrates the ends of the internal and external anal sphincter widely separated and bridged with intervening scar tissue of variable echogenicity (Figure 7-14). Many times, complete sphincter disruption is not seen, but attenuation of the sphincter mechanism is noted anteriorly, indicating a significant partial

FIGURE 7-14. This image depicts a complete anterior sphincter disruption in a female patient. The hypoechoic internal anal sphincter can be seen completely disrupted in its anterior location (A arrows). Similarly, the hyperechoic external anal sphincter is completely disrupted anteriorly (B arrows).

sphincter defect. An examining digit used to measure the perineal body distance in the mid anal canal can accentuate an anterior sphincter defect, helping to identify a sphincter injury (Figure 7-15).<sup>59</sup>

FIGURE 7-15. This image demonstrates the measurement of the anterior perineal body in this patient with an anterior sphincter disruption. The curvilinear hyperechoic structure (A) is the examiner's finger in the vagina. This technique can often accentuate the defect (B) seen in the internal anal sphincter and the external anal sphincter, and documents the decreased thickness of the anterior sphincter and perineal body.

Other causes of anatomic anal sphincter defects include anorectal trauma or surgery and congenital anomalies. Blunt or penetrating trauma to the perineum may involve the sphincter mechanism. Management often includes fecal diversion, and debridement of the associated perineal soft tissues. After the perineal wound has healed, EAUS may be used to assess anal sphincter anatomy to determine if sphincter reconstruction is necessary before colostomy closure.

Patients undergoing anorectal surgery may experience transient minor incontinence in the early postoperative period, which usually resolves spontaneously. Patients who have persistent symptoms of incontinence may warrant evaluation. EAUS provides an objective means to evaluate the anal sphincter mechanism in patients with postoperative fecal incontinence after anorectal surgery such as hemorrhoidectomy, fistulotomy, lateral internal sphincterotomy, or sphincteroplasty.

The surgical correction of congenital anorectal anomalies is based on reconstituting the anatomy of the anorectum. The goal of posterior sagittal anorectoplasty (PSARP) is to place the bowel within the striated muscle complex of the levator ani and external anal sphincter.<sup>60</sup> EAUS has been used to accurately confirm the position of the neo-anus within the anal sphincter complex comparing favorably with MRI.<sup>61</sup> EAUS in fact provided greater detail of the anal muscles than MRI and had better correlation with direct perineal muscle stimulation.<sup>61</sup> Adult patients who present with severe fecal incontinence after previous surgical repair of a congenital anorectal malformation can undergo successful PSARP.<sup>62</sup> Usually, the existing anus is anterior to the sphincteric muscle complex.<sup>62</sup> An EAUS can be performed to help define the relationship of the anus to the sphincteric mechanism.

The identification of localized sphincter defects is important in the evaluation of the incontinent patient, because these defects may be amenable to surgical repair. EAUS can clearly and objectively image the anal sphincter mechanism and has replaced needle electromyography as the procedure of choice for anal sphincter mapping. EAUS is better tolerated and less painful than needle electromyography sphincter mapping. Anorectal manometry and pudendal nerve terminal motor latency testing are complementary but do not definitively correlate with a surgically correctable defect.<sup>46,52,54,63,64</sup> EAUS remains the definitive test that can identify a surgically correctable defect in a symptomatic patient with fecal incontinence.

### Evaluation of Perianal Sepsis and Fistula-in-Ano

Typically, the diagnosis of a perianal or perirectal abscess is quite apparent on physical examination and only requires proper identification and prompt drainage. Occasionally, an abscess is strongly suspected on clinical grounds but is not readily identified on physical examination. In these situations, an EAUS may be useful in the evaluation of perianal or perirectal abscesses. EAUS can be helpful to localize an obscure abscess to plan the appropriate surgical intervention.

Often, clinical examination of perianal or perirectal abscesses is quite painful and examination under anesthesia is required. Because the ultrasound equipment is portable, the EAUS examination can be performed in the operating room while the patient is anesthetized. Abscesses appear as hypoechoic areas often surrounded by a hyperechoic border. In patients with perianal Crohn's disease, EAUS may be useful in distinguishing discrete abscesses that require surgical drainage from inflammation that requires medical treatment. The use of EAUS has also been evaluated in patients with ileoanal pouch anastomosis and can be helpful in demonstrating pouch pathology including inflammation, abscesses, and fistulas.<sup>65</sup>

The natural history of a drained perianal/rectal abscess is either complete resolution or fistula formation. The majority of fistulas that occur are simple intersphincteric fistulas that are easily identified and treated by simple unroofing. However, occasionally fistula tracts develop that are extensive and highly complex. These complex fistulas present a diagnostic challenge to even the most experienced colon and rectal surgeon. Use of EAUS can be helpful in identification of fistulous communications in patients with complex and recurrent fistula-in-ano.<sup>66-68</sup> Fistula tracts are generally hypoechoic defects that can be followed to identify direction and extent. The anatomic details of the fistula tract can be delineated in relation to the anal sphincter. The EAUS examination should include the anal canal and distal rectum to search for the presence of high blind tracts. Hydrogen peroxide has been used to enhance the imaging of complex fistula.<sup>69-72</sup> Hydrogen peroxide causes a release of oxygen, accentuating the fistula and appears as a brightly hyperechoic image on the ultrasound image. The technique increases the identification of the internal opening to greater than 90%.<sup>69,72</sup> An example of a fistula-in-ano with hydrogen peroxide enhancement is demonstrated in Figure 7-16. When evaluating an anal fistula with ERUS, it is important to use both the balloon-covered transducer to evaluate the perirectal region to assess for any supralevator extension as well as the plastic cap for evaluation of the anus and surrounding anatomy.

### Anal Canal Neoplasms

Endoanal ultrasonography images the normal anal canal and associated pathologies quite well. EAUS can have an important role in the evaluation of benign and malignant anal canal neoplasms. The normal anatomic structures are clearly defined and any changes in the normal anatomy and their relationships with specific anatomic structures are clearly defined. Benign neoplasms such as lipomas and leiomyomas can be demonstrated along with their relationship to adjacent anal canal structures. Lesions within the anal canal appear as hypoechoic areas. Tissue diagnosis may be obtained with ultrasound-directed needle biopsies when desired.

Anal canal malignancies are an uncommon cancer in the gastrointestinal tract. Diagnosis requires appropriate clinical

FIGURE 7-16. This image depicts a fistula-in-ano that has been enhanced by the introduction of hydrogen peroxide. The hyperechoic features posteriorly represent the hydrogen peroxide within the fistula tract (short arrows). There is an obvious hypoechoic defect in the internal anal sphincter in the midline posteriorly (A), representing the internal fistula opening. The hypoechoic horseshoe tract can be seen extending toward the patient's left.

evaluation and histologic confirmation by tissue biopsy. Anal canal malignancies evaluated by EAUS include leiomyosarcomas, malignant melanomas, anal canal adenocarcinomas, and squamous cell carcinomas. Squamous cell or epidermoid carcinoma of the anal canal are the most common anal canal malignancy. EAUS can be used in the initial evaluation to stage the lesion as well as in follow-up for patients with squamous cell carcinoma of the anal canal.<sup>73-76</sup> Because squamous cell carcinomas of the anus are primarily treated nonoperatively with combined chemoradiation therapy, it is desirable to have an accurate method of staging to assess response to multimodality therapy. EAUS accurately stages the initial tumor and can be used in follow-up to detect residual tumors as well as early recurrences after treatment. Surgical treatment in the form of abdominoperineal resection is reserved as salvage surgery for those patients who fail standard chemoradiation therapy.

Although clinical (digital) examination is important in the assessment of squamous cell carcinoma of the anus, EAUS is more precise in accurately measuring the actual size and circumferential involvement of the lesion. EAUS staging (uTNM) of anal cancers corresponds to the TNM [UICC (International Union Against Cancer)] staging (Table 7-3).<sup>4</sup> Tumor staging for anal cancer depends primarily on the maximal tumor diameter, which is accurately measured by EAUS. Additionally, the depth of invasion of the lesion can be measured in relationship to the sphincter mechanism. The extent of sphincter involvement can be determined and other staging systems stage these lesions based on depth of invasion.<sup>76,77</sup> One such staging system is depicted in Table 7-4.<sup>77</sup> The eval-

TABLE 7-3. Ultrasound staging classification (uTNM) for anal canal cancer

Primary tumor (T)	
Tx	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor 2 cm or less in greatest dimension
T2	Tumor more than 2 cm but no more than 5 cm in greatest dimension
T3	Tumor more than 5 cm in greatest dimension
T4	Tumor of any size that invades an adjacent organ(s), e.g., vagina, urethra, bladder (involvement of the sphincter muscle(s) alone is not classified as T4)
Regional lymph nodes (N)	
Nx	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in perirectal lymph node(s)
N2	Metastasis in unilateral internal iliac and/or inguinal lymph node(s)
N3	Metastasis in perirectal and inguinal lymph nodes and/or bilateral internal iliac and/or inguinal lymph nodes
Distant metastasis	
Mx	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

TABLE 7-4. Ultrasound staging classification by depth of invasion (uTNM) for anal canal cancer

uT1	Tumor confined to the submucosa
uT2a	Tumor invades only the internal anal sphincter
uT2b	Tumor penetrates into the external anal sphincter
uT3	Tumor invades through the sphincter complex and into the perianal tissues
uT4	Tumor invades adjacent structures

uation of squamous cell carcinomas of the anus should include an evaluation of the rectum with ERUS to determine the presence of metastatic lymph nodes within the mesorectum. The mesorectum as well as the anal canal can also be evaluated in follow-up after treatment. Any suspicious areas detected during follow-up may be biopsied if necessary.

### Three-dimensional Ultrasound

Three-dimensional ultrasound allows for multiplanar imaging of both the rectum and the anal canal. This new technology is currently being evaluated to compare its efficacy relative to conventional two-dimensional ultrasound as well as to other modalities such as MRI. Three-dimensional ultrasound can be used to assess anal fistulous tracts, to evaluate anal sphincter injury, as well as to stage both rectal and anal tumors. An example of a three-dimensional ERUS image (3D-ERUS) of a rectal cancer is shown in Figure 7-17.

Hunerbein et al.<sup>78</sup> compared standard two-dimensional ultrasound with 3D-ERUS and endorectal MRI and reported an accuracy for depth of wall invasion by rectal cancer of 84%, 88%, and 91%, respectively. Because of the small sample size, these differences were not statistically significant. However, they believed that the additional scan planes

FIGURE 7-17. This three-dimensional ultrasound image demonstrates an anteriorly based rectal cancer that extends full-thickness through the rectal wall (uT3). However, a clear hyperechoic plane can be seen between the prostate gland and the rectal tumor, as depicted by the arrows.

improved the understanding of three-dimensional imaging and facilitated interpretation of the findings. In another small study of 33 patients comparing conventional ERUS to 3D-ERUS, Kim et al.<sup>79</sup> reported no statistically significant differences in the two modalities in determining depth of invasion or lymph node status. However, it is of interest to note that the accuracy of 3D-ERUS was 90.9% for T2 lesions and 84.8% for T3 lesions compared with 84.8% and 75.8% for conventional ultrasound. The accuracy of 3D-ERUS for predicting lymph node status was 84.8% compared with 66.7% for conventional ERUS. They concluded that although there was no statistical advantage, three-dimensional imaging made the visualization of focal lesions and lymph nodes easier.

Three-dimensional EAUS has also been applied to benign anal disorders such as anal sphincter injury and anal fistula assessment. Several comparative studies have been reported evaluating its efficacy and comparing 3D-EAUS with MRI. West et al.<sup>80</sup> reported that 3D-EAUS and endoanal MRI were comparable for detecting external sphincter defects. Gold et al.<sup>81</sup> determined that 3D-EAUS revealed a direct relationship between the length of a sphincter tear and its radial extent. In addition, they demonstrated marked gender differences in anal sphincter configuration using three-dimensional ultrasound imaging. In the evaluation of anal fistula tracts, West et al.<sup>82</sup> reported equivalency between 3D-EAUS and endoanal MRI for the evaluation of anal fistula tracts. In a recent study

by Buchanan et al.,<sup>83</sup> 3D-EAUS was found to be very accurate in the assessment of both the internal opening and the primary tract of an anal fistula. They reported an accuracy of 90% in identifying the internal opening and an accuracy of 81% in delineating the primary tract. Three-dimensional EAUS was less accurate (68%) in identifying secondary tracts or extensions. In their study, the use of hydrogen peroxide did not increase the accuracy but in some instances it did make the tract and internal opening more conspicuous.

## Summary

Endoluminal ultrasound has been shown to be extremely useful in the evaluation and management of many benign and malignant anorectal conditions. ERUS has become the best imaging technique to accurately stage rectal cancers and anal canal tumors preoperatively. Moreover, ERUS can have a role in the follow-up evaluation of these patients. EAUS is the diagnostic test of choice in the evaluation of fecal incontinence and is used routinely. The EAUS has also been used to help define complex anal fistulas to facilitate their management. The accuracy of diagnosis is operator dependent and improves with experience. Endoluminal ultrasound has made a major contribution to the understanding and management of many anorectal conditions. Three-dimensional ultrasound may prove to be advantageous, but requires further study.

## Preoperative Management—Risk Assessment, Medical Evaluation, and Bowel Preparation

Conor P. Delaney and John M. MacKeigan

Preparation of the patient for surgery is a vital component of optimizing recovery after surgery, and must be individually tailored to the medical status of the patient.<sup>1</sup> Patients who undergo colorectal surgery may present in normal health, such as in a young patient undergoing hemorrhoid surgery, or may present in extreme ill health, such as the octogenarian with multiple medical conditions, who has developed perforated diverticulitis. Preoperative assessment and medical intervention are important components of care, and may account for the difference in perioperative mortality noted after abdominal and colorectal surgery between the United States and some European countries.<sup>2</sup>

Since the initial studies by Tyson and Spaulding in the 1950s, preparation of the bowel before surgery has been considered an essential component of care. More recently, this has become a contentious issue, and metaanalyses have suggested that bowel preparation provides no benefit, and may actually increase the incidence of some complications.

This chapter addresses the issues of medical evaluation and bowel preparation before surgery. These are considered on the background of reviewing some of the more important scoring systems for risk assessment before surgery, which permit comparison among different surgeons, institutions, and care pathways.

### Perioperative Risk Assessment Scoring Systems

The risk related to surgery is a function of many factors. Patient-related factors include the underlying disease processes and the patient's physical ability to tolerate the physiologic stress related to the surgical procedure. Increasing amounts of data now show that risk is also affected by the volume of a procedure performed at the medical institution, but perhaps most importantly by the experience, training, and volume of surgery performed by the individual surgeon.

Scoring systems assess the patients' risk for morbidity and mortality as a result of anesthesia and surgery. These systems generally use data acquired during pre-hospital and in-hospital care, and some supplement this with components measuring operative severity. Some classification systems are designed to allow comparison of results between institutions and surgeons, whereas others are designed to distinguish patients who subsequently will have postoperative adverse events from those who will not.<sup>3,4</sup> The influence of each of these factors on overall morbidity and mortality is currently unknown but an ideal risk scoring system would incorporate all of these factors allowing accurate evaluation of surgical risk to the patient.

Thus, a primary aim of a scoring system is the evaluation of therapeutic benefit, i.e., the ratio of the relative harm and the relative benefit that are likely to follow a specific operation for a specific illness, whether in a specific patient, institution, or health system. Parameters that are useful in this evaluation include the natural history of the disease process, and the urgency of a specific procedure. Age may have an influence on operative risk, as many elderly patients require concurrent management of multiple organ degenerative disease. Elderly patients often tolerate operations well but complications poorly, hence prediction of the potential morbidity of an operation is particularly important in this group of patients. Scoring systems also provide a useful means of comparing outcomes from different institutions and patient groups by correcting for different comorbidities. Various scoring systems have been developed in an effort to quantify the risk of a patient from disease or intervention, and systems can be classified as preoperative or physiologic (Table 8-1).

Some scores are useful in predicting outcomes in specific conditions, such as Ranson's for pancreatitis, Child for liver failure, and the Burns index, but they are not of use for the general assessment of patients with other disorders. Some studies have tried to predict risk in a less specific manner, and have suggested that a surgeon's gut feeling upon completion of a major procedure may be a good indicator of subsequent outcome.<sup>5</sup>

TABLE 8-1. Perioperative scoring systems (references in text)

Physiologic scores	Preoperative scores
APACHE (I and II)	ASA grading
E-PASS	Goldman cardiac risk index
ISS/TRISS	Hospital prognostic index
POSSUM	Prognostic nutritional index
P-POSSUM	Pulmonary complication risk
SAPS	
Sepsis score	
Sickness score	
Therapeutic intervention score	

## Risk Assessment for Complications from Specific Organ Systems

Some scoring systems define patient characteristics that are associated with increased morbidity and mortality because of involvement of a particular organ system. Scoring systems that have been described to predict the risk of death include those for respiratory,<sup>6</sup> gastrointestinal,<sup>7-10</sup> and cardiovascular disease.<sup>11,12</sup>

### Cardiac Risk

#### Goldman Cardiac Risk<sup>13</sup>

The Goldman risk model is probably the best-accepted model for pure determination of cardiac risk for surgery. Point scores are assigned to each of nine clinical factors and patients are divided into four risk classes based on the total point score (Table 8-2). This is an important score because it reminds clinicians of the major cardiac risk factors in noncardiac surgery. Although the system is easy to use and utilizes relative weighting of risk factors, it was designed in the 1970s, and has not been updated for modern practice in anesthesia, medicine, or surgery. Cardiac risk for patients undergoing noncardiac surgery has also been evaluated by other studies.<sup>11,12</sup>

TABLE 8-2. Goldman cardiac risk index

Cardiac risk event	Points
Myocardial infarction within 6 mo	10
Age >70 y	5
S3 gallop or jugular venous distension	11
Important aortic valve stenosis	3
Rhythm other than sinus, or sinus rhythm and atrial premature contractions on last preoperative electrocardiogram	7
More than five premature ventricular contractions per minute anytime before surgery	7
Poor general medical status	3
Intraperitoneal, intrathoracic, or aortic operation	3
Emergency operation	4

Class	Points	Life-threatening complication risk (%)	Cardiac death risk (%)
I	0–5	0.7	0.2
II	6–12	5	2
III	13–25	11	2

## Respiratory Risk

### Pulmonary Complication Risk

Findings on respiratory examination, chest X-ray, Goldman's cardiac risk index, and the Charlson comorbidity index have been used for predicting respiratory complications.<sup>6</sup>

## Risk Assessment for Postoperative Morbidity and Mortality

### American Society of Anesthesiologists Classification

The American Society of Anesthesiologists (ASA) classification system (Table 8-3)<sup>14</sup> was initially developed to alert anesthesiologists to preexisting diseases. Because of the ease of use, and the fact that no tests are required, it has also been used to estimate operative risk.<sup>15,16</sup> ASA class directly correlates with perioperative mortality and morbidity<sup>17-19</sup> and also correlates significantly with perioperative variables such as intraoperative blood loss, duration of postoperative ventilation, and duration of intensive care unit (ICU) stay.<sup>19</sup> The severity of operative procedure, higher ASA class, symptoms of respiratory disease, and malignancy predicted postoperative morbidity in one study.<sup>20</sup>

Disadvantages to using the ASA score are that the score awarded depends on the subjective clinical judgment of the attending anesthesiologist, and that the small numbers of groups available means there can be little meaningful comparison between different surgeons or institutions.

### Prognostic Nutritional Index

The prognostic nutritional index (PNI) was devised<sup>21</sup> to predict complication risk based on mortality, and correlates with postoperative sepsis and death. The PNI uses four factors, namely, serum albumin level, serum transferrin level, triceps skinfold thickness, and cutaneous delayed-type hypersensitivity. Serum albumin level, serum transferrin level, and delayed hypersensitivity were the only accurate predictors of postoperative morbidity and mortality. In addition to predicting postoperative morbidity and mortality, PNI can be used for predicting patients who might need nutritional support in the perioperative period. The authors concluded that perioperative nutritional support might reduce operative morbidity and mortality in malnourished patients, although this has not been routinely agreed with in the literature.

TABLE 8-3. ASA classification scheme

I	Normal healthy patient
II	Mild systemic disease
III	Severe, noncapacitating systemic disease
IV	Incapacitating systemic disease, threatening life
V	Moribund, not expected to survive 24 h
E	Emergency

### APACHE (Acute Physiology and Chronic Health Evaluation) Scoring Systems

APACHE was initially described in 1981<sup>22</sup> and subsequently replaced in 1985<sup>23</sup> by APACHE II. This score was initially designed primarily for patients in the ICU but has been used for the assessment of patients with severe trauma, abdominal sepsis, postoperative enterocutaneous fistulas, acute pancreatitis, and to predict postoperative outcome.<sup>24</sup> The main disadvantage is that it is not independent of the effects of treatment, thus scoring for emergency patients being admitted to the ICU is best performed before surgical intervention.<sup>25</sup> Other disadvantages are that it is relatively complex and does not take into consideration the nutritional status of the patient or cardiology findings that add to operative risk. APACHE scores also do not take into account the extent of surgery. The APACHE III has been proposed more recently, but it is also very complex for routine use.<sup>26</sup> Several simpler scoring systems have also been developed from the APACHE system. These include SAPS (simplified acute physiology score),<sup>27</sup> which uses 14 of the 34 variables, and SAPS II, which also takes into consideration the urgency of the procedure and any associated chronic medical illness.

### POSSUM

The POSSUM (Physiological and Operative Severity Score for enUmeration of Mortality and morbidity) was developed by multivariate discriminant analysis<sup>28</sup> of retrospective and prospective data, primarily to permit surgical audit for assessment of quality of care. It has been suggested that it works independent of geographical factors, and several publications have now come from the United States suggesting that it may also have a role in this health care system.<sup>2,29</sup>

POSSUM calculates expected death and expected morbidity rates based on 12 physiologic variables and six operative variables each of which are scored 1, 2, 4, or 8 (Table 8-4). The major advantage is that it predicts both morbidity and mortality and has successfully been used for a comparative audit of performance among surgical units, hospitals, and countries.<sup>2</sup> Disadvantages include that it does not take into account differences among surgeons, anesthetists, and operating time, all of which may influence outcome. This is because POSSUM was

TABLE 8-4. Parameters for calculation of the POSSUM score

Physiologic parameters	Operative parameters
Age (y)	Operative severity
Cardiac signs/chest X-ray	Multiple procedures
Respiratory signs/chest X-ray	Total blood loss (mL)
Pulse rate	Peritoneal soiling
Systolic blood pressure (mm Hg)	Presence of malignancy
Glasgow coma score	Mode of surgery
Hemoglobin (g/dL)	
White cell count ( $\times 10^{12}/l$ )	
Urea concentration (mmol/L)	
Na <sup>+</sup> and K <sup>+</sup> levels (mmol/L)	
Electrocardiogram	

developed as a scoring system for audit, so other factors may need to be considered when using POSSUM for risk assessment of patients for surgery. POSSUM also does not use primary diagnosis as a factor for scoring. Nevertheless, comparison of APACHE II with POSSUM showed that POSSUM is superior in predicting mortality in patients admitted to a high-dependency unit after general surgery.<sup>30</sup>

### Portsmouth Modification of POSSUM (P-POSSUM)

One concern with POSSUM has been that it may overpredict mortality and morbidity rates by up to six times with a minimum mortality of 1.1%. P-POSSUM was therefore developed using a different mathematical formula to counter these disadvantages,<sup>31</sup> with the minimum mortality score in P-POSSUM reduced to 0.2%. Whereas some studies found that both scoring systems overpredicted mortality rates for vascular surgery patients,<sup>32,33</sup> others found that P-POSSUM was a better predictor of mortality and morbidity than POSSUM for vascular,<sup>34</sup> gastrointestinal,<sup>35</sup> and laparoscopic colorectal surgery.<sup>36</sup>

### Other Scoring Systems

Various other scoring systems have also been developed primarily for assessment of critically ill patients in the ICU and for trauma and sepsis, and these are listed in Table 8-1.<sup>37-45</sup>

### Risk Assessment for Colorectal Disease

Preoperative pulmonary and nutritional problems have been significant contributing factors in patients who died from sepsis after colon resection in the elderly. Others have suggested that age, congestive heart failure, hepatic, renal or pulmonary impairment, and extent of involvement by malignancy and postoperative complications were associated with greater mortality after colon surgery. Subsequently, it has been reported that age influenced mortality but not 5-year survival.<sup>46</sup> Ondrula et al.<sup>47</sup> assessed the predictive value of a variety of preoperative risk factors on operative outcomes and defined a colon index that assessed patients' operative risk. More recently, POSSUM was found to allow a realistic comparison of performance of different units performing colorectal resection and also permit comparison of outcome after colorectal resection among different surgeons.<sup>48,49</sup> POSSUM has also been reported in patients undergoing laparoscopic colectomy<sup>29</sup> but even the P-POSSUM overpredicted mortality and morbidity. Further modifications may be required to provide a validated tool for comparisons between laparoscopic and open approaches to colorectal resection.

### Preoperative Medical Evaluation

Once a patient has a diagnosis requiring colorectal surgery, most surgeons intuitively categorize them into those needing minimal assessment, or extensive medical evaluation and

treatment before surgery. Young patients having minor surgery will require no assessment. Young patients having more significant surgery may require minor evaluation, whereas older patients having minor surgery may require a similar level of evaluation. Older patients, and those with more extensive comorbidities will require assessment and possible treatment before surgery. Few definite guidelines exist as to who requires any exact pattern of assessment, and the benefits of individual tests are described below.

At the Cleveland Clinic, a questionnaire called Health Quest is given to patients who complete this on-line. Based on their answers, a score of 1–5 is generated indicating a level of complexity of medical history that can help stratify patients for level of preoperative assessment.<sup>50</sup> This process is also associated with a reduction in preoperative surgical delay, and increased patient satisfaction.

Evaluation is performed with a combination of history, physical examination, and selected investigations. In a large prospective clinical-epidemiologic study, Arvidsson and colleagues<sup>3</sup> found that a standardized assessment before surgery, by a combination of questionnaires, interview, physical examination, and laboratory screening identified a high proportion of patients who were likely to have an adverse event in the postoperative period.

### Preanesthesia Interview

Of the techniques available that are used in preoperative evaluation of patients, namely, history, physical examination, and investigations, history taking is the most efficient and profitable.<sup>3,51</sup> A thorough review of previous medical records including history of anesthesia and surgery helps identify many potential problems that can occur perioperatively. Questionnaires have previously been found to be efficient and reliable for anesthesia preadmission assessment.<sup>52</sup> Thus, a preoperative questionnaire is suitable for patients undergoing daycare surgery, because most of these patients are at low risk.

History taking should include information on the condition for which the procedure is being performed, history of surgical procedures (local procedures that may complicate surgery such as reoperative pelvic surgery, as well as general procedures that may complicate recovery such as prior splenectomy), and prior outcomes with intubation and anesthesia. Special consideration should be given to cardiopulmonary function, allergy, renal and hepatic function, bleeding tendency, and medication use. History of chronic medical conditions of the cardiorespiratory system and medications including dosage is important. In children, history should be focused on other specific factors such as birth history and history of recent infections, especially pneumonia and upper respiratory tract infections. Aspirin and other nonsteroidal anti-inflammatory drugs are best discontinued 1 week before surgery. Other questions should pertain to immunization, smoking, and alcohol and drug use. Cessation of smoking 8 or more weeks before surgery helps optimize the mucociliary apparatus of the patient before surgery. Review of

functional status of the patient, activities of daily living (ADL), and social support are also important, although this primarily relates to longer term recovery, hospital stay, and likely discharge status from hospital, rather than direct perioperative morbidity and mortality.

History taking for cardiac assessment has been reasonably well standardized, and very well reviewed recently by Mukherjee and Eagle.<sup>53</sup> The primary factors to be considered are whether the patient has recent myocardial infarction, decompensated heart failure, unstable angina, symptomatic arrhythmias, or symptomatic valvular heart disease. In general, noninvasive testing is most effective in intermediate-risk patients, whereas invasive evaluation should be considered in those with multiple risk factors and ischemia on preoperative testing, because perioperative beta-blockade may be inadequate.

Formal anesthetic evaluation is also needed for many patients. Similar to the selective levels of medical work-up, not all patients will need to be seen by an anesthesiologist preoperatively. Young, healthy patients with normal anatomy, and no adverse findings in history or examination, may not need any evaluation. Patients having more major surgery should probably all meet the anesthesia service before surgery, for assessment as well as instruction about what will happen around the time of surgery. This may be expediently performed by nurse practitioners. Some patients with complex anesthetic histories or with major perioperative risk factors may require formal anesthetic assessment by a staff anesthesiologist. Usually, such guidelines are institution-specific, but it is recommended that the surgeon and anesthesiologist have a similar plan for assessment, so that unexpected surprises are avoided on the day of surgery.

### Physical Examination

A review of preoperative evaluation<sup>54</sup> noted that history and physical examination focusing on risk factors for cardiac, pulmonary, and infectious complications and determination of a patient's functional capacity are important for preoperative evaluation of patients. General indicators of fitness of a patient for surgery include activities of daily living competence (ADL) and general mobility. Specific evaluation for subtle signs of cardiopulmonary dysfunction is important, because these have been shown to correlate strongly with major perioperative complications.<sup>13</sup>

### Preoperative Tests

Preoperative tests serve to complement the history and physical examination in assessing the suitability of the patient for surgery. They have been used to assess levels of known disease, detect unsuspected but modifiable conditions that may be treated to reduce risk before surgery, or detect unsuspected conditions that may not be possible to treat, and therefore simply be baseline results before surgery.

Many patients undergoing minor surgery need minimal investigation, even if they have chronic medical conditions. Review of current evidence indicates that routine laboratory tests are rarely helpful except in the monitoring of known disease states. New guidelines have a significant impact on reducing preoperative testing and have not caused an increase in untoward perioperative events.<sup>55,56</sup> Historically, ordering routine preoperative investigations was quite often driven more by personal experience than by scientific evidence.<sup>57</sup> This led to inefficient clinical practice, with healthy patients undergoing useless, time-consuming, costly, and sometimes harmful procedures. A prospective study found that whereas 16% of results were abnormal, only 0.013% caused a change in management for 400 patients undergoing elective surgery.<sup>58</sup> Higher complication rates were significantly associated with the extent of surgery, but not with abnormal preoperative blood results. Other studies have also found that only a small percentage of abnormal preoperative investigations changed management.<sup>59</sup> This is especially true, as a repeat test is an adequate response to most abnormal biochemical results because an abnormal test does not necessarily correlate with pathology. Because reference intervals of most tests take the normal distribution and standard deviation of the population into consideration, cut-off points for normality are set such that patients whose test results exceed the upper 2.5% of healthy individuals or are below the lower 2.5% of healthy individuals are said to have abnormal results. Thus, 5% of patients whose values are outside the reference range do not necessarily have disease and may be normal. The greater the number of tests ordered, the greater the probability of finding a result outside the reference range.

Age, history of chronic heart disease, renal disease, emergency surgery, and type of operation are predictors of the risk of mortality.<sup>60</sup> Fit, young patients undergoing minor and intermediate procedures do not need routine preoperative investigations and in the pediatric age group, a thorough clinical examination has been found to be of greater value than routine laboratory screening. A good history and physical examination have been said to be more important rather than laboratory data in the development of a treatment plan for anesthesia.

Quality cost-effective preoperative preparation of patients undergoing anesthesia and surgical procedures is a central issue in perioperative patient management. Minimizing routine preoperative testing results in better utilization of resources and a greater cost-benefit ratio without adverse effect to the patient. Review of preoperative evaluation of patients found that 60% of the amount spent on preoperative laboratory testing was wasted.<sup>61</sup> False-positive and borderline tests led to further investigation causing reduced efficiency of practice, creating the potential for iatrogenic disease and increasing medicolegal risk. Thus, guidelines for preoperative testing based on best available evidence are important for efficient resource utilization and prevention of undue surgical risk to the patient. Although the general consensus is that screening must be replaced by indicated testing, the danger

identified is that some indicated tests may also be abandoned in the quest for reducing routine investigations.<sup>62</sup> Review of previous tests helps avoid duplication of tests and also helps identify potential problems.

## Assessment of Specific Organ Systems

### *Cardiac Evaluation*

The detection of a rhythm other than sinus and the presence of premature atrial contractions and frequent premature ventricular contractions increase the risk of perioperative cardiac events.<sup>13</sup> Yield of electrocardiogram in unselected patients is highly correlated to age but most dysrhythmia can be suspected from physical examination.<sup>63</sup> The American College of Cardiology (ACC) and American Heart Association (AHA) recommendations for preoperative cardiac evaluation consider the magnitude of the particular procedure being performed and patient factors that influence perioperative cardiac risk. History of coronary artery disease, cardiovascular procedures, and symptoms of angina or congestive heart failure are important. Patients without symptoms and with a normal cardiac stress test within 2 years or coronary artery bypass graft in the last 5 years, those who are clinically stable and underwent angioplasty 6 months to 5 years previously do not need any further assessment. Patients who had an angioplasty within 6 months and those having emergency surgery may need cardiac evaluation and angiography. Patients with intermediate risk and poor functional capacity may need stress testing. Assessment of left ventricular function by radionuclide scan or echocardiography is also indicated for patients in whom an impaired left ventricular function is suspected on clinical examination or radiology although the best test remains unclear.<sup>64</sup> Further cardiac evaluation is only needed in patients with definite clinical predictors identified from history, physical examination, electrocardiogram, and functional status along with the risk associated with the operation itself. Cardiac interventions are generally only recommended for patients who would otherwise have benefited regardless of any unplanned noncardiac surgery. These recommendations have been reviewed and summarized by the ACC ([www.acc.org/clinical/guidelines/perio/update/fig1.htm](http://www.acc.org/clinical/guidelines/perio/update/fig1.htm)) and others.<sup>53,65</sup>

### *Transfusion and Hematologic Evaluation*

Most patients with anemia tolerate operations well unless they have associated disease, and therefore anemia rarely changes management unless operative blood losses are expected to be great. Risk of thromboembolism and bleeding disorders can be assessed by a detailed history and by tests that measure coagulation factors (prothrombin and partial thromboplastin time) and that assess platelet count and function (bleeding time). Measures to reduce the risk of thromboembolism have been well documented and are part of the practice parameters available from the American Society of Colon and Rectal Surgeons<sup>66,67</sup> (see Appendix A).

Blood grouping and cross-matching is obviously critical when planning major surgery in which significant blood losses may occur. An important consideration is to have a routine sample for blood type on file for patients undergoing major surgery, even if transfusion is not expected, and cross-matching would not usually take place. This allows a double level of security when urgent samples are sent if bleeding occurs during surgery. This may help avoid the risk of transfusion reaction if there is concern about errors with sample labeling or source at any time.

Anemic patients who are scheduled for elective surgery may be treated preoperatively by allogenic transfusion but consideration is also given to autologous donation, erythropoietin, intraoperative hemodilution with autotransfusion, or consideration of cell salvage techniques, which are still being evaluated in colorectal surgery. Preoperative autologous donation (PAD) has been criticized recently because of cost-ineffectiveness, large wastage of PAD units, and the potential for leaving patients more anemic after surgery than without PAD.<sup>68</sup> Techniques including acute normovolemic hemodilution and cell salvage may be more efficient; however, investigations into their use continue.<sup>69</sup>

### *Renal Function Evaluation*

When indicated, measurement of serum electrolytes in the preoperative period helps in preventing perioperative problems. This is particularly true for serum potassium, because both hypokalemia and hyperkalemia may lead to cardiac conduction disturbances. Normal renal function is necessary for the excretion of the nondepolarizing muscle relaxants used for anesthesia and surgery. Renal function is also a consideration when choosing postoperative analgesic regimens including nonsteroidal medications such as Ketoralac. Age, hypertension, and diabetes may be indications for preoperative selective renal function testing.

### *Respiratory Tract Evaluation*

Patients with a history of chronic lung disease require careful assessment to minimize problems with anesthesia. In addition, patients with grossly normal lungs may rarely develop respiratory abnormalities secondary to anesthetic agents and operation. Common pulmonary complications after surgery are atelectasis, pneumonia, and bronchitis and predisposing risk factors include cough, dyspnea, smoking, history of lung disease, obesity, and abdominal or thoracic surgery. Cessation of smoking 8 weeks before surgery is beneficial to the patient by allowing recovery of the mucociliary apparatus. Bronchodilators are helpful in patients with asthma and bronchitis. Active pulmonary infection should be treated before surgery when possible. A Global Initiative for Chronic Obstructive Lung Disease (COLD) now recommends optimal treatment for COLD patients, and these treatments may need to be optimized before surgery.

The incidence of abnormalities detected on a routine preoperative chest film is higher in elderly patients but most occur in patients with recognizable risk factors. Preoperative chest X-rays may be of value in ruling out metastases but do not otherwise have a major influence on the decision to operate or on the type of anesthesia, and abandonment of routine ordering of preoperative chest X-rays does not produce adverse patient effects.<sup>70</sup> The Royal College of Radiologists recommended preoperative chest X-rays only for patients with acute respiratory symptoms, possible metastases, those with suspected or established cardiorespiratory disease without a chest X-ray in the preceding 12 months, and recent migrants from endemic countries. Other studies also suggest using specific indications for preoperative testing rather than routine X-rays, culminating in a metaanalysis by Archer and colleagues.<sup>71</sup>

There are no well-established guidelines as to who requires pulmonary function testing. Such candidates may include patients with chronic pulmonary disease, wheezing or dyspnea on exertion, chest wall and spinal deformities, morbid obesity, heavy smokers with persistent cough, thoracic surgery, elderly patients (>70 years of age), and patients who are to undergo upper abdominal surgery. The American College of Chest Physicians criteria recommend preoperative spirometry only in patients undergoing lung resection, those who undergo cardiac and upper abdominal surgery in the presence of a history of smoking and dyspnea, and patients with pulmonary symptoms and uncharacterized disease scheduled for prolonged lower abdominal surgery.

### *Neurologic System*

The prevalence of occult cerebrovascular disease in elderly patients, who constitute a large proportion of patients requiring surgical attention, is a special concern. An asymptomatic carotid bruit indicates the presence of peripheral vascular disease and is an indication for further evaluation by duplex scanning. However, prophylactic endarterectomy is not indicated usually, because the increased risk of a perioperative stroke compared with the unselected population is small.<sup>72</sup> Symptomatic disease that is untreated or undiagnosed before preoperative assessment should be assessed and treated before all but emergency surgery. Patients at high risk may be kept on aspirin products during the time of surgery to minimize their risk of stroke. Some may require endarterectomy before their scheduled surgery, although this is quite rare.

### *Metabolic and Endocrine System*

Assessment for diabetes, thyroid disorders, and other endocrine problems is an integral part of preoperative evaluation. Obesity is now so prevalent that fasting blood glucose in obese patients may pick cases of unexpected diabetes.<sup>73</sup> Pregnancy may dictate reassessment of the indication for surgery, type of procedure being performed, and issues related to anesthesia. Patients on steroids may need extra dosage in the

perioperative period. Patients with known diabetes will need careful management of their blood sugar in the per-operative period, with standard recommendations for insulin and oral hypoglycemic use.

### *Nutritional Assessment and Hepatic Function*

Nutritional measurements help in assessing the physiologic status and optimizing function of the patient with regard to immunology, fluid balance, and metabolic response to trauma and surgery. Patients at particular concern for malnutrition are those who have lost more than 10% of their body weight in the previous 6 months, and those with an albumin less than 3 g/dL. Malnourished patients have increased complications after surgery, although nutrition must be supplemented for at least 2 weeks before clinical outcome parameters are improved.<sup>74</sup>

Abnormal liver function may affect hemostatic mechanisms and drug metabolism, but is an unusual clinical problem. Significant liver impairment is detectable on certain standard clinical and laboratory examinations, but is not routinely evaluated biochemically. Hepatitis may pose increased risk to the medical personnel taking care of the patient.

### *Preoperative Assessment Specific for Colorectal Procedures*

For patients undergoing surgery for colorectal disorders, a previous major laparotomy may preclude laparoscopic surgery or indicate an increased risk of conversion to open surgery. Body habitus of the patient, mental status, visual acuity, and the presence of other disorders such as arthritis may determine the decision on whether a stoma is formed and its placement. Assessment of patients' attitudes toward surgery, addressing their concerns, and counseling them regarding what to expect during hospitalization forms an integral part of the preoperative evaluation.

### *Current Recommendations<sup>1,54</sup>*

Tests that need to be performed include hemoglobin for evidence of anemia and as a baseline level for postoperative management. Renal and liver function tests are not routinely indicated but rather in patients with medical conditions or taking medication that would indicate these tests. Preoperative blood glucose determination is obtained in patients 45 years of age or older because current recommendations suggest that all patients older than 45 years ought to be screened; diabetes mellitus also increases perioperative risks. A urine pregnancy test ought to be considered for all women of childbearing age. Coagulation tests are only indicated in patients on anticoagulation, with a family or personal history of bleeding disorder, or those with liver disease. Patients undergoing major surgery with a potential for blood loss should have a type and screen taken for filing in the laboratory, even if transfusion is not expected. This may help minimize the risk of later transfusion reaction.

Electrocardiogram is indicated in male patients older than 40 years of age, females older than 50 years, and those with a history suggestive of cardiac disorders. Chest X-rays are performed on the basis of findings from the medical history or physical examination. As part of preoperative risk assessment, patients found to have medical conditions requiring further specific therapy before surgery should also be considered for more intensive medical supervision. This is important while in the hospital for their surgery, and also as part of their post-discharge follow-up.

## Bowel Preparation

The practice of mechanical bowel preparation (MBP) before surgery has undergone major changes over the last century. Mechanical preparation became routine for all surgeons by the start of the 1990s,<sup>75</sup> and this was used in combination with oral or intravenous antibiotic prophylaxis. This practice was thought to offer less risk of anastomotic leak, and to reduce the risk of wound infection, both postulated to be related to the bacterial load of stool. There are approximately  $10^9$  to  $10^{11}$  anaerobic bacteria and  $10^5$  to  $10^7$  aerobic bacteria in the colon, per gram of stool. The normal colonic flora comprises approximately 20 species of aerobic bacteria and more than 50 species of anaerobic bacteria. *Bacteroides fragilis* is the most frequently cultured species, followed by clostridia and peptostreptococci, in postoperative infections in colon and rectal surgery.

### Method of Bowel Preparation

The techniques used to mechanically prepare the bowel have changed hugely over the last 25 years. When Goligher reported outcomes in the 1970s, patients were restricted to a liquid diet for 3–5 days, before being given cathartic agents and enemas.<sup>76</sup> Some authors recommended 10 L of crystalloid solution by nasogastric tube while the patient remained on the commode.<sup>77</sup> Others recommended diet restriction for up to 10–14 days. These dietary restrictions were combined with oral aperients such as castor oil, and the use of enemas before surgery. Such protocols were associated with problems of fluid overload, hyponatremia, and nausea and vomiting.

The description of polyethylene glycol (PEG) preparations, which were minimally absorbed and could irrigate the bowel effectively, changed MBP practice. Preparation time was shortened to 1 day by drinking 4 L of a balanced electrolyte solution which would not be absorbed or metabolized.<sup>78</sup> Studies quickly showed that PEG provided better bowel preparation and was more easily tolerated by patients than the traditional 5-day regimes.

Sodium phosphate was then developed and used to clean bowel for colonoscopy. Similarly with this product, patient acceptance was high, because volumes to drink were smaller. Transient phosphatemia was noted but was rarely a significant

event.<sup>79</sup> The new solution was quickly used for elective colonic surgery.<sup>80</sup> The preparations were also given at home, so that patients could come to the hospital the morning of surgery. Although this practice adequately cleans bowel, it does mean that patients tend to need more fluid resuscitation in the perioperative period.<sup>81</sup> The lower-volume sodium phosphate preparations are now used routinely by many surgeons, but should be avoided in those with significant history of cardiac or renal dysfunction.

The most recent development is the description of a sodium phosphate pill. This may now be taken as a series of 28–32 pills on two occasions to give an effective preparation, although some concerns remain about hydration and electrolyte issues.<sup>82</sup> This has been reported to give equivalent results at bowel cleansing for colonoscopy<sup>83</sup>; however, many clinicians do not use this form of preparation because of concerns about electrolyte imbalance.<sup>84</sup> Indeed, any sodium phosphate preparation may cause hypocalcemia, hyperphosphatemia, and hypokalemia, leading to increased caution for their use in the elderly and those with renal dysfunction.

### Whether to Use an MBP

Over the last decade, several studies have suggested that a mechanical preparation may not be necessary, and these data will be reviewed here. Initial studies included several case series that suggested low anastomotic leak rates could be obtained without bowel preparation.<sup>85,86</sup> These results were reminiscent of the trauma literature suggesting that equally good or better outcomes could be achieved performing repair in unprepared bowel.<sup>87</sup>

These studies have been accompanied by a series of randomized, controlled trials evaluating the presence or absence of MBP, culminating in the recent publication of a Cochrane review on the subject (Table 8-5).<sup>88–94</sup> Of the five randomized trials over the last decade, two showed higher anastomotic leak rates with bowel preparation. The remaining trials showed no difference. Interestingly, some authors suggested that anastomotic leak may be worse in those who received a bowel preparation who had a poor result, leaving the colon loaded with liquid stool. No study showed a worse outcome in control patients (no preparation).

A Cochrane review was performed to analyze all randomized, controlled data and specifically to determine the effect of MBP on morbidity and mortality rates after elective colorectal surgery.<sup>93</sup> Of patients with anastomoses, there were 576 MBP patients and 583 without MBP. There was no difference in anastomotic leak rates for low anterior resection (12.5% versus 12%), or colonic surgery (1.2% versus 6%) in patients with or without MBP. Overall anastomotic leak rates were significantly lower without MBP (5.5% versus 2.9%;  $P = .02$ ). Mortality, peritonitis, reoperation, wound infection, and extraabdominal complications were similar between groups. The results failed to support the hypothesis that MBP reduces complication rates, but because there was no a priori hypothesis that MBP might increase complication rates, this could not be stated.

These data certainly show the safety of performing anastomosis in unprepared bowel in patients undergoing gynecologic or other surgery who have not had MBP and are found to have other pathology. Furthermore, this metaanalysis provides important evidence questioning the routine use of MBP in elective colorectal surgery. Whereas avoidance of bowel preparation may not be possible for laparoscopic approaches for technical reasons, it should be considered for open surgery, perhaps especially when using PEG preparations.<sup>94</sup>

### Bowel Preparation in Special Situations

Obviously, patients with acute intestinal or colonic obstruction cannot be given a high-volume or cathartic bowel preparation. Certain other patients are not suitable for bowel preparation. Perhaps the most important example are those with obstructive symptoms, or a chronic partial obstruction. Most surgeons would avoid a bowel preparation in this circumstance, and if necessary perform an on-table lavage before anastomosis. This practice is further supported by the data suggesting that bowel preparation may be unnecessary.

Some surgeons will reserve use of milder preparative agents for patients with chronic partial obstruction, such as that seen in cases of longstanding Crohn's disease. Options here would include prescribing small volumes of magnesium citrate, or managing the patient with older regimens, such as dietary restriction for a longer period of time than overnight.

TABLE 8-5. Randomized, controlled trials and Cochrane report relating to preoperative mechanical bowel preparation (all results as MBP versus no MBP, %)

Author	Year	n	Anastomotic leak	Wound infection	Mortality

## Prophylactic Antibiotic Usage (See Appendix B)

Removing the bulk of the stool in a patient was believed to reduce the risk of complications; however, this remained unproven. Antibiotics were additionally used to further reduce the risk of wound infection and possibly other complications. In the initial phases, oral antibiotics were used and given over the days preceding surgery. More recently, there has been a major shift toward using parenteral antibiotics to do this job.

Neomycin and erythromycin were initially chosen as suitable oral antibiotics for prophylaxis of wound infection in colorectal cases. Such oral antibiotics are given at three time points the day before surgery (1 PM, 2 PM, and 11 PM the day before surgery for an 8 AM start time), in an effort to sterilize the bacteria within the bowel lumen. Antibiotics were shown to reduce bacterial counts by 1000-fold.<sup>95</sup> These agents were inexpensive, largely remained in the bowel lumen, and were therefore thought to be suitable for this technique. Erythromycin has now been replaced by metronidazole because of its improved activity against anaerobes, and less gastrointestinal side effects. Although these agents can be effective,<sup>96</sup> the results can be equaled or bettered by using parenteral medications.<sup>97</sup>

Over the last 20 years, many studies were performed to evaluate parenteral antibiotics for all forms of general surgery, and also for colorectal indications. Because of differences in trial design, antibiotics used, and definitions of wound infection and other outcome parameters, many of these studies are hard to compare with each other. Over this time, there was an evolution from using antibiotics for 5 days, down to the current situation in which they are generally given to cover the time of surgery itself, or used for 24 hours maximum, unless a therapeutic course is indicated for clinical reasons. This effort to minimize the number of doses of antibiotics that is given has been supported by microbiologists and infectious disease specialists, in the hope of reducing cases of nosocomial infection seen in association with prolonged antibiotic usage, particularly that with *Clostridium difficile*, which is being seen in epidemic proportions in some geographical areas and institutions. Furthermore, in the 17 trials comparing single-dose to multiple-dose (two or more doses) regimens, using the same antibiotic or combinations of antibiotics, no trial found a difference in wound infection rates, and a pooled analysis also showed no statistically significant difference.<sup>96</sup> This single-dose policy also reduces risk of toxicity, costs, and possibility of developing resistance to the antibiotic used.<sup>98</sup>

Further knowledge has also provided awareness that the essential time to have coverage (adequate systemic levels) with antibiotics is from the time of incision to the time of skin closure. Thus, prophylactic antibiotics are ideally given at the time of anesthetic induction, although the randomized, controlled trials permitted up to 1 hour after this time, and if necessary are

repeated after 4–6 hours to keep adequate circulating levels, particularly if there has been significant blood loss.

Antibiotics need to cover Gram positive, negative, and anaerobic bacteria, and regimes such as ampicillin, gentamicin, and metronidazole used to be typical. Current choices usually include a second-generation cephalosporin with metronidazole, or an agent such as amoxicillin/clavulanic acid which avoids the need for metronidazole. In patients with penicillin allergy, ciprofloxacin may be used instead of the cephalosporin, or another alternative would be gentamicin, clindamycin, and metronidazole, although we prefer to avoid clindamycin because of concerns with nosocomial infection. These issues have been excellently reviewed elsewhere in a systematic review, documenting outcomes for each major antibiotic combination.<sup>96</sup>

A final issue relates to the combination of oral and parenteral agents. Some surgeons like this practice, thinking that this may further reduce infectious complications. One recent study has combined a randomized trial comparing oral neomycin and metronidazole with placebo in colonic surgery patients receiving parenteral amikacin and metronidazole. The combination of oral and intravenous antibiotics reduced wound infection rates, and this was supported by a meta-analysis of prior literature.<sup>99</sup>

## Prophylaxis for Endocarditis and Prosthesis

Patients undergoing invasive colorectal procedures are at varying risk for endocarditis and infection of prosthesis. The American Society of Colon and Rectal surgeons has published Practice Parameters (Appendix B) to guide surgeons on selecting appropriate measures for at risk patients. For Additional discussion, see Chapter 9.

## Communication with the Patient and Laying the Groundwork for Postoperative Recovery

No preoperative visit is complete without providing information on expected postoperative outcomes. This discussion helps the patient to build confidence and trust in the surgeon. Such discussion is likely to be an important component of any postoperative care pathway, and this may help lead to significant reduction in postoperative stay.<sup>100–102</sup>

Patients can be advised of the surgery they will undergo, their expected milestones in recovery, and possible complications, including issues such as readmission, which may occur in 10% or more of these patients undergoing major abdominal surgery.<sup>103</sup>

## Conclusion

Assessment of the patient undergoing surgery is of extreme importance in providing patients with a safe recovery from their operation. This permits stratification of patients into groups that require intensive, moderate, or minimal investigation or treatment before anesthesia. Tests to investigate patients should be used selectively based on increasingly accepted guidelines. Patients who need such evaluation and treatment before surgery should also be seen by the relevant medical specialty when in the hospital, and receive any necessary instructions for appropriate medical follow-up after their surgery.

MBP continues to be used by the majority of colorectal surgeons, based on traditional practice patterns. Several randomized, controlled trials now suggest that this practice may be unnecessary. Patients undergoing bowel resection should be given antibiotic prophylaxis using one dose of parenteral broad-spectrum agents at the time of induction of anesthesia.

## Appendix A: Practice Parameters for the Prevention of Venous Thromboembolism

### Risk Classification

#### Low-risk Patients

The typical low-risk patient is one undergoing minor surgery who has one or no risk factors. No specific measures are recommended for patients at low risk other than early ambulation. Unprotected, these patients have a 2% chance of calf vein thrombosis and a negligible risk of pulmonary embolus.

#### Moderate-risk Patients

The typical moderate-risk patient is older than 40 years of age, undergoing major abdominal surgery, with no other major risk factors. Moderate-risk patients can be treated with either intermittent pneumatic compression (IPC) alone or low-dose unfractionated heparin (LDUH). Moderate-risk patients have two risk factors. Unprotected, these patients have a 10%–20% risk of calf vein thrombosis, and a 1%–2% chance of a pulmonary embolism.

#### High-risk Patients

High-risk patients have three or four risk factors. The typical high-risk patient is older than 40 years of age, is having major abdominal surgery, and harbors additional risk factors. High-risk patients can be treated with LDUH (bid or tid) or low-molecular-weight heparin (LMWH), although standard unfractionated heparin seems to be more cost effective. If heparin cannot or should not be used, IPC should be substituted. When heparin has not been started preoperatively, the patient should be reevaluated for postoperative heparin. Unprotected, these patients have a 20%–40% risk of calf vein thrombosis and a 2%–4% risk of pulmonary embolism.

#### Very High-risk Patients

A high-risk patient is upgraded to a highest-risk category when certain additional risk factors are present. These include a history of thromboembolic events, hypercoagulable states, and possibly malignancy. Assuming no contraindication, highest-risk patients ideally should receive pharmacologic treatment such as LDUH (bid or tid) or LMWH. Untreated,

TABLE 8-A.1. Recommendations for VTE prophylaxis by risk classification

	Thromboprophylaxis by risk classification*			
	Low	Moderate	High	Highest
Example	Ambulatory surgery, no risk factors	Major abdominal sx, age > 40 y, no other risk factors	Major abdominal sx, age > 60 y, additional risk factors	Major abdominal sx, prior VTE, malignancy, or hypercoagulable state
Calf vein thrombosis (without prophylaxis)	2	10–20	20–40	40–80
Clinical PE	0.2	1–2	2–4	4–10
Primary prophylaxis	None	IPC	LDUH (q 8–12 h) or LMWH	LDUH (q 8–12 h) or LMWH
Alternate prophylaxis	None	LDUH (q 12 h) or LMWH	IPC†	Heparin and IPC‡

Figures are percentages.

sx, symptoms; VTE, venous thromboembolism; PE, pulmonary embolism; q 8–12 h, every 8–12 hours.

\*Modified with permission from Clagett GP, Anderson FA Jr, Geerts W, et al. Prevention of venous thromboembolism. *Chest* 1998;114:531S–560S.

†Intermittent pneumatic compression boots offer prophylaxis where the risk of bleeding is high. Heparin may be started postoperatively after the risk of bleeding has passed.

‡Some data suggest that IPC combined with heparin may offer increased protection. Where the risk of bleeding is high, IPC may be used intraoperatively and heparin may be added postoperatively after the risk of bleeding has passed.

these patients have a 40%–80% risk of calf vein thrombosis and a 4%–10% risk of pulmonary embolism.

Intuitively, there may be some advantage to a strategy of dual methods, i.e., combining intermittent pneumatic compression with heparin. Several investigators have suggested this. This has been shown to be efficacious for patients undergoing cardiac and hip replacement surgery, but thus far there are no published data for colon and rectal surgery patients.

## Appendix B: Practice Parameters for Antibiotic Prophylaxis to Prevent Infective Endocarditis or Infective Prosthesis During Colon and Rectal Endoscopy

These parameters are based in part on the recently updated recommendations made by the AHA and the previously published parameters developed by The American Society of Colon and Rectal Surgeons. According to the AHA, the risk for endocarditis is determined by the patient's preexisting cardiac condition and the surgical procedure in question. The major changes in the new AHA guidelines are the following: 1) it was emphasized that invasive procedures are not the cause of most cases of endocarditis; 2) cardiac conditions are stratified by the potential outcome if endocarditis develops; 3) procedures causing bacteremia are more clearly specified; 4) an algorithm for antibiotic prophylaxis for patients with mitral valve prolapse was developed; 5) prophylactic regimens for oral or dental procedures were modified; and 6) prophylactic regimens for genitourinary and gastrointestinal procedures were simplified. The AHA considers lower gastrointestinal endoscopy to be a low-risk procedure for initiating problematic bacteremia, and The Standards Task Force concurs. The Task Force considered other direct and indirect support for the use of antibiotic prophylaxis in patients with cardiac or other prostheses. It is the consensus of The Standards Task Force that prophylaxis be considered only for the high-risk groups listed in Table 8-B.1. The complex nature of individualized patient care does not allow standards to be spelled out for every clinical category.

TABLE 8-B.1. Conditions associated with endocarditis (high risk)

Prosthetic cardiac valves
History of endocarditis
Surgically constructed systemic pulmonary shunts
Complex cyanotic congenital heart disease
Vascular grafts (first 6 months after implantation)

## Postoperative Management: Pain and Anesthetic, Fluids and Diet

Tracey D. Arnell and Robert W. Beart, Jr.

Many of the major advancements and changes in the care and survival of the surgical patient have occurred in the postoperative period. This is frequently recognized in regard to critical care, but has been just as remarkable in the non-intensive care unit patient. Significant changes in reimbursement and patient population patterns have either driven, or allowed for, better survival, less morbidity, earlier discharge, and more ambulatory procedures. The major changes have been in the areas of postoperative feeding, activity, pain control, and ulcer and deep venous thrombosis (DVT) prophylaxis. In an attempt to incorporate this knowledge and in conjunction with physician extenders such as nurse practitioners and physician assistants, patient care pathways are being increasingly instituted and validated. The focus of this chapter will be on the non-intensive care unit inpatient.

### Pain Control

The trends toward decreased length of hospital stay and more ambulatory procedures necessitate a good understanding of the mechanisms of pain and its relief. It has been clearly demonstrated that adequate pain control is necessary to maximize cardiac and respiratory function and decrease the risk of complications.<sup>1-3</sup> On a more practical note, the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) now requires specific assessment and documentation of treatment of pain. Despite this, the management of acute pain is still less than ideal. In a survey of 250 patients who had undergone surgery (38% outpatient), 82% of respondents reported experiencing pain. Of these, 39% described severe to extreme pain and 47% moderate pain. One might think this is a result of the trend toward ambulatory procedures, but it was more common in the inpatient setting.<sup>4</sup> Although of course not all inclusive, what follows is a review of the components of pain and options for treatment.

### Physiology

The subjective sensation of pain is made up of many components, both physical and psychological. One definition is that

acute pain is “the initiation phase of an extensive, persistent nociceptive and behavioral cascade triggered by tissue injury.” The cascade begins with tissue injury that causes nociceptive neurons to begin firing and the local release of inflammatory mediators in the periphery. Once nociceptors become sensitized, the threshold necessary for further activation is lowered and their discharge rate increases. Put simply, less painful stimuli ultimately result in more pain perception. This effect is amplified by the environment of inflammation and its mediators. The nociceptive signals are carried by A delta and C fibers to the spinal cord dorsal horn and the ascending pathways to the central nervous system. Integration of signals occurs at all levels in this pathway. Different analgesic choices will target different parts of this cascade. As a result, analgesic types can be combined to more effectively manage multiple components of pain.<sup>5</sup>

### Techniques

In the inpatient setting of abdominopelvic surgery, the major modalities of postoperative pain control are patient-controlled anesthesia (PCA), opioids, nonsteroidal antiinflammatory drugs (NSAIDs), and epidural anesthesia. Preemptive analgesia is another tactic and includes preincisional infiltration of local anesthetics and administration of NSAIDs and intraoperative epidural anesthesia. Along less traditional lines, massage, acupuncture, and biofeedback therapy are being used in some institutions.

### Opioids

Opioids are the most frequently used medication in perioperative pain management. Their mechanism is via specific opioid receptors as well as nonspecific antiinflammatory actions. They block transmission of nociceptive afferent signals in the spinal dorsal horn and involve efferent messaging by activating inhibitory pathways supraspinally. Additionally, they act locally in the areas of tissue injury to inhibit inflammation.<sup>5</sup>

Opioid side effects include respiratory depression, pruritus, nausea, vomiting, and constipation. Titration of morphine to pain is extremely important in avoiding respiratory depression because the respiratory center receives nociceptive input that counterbalances the depression. When pain is reduced by other means such as adjunct medications and nerve blocks, the amount of morphine must be reduced. Partial agonists have been developed (buprenorphine, tramadol) that may reduce these complications, but presently they are infrequently used and clinical experience is lacking.<sup>6,7</sup>

The most frequently used opioid is morphine, and it is against which all other choices are compared. The second most frequently used opioid is meperidine and it will be discussed specifically. Initially, it was developed as an anticholinergic agent but was found to have analgesic effects. The anticholinergic effect and the potential for less smooth muscle spasm in areas such as the colon, biliary tract, and renal system is one reason it continues to be used in acute pain management. In fact, when used in equianalgesic doses with morphine, meperidine has the same spasmodic effect on smooth muscle.<sup>8</sup> The analgesic effects of meperidine are inferior to those of morphine, and its duration of effectiveness is significantly less than 4 hours. Compounding this ineffectiveness is the use of the intramuscular (IM) route. The absorption is highly variable with variable blood levels resulting in poor pain control. In one series, only 30% of postoperative patients achieved 50% pain relief after injection of 100 mg of meperidine.<sup>9,10</sup> Meperidine causes central nervous system excitation, seizures, increased respiratory depression, has a propensity for addiction, and produces metabolites with little analgesic but significant neurotoxic potential.<sup>8</sup> All of these factors have led the JCAHO to discourage the use of meperidine in its pain guidelines. At best, meperidine, given its short duration of action and significant risk of serious side effects with repeated use, should have an extremely limited role in pain management of postoperative patients.

The route of administration of opioids is more important than the specific opioid used in terms of onset of action. For the intravenous (IV) route and the oral route, there is little difference among various opioids. The IV route is effective within minutes, whereas the oral route varies between 1 hour for standard release and 2–4 hours for sustained relief. The greatest variability occurs with IM administration based on the lipophilic nature of the drug. The more lipophilic, the quicker the onset of pain relief.<sup>11</sup>

For IV delivery, PCA has been used successfully for more than 30 years and is one of the recommended modes of pain control by the American Society of Anesthesiologists in their practice guidelines. Improved pain control, patients' satisfaction, and decreased pulmonary complications have been found in two large reviews comparing PCA with conventional opioid analgesia in postoperative patients.<sup>12,13</sup> Although more expensive, PCA opioid use is a safe and effective mode of delivery. Making the transition from IV pain control to oral pain control should be made with knowledge of the pain requirements based on the most current IV dosages. Table 9-1 lists equianalgesic doses of the IV and oral forms of several frequently used medications.

## Nonopioid

### *Nonsteroidal Antiinflammatory Drugs*

As previously described, the mechanism of pain production and perception is altered by the inflammatory cascade. By decreasing the production of mediators such as prostanoids, the perception of painful stimuli may also decrease. Nonsteroidal medications inhibit cyclooxygenase (COX) in the periphery and spinal cord and this may be the mechanism by which they are effective in diminishing hyperalgesia.<sup>14</sup> Their action is mediated by their effect on COX-2 receptors and result in analgesic and antiinflammatory effects. The side effects are largely a result of inhibition of COX-1 receptors which occur most frequently in the gastrointestinal (GI) tract, renal tissue, and platelets. The effectiveness of NSAIDs in the management of acute pain has been demonstrated in multiple disciplines of surgery including but not limited to orthopedic, oral, abdominal, and spinal surgery. There remain concerns regarding their safety in the surgical patient because of the risk of GI bleeding and, especially, surgical site bleeding. Overall, the use of these agents in postoperative surgical patients has been found to be safe, but there are risks of GI bleeding, renal injury, and surgical bleeding. In the largest review of the use of ketorolac in 1996, 10,272 patients receiving ketorolac were compared with 10,247 receiving opiates. The rate of complications for ketorolac compared with opiates was GI bleeding 2.1% versus 1.9%, serious operative site bleeding 1.5% versus 1.8%. In subanalysis, it was found that the major risk factors that significantly increased these

TABLE 9-1. Equianalgesic dosages of frequently prescribed IV and oral medications

	Approximate equianalgesic		Starting dosage, adults >50 kg	
	IV/SC/IM	PO	IV/SC/IM	PO

risks were patient age greater than 75, daily dosage exceeding 105 mg/day, and courses longer than 5 days.<sup>15</sup> Used within these parameters, NSAIDs are safe and effective as an adjunct or by themselves for the postoperative patient.

### *Antihistamines*

Histamine is known to activate nociceptive fibers and may participate in mediating pain. For this reason, antihistamines have been proposed as adjuncts to pain management. The mechanism of antihistamines in analgesia is unclear but may involve opioid receptors or presynaptic inhibition of histamine receptors. Despite positive findings in animal models, clinical studies have been conflicting. The confounding factors of sedation and poor methodology do not allow for recommendations for their use as single agents. As adjuncts, they may have benefit although the same confounding factors exist in these data. As more selective antihistamines with less sedation become available, these questions may be answered.<sup>16</sup>

### Epidural Anesthesia

Epidural anesthesia functions at the dorsal horn preventing afferent conduction of nociceptive stimuli. For patients undergoing laparotomy and lower abdominal and pelvic surgery, epidural anesthesia may have better pain control, patient satisfaction, and potentially return of bowel function with fewer side effects.<sup>17,18</sup> In a randomized study of colorectal patients undergoing thoracic epidural placement for colorectal resections, resolution of ileus and control of postoperative pain was significantly improved compared with those receiving a PCA.<sup>19</sup> These findings were supported in a series of patients undergoing proctocolectomy.<sup>20</sup> In a series of patients undergoing laparoscopic colon resection randomized to epidural versus PCA, the differences were not significant. The type of medication infused may also have a significant influence on the outcomes postoperatively as discussed in a Cochrane review in which those patients receiving local epidural anesthetics had reduced GI paralysis with comparable pain control.<sup>21</sup> The additional time and cost involved with an epidural has been the primary reason it has not been adopted in a more widespread manner.

### Preemptive Analgesia

The debate over the effectiveness of preemptive analgesia continues. Initial animal studies demonstrated that the doses of analgesia necessary to prevent central hyperexcitability in rats was significantly less than that necessary to reverse it.<sup>22</sup> The concept is that by preventing the initial stimulation of central pain pathways, there will be decreased sensitization to noxious stimuli. When increased sensitization occurs, it is referred to as hyperalgesia and suggests that the same stimuli will produce different degrees of effects based on the state of the target. Hyperalgesia may result from upregulation of afferent pathways and the inflammatory mediators involved in the perception of pain.<sup>23</sup> This led to the evaluation of preemptive analgesia in human studies.

A review of the 80 randomized controlled trials regarding the comparison of preemptive and postoperative pain relief attempted to reach a consensus regarding preemptive analgesia trials in humans. The only end point examined was level of pain. The trials were divided into NSAIDs, IV opioids, epidural analgesia, caudal analgesia, and peripheral local anesthetics. Although there were a few studies that demonstrated improved pain control at various time points postoperatively, this was not consistent and not overall. The findings were that “timing of analgesia did not influence the quality of postoperative pain control, whatever the type of preemptive analgesia.”<sup>24</sup> A comparison of preincisional versus postincisional epidural anesthesia with a combination of lidocaine and fentanyl including a control with a sham epidural showed very minimal difference between the former two groups in terms of postoperative morphine consumption. There was a 20% decrease in morphine use compared with the sham epidural as might be expected.<sup>25</sup> It has been suggested that the focus should shift from comparing preoperative and postoperative analgesia, to developing more comprehensive, multimodality paradigms of surgical pain control.

### “Nontraditional” Adjuncts

Acupuncture and acupressure have been used for thousands of years and are now being increasingly used in Western medicine. There are many reports of their use in control of surgical pain, but few of these are randomized. The studies that have been randomized have been mixed in their findings as well as the type of acupuncture or acupressure. The methods include needles, pressure, and electrical stimulation and the number and location of sites is variable. The purported benefits are decreased need for opioids, decreased nausea, and lower plasma cortisol and epinephrine release.<sup>26,27</sup>

Modalities that address the psychological perception of pain, rather than only the physiologic, are being examined. It has been suggested that techniques such as massage may better address the psychological aspect. In the one randomized study of this in patients with acute surgical pain, there was no difference in the consumption of opioids in 202 patients.<sup>28</sup> For similar reasons, relaxation techniques and the use of music have been suggested.

Overall, the data are very limited for these therapies. Most have few risks associated with them (acupressure, psychological methods) and are becoming available in some hospitals. Their role in the management of acute postoperative pain remains to be seen in larger, randomized trials.

### Perioperative Fluid Management

Basic fluid requirements under normal circumstances are approximately 2500 cc/day in a 70-kg adult. This allows for the 1500 cc of urine necessary to excrete waste products including urea, potassium, and sodium. A very simple formula

for calculating basic fluid needs is 1500 cc for the first 20 kg with 20 cc/kg for the remaining weight. As a result of surgical stress, there is an increase in renin, aldosterone, and antidiuretic hormone release and activation of the sympathetic system resulting in sequestration of fluid (third spacing) and increased volume requirements. Additional losses may occur from blood loss, diarrhea, nasogastric tubes, and abdominal drains and these should be accounted for. Assuming a return to homeostasis, this fluid retention begins to resolve with a return to normal of the hormones and sympathetic nervous system. Table 9-2 lists the composition of the frequently administered colloids and should serve as a guide for replacement based on calculated fluid losses.

The management of perioperative fluid has not received much attention in terms of postoperative recovery and complications until recently. It may be that the routine administration of maintenance IV fluids is deleterious. In two randomized controlled trials of colorectal patients, a relatively restricted perioperative fluid administration schedule was used. The groups randomized to the restricted fluid had fewer complications in terms of cardiopulmonary events and tissue healing complications as well as quicker resolution of intestinal ileus.<sup>29,30</sup> The difference in cardiopulmonary complications was also found in a Cochrane review of patients undergoing orthopedic surgery.<sup>31</sup> There is still little information about perioperative fluid management of patients, but changes in standard regimens may be on the horizon.

## Ulcer Prophylaxis

In many institutions, ulcer prophylaxis is a routine part of the postoperative orders. In patients without risk factors, or personal history, this is unnecessary. The incidence of clinically significant GI bleeding in hospitalized patients in this age of ulcer prophylaxis has been well characterized for the critically ill and is less than 0.2%.<sup>32</sup> In this population, mechanical ventilation, coagulopathy, prolonged hypotension, and organ failure have been the most consistently identified risk factors for the development of stress ulcer bleeding.<sup>33,34</sup> Despite this information, inappropriate use of these agents continues as demonstrated in a review of 226 patients admitted to the medical unit. In this population, prescribed ulcer prophylaxis was not indicated in 65% of patients yet a significant number of these patients were discharged on these medications.<sup>35</sup>

The choice of agents for prophylaxis has greatly increased. Table 9-3 lists the most common agents, mechanisms, and

TABLE 9-3. Mechanism of frequently used ulcer prophylaxis medications

	Mechanism
Antacids	• Neutralizes acid
Sucralfate	• Mucosal production • Stimulates mucous, HCO <sub>3</sub> , prostaglandin secretion (inhibits acid secretion) • Coat ulcer base
H2 Antagonists	• Blocks stimulation of histamine receptor and production of H <sup>+</sup>
Proton pump inhibitors	• Blocks H <sup>+</sup> /K <sup>+</sup> ATPase pump (final step of acid production)

effectiveness. In a review of the studies comparing therapies for stress ulcer prophylaxis, Hiramoto et al.<sup>36</sup> concluded that H2 antagonists, sucralfate, and proton pump inhibitors are effective in decreasing the risk of clinically significant bleeding. Proton pump inhibitors, however, are the most potent gastric acid suppressant and, theoretically, may be more effective.

## DVT Prophylaxis

Although the occurrence of a fatal pulmonary embolism (PE) is rare, venous thromboembolism (VTE), both symptomatic and asymptomatic, is relatively common in the surgical patient. In one study, 0.8% of patients admitted after surgical procedures developed symptomatic VTE. Of note, 66% of these occurred in the 3 months after discharge.<sup>37</sup> PE is the most preventable cause of death in hospitalized patients in the United States and was listed as the cause of death in 0.45% of deaths.<sup>38</sup> In light of the many available, low-risk forms of prophylaxis, this should be a part of the care of the postoperative patient.

Of the different therapies available, the costs and potential risks are variable. The potential risk factors are many, and are listed in Table 9-4.<sup>39</sup> Stratification of patients based on their risk for occurrence of VTE/PE should guide the choice of prophylaxis (Table 9-5). Each of the proposed therapies will be discussed in regard to institution, dosage, and effects.

## Elastic Stockings

The literature available on the use of elastic stockings is based on the use of graduated compression stockings. They function by compressing the lower extremity in a gradual manner, with the greatest pressure at the ankle, encouraging venous return. If not fitted properly, they may actually be constrictive and increase the venous pressure below the knees, decreasing

venous return.<sup>40</sup> In a Cochrane review, they did reduce the risk of VTE in moderate-risk patients.<sup>41</sup> As a solo prophylaxis, they should be reserved for the low-risk patient. Otherwise, they should be used in conjunction with other measures.

### Sequential Compression Devices

These devices offer a very effective, low-risk prophylaxis for DVT. The mechanism is both direct and systemic. Locally, they compress the deep venous system decreasing stasis and encouraging venous return. On a systemic level, they increase the fibrinolytic activity by reducing plasminogen activator.<sup>42</sup> There are several types available including a foot pump, calf- and thigh-high devices. There are experimental and clinical data that suggest the devices may be equivalent, although the original studies were based on the thigh-high devices. Killewich et al.<sup>43</sup> studied the hemodynamics of the foot pump system and their conclusions were that there are measurable increases in the venous outflow with these devices. In patients undergoing hip replacement, the foot pump was equally effective as compared with low-molecular-weight heparin (LMWH).<sup>44</sup> No direct comparisons of the different devices are available.

An additional consideration is compliance. For maximal benefit in patients undergoing surgery, they should be placed before the induction of anesthesia and functioning throughout an operation. Postoperatively, their effectiveness can be

compromised because of patient, physician, and nursing compliance. Cornwell et al.<sup>45</sup> observed the compliance of trauma patients with the use of sequential compression devices (SCDs). They defined full compliance as the SCDs being on the patient and functioning upon six observations. Based on this, 19% of patients were fully compliant and SCDs were on in 53% of observations.<sup>45</sup> When used properly, SCDs are a safe and effective prophylactic measure in the low- and moderate-risk patient.

### Low-dose Unfractionated Heparin

Unfractionated heparin has been evaluated since the 1970s as a form of prophylaxis and has been shown to be safe in the majority of surgical patients. It consists of molecules that range in size from 3000 to 33,000 Da and binds to antithrombin (ATIII) and accelerates the inhibition of thrombin and other coagulation factors, particularly factor X. In a large randomized trial from 1970, low-dose unfractionated heparin (LDUH) decreased the risk of fatal PEs in the postoperative population from 0.7% to 0.1% in 4000 patients.<sup>46</sup> This was supported in a large metaanalysis of 70 randomized trials. The risk of DVT, PE, and fatal PE was decreased by more than 50%.<sup>47</sup> Although effective, one concern has been the risk of bleeding in the postoperative patient. There has been a small increase in postoperative bleeding in most studies, but the majority of these events are wound hematomas.

A more frequent side effect of heparin is heparin-induced thrombocytopenia (HIT). It is less common with prophylactic than therapeutic heparin, but may occur in 5%–15% of patients. HIT may cause a paradoxical hypercoagulable state with arterial and venous thrombosis. The platelet count should be followed in patients receiving routine heparin and discontinued immediately if diminishing.

It is recommended that subcutaneous (SC) heparin be started within 2 hours of an operation and continued until the patient is fully ambulatory. The dosage is generally 5000 U every (q) 12 hours. This may be increased in those patients in the high-risk category to 7500 U q 12 hours or 5000 U q 8 hours.

### Low-Molecular-Weight Heparin

LMWH consists of heparin molecules in a smaller range and size than LDUH (3500–6000 Da). The mechanism is the same

TABLE 9-5. DVT prophylaxis guidelines

	Age (y)	Surgery	Risk factors	DVT	PE	Recommendation
Low	<40	Minor	None	0.4%	<0.5%	Early ambulation <i>or</i> Elastic stockings <i>or</i> IPC
Moderate				2%–4%	1%–2%	Early ambulation <i>and</i> Elastic stockings <i>or</i> IPC <i>or</i> LDUH <i>or</i> LMWH
A	Any	Minor	Present	4%		
B	<40	Major	None			
C	40–60	Minor	None			
High				4%–8%	2%–4%	Early ambulation <i>and</i> Elastic stockings <i>and</i> IPC <i>or</i> LDUH <i>or</i> LMWH
	>60	Minor	±Other			
	>40	Major	None			
	<40	Major	Present			

as LDUH regarding the acceleration of ATIII inactivation of Xa, but it does not inactivate thrombin. It also does not bind as strongly to plasma moieties so has greater bioavailability, longer half-life, and more predictable plasma levels. Because of this, partial thromboplastin time does not need to be monitored.<sup>48</sup> The incidence of HIT is also lower than LDUH (2.7% versus 0%).<sup>49</sup>

LMWH is at least as effective as LDUH in preventing DVT in postoperative general surgery and colorectal surgery patients without an increase in bleeding complications. A large European trial randomized 1351 patients undergoing abdominal surgery to LDUH or LMWH. The incidence of thromboembolic complications was equal (4.3% versus 4.7%), but patients in the LMWH group experienced fewer bleeding complications, primarily wound hematomas (8.3% versus 11.8%).<sup>50</sup> A metaanalysis of only prospective randomized trials of 5520 patients, including one trial with 1300 colorectal patients, confirmed these results.<sup>51</sup>

With this type of evidence, the question may be why LMWH is not the standard prophylaxis for surgical patients rather than LDUH. Primarily, it is the issue of cost-effectiveness. Based on their findings in a randomized prospective trial of 936 colorectal surgery patients, the authors of the Canadian Multicentre Colorectal Deep Vein Thrombosis Prophylaxis Trial attempted a cost analysis in both Canadian and US dollars for the use of LDUH and LMWH (enoxaparin). Based on their findings of equal effectiveness and a trend toward more bleeding in the LMWH group, they concluded that LDUH was more cost effective. Even with the assumption of greater effectiveness and equal bleeding, LMWH was twice as expensive as LDUH therapy. Their conclusion was: "Although heparin and enoxaparin are equally effective, low-dose heparin is a more economically attractive choice for thromboembolism prophylaxis after colorectal surgery."<sup>52,53</sup>

## Duration

The risk of DVT and PE does not end with the discharge of the patient from the hospital. This is especially true given the decreasing lengths of stay and, therefore, the decreasing time available for prophylaxis while patients are hospitalized. In addition to the previous study cited by White et al. in which 66% of events occurred following discharge. Agnelli et al. found that 40% of DVT/PE events in patients operated on for cancer happened more than 21 days following surgery.<sup>37,59a</sup> It has been postulated that screening patients prior to discharge for DVT using ultrasound or venography and continuing anticoagulation in the population with positive findings would identify a population requiring continued anticoagulation. Pelligrini et al. reported in a prospective series of orthopedic patients that this was not successful in decreasing outpatient events, as 2.2% of patients with negative venograms developed a DVT requiring readmission with three deaths (0.15%).<sup>60a</sup> In a randomized prospective trial of 332 patients deemed high

risk having undergone curative pelvic or abdominal cancer resection, those patients who received 21 additional days of enoxaparin had a 4.8% rate of DVT versus 12.0% in the group receiving only in hospital prophylaxis.<sup>61a</sup> Given these findings, consideration for extended prophylaxis in patients who are at moderate and high risk for thrombotic events must be given.

The American Society of Colon and Rectal Surgeons Practice Parameters for prevention of venous thromboembolism are presented in Appendix A, Chapter 8.

## Anticoagulation

Although there are fairly well-defined recommendations available for the preoperative management of patients on chronic anticoagulation therapy, there is little regarding the postoperative resumption of therapy. The urgency and timing of postoperative anticoagulation can be inferred from the data regarding risk of adverse thromboembolism overall, tempered by an understanding of the risk of bleeding. Clearly, postoperative bleeding risks are influenced by the surgical procedure performed.

Overall, the risk of thrombotic and embolic events may be increased in the surgical patient and those in whom warfarin therapy has been abruptly stopped. In surgical patients not anticoagulated, changes in levels of fibrin D-dimer and other hemostatic markers associated with thrombosis have been found to be increased.<sup>54,55</sup> In those patients taking oral anticoagulation, there is biochemical evidence that there may be a rebound hypercoagulable state after the withdrawal of oral anticoagulation, perhaps increasing the risk even more.<sup>56</sup> Most studies have not borne this out in clinical practice, however.

An estimation of risk will help in guiding the need and timing for beginning anticoagulation postoperatively. A summary of the risk categories based on diagnosis and the general recommendation for anticoagulation is shown in Table 9-6.<sup>57,58</sup>

## Diet

The resumption of a diet is critical to the recovery of the patient undergoing intestinal surgery. Before discharge, it is accepted that patients should tolerate oral analgesia, not require IV hydration, and demonstrate return of intestinal tract function. The order in which these occur varies by practitioner, however. The most traditional approach to these patients is postoperative nasogastric tube decompression, followed by advancement of oral intake based on demonstration of GI function by flatus and bowel movements. On the other extreme is the institution of a regular diet immediately after surgery with changes based on the clinical status. Much literature has accumulated in reference to the viability of these approaches.

Since the 1980s, many groups have evaluated the need for nasogastric tube decompression in the elective abdominal surgery patient.<sup>58-61</sup> The trials failed to show a benefit in

reduction of complications including anastomotic, hospital stay, or return to normal GI function. Combined with the patient discomfort and the loss of the lower esophageal sphincter as a protective mechanism, this has prompted most surgeons to abandon their routine use.

The advent of laparoscopic colon resection has facilitated a more aggressive approach to postoperative feeding regimens.<sup>62,63</sup> Several trials demonstrated that the majority of patients tolerated oral intake in the immediate postoperative period, regardless of the presence or absence of traditional markers of return of GI function. This approach has been used in the open colectomy patients as well. In a nonrandomized study of elderly patients (mean age, 77 years) undergoing open colon resection, 90% tolerated early feeding (clear liquids on day 2, regular diet day 3). There were no anastomotic leaks or abscesses in this group.<sup>64</sup> In a recent metaanalysis, 11 studies with 837 patients were identified which compared liberalized diet immediately postoperative to nothing by mouth until evidence of GI function. These included patients undergoing all types of GI surgery, not specifically colon surgery. Overall, there was a reduction in postoperative infections, both directly related to the surgical procedure and other infections such as pneumonia. There were actually fewer anastomotic complications and a shorter length of stay. The only negative finding was a small increase in the number of patients experiencing vomiting. This did not translate to more wound complications.<sup>65</sup>

In addition to having been shown to be safe and well tolerated, there are several theoretical advantages to early feeding. The potential benefits are related to maintenance of intestinal integrity from a biochemical and immunologic perspective. It has been clearly shown that malnutrition in the surgical patient is associated with increased morbidity and mortality.<sup>66–68</sup>

This has increased the interest in achieving adequate postoperative nutrition. In animal models, survival from peritonitis is significantly improved with enteral nutrition, and almost universally fatal with administration of TPN.<sup>69</sup> In one of the largest prospective, randomized clinical trials, Bozzetti et al.<sup>70</sup> randomized 159 malnourished postoperative cancer patients each to enteral versus parenteral nutrition. Seventy-nine of these patients underwent colon surgery, approximately equally divided between the two groups. Overall, there were fewer complications in the enterally fed group (34% versus 49%). Anastomotic leaks and intraabdominal abscesses were not significantly different between the groups. Of note, 21% of enterally fed patients required reduction in caloric intake or switch to parenteral nutrition (8%).<sup>70</sup>

In summation, early feeding after elective abdominal surgery and specifically colon surgery, has been shown to be safe and generally well tolerated. This may improve patients' comfort, and there is a growing body of evidence that early nutrition may improve outcome and reduce complications. These data are most convincing for the malnourished patient, and for the use of enteral nutrition.

## Steroids

It is not infrequent that patients undergoing colorectal surgical procedures are taking exogenous steroids. Usually this is in the inflammatory bowel disease population, but there are many other clinical situations that may be encountered. Important considerations include identifying those patients at risk for adrenal insufficiency, equivalent oral and parenteral dosages, the effect of surgical stress on dosage requirements,

and the timing of tapering to presurgical dosages or cessation of treatment. A brief review of the physiology of steroid homeostasis will help in understanding the recommendations.

Glucocorticoids are essential for protein, carbohydrate, and fat metabolism. Their overall effect is to increase gluconeogenesis by allowing for the production of amino acids by proteolysis and lipolysis. They also stimulate metabolism by their inotropic effects and enhancement of norepinephrine and epinephrine. Glucocorticoid production in the adrenal cortex is stimulated by the anterior pituitary gland via adrenocorticotropic hormone. The hypothalamus stimulates the pituitary by secreting corticotrophin-releasing hormone. Both of these regulatory hormones are inhibited by the end product cortisol by negative feedback. The usual production of cortisol in an unstressed individual is approximately 20 mg/day. During periods of maximal stress, this production may increase up to 150 mg/day.<sup>71-74</sup> The degree of stress is directly related to the magnitude of the procedure, and the anesthetic, with general anesthesia producing the greatest increases.<sup>75</sup>

It has been clearly demonstrated that adrenal atrophy and suppression occurs with exogenous steroid administration. This is a result of the negative feedback effect on adrenocorticotropic hormone by exogenous cortisol and the lack of stimulation of the adrenal cortex. This can take up to 1 year to recover and patients are frequently asymptomatic during this time if not exposed to stress. During this period, the potential for acute adrenal insufficiency exists.

In actuality, the occurrence of adrenal insufficiency in the surgical population is quite rare. The majority of reports are anecdotal. In fact, in one of the only randomized studies recently, those patients randomized to receiving only their usual daily dosage of steroid perioperatively did not experience symptoms of adrenal insufficiency. The numbers were too small (N = 18, N = 12 in the placebo group) to detect a small difference and the dosages of steroids in most patients were quite low, but this supports the rarity of the occurrence.<sup>76</sup> Salem et al.<sup>77</sup> reviewed the body of evidence regarding the perioperative use of steroid coverage. As they describe, the current usage is based on two anecdotal reports in 1952 which led to recommendations that became the standard of care. From their review, they conclude that the vast majority of patients are over-treated and recommendations should be tailored to identifiable populations at greatest risk. These populations are stratified based on the dosage and duration of treatment an individual patient has received. The risk of suppression can be predicted and this is shown in Table 9-7. As to the question of testing of the adrenal axis, it has not been clearly demonstrated that identified suppression leads to clinical insufficiency.<sup>78,79</sup>

The duration of the taper postoperatively is most impacted by the surgical procedure. For most outpatient procedures, the degree of postoperative stress is considered minor and patients can be returned to their preoperative dose immediately. For major surgery, stress dosages should be continued until signs of surgical stress have resolved. This varies from patient to patient as postoperative ileus, cardiac and pulmonary

TABLE 9-7. Risk of adrenal suppression from exogenous steroids and recommendations for replacement

	Dose	Duration	Recommendation
High risk*	>20 mg/d	>3 wk	<ul style="list-style-type: none"> <li>• 100 mg at induction</li> <li>• 100 mg q 8 hrs throughout period of "stress"</li> </ul>
Intermediate	>5 mg/d <20 mg/d	>3 wk	<ul style="list-style-type: none"> <li>• Prophylaxis <i>or</i></li> <li>• Testing of the axis</li> </ul>
Low	Any dose <5 mg/d	>3 wk Any time	<ul style="list-style-type: none"> <li>• No prophylaxis</li> </ul>

\*Patients with Cushing's syndrome are considered high risk regardless of dosage or duration of steroid administration.

complications and infections pose additional stress. For patients with an uncomplicated postoperative course, this generally begins on the third day. Once the taper begins, it can be carried out rapidly over a period of a few days to the preoperative dosage. Table 9-8 shows the equivalent steroid dosages for the parenteral and enteral steroids.<sup>73,77,80</sup>

It is important to recognize the signs of adrenal insufficiency because they may occur both in the immediate postoperative period and beyond in the event of a complication. These include bowel obstruction, anastomotic leak, surgical and nonsurgical infections. Symptoms may include hypoglycemia, cardiovascular collapse, fatigue, abdominal pain, nausea, and vomiting. In the postoperative patient presenting with a change in intestinal function, steroid withdrawal should be considered in the at-risk population. Stelzer et al.<sup>81</sup> reviewed their 60 steroid-dependent patients who underwent pouch surgery and developed signs and symptoms of a bowel obstruction. They found that 43 had no objective signs of mechanical obstruction and promptly resolved their symptoms within 4 hours of steroid administration. At the other extreme of intestinal function, Rai and Hemingway<sup>82</sup> reported on a patient presenting with high ileostomy output which was responsive to steroids.

## Clinical Pathways

With an awareness of the benefits of practicing evidence-based medicine, the development of standardized postoperative protocols is a reasonable next step. Potential benefits include decreased length of stay with more efficient utilization of hospital beds and personnel, and potentially fewer mistakes because of standardization of care. Many groups have reported their successful application of such clinical pathways specifically in regard to colorectal surgery. The protocols are variable with respect to pain management and

TABLE 9-8. Equivalent steroid dosages

Glucocorticoid	Equivalent dose (mg)	Half-life (h)
Prednisone	5	18-36
Dexamethasone	0.5	36-54
Hydrocortisone	20	8-12
Methylprednisolone	4	18-36

the use of cathartics, but individually show a reduction in length of stay with acceptable outcomes. The major end points have been length of stay, readmission rate, complication rate, and patient satisfaction.

The trend toward earlier discharge began first with the laparoscopic colon resection patients. In 1995, Bardram et al.<sup>83</sup> prospectively followed eight patients over the age of 70 undergoing laparoscopic-assisted colectomy (extracorporeal anastomosis). The regimen involved thoracic epidural catheters intra- and postoperatively for pain control with the avoidance of opioids. A protein-enriched diet and ambulation were begun immediately according to a predetermined protocol. Patients were discharged after they had a normal bowel movement. Six of eight patients went home on the second day; two patients waited until day 3 because of "social" reasons. There were no readmissions and all patients were satisfied.<sup>83</sup> These results were reproduced in a group of 16 patients with a median age of 71 years undergoing open sigmoid colectomy. The protocol consisted of an epidural catheter during and after surgery for pain control. Immediately after surgery, a regimen of mobilization, cisapride and magnesium, and liberal diet including protein drinks was begun. The median length of stay was 2 days (range, 2–6 days) and readmissions were 3, not related to intestinal complications (headaches, social secondary to blindness) and there were no complications.<sup>84</sup>

Recently, a randomized trial compared patients undergoing open intestinal resection who followed a "fast-track" versus the "traditional" pathway. The traditional patients had a nasogastric tube placed that was removed when the drainage was low, and had sips of liquids until the occurrence of flatus and/or stool. The fast-track patients began a regular diet if they tolerated liquids the evening of surgery and were encouraged to ambulate. No epidural catheters were used. The length of stay was significantly shorter (5.4 versus 7.1 days) and there was no difference in readmissions, complications, or patient satisfaction.<sup>85</sup> The same group has demonstrated that this approach is feasible and safe in the patient with significant comorbidity undergoing "complex" operations as well.<sup>86</sup>

Factors that are not necessarily emphasized in these studies, but are clearly present, include the involvement of ancillary staff and patient education. Preoperatively, patients should be educated regarding the expectations of the pathways in terms of their activity and diet. Additionally, an attempt to explain realistic expectations of what patients may expect in terms of pain and discomfort will help in compliance with the protocol. The caregivers, both family and hospital staff, must also be involved and aware of the pathway. Preoperative printed instructions and wall charts may help in achieving this understanding.

## Conclusion

Clearly, the many facets to the postoperative care of the individual patient are complex and as varied as the population treated. The goal of this summary is to provide general recommendations

and a framework on which to guide medical decision making. Consistency in postoperative care helps ancillary staff and patients in regard to expectations and understanding their course, but as the clinical situation evolves, changes may be necessary. A basic knowledge of the principles involved and the options available is crucial in delivering the appropriate care.

## Postoperative Complications

David W. Dietz and H. Randolph Bailey

The ability to minimize, recognize, and treat postoperative complications is one of the most important aspects of surgery. This chapter will focus on those surgical complications most often encountered by colorectal surgeons: injuries to the bowel and genitourinary structures, pelvic hemorrhage, small bowel obstruction, wound infections, abscesses, and anastomotic leaks, strictures, and bleeding.

### Unrecognized Enterotomies and Enterocutaneous Fistulae

Patients undergoing extensive adhesiolysis are at highest risk for enterotomies. An enterotomy in and of itself is not a complication, rather it is the failure to recognize and adequately repair an enterotomy that leads to trouble. In cases in which any significant degree of adhesiolysis is performed, the entire bowel should be carefully inspected at the end of the procedure. Although the natural history of serosal tears is unknown, they should be repaired when recognized with imbricating seromuscular sutures. Full-thickness enterotomies can be repaired using a number of different and equally effective techniques; one common method is a two-layer closure using an inner layer of absorbable seromuscular stitches (i.e., 3-0 Vicryl) and an outer layer of permanent Lembert stitches (i.e., 4-0 Ethibond). In cases in which multiple enterotomies have occurred within a short segment of bowel, resection of the involved segment with primary anastomosis is performed. If the mesentery has also been injured during the course of adhesiolysis, the viability of the bowel ends should be confirmed before anastomosis.

Failure to recognize an enterotomy at the time of surgery will lead to one of several postoperative complications. The patient may develop peritonitis within the first 24 to 48 hours after surgery. This may be difficult to detect in the background of narcotic analgesia and the surgeon and patient's expectation of postoperative incisional pain. The diagnosis is purely based on patient appearance and examination. The usual markers of bowel perforation (leukocytosis, fever, and

pneumoperitoneum) are not reliable, because they are normal findings in the early postoperative patient. A high index of suspicion should be maintained with a low threshold for reexploration. Reoperation within the first several days is usually not difficult because significant adhesions have not yet formed. Most enterotomies found in this situation can be repaired primarily, provided that the bowel edges are viable. Should the repair fail, if the repair can be placed directly under the midline fascial closure, this may result in the development of a direct enterocutaneous fistula rather than recurrent peritonitis. If conditions are not favorable for primary repair, a stoma should be created. An especially difficult situation is that in which bilious fluid is encountered at reexploration but no enterotomy can be found. After running both the small and large bowel at least twice and excluding a duodenal, gastric, or gallbladder injury, the only remaining option may be to place drains in both paracolic gutters and the pelvis in hopes of creating a controlled enterocutaneous fistula. Insufflation of the small bowel with carbon dioxide gas through a nasogastric tube has also been described as a method for localizing small enterotomies. Gas bubbles may be seen emanating from the site of injury after the abdomen has been filled with saline.

An unrecognized enterotomy may also present as an enterocutaneous fistula, with enteric drainage emanating from the incision or wound later in the postoperative course. If there are no signs of sepsis, a nonoperative approach may be considered, especially if the patient is more than 1 week removed from surgery. The patient is placed on complete bowel rest, a nasogastric tube is placed, broad-spectrum antibiotic coverage is initiated, and a computed tomography (CT) scan is obtained to assess for an associated abscess or fluid collection. If a fluid collection greater than 4 cm in diameter is present, percutaneous, radiologically guided drainage should be used. If available, an enterostomal therapist should be involved to assist with pouching the fistula in order to protect the skin from irritating enteric contents. In most cases, parenteral nutrition will be started to meet the patient's caloric and protein requirements in anticipation of a prolonged period

of fasting. H2 antagonists should be added to decrease gastric secretions. Somatostatin analogs may also be used to decrease the volume of fistula output, although they do not seem to increase the rate of spontaneous fistula closure.<sup>1</sup> The rate of spontaneous small bowel fistula closure varies but is typically less than 50%. Chances of spontaneous closure are thought to be reduced by high output because of proximal location, distal obstruction, local sepsis, radiation exposure, a short or epithelialized tract, malignancy, a foreign body in the tract (e.g., mesh, sutures), Crohn's disease, and malnutrition.<sup>2</sup>

Most enterocutaneous fistulae that close spontaneously will do so within the first month. If the fistula persists, fibrin glue injection can be attempted. Several reports have been published describing this technique and successful closure has been achieved in some cases.<sup>3-5</sup> Although no large series exists to define the success rate, little is lost in making the attempt. Surgical intervention should be delayed until all sepsis has resolved, adequate nutrition has been restored, and intraabdominal adhesions have softened to the point of allowing safe reoperation. Most authors recommend a delay of at least 6 weeks since the last laparotomy, but 3-6 months may be more appropriate.<sup>6,7</sup> The ultimate healing rate after definitive surgical repair is approximately 80%.<sup>7</sup>

## Anastomotic Complications

Anastomotic complications are among the most feared in colorectal surgery. They can lead to emergent reoperation and/or a prolonged, complicated, and costly postoperative hospitalization. If the patient recovers from the acute event, chronic sequelae may develop because of stricture or pelvic fibrosis leading to poor bowel function and the possibility of further revisionary surgery or permanent fecal diversion.

Anastomotic complications are usually related to technical factors (ischemia, tension, poor technique, stapler malfunction) or preexisting conditions in the patient such as local sepsis, poor nutrition, immunosuppression, morbid obesity, and radiation exposure. The contribution of the former may be minimized by a careful, methodical approach to construction of the anastomosis (Table 10-1). For colorectal anastomoses, a tension-free anastomosis may be achieved by full division of the lateral attachments of the descending colon, complete mobilization of the splenic flexure, high ligation of the

TABLE 10-1. Steps to minimize risk of leak from colorectal or coloanal anastomoses

1. Ensure good blood supply (pulsatile bleeding from marginal artery at level of anastomosis)
2. Ensure tension-free anastomosis by complete mobilization of splenic flexure (includes high ligation of IMA and ligation of inferior mesenteric vein at lower border of pancreas)
3. Avoid use of sigmoid colon in creation of anastomoses
4. Inspection of anastomotic donuts for completeness after circular stapled anastomoses
5. Air or fluid insufflation test to rule out anastomotic leak immediately after construction in the operating room

inferior mesenteric artery (IMA), separation of the omentum from the distal transverse colon and mesocolon, and division of the inferior mesenteric vein at the lower edge of the pancreas. Adequate blood supply should be confirmed by cutting across the marginal artery or bowel wall with anything less than pulsatile bleeding considered unacceptable. Further colon resection should be performed until adequate bleeding is encountered. If necessary, anastomoses between the hepatic flexure or distal ascending colon and rectum are easily achieved by passing the colon through a window in the mesentery of the terminal ileum.

Nutritional status, degree of immunosuppression, and general medical condition should be considered when deciding whether or not to perform a primary anastomosis. If severe malnutrition (albumin <2.0 or weight loss >15%) or significant immunosuppression (chemotherapy, high-dose steroids) are present, an end colostomy and Hartmann stump will minimize the risk of complications. Colostomy takedown can then be performed if and when these factors have been corrected. Preoperative weight loss, if able to be accomplished by the morbidly obese patient, will make the construction of deep pelvic anastomoses easier. When operating in the radiated pelvis, one end of the bowel used to construct the anastomosis should come from outside the field of radiation.

## Bleeding

Anastomotic bleeding is common and varies greatly in severity. In most cases, bleeding is minor and is manifested by the passage of dark blood with the patient's first bowel movements after surgery. In rare instances, bleeding can be massive and require transfusion and active intervention.

Bleeding can occur after either stapled or hand-sewn anastomoses, but is probably more common with the former. This complication can be reduced by careful inspection of the staple line, particularly in the case of side-to-side/functional end-to-end anastomoses. Before closing the enterotomy through which the stapler was introduced, the linear staple line can be everted and inspected. Bleeding points should be controlled with sutures rather than cautery to prevent a deep burn injury which may lead to delayed leak. The incidence of bleeding from the linear staple line can be minimized by using the antimesenteric borders of each limb to construct the anastomosis, thus avoiding inclusion of the mesentery in the staple line.

Bleeding from circular stapled anastomoses or from the staple lines of ileal or colonic J pouches is usually not diagnosed until after the patient has left the operating room. After performing proctoscopy to evacuate clot from the rectum or neorectum, a rectal tube is inserted and a 1:100,000 solution of saline and epinephrine is instilled. The tube is then clamped for 15 minutes. If bleeding persists after the solution is allowed to drain, the procedure may be repeated. If bleeding continues or hypotension develops, the patient should be returned to the operating room for transanal examination of the anastomosis or pouch under anesthesia. Bleeding from anastomoses that

are not accessible using these techniques (i.e., ileocolic or small bowel to small bowel) may be managed with supportive care and correction of any underlying coagulopathy. If bleeding is severe, angiography may be required to localize the site and allow selective infusion of vasopressin. Alternatively, colonoscopy may be used. If the anastomosis can be visualized, the bleeding site can be treated with either cautery or injection of epinephrine. In rare cases, reoperation with resection of the bleeding anastomosis is required.

## Leaks

The incidence of anastomotic leak varies widely and is related to the factors listed above as well as the type of anastomosis. The lowest leak rates are seen after small bowel or ileocolic anastomosis (1%–3%) whereas the highest occur after coloanal anastomosis (10%–20%). Vignali et al. reported on 1014 colorectal anastomoses. The overall clinical leak rate was 2.9%. The incidence of leak was strongly associated with the distance of the anastomosis from the anal verge. Eight percent of low anastomoses (<7 cm from anal verge) leaked compared with only 1% of high anastomoses (>7 cm from anal verge). Although diabetes mellitus, use of a pelvic drain, and duration of surgery were each related to anastomotic leak in the univariate analysis, only low anastomosis was predictive in the multivariate model.

Another high-risk anastomosis is the ileal pouch-anal anastomosis. Leak rates of 5%–10% have been reported.<sup>8–10</sup> Data from series of ileal pouch-anal anastomosis in patients with ulcerative colitis identify prednisone dosage >40 mg/day as a significant risk factor.

## Role of Fecal Diversion

The creation of a proximal diverting stoma minimizes the severe consequences of an anastomotic leak but it does not reduce the incidence of leak itself.<sup>11–13</sup> A diverting stoma should be considered for any high-risk anastomosis [coloanal, low colorectal (<6 cm from anal verge)]. In addition, patient factors such as severe malnutrition, significant immunosuppression, and purulent peritonitis or pelvic sepsis should be considered as indications for diversion. Consideration should also be given to the patient's comorbidities and general condition; in cases in which the "physiologic reserve" necessary to tolerate an anastomotic leak does not exist, the use of a proximal stoma should be strongly entertained. Neoadjuvant radiation therapy does not seem to increase the incidence of anastomotic leak in patients undergoing restorative proctectomy for rectal cancer<sup>14,15</sup> but this may be because of the tendency for surgeons to cover these anastomoses with a proximal stoma, thus reducing the clinical manifestations of a leak. In fact, recent data from a large randomized trial assessing the efficacy of short-course neoadjuvant radiation therapy in rectal cancer found that a protecting stoma reduces the need for surgical intervention should an anastomotic leak occur.<sup>16</sup>

## Role of Pelvic Drains

The use of pelvic drains is controversial. Whereas surgeons have long believed that preventing the collection of fluid or hematoma in the pelvis minimizes risk of anastomotic leak, the use of drains has not been shown to be of benefit or harm in a recent, large randomized study<sup>17</sup> and in a metaanalysis.<sup>18</sup> However, examination of the data from the Dutch TME trial showed that the use of pelvic drains reduced the incidence of clinical anastomotic leak after short-course neoadjuvant radiation therapy from 23% to 9%. In the absence of data suggesting harm, the authors routinely drain low colorectal or coloanal anastomoses, especially after neoadjuvant therapy.

## Management of Anastomotic Leak

Anastomotic leaks can be divided into "free" and "contained" varieties. Free leaks are those in which fecal contents leak from the anastomosis and spread throughout the abdominal cavity. Patients usually present with fever, tachycardia, leukocytosis, and diffuse peritonitis. Feculent fluid may present itself through the surgical incision or via the pelvic drains. Hypotension and other signs of systemic sepsis may ensue. If the patient is stable, radiologic investigation is helpful to localize the leak and to determine its size and severity.

Patients with "free" leaks should be taken to the operating room after fluid resuscitation and administration of broad-spectrum intravenous antibiotics. Surgical treatment will be dictated by the findings at operation. Most leaking colorectal anastomoses will require abdominal washout and takedown of the anastomosis with creation of an end-colostomy and Hartmann stump. If the stump cannot be stapled or sutured closed because of the friability of the tissues, transabdominal pelvic and perianal drains should be placed. However, leaking ileocolic or small bowel to small bowel anastomoses can occasionally be repaired primarily in carefully selected circumstances, i.e., small defect with viable edges. However, resection of the anastomosis with either reconstruction or creation of a stoma is the wisest and most conservative option. Placing the repaired anastomosis directly under the midline incision will usually result in an enterocutaneous fistula rather than a second bout of peritonitis should the repair fail. If the viability of the bowel ends is questionable, takedown of the anastomosis and creation of a stoma is mandatory. Small defects in colorectal anastomoses may also, under ideal circumstances, be repaired primarily and covered with a proximal ileostomy. This is contraindicated, however, if there is a significant fecal load present between the ileostomy and the site of repair.

"Contained" leaks are those in which the extravasation of contrast material is limited to the pelvis and usually result in the development of a pelvic abscess (Figure 10-1). If the abscess cavity is small and contrast flows freely back into the bowel, the patient may be treated with intravenous antibiotics, bowel rest, and observation. If the abscess is larger or somewhat removed from the site of the anastomosis, then

FIGURE 10-1. Pelvic abscess resulting from ileocolic anastomotic leak (white arrow). Extravasated enteric contrast can be seen in the right pelvis tracking down toward the abscess.

percutaneous abscess drainage using CT or ultrasound guidance may avoid laparotomy. Such leaks rarely require subsequent fecal diversion.

### Fistulae

Anastomotic leaks may also result in fistulae to the skin, vagina, male genitourinary system, or chronic presacral abscess (presacral sinus). Colocutaneous fistulae will frequently close with conservative management consisting of either bowel rest with total parenteral nutrition or a low residue diet and pouching of the fistula to protect the surrounding skin. If drainage persists, reoperation for fistula takedown and reconstruction of the anastomosis can be performed after a delay of 3–6 months. Patients can usually eat a normal diet during this time period to maintain nutritional status. Fibrin glue injection has been reported as a successful alternative to surgery (see above).

Colovaginal fistulae are usually the consequence of either an anastomotic leak necessitating through the vaginal cuff in a patient who has undergone a prior hysterectomy or the inclusion of the vagina during creation of a stapled anastomosis. In either case, spontaneous closure is rare. If the vaginal drainage is copious and intolerable to the patient, proximal fecal diversion may be necessary. An alternative measure to avoid a stoma during the period of fistula maturation is to use a large-volume daily enema to evacuate the colonic contents at a predictable time each day. After a waiting period of 6–12 weeks, reoperation may be performed. Options include attempts at local repair using mucosal flaps (colonic or vaginal)/sleeve advancements or laparotomy with redo coloanal

anastomosis, either primary or delayed (“Turnbull-Cutait pullthrough”).

Chronic presacral abscess or sinus may result from a posterior leak in a coloanal or ileal pouch-anal anastomosis. Patients may have an occult presentation consisting of vague pelvic pain, fevers, frequency of stool, urgency, and bleeding. A pelvic CT scan will usually show presacral inflammatory changes and a contrast enema will confirm the presence of a sinus tract originating from the posterior midline of the anastomosis and extending cephalad into the presacral space. Examination under anesthesia can then be performed with careful inspection of the anastomosis. A probe or clamp is placed through the anastomotic defect and the chronic presacral cavity is simply lain open using cautery and gently curetted of granulation tissue. This will allow free drainage of the presacral abscess and healing by secondary intention. This may result in a chronic posterior sinus or “pseudo-diverticulum.”

### Stricture

Anastomotic stricture may be the end result of anastomotic leak or ischemia. It typically presents 2–12 months after surgery with increasing constipation and difficulty evacuating. If the initial resection was done for malignancy, recurrence as a cause of the stricture must be excluded with a combination of CT scan and fluorodeoxyglucose–positron emission tomography (PET) scan. Biopsy is mandated if a mass or abnormality is identified. Low colorectal, coloanal, or ileal pouch-anal anastomotic strictures may be successfully treated with repeated dilatations using an examining finger or rubber dilators. Dilation is more successful if initiated within the first few weeks after surgery. In fact, almost all coloanal or ileoanal anastomoses will stricture to some degree during the early postoperative period, especially if a diverting stoma is present. All such anastomoses should undergo digital examination at 4–6 weeks after surgery and just before stoma closure (usually at 2–3 months). Strictures are usually soft and easily dilated during these examinations. Higher colorectal, colocolic, or ileocolic strictures may be approached using endoscopic balloon dilatation (Figure 10-2). If these measures fail, or if the stricture is extremely tight or long, revisionary surgery may be required. These are difficult operations, however, because of the pelvic fibrosis that develops after anastomotic leak and complications are common. In some cases, permanent fecal diversion is the only option.<sup>19,20</sup>

## Genitourinary Complications

### Ureteral Injuries

Injury to the ureters typically occurs at one of four specific points in the procedure. The first is during high ligation of the IMA where the junction between the upper and middle thirds of the left ureter lies in close proximity to the vessels. Failure

FIGURE 10-2. Endoscopic balloon dilatation of a colorectal anastomotic stricture. **A** Five-millimeter colorectal anastomotic stricture. **B** Balloon dilator inflated. **C** Result.

to mobilize the ureter laterally before ligation of the IMA may result in its inclusion with the vascular pedicle when clamped and subsequent division. It is good practice to always confirm the position of the left ureter before and after applying clamps to the IMA and before division of the vessel. Injury at this level is usually limited to transection and can be repaired primarily using an end-to-end, spatulated anastomosis performed over a stent. The second point of danger is during mobilization of the upper mesorectum near the level of the sacral promontory. It is at this point that the ureters cross over the bifurcation of the iliac artery and course medially as they enter the pelvis. The left ureter may be closely associated with the sigmoid colon and can even be adherent secondary to prior inflammatory processes. The injury may be tangential

and not readily recognized in the setting of a phlegmon or abscess. Ureteral stents in this setting are most beneficial in identifying the injury rather than preventing it. Injury at this level is usually managed by either primary repair or ligation of the distal stump and creation of a ureteroneocystostomy with a Boari flap or psoas hitch repair.

The third point of risk is during the deepest portion of the abdominal phase of the operation. Anterolateral dissection in the plane between the lower rectum, pelvic sidewall, and bladder base can result in ureter injury at the ureterovesical junction. The ureter may also be injured at this level during division of the lateral stalks. The final area of risk is during the most cephalad portion of the perineal phase of the operation. If exposure is limited (obese patient, android pelvis), the ureter

may be unknowingly divided near the ureterovesical junction. In either of these circumstances, the injury can be managed by creating a ureteroneocystostomy. The ureter is reimplemented into the bladder by tunneling the ureter through the bladder wall and creating a mucosa to mucosa anastomosis.

Should ureteral injury occur, the key to minimizing its consequence is immediate (intraoperative) recognition and repair of the injury. In cases in which a difficult pelvic dissection is anticipated, because of prior pelvic surgery, inflammation, or a locally advanced tumor, the preoperative placement of ureteral stents can be invaluable. Although the literature does not demonstrate that stents prevent ureteral injuries, palpation of the stents can aid in localization of the ureters and can also facilitate identification and repair should injury occur. In cases in which the surgeon is suspicious of occult injury, indigo carmine can be administered intravenously. After several minutes, the urine will turn blue-green and the operative field can then be inspected for staining. Unfortunately, the literature suggests that less than 50% of ureteral injuries are identified intraoperatively, usually because the injury is not suspected. Ureteral stents should be used selectively, however, because their use can lead to complications such as obstruction secondary to hematoma, perforation, or acute renal failure.

### Urethral Injuries

Iatrogenic injury to the urethra may be the result of abdominoperineal resection (APR). The injury typically occurs during the perineal portion of the procedure and usually involves the membranous or prostatic portion. Intraoperatively, urethral injury may be recognized by visualization of the Foley catheter through the defect. These injuries may be difficult to avoid in the presence of a large, deeply penetrating anterior tumor in which involvement of the prostate gland can occur. Desmoplastic reaction to the tumor or edema from neoadjuvant radiation therapy may also obscure anatomic planes. Small injuries can be repaired at the time of surgery using 5-0 chromic sutures with the Foley catheter left in place to stent the repair for 2–4 weeks. Larger injuries or those not presenting until the postoperative period (urine draining from the perineal wound) require proximal urinary diversion via suprapubic catheter and delayed repair. This should be performed by a skilled urologist with experience in urethral reconstruction and typically utilizes a gracilis muscle flap.

### Bladder Injury

Bladder injuries are relatively frequent and are, in most cases, related to resection of an adherent rectosigmoid tumor or diverticular phlegmon. When created purposefully or recognized immediately, defects in the bladder dome are easily repaired in two layers with a Foley catheter then left in place for 7–10 days postoperatively. Before removal, a cystogram

may be obtained to confirm healing. Injuries to the base of the bladder are more problematic. The major risk of repair in this situation is occlusion of the ureteral orifice at the trigone. Most urologists advocate opening of the bladder dome to gain access to the bladder lumen with subsequent repair of the trigone injury under direct vision from the interior. Ureteral patency is confirmed at the conclusion of the repair before closing the cystotomy. Injuries not recognized at the time of surgery will present in the postoperative period with urine in the abdominal cavity, pneumaturia, or fecaluria. Initially, fecal and urinary diversion may be necessary to temporize the situation until reoperation can be safely performed. At that time, takedown of the colovesical fistula is performed with primary repair of the bladder. If available, omentum should be interposed between the bladder repair and any bowel anastomosis. Catheter drainage of the bladder is maintained for 1–2 weeks.

### Urinary Dysfunction

Urinary dysfunction is one of the most common urinary complications of APR.<sup>21</sup> Some degree of voiding difficulty occurs in up to 70% of patients after APR, but it is usually confined to the early postoperative period. In most instances, urinary retention is the result of denervation of the detrusor muscle causing partial paralysis. Bladder contractility is under parasympathetic control via pelvic nerve branches originating from the inferior hypogastric plexus. These nerves can be injured if the endopelvic fascia is breached, especially during blunt dissection of the rectum. Temporary dysfunction of these nerves is nearly universal after APR, even when a meticulous sharp dissection is used. Most patients, however, will only require maintenance of a Foley catheter for 5–7 days postoperatively. In a small percentage of patients, the problem persists beyond several months and urologic consultation is required. A small percentage of these patients may require prostatectomy or even intermittent self-catheterization on a long-term basis.

### Sexual Dysfunction

Recent series report an incidence of sexual dysfunction of 15%–50% in male patients undergoing APR for rectal cancer.<sup>22–24</sup> This wide range is likely attributable to several factors such as patient age, preoperative libido, use of adjuvant radiation therapy, varying definitions of dysfunction, time point of follow-up, and social barriers preventing a frank discussion of the problem. The type of dysfunction is dependent on the pattern of nerve injury. Damage to the superior hypogastric (sympathetic) plexus during high ligation of the IMA or to the hypogastric nerves at the sacral promontory during mobilization of the upper mesorectum, results in ejaculatory problems such as retrograde ejaculation. This is the most common type of sexual dysfunction seen in male patients after APR and is also the type most likely to resolve with time (6–12 months). Damage to the pelvic plexus during

the lateral dissection or to the nervi erigentes or cavernous nerves while dissecting the anterior plane (abdominal or perineal phase) may result in erectile dysfunction. The cavernous nerves arise from branches of the pelvic plexus and course anterior to Denonvillier's fascia at the lateral border of the seminal vesicles. Parasympathetic innervation from these routes controls the inflow to and retention of blood within the corpora cavernosa. The important anatomic relations of the pelvic nerves are illustrated in Figure 10-3.

Risk of injury to these nerves may be reduced by tailoring the anterior dissection based on the location of the tumor. The highest risk of parasympathetic nerve injury occurs when dissection is performed in the plane anterior to Denonvillier's fascia and flush with the posterior aspect of the seminal vesicles and prostate. Whereas some believe that this plane is a vital part of total mesorectal excision for any low rectal cancer, others will only include Denonvillier's fascia in the resection specimen for an anterior tumor where it may help obtain a clear radial margin.<sup>25</sup> For posterior tumors, Denonvillier's fascia is preserved by dissecting between it and the fascia propria of the rectum in order to protect the small cavernous nerves. Using a "nerve sparing" approach to total mesorectal excision, several authors have reported an incidence of erectile dysfunction of 5%–15% after proctectomy for rectal cancer. Factors shown to increase risk are older age, poor

preoperative libido, and low rectal tumor requiring APR (two- to threefold increase compared with low anterior resection).

Although harder to quantify, sexual dysfunction also occurs in women after proctectomy. It is characterized by dyspareunia and inability to produce vaginal lubricant and achieve orgasm. The incidence is lower than that seen in males and varies between 10% and 20%.<sup>26</sup>

### Female Infertility

Several recent studies have documented decreased fertility in women who have undergone restorative proctocolectomy for ulcerative colitis or familial adenomatous polyposis.<sup>27,28</sup> The postoperative infertility rate exceeds 50% in this group when defined as "one year of unprotected intercourse without conception." This has important implications in both preoperative patient counseling and in the modification of operative technique to minimize the effect of pelvic adhesions on fertility. Women of childbearing age should be informed of this potential complication before elective restorative proctocolectomy because it may influence the timing of surgery. In addition, because pelvic adhesions are thought to interfere with egg transit from the ovary to the fallopian tube, measures to minimize their occurrence may be of benefit. Tacking the ovaries to the anterior abdominal wall outside of the pelvis and wrapping the adnexa with an anti-adhesion barrier sheet are frequently used techniques but there are no data to support their efficacy.

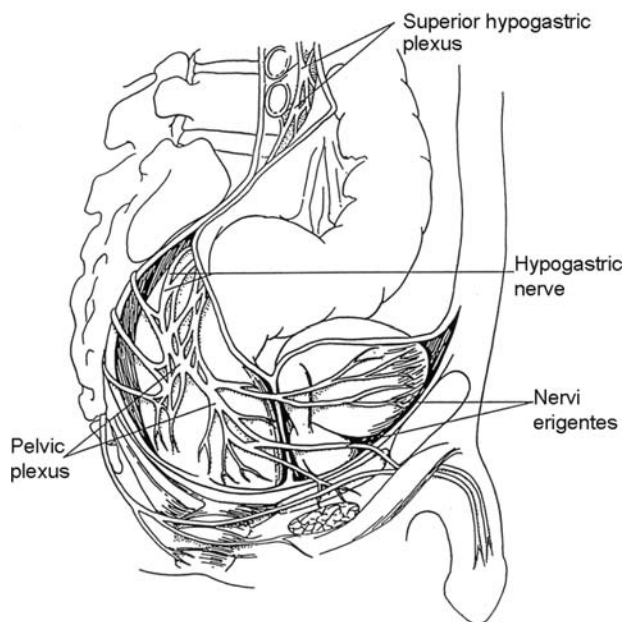

FIGURE 10-3. Anatomic relations of the pelvic nerves. Damage to the superior hypogastric plexus during high ligation of the IMA or to the hypogastric nerves at the sacral promontory during mobilization of the upper mesorectum results in retrograde ejaculation. Damage to the pelvic plexus during the lateral dissection or to the nervi erigentes or cavernous nerves while dissecting the anterior plane may result in erectile dysfunction.

### Trapped Ovary Syndrome

Trapped ovary syndrome is a fairly common complication after restorative proctocolectomy in young women. The adhesions that form after ileal pouch-anal anastomosis trap the ovaries in the pelvis and cover the fallopian tubes. With each ovulatory cycle, there is release of fluid into the pelvic cavity defined by these adhesions. As fluid accumulates and the cavity expands, patients will complain of pelvic or lower abdominal pain relevant to the side of the trapped ovary. A CT scan or ultrasound will reveal a cystic lesion in the pelvis containing no air and with no surrounding inflammatory reaction. Operative findings are a cyst containing clear or tan fluid, surrounded by adhesions and with the ovary attached. Treatment consists of unroofing and evacuation of the cyst, pelvic adhesiolysis, and suspension of the ovary to the pelvic brim or iliac fossa with sutures. Trapped ovary syndrome may be prevented by suspending the ovaries at the time of restorative proctocolectomy and by placement of an adhesion barrier film in the pelvis.

### Small Bowel Obstruction

Perhaps the most critical components in the management of patients with bowel obstruction are the recognition and prevention of the disastrous effects of bowel ischemia. Timely

surgical intervention, before the development of transmural necrosis, will limit complications and improve outcome. In one recently published series of more than 1000 patients undergoing surgery for small bowel obstruction, nonviable strangulated bowel was present at laparotomy in only 16% of cases but the risk of death in this group was increased four-fold.<sup>29</sup> It is also important to distinguish between early (<30 days) and late postoperative small bowel obstruction.

## Presentation and Diagnosis

Nausea and vomiting, colicky pain, abdominal bloating, and obstipation are the hallmark signs of small bowel obstruction. The degree to which each of these contributes to the clinical picture will depend on the location, degree, and duration of the obstruction.

The commonly regarded hallmarks of strangulated bowel are fever, tachycardia, leukocytosis, sepsis, peritoneal signs, and the presence of continuous as opposed to intermittent pain. If any of these are found, the suspicion of ischemia should be high. These signs may also be found in patients without strangulation and are, therefore, nonpathognomonic. In many cases, however, this determination is not made until laparotomy, and timely surgical intervention in symptomatic patients may be the best means of avoiding the progression to bowel ischemia. This fact is underscored by a report from Sarr and colleagues<sup>30</sup> who found that the traditional clinical parameters frequently used to predict strangulation were neither sensitive nor specific. Nearly one-third of patients with strangulation were not diagnosed until the time of surgery.

## Radiographic Studies

### *Plain Radiographs*

An acute abdominal series is the initial imaging study performed in most patients suspected of having small bowel obstruction and consists of both upright and supine abdominal films and an upright chest X-ray. Typical findings include dilated, air-filled loops of small bowel, air-fluid levels, and an absence or paucity of colonic air. These findings may be absent, however, when the obstruction is proximal or the dilated bowel loops are mostly fluid filled. The sensitivity of plain radiographs in detecting small bowel obstruction is approximately 60%. The findings of pneumatosis intestinalis or portal vein gas is worrisome for advanced bowel ischemia.

### *CT Scan*

Abdominopelvic CT scanning is increasingly used as a primary imaging modality in patients suspected of having small bowel obstruction. In addition to establishing the diagnosis, CT may also be able to precisely define a transition point and reveal secondary causes of obstruction such as tumor, hernia, intussusception, volvulus, or inflammatory conditions such as

Crohn's disease and radiation enteritis. CT may also reveal closed loop obstructions or signs of progressing ischemia such as bowel wall thickening, pneumatosis, or portal vein gas. Several studies have shown that the sensitivity of CT in diagnosing small bowel obstruction approaches 90%–100%.

### *Contrast Studies*

Contrast studies using water-soluble agents are frequently used in patients with acute small bowel obstruction. In patients with distal small bowel obstruction, a contrast enema is an efficient means by which colonic obstruction can be excluded. Antegrade studies of the small bowel can help to differentiate partial from complete obstruction, and may therefore predict the need for surgical intervention. In fact, some authors have used small bowel contrast studies as a "screening test" for patients presenting with adhesive obstructions. Failure of contrast material to reach the colon by 24 hours is used as an indication for prompt surgical exploration. Several studies have also shown that the antegrade administration of contrast agents may speed the resolution of partial small bowel obstruction, presumably through an osmotic effect. However, conflicting data also exist and the therapeutic effects of the small bowel contrast study remain to be defined.

## Initial Therapy and Nonoperative Management

Once the diagnosis of small bowel obstruction is made, the patient is admitted to the hospital. Those with peritonitis, perforation, or signs of ischemic bowel are immediately prepared for laparotomy with expeditious correction of fluid and electrolyte deficits. A urinary catheter is inserted to guide resuscitation with the end points being resolution of tachycardia and hypotension and/or achieving a urine output of at least 0.5 cc/kg/h. Broad-spectrum antibiotic coverage is initiated. A nasogastric tube is inserted preoperatively to decompress the stomach, because these patients are at risk for aspiration on induction of general anesthesia.

If signs of perforation or ischemia are not present, a trial of expectant management may be undertaken. Patients with partial small bowel obstructions secondary to adhesions will resolve with a nonoperative approach in 80% of cases.<sup>31–33</sup> The success rate for patients initially presenting with complete obstruction is significantly lower. The nonoperative management of small bowel obstruction consists of fluid and electrolyte replacement, bowel rest, and tube decompression. The debate between standard nasogastric tube versus long nasoenteric tube decompression has mostly settled in favor of the nasogastric tube. This is in part attributable to the fact that long tubes with mercury-weighted tips (Miller-Abbott) are no longer available for use (because of concern about the elemental Mercury) and have been replaced with a balloon-tipped tube (Gowen tube) that requires endoscopic placement. Long tubes are more difficult to place, requiring special

expertise, serial radiographic studies, or endoscopy to guide insertion. There has been some recent resurgence in interest in the use of nasoenteric tubes, mostly among radiologists. Indications for long tube management of small bowel obstruction include early postoperative obstruction and recurrent partial obstruction where the transition point is difficult to identify on contrast studies.

Narcotic analgesics may be administered to comfort the patient, but not to the point of diminishing mental status. The practice of withholding pain medication to avoid masking the signs of perforation or ischemia is probably unnecessary. Serial abdominal examinations (ideally just before the next dose of analgesics) should be performed to assess for increasing tenderness or the presence of peritoneal signs. Any change in the patient's condition that suggests developing bowel ischemia mandates exploratory laparotomy. In general, a nonoperative course may be followed for 24–48 hours. If the obstruction has not resolved within that time period, it is unlikely to do so and laparotomy is advised.

### Decision to Operate

Several studies have attempted to define certain criteria that would reliably predict the presence or absence of strangulated bowel. Unfortunately, none have been shown to be particularly accurate and the best tool remains sound clinical judgment. Certainly, patients with fever, peritonitis, pneumoperitoneum, or overt sepsis should undergo emergent laparotomy because these are hard signs of transmural bowel necrosis. The presence of early ischemia, however, is much more difficult to discern. It is not uncommon for patients with small bowel obstruction to present with tachycardia, relative hypotension, mild acidosis, and leukocytosis, all of which may be secondary to dehydration. These patients should be aggressively rehydrated with isotonic intravenous fluids and the above parameters should be reassessed. Persistence of any of these signs after fluid resuscitation should prompt immediate laparotomy. Adherence to this simple algorithm should minimize the progression to strangulation while limiting the number of unnecessary laparotomies.

Distinguishing between partial and complete obstruction is also a key element in deciding which patients should be taken for early operation. As stated above, the likelihood of resolution of a complete obstruction with expectant management is low (20%). Delaying operative therapy until after a nonviable strangulation or perforation has occurred will substantially increase the mortality rate. Although this distinction may be difficult to make clinically, there are some useful caveats. The passage of stool or flatus cannot be relied on as an accurate predictor because patients with complete obstruction may continue to pass stool and flatus until the bowel distal to the site of obstruction is evacuated. However, if this continues for more than 12 hours after the onset of obstructive symptoms, the likelihood of complete obstruction is diminished. The passage of large volumes of nonbloody, watery stool along with

vomiting and distension is pathognomonic for partial small bowel obstruction. The onset of flatus, however, usually signals the beginning of resolution of the obstruction because flatus is produced from swallowed air.

### Surgical Technique

After the adequacy of resuscitation is confirmed and broad-spectrum antibiotics active against enteric pathogens are administered, the peritoneal cavity is entered through a midline incision. This is a point in the operation where the risk of inadvertent enterotomy is very high because bowel loops are distended and often adherent to the undersurface of the abdominal wall. Once the fascia is encountered, the application of gentle pressure with the bevel of the scalpel blade, rather than a cutting stroke, is used to breach the peritoneal cavity. Using this technique, it is usually possible to recognize an adherent bowel loop before enterotomy occurs.

In the most favorable scenario, a single constricting band will be encountered that can be sharply divided to relieve the obstruction. In the worst cases, the peritoneal cavity will be totally obliterated by scar tissue. An orderly and systematic approach to adhesiolysis is advised in these instances. First, the underside of the midline scar is cleared so that the entire length of the incision can be opened if necessary. Next, adhesions to the abdominal wall are dissected laterally until both paracolic gutters are reached. This will allow the placement of a self-retaining retractor to facilitate exposure. In cases in which bowel distension is severe, needle decompression may be used to gain additional working space. Particularly severe adhesions that defy identification of the bowel and peritoneal surfaces ("frozen abdomen") may be injected with saline through a fine-gauge needle to separate the surfaces and thus facilitate adhesiolysis. Attention is then turned to the pelvis where the most difficult adhesions are often encountered. Rather than separating individual bowel loops at this stage, the small bowel residing in the pelvis should be mobilized "en-masse" by lysing adhesions to the pelvic structures in an anterior to posterior manner in order to roll the mass of intestine up and out of the pelvis. The final portion of this stage of the operation involves mobilizing the plane between the small bowel mesentery and the retroperitoneum until the duodenum is encountered. Only at this point are all adhesions between individual bowel loops lysed in order to free the entire length of the small intestine. The bowel is then inspected for any coexisting pathology and for enterotomies or serosal tears created in the course of mobilization.

Assessment of bowel viability is usually possible by using the triad of color, peristalsis, and mesenteric pulsations. In cases in which these signs are questionable, the ischemic segment should be wrapped in warm, wet packs and viability reassessed after 15 minutes. If viability is still in doubt, use of the Doppler probe or systemic injection of fluorescein dye followed by inspection of the bowel under a Wood's lamp may aid in decision making. If the area in question is a short

segment, it may be best to proceed with resection. If an extensive segment of questionable viability is present, then a second-look operation 24 hours later should be planned before committing the patient to a massive small bowel resection.

There is some debate as to the need for complete adhesiolysis when the point of obstruction is encountered early in the operation. It is our policy to divide the majority of adhesions if this can be done safely. This will facilitate inspection of the entire length of the small bowel and allows for the placement of anti-adhesion barriers if desired (see below).

## Special Situations

### *Early Postoperative Bowel Obstruction*

Early postoperative bowel obstruction is generally defined as mechanical obstruction occurring within 1 month of abdominal or pelvic surgery. This condition is special in that attempts at relaparotomy in the early postoperative period frequently result in disastrous complications. The mantra of “never let the sun rise or set on a patient with bowel obstruction” should not be broadly applied in this group. An intense inflammatory response usually begins within the abdomen at 7–10 days postoperatively and persists for at least 6 weeks. If forced to operate during this period of time, the surgeon is likely to encounter dense hypervascular adhesions that may obliterate the peritoneal cavity. The risk of enterotomy and subsequent fistulization is extremely high. In addition, vascular or extensive serosal injury of the bowel may lead to massive resections. Therefore, immediate reoperation for early postoperative bowel obstruction is not advised, especially considering the fact that the development of strangulation in this setting is extremely rare. These patients should be managed conservatively with nasogastric or long tube suction and intravenous fluids. If resolution does not occur within the first 5–7 days, a percutaneous gastrostomy tube may be placed for longer-term decompression, and the patient is started on hyperalimentation. Patients may be discharged from the hospital on this regimen and laparotomy performed in 6 weeks if the obstruction has not resolved. However, if peritonitis or signs of sepsis are present initially or develop during the course of nonoperative therapy, a CT scan should be performed immediately. Any abscess or fluid collection caused by an enteric leak can be percutaneously drained and a controlled enterocutaneous fistula established. Exploration is usually only required in cases of ischemic or necrotic bowel. There is a place for very early exploration within the first 10 days postoperatively if obstruction is recognized promptly. The adhesions encountered during this time period have not usually become severe and can be dealt with safely.

### *Anastomotic “Overhealing”*

Anastomotic overhealing is a rare cause of postoperative small bowel obstruction. It is most often attributable to early

adhesion and healing of the staple lines of the linear cutter between the limbs of a functional end-to-end/side-to-side anastomosis. This is best prevented by maximally distracting the two staple lines as the transverse staple line is placed to close the enterotomy made to introduce the side-to-side stapler. When this occurs in the early postoperative period, it will be easily diagnosed with a water-soluble contrast study, especially if administered via a long tube near the point of obstruction. The treatment should be conservative initially and may include long tube decompression. In some cases, the balloon-tipped catheter itself has broken through the healing web and relieved the obstruction. In the case of an obstructed ileocolic anastomosis, colonoscopic balloon dilatation may be carefully used. Operative intervention should be a last resort and usually requires resection and reanastomosis.

## Prevention of Adhesions

More than 90% of patients undergoing abdominal surgery will develop some degree of intraabdominal adhesions. Adhesion formation can occur wherever the visceral or parietal peritoneum has been disturbed. Once an area of injury is established, fibrin is deposited and then organizes to form a matrix for collagen deposition. Bowel motility and endogenous lubricants attempt to counteract this process, but in most cases, adhesions will eventually result as the deposited collagen matures. As discussed earlier, the progression from early to mature adhesions usually takes approximately 6 weeks.

Several strategies have been developed to minimize, prevent, or influence adhesion formation. Gentle handling of tissues, avoiding the deposition of talc by wearing powder-free gloves, and copious lavage of the peritoneal cavity at the conclusion of the operative procedure are simple means that should be used in all cases. In instances in which particularly severe adhesion formation can be anticipated, for instance patients with multiple recurrences of small bowel obstruction, the use of long intestinal tubes placed at the conclusion of surgery to “splint” the bowel open during adhesion formation has been advocated. This is usually accomplished by inserting a Baker tube via a proximal jejunostomy.

Recently, several chemoprophylactic agents have been developed in an attempt to reduce or eliminate adhesions through a barrier mechanism. The best studied of these is a bioresorbable membrane of modified sodium hyaluronate and carboxymethylcellulose. A large multicenter study by Becker et al.<sup>34</sup> has shown that this material substantially reduces the extent, incidence, and severity of adhesion formation. Its efficacy in reducing the incidence of adhesive bowel obstruction has recently been reported.<sup>35</sup> However, the decrease in incidence of bowel obstruction from 3.4% in the control group to 1.8% in the treatment group is of uncertain clinical significance. The use of adhesion barriers in patients at high risk for subsequent reoperation because of disease or previous adhesions may be justified by the likely improvement in the ease and safety of the subsequent abdominal reentry and

explorations. One of the problems with the barrier material is that it only prevents adhesions between the surfaces where it is applied.

## Pelvic Bleeding

Serious pelvic bleeding may be encountered during proctectomy and is usually caused by injury to the presacral venous plexus or the internal iliac vessels or their branches. Although rare, pelvic bleeding can be a devastating event and is a significant cause of operative mortality. Presacral venous hemorrhage is especially challenging because the anatomy and fragility of the presacral venous plexus make control of bleeding difficult. Attempts at electrocoagulation or suture ligation of these vessels usually results in an increase in bleeding and is not advised. Direct finger pressure should be used to gain temporary control of bleeding while allowing the anesthesia team to “catch up” with the resuscitation. Once the patient is stabilized, several methods exist for permanent hemostasis. The most common of these is the use of sterile thumbtacks or specially designed “occluder pins” that are driven into the sacrum at right angles and directly over the site of bleeding.<sup>36,37</sup> If this is unsuccessful, a rectus abdominus muscle flap may be rotated down into the pelvis based on the inferior epigastric pedicle. Heavy sutures are then placed on either side of the sacrum and tied down to compress the rectus flap against the sacrum to tamponade the bleeding.<sup>38</sup> Other methods to control presacral bleeding have also been described<sup>39–42</sup> such as removing a 2 × 2 cm square of rectus muscle and tacking this to the sacrum with absorbable sutures placed on either side of the bleeding site and tied tightly to secure the muscle patch. Application of electrocautery to the muscle then produces a secure coagulum on the surface of the bleeding venous plexus. If these measures fail, pelvic bleeding may be controlled by packing several laparotomy sponges tightly into the pelvis with the ends being brought out through the lower portion of the abdominal wound. The abdomen is then closed and the patient is taken to the intensive care unit for blood transfusion, fluid resuscitation, correction of coagulopathy, and general support. After 24–48 hours, the patient is returned to the operating room for removal of the packs.<sup>43</sup>

## Wound Infection and Intraabdominal Abscess

### *Wound Infection*

Because of the large bacterial content of the colon ( $10^{10}$  anaerobes and  $10^8$  aerobes/gram of stool), wound infection rates are high after colorectal surgical procedures.<sup>44,45</sup> The introduction of an oral antibiotic preparation before surgery by Nichols and Condon reduced wound infection rates from 40% historically to the present day level of 5%–10%. In many centers, a single parenteral dose of antibiotics at induction has replaced the more complicated “Nichol’s prep.” Several

single-agent or combination choices exist, each with adequate gram-negative and anaerobic coverage. Risk factors for wound infection have been identified and include malnutrition, diabetes mellitus, immunosuppression, age >60 years, American Society of Anesthesia score >2, fecal contamination, length of hospitalization before surgery, and extensive surgery.<sup>46</sup> Recently, there is a growing body of literature that shows that mechanical bowel preparation does not decrease the incidence of wound infection. Several metaanalyses have examined this question and are in agreement.<sup>47–49</sup> The largest and most recent also found that the risk of anastomotic leak was actually increased in patients receiving a bowel preparation (odds ratio 1.75).<sup>50</sup>

Wound infections typically present on or around the fifth postoperative day and are characterized by erythema, warmth, tenderness, fever, and purulent drainage. Initial treatment consists of opening a portion of the skin incision over the area of maximal change to allow drainage. Antibiotics are not prescribed unless there is cellulitis present. If a significant amount of necrotic tissue is present, it should be débrided. Once the wound is adequately drained, a packing regimen is begun and the wound is allowed to heal by secondary intention. Large wounds may be treated with application of a vacuum-assisted wound closure device. After the wound has been débrided by several days of wet to dry dressing changes, the vacuum-assisted closure device is applied (V.A.C.; KCI Therapeutic Services, San Antonio, TX). The advantages of this system are simplification of wound care and quicker closure. The dressing only needs to be changed every 4–5 days and wounds typically close within several weeks.

Several situations require more aggressive treatment. Deep infection involving the rectus muscle and fascia may occur and result in dehiscence. These patients should be taken back to the operating room for debridement of the necrotic fascial edges and repair of the dehiscence. Invasive wound infections with either clostridium perfringens or beta-hemolytic streptococcus is a potentially life-threatening complication. These infections may have an atypical presentation in that they can occur within the first 1–2 days after surgery and may be associated with minimal skin changes. The combination of fever and unusually severe wound pain early in the postoperative course should prompt opening of the skin incision. A necrotizing infection is suggested by the drainage of thin gray fluid. The key to timely diagnosis and treatment of these severe infections is a high level of suspicion. The patient should be taken to the operating room for a thorough wound exploration. All devitalized tissue should be removed and the fascia excised back to healthy, bleeding edges. Broad-spectrum antibiotic coverage should include high-dose penicillin.

### *Intraabdominal Abscess*

Intraabdominal abscesses can result from anastomotic leaks, enterotomies, or spillage of bowel contents at the time of surgery. Patients will usually present with fever, leukocytosis,

and abdominal or pelvic pain 5–7 days after surgery. The diagnostic modality of choice is a CT scan of the abdomen and pelvis performed with intravenous and oral contrast (and rectal contrast in the patient with a colorectal anastomosis). The finding of a fluid collection with a thickened, enhancing rim and surrounding inflammatory stranding is diagnostic. Air bubbles may also be present in the collection. Proximity to a staple line and the presence of contrast material in the abscess suggest an anastomotic leak as its cause.

Most intraabdominal or pelvic abscesses can be successfully treated with percutaneous catheter drainage performed under ultrasound or CT guidance. Intravenous antibiotics should also be administered. The CT scan is repeated 48 hours after drainage to assess its efficacy. Further follow-up is usually performed by contrast studies obtained by injecting the drainage catheter. Once the abscess cavity has collapsed and no fistula to the bowel is identified, the catheter can be

safely removed. Some abscesses cannot be drained percutaneously because of their location and lack of a safe “radiographic window” for drainage. Reported success rates for percutaneous drainage of intraabdominal abscesses range from 65% to 90% and depend on size, complexity, etiology, and microbial flora.<sup>51–54</sup>

### Perineal Wound Infection

Perineal wound infection and delayed healing are major causes of morbidity after APR with the incidence ranging from 11% to 50%.<sup>55–58</sup> The rigidity of the lower pelvis combined with wide resection of the perineal soft tissues and levator muscles is mostly to blame, because this results in dead space cephalad to the skin closure which is easily infected.<sup>59</sup> Technical modifications that may help reduce the incidence of perineal wound problems include reapproximation of the

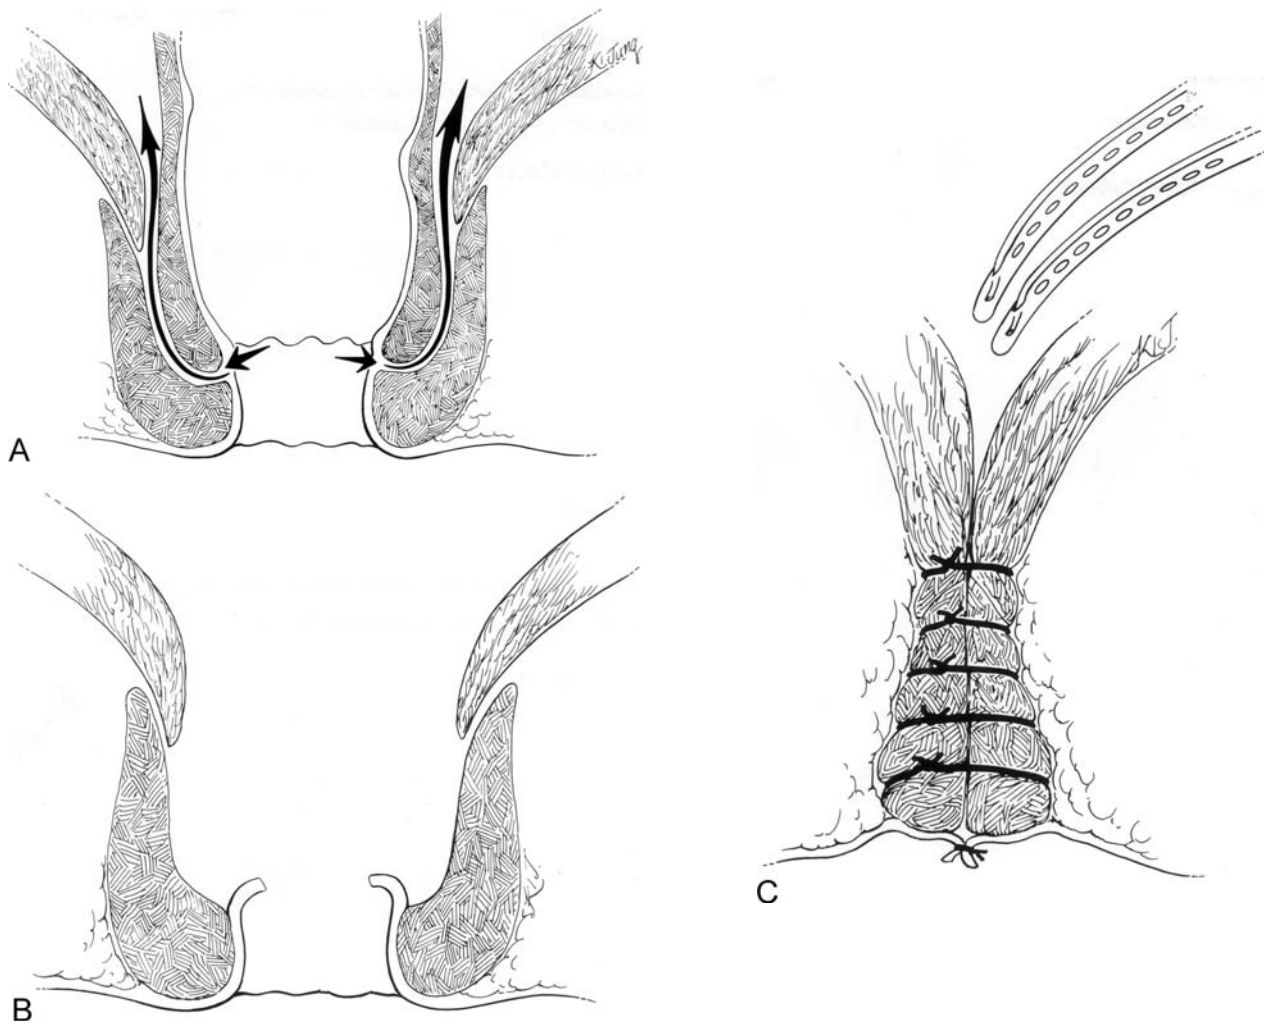

FIGURE 10-4. Technique of intersphincteric proctectomy. **A** The mucosa overlying the intersphincteric groove is incised near the dentate line and the dissection is carried cephalad between the internal and external sphincters. **B** This results in retention of the external sphincters and levators which are then able to be closed in the midline. **C**

subcutaneous tissues, suction drainage of the pelvis (with or without irrigation) to prevent hematoma formation and resultant fibrosis,<sup>60</sup> and filling of the dead space with an omental pedicle graft.<sup>61–65</sup> The area of raw surface deep in the pelvis also frequently fills with small bowel and may lead to small bowel obstruction. The bowel can be excluded from the pelvis by closing the pelvic peritoneum when possible, pulling the uterus posteriorly to close the defect, or by rotating the cecum into the pelvis. The use of absorbable mesh has also been described, but this has been associated with multiple reports of obstruction and fistulization. If possible, based on oncologic factors, a cuff of levator muscle can be left by incising the pelvic floor just outside of the external sphincter muscle. This should always be possible for small rectal cancers. This allows closure of the levator muscles in the midline and prevents dead space formation and perineal hernia. Several risk factors for perineal wound complications have been identified. Foremost among these is the use of neoadjuvant radiation therapy. In one study, the incidence of perineal wound infection increased from 13% to 34% with the addition of preoperative radiation whereas the rate of nonhealing at 30 days increased from 19% to 51%. Rates of perineal wound complications were even higher if intraoperative radiation was used.<sup>66</sup> Other factors are long operative time (>300 minutes), intraoperative hypothermia, and fecal contamination during the perineal dissection.<sup>67,68</sup> Patients with anorectal Crohn's disease are also at increased risk when undergoing APR for rectal cancer. However, an intersphincteric dissection in patients with inflammatory bowel disease allows closure of the external sphincter and may improve wound healing (Figure 10-4).

If infection does occur, the skin should be opened to allow drainage and a program of wet to dry packing begun. A vacuum-assisted closure device can then be placed, as described above. In cases in which a chronic perineal sinus develops, closure of the defect will require wound debridement and myocutaneous flap reconstruction with gracilis, inferior gluteus, or rectus abdominus muscle.

## Benign Anorectal: Hemorrhoids

José R. Cintron and Herand Abcarian

### Anatomy

Hemorrhoids are cushions of specialized, highly vascular tissue found within the anal canal in the submucosal space. The term “hemorrhoidal disease” should be reserved for those vascular cushions that are abnormal and cause symptoms in patients. These cushions of thickened submucosa contain blood vessels, elastic tissue, connective tissue, and smooth muscle.<sup>1</sup> The anal submucosal smooth muscle (Treitz’s muscle) originates from the conjoined longitudinal muscle (see Figure 11-1). These smooth muscle fibers then pass through the internal sphincter and anchor themselves into the submucosa, thereby contributing to the bulk of the hemorrhoids and suspending the vascular cushions at the same time.<sup>2</sup> Some of the vascular structures within the cushion when examined microscopically lack a muscular wall. The lack of a muscular wall characterizes these vascular structures more as sinusoids and not veins. Studies have shown that hemorrhoidal bleeding is arterial and not venous because hemorrhage from disrupted hemorrhoids occurs from presinusoidal arterioles that communicate with the sinusoids in this region.<sup>1</sup> This is supported by the bright red appearance and the arterial pH of the blood.<sup>3</sup> The venous plexus and sinusoids below the dentate line which constitute the external hemorrhoidal plexus drain primarily via the inferior rectal veins into the pudendal veins which are branches of the internal iliac veins. Venous drainage also occurs to a lesser extent via the middle rectal veins to the internal iliac veins. This overlying tissue is somatically innervated and is therefore sensitive to touch, pain, stretch, and temperature. The subepithelial vessels and sinuses above the dentate line which constitute the internal hemorrhoid plexus are drained by way of the middle rectal veins to the internal iliacs.

The vascular cushions within the anal canal contribute to anal continence and function as a compressible lining that protects the underlying anal sphincters. Additionally, the cushions are critical in providing complete closure of the anus, further aiding in continence. As an individual coughs, strains, or sneezes, these fibrovascular cushions engorge and maintain closure of the anal canal to prevent leakage of stool

in the presence of increased intrarectal pressure. These cushions account for approximately 15%–20% of the anal resting pressure.<sup>4</sup> Additionally, this tissue likely supplies important sensory information that enables individuals to discriminate between liquid, solid, and gas, further aiding in continence. It is essential to consider that while undertaking any treatment for hemorrhoidal disease the fibrovascular cushions are a part of normal anorectal anatomy and are important in the continence mechanism. Therefore, surgical removal may result in varying degrees of incontinence particularly in individuals with marginal preoperative control. There are three main vascular cushions that are found anatomically in health as well as in disease. The cushions are located in the left lateral, right anterior, and right posterior positions of the anus. This specific configuration has been shown in cadaver studies to be present only 19% of the time.<sup>1</sup> Most individuals have additional smaller accessory cushions present in between the main cushions. This anatomic configuration apparently bears no relationship to the terminal branching of the superior rectal artery. The position of hemorrhoids within the anal canal, however, remains remarkably consistent. The configuration of these cushions is quite constant and borne out by the fact that the same configuration can be found in children, the fetus, and even in the embryo.<sup>1</sup> The topographic location of pathology around the anus should be described in anatomic terms (anterior, posterior, right lateral, left lateral, etc.) and not by the numbers on the face of a clock. In this way, regardless of whether the patient is in a prone, supine, or lateral position, the pathology can always be accurately located.

### Etiology

Etiologic factors thought to be contributory to the pathologic changes in the vascular cushions include constipation, prolonged straining, irregular bowel habits, diarrhea, pregnancy, heredity, erect posture, absence of valves within the hemorrhoidal sinusoids, increased intraabdominal pressure with

FIGURE 11-1. Anal cushion showing Treitz's muscle derived from the conjoined longitudinal muscle of the anal canal.

obstruction of venous return, aging (deterioration of anal supporting tissues), and internal sphincter abnormalities. Patients with hemorrhoid disease have been shown to have increased anal resting pressures when compared with controls.<sup>5,6</sup> This increased resting pressure returns to normal after hemorrhoidectomy, but it is unclear whether the hemorrhoids are the cause of this increase.<sup>7</sup> Manometry also shows the presence of increased ultra slow waves in patients with hemorrhoid disease but the exact significance of this is unclear.<sup>8</sup> In pregnant women, approximately 0.2% require an urgent hemorrhoidectomy for incarcerated and prolapsed hemorrhoids.<sup>9</sup> Rigorous proof of the theories mentioned, however, is lacking. One of the most important etiologic theories is the "sliding anal cushion theory."<sup>1</sup> Thompson concluded that a sliding downward of the anal lining is responsible for the development of hemorrhoids. Repeated stretching of the anal supporting tissues (submucosal Treitz's muscle and elastic connective tissue framework) which normally functions to anchor and suspend the anal canal lining causes fragmentation of the supporting tissues and subsequent prolapse of the vascular cushions. Furthermore, straining and irregular bowel habits may be associated with engorgement of the vascular cushions making their displacement more likely. This theory is further supported by histologic studies that have shown deterioration of the anal supporting tissues by the third decade of life.<sup>10</sup> Additionally, vascular changes that seem to be associated with the development of hemorrhoids include increased arteriovenous communications, vascular hyperplasia, and increased neovascularization with increased CD105 immunoactivity.<sup>3,5,11</sup>

## Epidemiology

The reported prevalence of hemorrhoids in the United States is 4.4%, peaking between the ages of 45 and 65. Increased prevalence rates are seen in Caucasians and in individuals with higher socioeconomic status.<sup>12</sup> Whether this is secondary to differences in health-seeking behavior rather than true prevalence remains to be proven. The prevalence of hemorrhoids is reported to have decreased during the later half of the 20th century; however, this is based on population-based surveys and needs to be interpreted with caution because it reflects self-reporting of symptoms without corroboration via physical examination.<sup>13</sup>

## Classification

Hemorrhoids are divided into two types, external and internal. External hemorrhoids are located in the distal one-third of the anal canal, distal to the dentate line, and are covered by anoderm (modified squamous epithelium lacking any skin appendages) or by skin. Internal hemorrhoids are located proximal to the dentate line and are covered by columnar or transitional epithelium. Because this overlying tissue is viscerally innervated, it is not sensitive to touch, pain, or temperature, making it easily amenable to office procedures. Internal hemorrhoids are further subclassified into degrees based on size and clinical symptoms as initially reported by Banov et al.<sup>14</sup> (see Table 11-1). Mixed or combined hemorrhoids are defined as the presence of both internal and external hemorrhoids.

## Symptoms

Patients with anal complaints from whatever etiology frequently present at the office complaining of "hemorrhoids or piles." Many patients referred or coming into the office complaining of "hemorrhoids" frequently are found to have other anal problems such as pruritus ani, anal fissures, fistulas, and skin tags. A careful history and physical examination including anoscopy by an experienced individual is mandatory and will frequently lead to the correct diagnosis. The presence, quantity, frequency, and timing of bleeding and prolapse should be noted. Patients with hemorrhoid disease may complain of bleeding, mucosal protrusion, pain, mucus, discharge, difficulties with perianal hygiene, a sensation of incomplete evacuation, and cosmetic deformity.<sup>5,15</sup> A thorough dietary and medication history should also be done because certain medications, diets, and or dietary indiscretions cause or exacerbate constipation or diarrhea.

Symptoms from external hemorrhoids are usually secondary to thrombosis and physical examination shows a tender, bluish-colored lump at the anus distal to the dentate line associated with acute pain. Thrombosed external hemorrhoids can bleed secondary to pressure necrosis and subsequent

TABLE 11-1. Classification of internal hemorrhoids

	First degree	Second degree	Third degree	Fourth degree
Finding	Bulge into the lumen of the anal canal ± painless bleeding	Protrude at the time of a bowel movement and reduce spontaneously	Protrude spontaneously or with bowel movement, require manual replacement	Permanently prolapsed and irreducible

Signs	<ul style="list-style-type: none"> <li>• Bright red bleeding</li> <li>• Bleeding at end of defecation</li> <li>• Blood drips or squirts into toilet</li> <li>• Bleeding may be occult</li> </ul>	<ul style="list-style-type: none"> <li>• Bright red bleeding</li> <li>• Prolapse with defecation</li> </ul>	<ul style="list-style-type: none"> <li>• Bright red bleeding</li> <li>• Blood drips or squirts into toilet</li> <li>• Prolapsed hemorrhoids reduce manually</li> <li>• Perianal stool or mucous</li> <li>• Anemia extremely rare</li> </ul>	<ul style="list-style-type: none"> <li>• Bright red bleeding</li> <li>• Blood drips or squirts into toilet</li> <li>• Prolapsed hemorrhoids always out</li> <li>• Perianal stool or mucous</li> <li>• Anemia extremely rare</li> </ul>

ulceration of the overlying skin. External skin tags are folds of skin that arise from the anal verge. These tags may be the end result of prior episodes of thrombosed external hemorrhoids. Enlarged skin tags or external hemorrhoids may interfere with anal hygiene leading to perianal burning or pruritus.

Internal hemorrhoids are painless unless thrombosis, strangulation, gangrene, or prolapse with edema occurs. Despite what is written, patients will frequently come to the office complaining of “painful hemorrhoids” even when none of these conditions exist. Once other sources of pain are ruled out, careful inquiry regarding the description of their pain further elucidates that patients frequently describe their anal pain as “burning” in nature. This may be secondary to perianal irritation from mucous or fecal leakage leading to secondary pruritus ani. Bleeding from internal hemorrhoids is bright red and associated with bowel movements. The bleeding usually occurs at the end of defecation. The patient may complain of blood dripping or squirting into the toilet or blood on the toilet tissue. Bleeding may also be occult leading to guaiac-positive stools or rarely to anemia. Prolapse of the hemorrhoid cushions may manifest itself as an anal mass, mucous discharge, or a sensation of incomplete evacuation. The examiner should ascertain whether the hemorrhoids reduce spontaneously or require manual reduction.

## Differential Diagnosis

Because most patients that come into the office or emergency room with anal symptomatology complain of “hemorrhoids,” it is important to rule out other causes (see Table 11-2). If the patient’s main complaint is anal pain, then other diagnoses should routinely be sought unless thrombosis or prolapse of hemorrhoids is obvious. The causes of pain are almost invariably found in pathology distal to the dentate line, i.e., fissure, abscess, fistula, external hemorrhoid thrombosis, or prolapsed thrombosed internal hemorrhoids.

## Examination

After a general patient assessment, the patient is ideally examined in the prone jackknife position on a proctologic table. Patients with a history suggestive of hemorrhoid disease with an unremarkable examination in the prone jackknife position should be examined in a sitting position on the commode while asking the patient to strain. Oftentimes, pathology is uncovered when gravity assists in the examination. In patients who are unable to tolerate the jackknife position (morbidly obese, pregnant, elderly, patient with knee or hip

TABLE 11-2. Differential diagnoses

joint pathology, pulmonary disease) or when a proctologic table is not available, examination should be performed in the modified left lateral (Sims) position. The location of all anal pathology is described anatomically (anterior, posterior, left lateral, right lateral, etc.) and not by the numbers on the face of a clock. In this way, the pathology can easily be located regardless of what position the patient is in. Calmly reassure your patients at the start of the examination and routinely discuss what you are about to do before actually carrying out anal inspection, palpation, digital rectal examination, anoscopy, and proctoscopy, which should be performed on all patients if feasible.

Gentle spreading of the buttocks allows careful inspection of the squamous portion of the anal canal as well as the perianal, genital, perineal, and sacrococcygeal regions. Skin tags, external hemorrhoids, fissures, fistulas, infection, hemorrhoid prolapse, mucosal prolapse, rectal prolapse, tumors, skin lesions, thrombosis, and rashes all can be diagnosed on careful visual inspection if present. Palpation of the perianal region can localize pain, tenderness, induration, or masses. Digital examination gently performed localizes pain, masses, abscesses, and assesses sphincter tone. Anoscopy permits visualization of the anoderm and internal hemorrhoidal cushions. Anoscopy is best performed with a side-viewing anoscope especially when hemorrhoid ligation is being considered. A multi-slotted anoscope is also available and was developed to facilitate the synchronous exposure and placement of multiple hemorrhoid bands without the need to reposition the anoscope. This may offer less postligation pain and decreased need for repeat ligation in comparison to the conventional anoscope for banding.<sup>16</sup> Although the degree of prolapse may be ascertained if the patient is asked to strain, a more accurate assessment of prolapse can be made if inspection takes place while the patient is sitting and straining on a commode. Proctoscopy or flexible sigmoidoscopy must be performed when possible to assess the rectum and lower colon for neoplasms and inflammatory bowel disease.

At a minimum, all patients with anorectal complaints must undergo anoscopy, rigid proctosigmoidoscopy, and/or flexible sigmoidoscopy and further work-up depends on findings at physical examination, patient age, and history. Although patients may be too uncomfortable to undergo these procedures at the initial visit, it is important that they are performed before discharging the patient from your care. Sole reliance on a patient's description of hematochezia to make a diagnosis is inaccurate and further workup is warranted.<sup>17</sup> Practice guidelines from the American Society for Gastrointestinal Endoscopy and the Society for Surgery of the Alimentary Tract suggest, at a minimum, anoscopy and flexible sigmoidoscopy for bright-red rectal bleeding.<sup>18</sup> Total colon examination via colonoscopy or air-contrast barium enema is indicated when no source is evident on anorectal examination, the bleeding is atypical for hemorrhoids, anemia or Hemocult-positive stool is present, or significant risk factors for colonic neoplasia exist (age, family history, or personal

history of polyps).<sup>18–20</sup> Because hemorrhoids are rarely the cause of anemia (0.5 patients/100,000 population), total colon examination is indicated even in the very young patient.<sup>21,22</sup> Patients less than 40 years of age with hemorrhoid disease compatible with their symptomatology probably require no further work-up. Patients older than 40 years of age with minimal hemorrhoid disease, additional symptoms, or positive family history for colorectal cancer should undergo a total colon examination with either a colonoscopy or double contrast barium enema to identify other etiologies for bleeding that are not obvious on initial examination.

## Treatment

Treatment for symptomatic internal hemorrhoids varies from simple reassurance to operative hemorrhoidectomy. Treatments are classified into three categories: 1) dietary and lifestyle modification; 2) nonoperative/office procedures; and 3) operative hemorrhoidectomy. In general, less symptomatic hemorrhoids, such as those that cause only minor bleeding, can be treated with simple measures such as dietary modification, change in defecatory habits, or office procedures. More symptomatic hemorrhoids such as third or fourth degree are more likely to require operative intervention.

### Dietary and Lifestyle Modification

Because prolonged attempts at defecation, either secondary to constipation or diarrhea, have been implicated in the development of hemorrhoids, the main goal of this treatment is to minimize straining at stool. This is usually achieved by increasing fluid and fiber in the diet, recommending exercise, and adding supplemental fiber agents (psyllium) to the diet in patients unable to consume sufficient amounts of fiber in their diets. Despite common teaching, little good evidence exists regarding the benefit of fiber in preventing or managing hemorrhoid disease. Reduced hemorrhoidal bleeding has been shown with the use of psyllium in a double-blind, placebo controlled trial; however, other studies are less favorable.<sup>23–26</sup> Psyllium works in conjunction with water to add moisture to the stool and subsequently decrease constipation. Psyllium may also be therapeutic in treating diarrhea. It may add bulk to liquid stools therefore increasing the consistency and decreasing the volume. Dietary modification with fiber supplementation (psyllium, methylcellulose, calcium polycarbophil) is one of the mainstays of therapy for patients with hemorrhoidal disease. In the majority of cases, symptoms of bleeding and pain improve over a 6-week period. A diet high in fiber (20–35 g/day) including the consumption of plenty of fruits and vegetables is recommended especially if the patient has a history of constipation or straining. A common problem with fiber supplementation is noncompliance because of either poor palatability or symptoms of bloating, increased flatus, and abdominal cramps. Compliance is improved by

TABLE 11-3. Fiber supplements

Type of fiber	Trade name	Available fiber
Psyllium	Metamucil™	3.4 g/teaspoon
	Metamucil capsules™	0.52 g/capsule
	Konsyl™	6.0 g/teaspoon
Methylcellulose	Citrucel™	2.0 g/dose
Calcium polycarbophil	FiberCon™	0.5 g/capsule
	Konsyl fiber tablets™	0.5 g/tablet

starting at lower doses and slowly increasing the quantity of fiber ingested until the desired stool consistency is achieved. Some common fiber products currently available are listed in Table 11-3. If dietary modification fails to relieve symptoms, then further therapy is indicated (see Table 11-4).

Frequently, a change in defecatory habits will resolve symptoms. Oftentimes, simply asking an individual to curtail reading on the commode resolves the hemorrhoidal symptoms. Lifestyle and dietary modifications along with ruling out proximal sources of bleeding are all that is required for the majority of patients complaining of hemorrhoidal disease.

## Medical Therapy

Rigorous levels of evidence do not exist to support the use of topical therapies, whether physical or pharmacologic (sitz baths, anesthetics, phlebotonics, corticosteroids, or ice). Most studies have used poor methods with lack of controls, multiple associated components, and heterogeneous preparations. Therefore, firm recommendations cannot be made at the time of the writing of this chapter. Cochrane reviews on related registered Cochrane titles are listed in Table 11-5.<sup>27-29</sup>

Despite the lack of any rigorous evidence, probably the most effective topical treatment for the relief of symptoms comes in the way of warm (40°C) sitz baths. Soaking time should be limited (15 minutes) to prevent edema of the perianal and perineal skin. The application of ice packs to the anal region also may relieve symptoms and is acceptable provided that contact time is not prolonged. Pharmaceutical preparations such as creams, ointments, foams, and suppositories have little pharmacologic rationale in the management of hemorrhoidal disease. Suppositories never remain within the anal canal and usually end up in the lower rectum where they may provide an emollient effect or lubrication to the stool. Popular topical soothing agents are frequently combined with corticosteroids and or anesthetics. Although individuals may report empirical symptomatic benefit with their use, patients must be advised against prolonged use because of possible local allergic effects or sensitization of the skin.

There have been several phlebotonics that have been evaluated in the literature. Citrus bioflavonoids and related substances are widely used in Europe to treat diseases of the blood vessels and lymph system, including hemorrhoids, chronic venous insufficiency, leg ulcers, easy bruising, nosebleeds, and lymphedema after breast cancer surgery. These compounds are thought to work by strengthening the walls of blood vessels, increasing venous tone, lymphatic drainage, and normalizing capillary permeability. The major bioflavonoids found in citrus fruits are diosmin, hesperidin, rutin, naringin, tangeretin, diosmetin, narirutin, neohesperidin, nobiletin, and quercetin. Flavonoids are reported to have numerous health benefits. They are the natural pigments in fruits and vegetables. Our body cannot produce bioflavonoids. Diosmin (Daflon) is

TABLE 11-5. Registered Cochrane review titles on hemorrhoid management

Cochrane review title	Author	Primary aim
Laxatives and topical treatments for hemorrhoids <sup>27</sup>	Alonso-Coello and Lopez-Yarto <sup>27</sup>	To determine the efficacy of laxatives and topical treatments in improving the symptoms derived from symptomatic hemorrhoids
Nonoperative treatment for hemorrhoidal disease <sup>28</sup>	Thaha, Campbell, and Steele <sup>28</sup>	To determine the long-term therapeutic efficacy of various non-operative treatment methods in controlling hemorrhoidal symptoms
Phlebotonics for hemorrhoids <sup>29</sup>	Alonso, Johanson, Lopez-Yarto, <sup>29</sup> and Martinez	To determine the efficacy of phlebotonics in improving the symptoms derived from symptomatic hemorrhoids
Circular stapled anopexy versus excisional hemorrhoidectomy for the treatment of hemorrhoidal disease	Thaha, Campbell, Staines, Nyström, Steele <sup>180-182</sup>	To assess stapled anopexy with excisional methods

probably the best studied but has not been approved for use in the United States.<sup>30-32</sup> Other phlebotonics include:

*Natural products:* flavonoids;<sup>33,34</sup> rutosides<sup>35-37</sup> (troxerutin, buckwheat herb extract, *Ruscus aculeatus*), diosmine, hidrosmin, ginkgo biloba, saponosides; escin (horse chestnut seed extract).

*Synthetic products:* calcium dobesilate, naftazone, ami-naftone, chromocarbe, and others: iquinosa, flunarizine, sulfomucopolysaccharide.

Calcium dobesilate (calcium 2,5-dihydroxybenzenesulfonate) is a drug with previously demonstrated efficacy in the treatment of diabetic retinopathy and chronic venous insufficiency. These beneficial effects of the drug are related to its ability to decrease capillary permeability, platelet aggregation, and blood viscosity and to increase lymphatic transport. A randomized, double-blind, controlled study was conducted to investigate the efficacy of oral calcium dobesilate therapy in treating acute attacks of internal hemorrhoids. Twenty-nine well-documented adult patients with first- or second-degree internal hemorrhoids were treated with calcium dobesilate for 2 weeks, whereas 16 patients received only a high-fiber diet to serve as control. The symptom and anoscopic inflammation scores obtained with calcium dobesilate treatment were significantly better than those with diet only ( $P = .0017$  and  $P = .0013$ , respectively). Together with recommendations about diet and bowel discipline, oral calcium dobesilate treatment provided efficient, fast, and safe symptomatic relief from acute symptoms of hemorrhoidal disease. This symptomatic healing is associated with a significant improvement in the anoscopically observed inflammation.<sup>38</sup> Symptomatic improvement has been shown in other studies but results are not always consistent, especially when fiber is included.<sup>30-32,39</sup>

## Office Treatments

### Rubber Band Ligation

Rubber band ligation is a method of tissue fixation and one of the most widely used techniques in the United States. It can be used to treat first-, second-, and third-degree internal hemorrhoids. The most common method currently in use for the outpatient treatment for hemorrhoids was originally described by Barron<sup>40</sup> in 1963. He reported satisfactory results in 150 patients, the majority of which were treated in the outpatient setting. The rubber band is placed on the redundant mucosa a minimum of 2 cm above the dentate line which causes strangulation of the blood supply to the banded tissue, which sloughs off in 5-7 days leaving a small ulcer that heals and fixes the tissue to the underlying sphincter. Rubber band ligation is frequently recommended for individuals with first- or second-degree hemorrhoids and, in some circumstances, third-degree hemorrhoids.

Several commercially available types of hemorrhoid ligators are available including a suction ligator (McGown<sup>TM</sup>,

Pembroke Pines, FL) (see Figure 11-2A) that draws the hemorrhoid tissue into the ligating barrel via suction, and closing the handle inserts a band around the hemorrhoid.<sup>41</sup> The advantage of this ligator is that only one hand is required for placement of the band, making an assistant unnecessary for the procedure. The disadvantage of the suction ligator is that the ligating barrel is smaller than other ligators, hence less tissue is banded. With the conventional ligators, an atraumatic clamp is used to draw hemorrhoid tissue into the barrel of the ligator and a small rubber band is placed (see Figure 11-2B). A disadvantage compared with the suction ligator is that two hands are required for placement of a band necessitating an additional assistant for the procedure. An advantage is that a greater amount of excess hemorrhoid tissue can be eliminated with these ligators. Ligation of internal hemorrhoids using an endoscopic variceal ligator has been shown to be safe and reportedly controls bleeding and prolapse in approximately 95% and 90% of patients, respectively, with a major complication rate of less than 4%.<sup>42-44</sup> Malposition of bands utilizing the endoscopic ligator approach requiring their removal has been reported as high as 5% in patients.<sup>43</sup> Cost effectiveness of this endoscopic ligation procedure has not been compared with hemorrhoid banding with traditional instruments. An alternative device developed for hemorrhoid banding consists of a disposable syringe-like hemorrhoid ligator, invented to

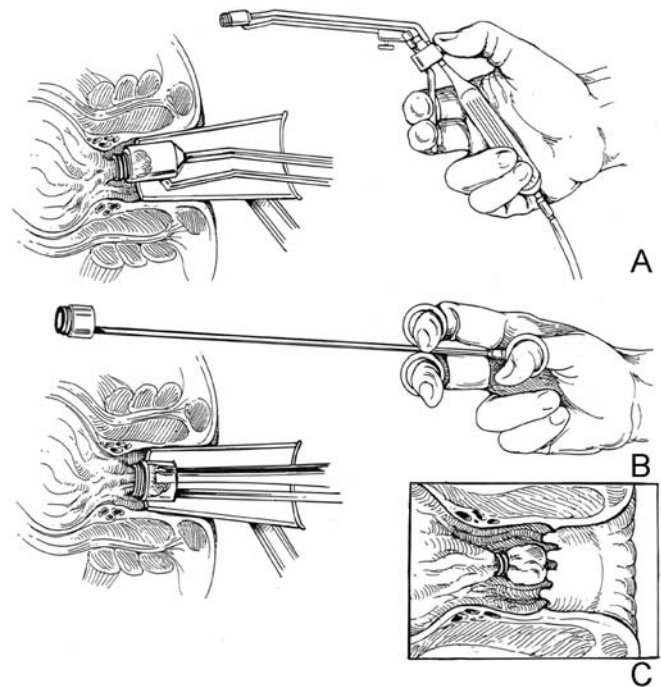

FIGURE 11-2. Banding an internal hemorrhoid. **A** The internal hemorrhoid is teased into the barrel of the ligating gun with a McGown suction ligator, or **B** a McGivney type ligator. **C** The apex of the banded hemorrhoid is well above the dentate line in order to minimize pain. (Reprinted from Beck D, Wexner S. *Fundamentals of Anorectal Surgery*. 2nd ed. Copyright 1998, with permission from Elsevier.)

simplify the banding procedure for both patient and surgeon<sup>45</sup> (see Figure 11-3). This single-operator ligator, with its own suction mechanism, was designed for use without the need of an assistant or an anoscope. By pointing the ligator directly toward the appropriate site and by measuring the distance from the anal margin using reference markings on the ligator, the bands can be placed accurately in a blind manner inside the rectum for the treatment of symptomatic internal hemorrhoids. Before the band is discharged, rotating the ligator 180

degrees while applying suction will alert the operator if the application site is not appropriate. O'Regan<sup>45</sup> reported a 97% success rate with two major complications (one episode of bleeding and one of perianal sepsis) in 480 patients.

Rubber band ligation can be performed safely with the patient in various positions; however, the prone jackknife position provides the best exposure. Anesthesia is not required for this procedure. Rectal preparation with enemas is not required but may be used if desired. A standard

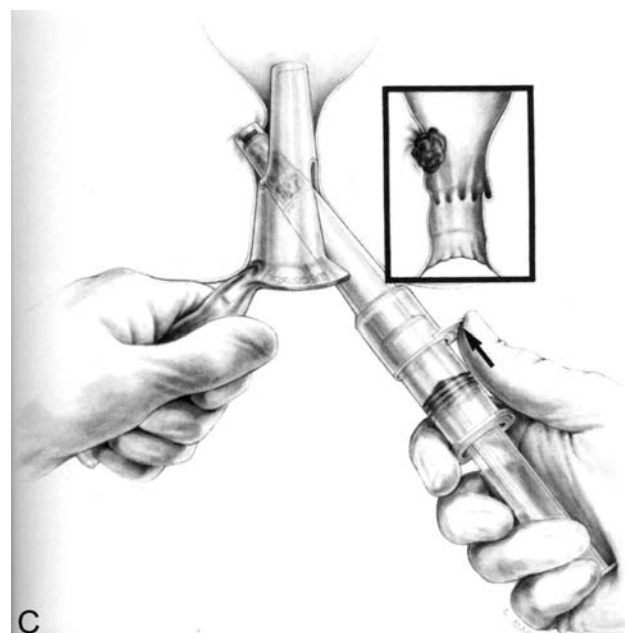

FIGURE 11-3. A O'Regan disposable banding system (Medsurge Medical Products Corp., Vancouver, Canada). B, C Technique of internal hemorrhoid ligation using the O'Regan ligating system.

commercially available ligator, good lighting, and a slotted anoscope are all that is required. The largest hemorrhoid bundle is routinely banded first. A single or double band is placed on one hemorrhoid bundle. Care is taken to place the band at least 2–3 cm above the dentate line approximately at the level of the anorectal ring or apex of the hemorrhoid. It is imperative to avoid banding too close to the dentate line or incorporating internal sphincter into the ligator because this can potentially lead to severe pain or pelvic sepsis. It has been shown that multiple hemorrhoid groups can be banded at a single session with no significant increase in morbidity when compared with single ligation.<sup>16,46–50</sup> Some surgeons prefer banding one group initially to monitor patient response and then perform multiple bandings at a subsequent session if the initial banding was well tolerated.

Patients are instructed that normal activities may be resumed immediately after banding and they may experience a feeling of incomplete evacuation or anal pressure. Approximately 5–7 days after the procedure, the banded tissue sloughs off at which time the patient may notice a small amount of bleeding. Patients should be advised to avoid aspirin or platelet-altering drugs after banding for a period of 7–10 days to minimize delayed hemorrhage; however, there is no level I evidence to support this recommendation. It is an absolute contraindication to band patients on sodium warfarin or heparin therapy because subsequent sloughing of tissue may lead to massive hemorrhage.

Complications of hemorrhoid banding include pain, thrombosis, bleeding, and life-threatening perineal or pelvic sepsis. The most common complication of rubber band ligation is pain, which is reported in 5%–60% of patients.<sup>21,48,51–53</sup> Pain is usually minor and relieved with sitz baths and analgesics. A dull, persistent ache is common for the first 1–2 days after banding. Significant anal pain is rare but is often secondary to a malpositioned rubber band placed too close to the dentate line. If the pain is experienced immediately after the banding, then the rubber band can be removed with a hooked cutting probe or hooked scissors. The subsequent development of aching pain is generally treated with sitz baths and analgesics. Constipation should be avoided during this period because it has been shown to worsen the outcome of rubber band ligation.<sup>54</sup> Rarely, hemorrhoid banding can result in thrombosis of internal and external hemorrhoids resulting in significant pain. Bleeding when it occurs is generally minor and occurs immediately after banding or 7–10 days later when the band falls off. Massive bleeding is a rare occurrence but may require operative intervention to control persistent hemorrhage. This may be minimized by having patients withhold aspirin or other nonsteroidals during the postbanding period. Other complications such as abscess, thrombosis, band slippage, priapism, and urinary dysfunction occur in less than 5% of patients.<sup>55</sup> There have been several reported cases of life-threatening perineal and/or pelvic sepsis after hemorrhoid banding.<sup>56–58</sup> This necrotizing perineal or pelvic sepsis is rare but mandates emergent attention. The triad of increasing pain,

fever, and urinary dysfunction or retention either alone or together suggests the diagnosis.<sup>59</sup> These patients require intensive care unit admission, intravenous antibiotics, emergent examination under anesthesia, and debridement of all necrotic tissue. The risk of necrotizing infection seems to be increased in individuals with immune compromised states, including patients with uncontrolled acquired immunodeficiency syndrome, neutropenia, and severe diabetes mellitus.<sup>60</sup> Although the evidence is anecdotal in nature, caution is recommended in selecting these patients for rubber band ligation treatment.

Success rates with rubber band ligation will vary depending on length of follow-up, degree treated, and criteria for success.<sup>21,49,53,61</sup> Approximately two-thirds to three-quarters of all individuals with first- and second-degree hemorrhoids respond to banding although this may need to be repeated at a later date.<sup>54,62,63</sup> More than one banding session is usually required. The majority of patients experience relief of symptoms without further treatment. As previously mentioned, hemorrhoids can be banded at a single session or at multiple sessions. A retrospective study comparing single versus multiple banding identified greater discomfort (29% versus 4.5%) and more vasovagal symptoms (12.3% versus 0%) with multiple hemorrhoids being banded at a single session.<sup>49</sup> Bat et al.<sup>55</sup> prospectively studied complications in 512 patients undergoing hemorrhoid banding. Minor complications developed in 4.6% of patients including pain, band slippage, mucosal ulcer, and priapism. Hospitalization for major complications was necessary in 2.5%, and included massive hemorrhage, severe pain, urinary retention, and perianal sepsis. Savioz et al.<sup>62</sup> investigated relapse rates after banding in 92 individuals. They found 23% of patients required repeat banding over 5 years and 32% at 10 years, and believed hemorrhoid banding to be a durable procedure. Bayer et al.<sup>64</sup> followed 2934 patients banded over a 12-year period. Seventy-nine percent required no further therapy, whereas 18% required repeat banding because of recurrence. Hemorrhoidectomy was necessary in 2.1% related to persistent symptoms.

#### *Infrared Photocoagulation, Bipolar Diathermy, and Direct-Current Electrotherapy*

These techniques rely on coagulation, obliteration, and scarring which eventually produce fixation of the hemorrhoid tissue. Infrared photocoagulation utilizes infrared radiation generated by a tungsten-halogen lamp applied onto the hemorrhoid tissue through a solid quartz light guide<sup>65</sup> (Redfield Corporation, Montvale, NJ) (see Figure 11-4). The infrared coagulator light is converted to heat which coagulates tissue protein and evaporates water from cells leading to inflammation, eschar formation, and eventual scarring which assists in fixation of the hemorrhoid group.

The amount of destruction depends on the intensity and the duration of application. The procedure is performed by applying the tip of the infrared coagulator near the apex of the

FIGURE 11-4. Infrared coagulator IRC2100™ (Redfield Corporation, Rochelle Park, NJ).

hemorrhoid for a 1.0- to 1.5-second pulse of energy. Approximately three to four applications per hemorrhoid are performed and one to three hemorrhoids undergo treatment per session.<sup>53</sup> The application of the tip to the hemorrhoid produces a 3- to 4-mm<sup>2</sup>-diameter area of coagulation with a depth of penetration of approximately 2.5 mm that ulcerates and scars in 2 weeks providing fixation of the hemorrhoid and cessation of bleeding<sup>66</sup> (see Figure 11-5). Complications are very infrequent and may include pain or fissure secondary to inappropriate placement of the tip too close to the dentate line

FIGURE 11-5. Infrared photocoagulation. The infrared photocoagulator creates a small thermal injury. Thus, several applications are required for each hemorrhoidal column. [Reprinted from Beck D. Hemorrhoids. Handbook of Colorectal Surgery. 2nd ed. Copyright 2003 by Taylor & Francis Group LLC (B). Reproduced with permission of Taylor & Francis Group LLC (B) in the format Textbook via Copyright Clearance Center.]

or bleeding caused by excessive application of the probe tip. The infrared coagulator works best with small, bleeding, first- and second-degree hemorrhoids. It has been described to be slightly less painful than rubber banding.<sup>67</sup> In three randomized trials, hemorrhoid bleeding was successfully controlled in the majority of patients with first- and second-degree hemorrhoids.<sup>53,66,67</sup>

Bipolar diathermy or coagulation (BICAP; Circon ACMI, Stamford, CT) is essentially electrocautery in which the heat does not penetrate as deeply as in monopolar coagulation.<sup>68,69</sup> The diathermy is applied in 1-second pulses at approximately 20 watts until the underlying tissue coagulates. The depth of injury is 2.2 mm and, unlike infrared photocoagulation, the depth does not increase with multiple applications at the same site which frequently is necessary.<sup>66,69</sup> First-, second-, and third-degree hemorrhoids have been treated with success rates varying from 88% to 100% whereas up to 20% of patients may need excisional hemorrhoidectomy for prolapsing tissue.<sup>21,51,66,68-70</sup>

Direct-current electrotherapy is applied through a probe placed via an anoscope onto the mucosa at the apex of the hemorrhoid. Application of the 110-volt direct current is set to the maximal tolerable level (approximately 16 mA) and then left in place for approximately 10 minutes.<sup>51,69-73</sup> Multiple treatments are required to the same site in up to 30% of patients with second- and third-degree hemorrhoids.<sup>71</sup> Adequate control of bleeding in up to 88% of patients is obtained when adequate current levels and contact time are used.<sup>51,69</sup> This technique, however, has not been widely accepted primarily because of the lengthy treatment times and limited effect in higher-degree hemorrhoids.<sup>73</sup> Reported complications include pain, ulcer formation, and bleeding.

### Sclerotherapy

This office method relies on the injection of chemical agents into hemorrhoids that create fibrosis, scarring, shrinkage, and fixation of the hemorrhoid by obliterating the vascularity with a sclerosant solution. This procedure takes minutes to perform in the office and does not require anesthesia. Frequently used agents include 5% phenol in oil, 5% quinine and urea, or hypertonic salt solution. Approximately 2-3 mL of the sclerosant is injected into the submucosa of each hemorrhoid bundle at least 1 cm proximal to the dentate line with a 25-gauge spinal needle or specialized hemorrhoid needle (Gabriel). Care should be taken to avoid intramucosal or intramuscular injection in order to prevent mucosal sloughing with ulceration or excessive pain, respectively. Sclerotherapy should not be performed in the face of anorectal infection or with prolapsed thrombosed hemorrhoids. Sclerotherapy can be used in patients on long- or short-term anticoagulation. Repetitive sclerotherapy should be used with caution because of the potential of scarring and stricture formation. Complications are infrequent and usually related to incorrect placement of the sclerosant.<sup>53,74</sup> Rarely, a patient may develop

impotence, urinary symptoms, or an abscess secondary to a misplaced injection or granulomatous reaction to the oil-based sclerosant.<sup>75</sup> Sclerotherapy works best for first- and second-degree hemorrhoids. Walker et al.<sup>53</sup> reported a 30% recurrence rate of symptoms 4 years after initial successful injection. Khoury et al.<sup>76</sup> performed a prospective, randomized study in 120 consecutive patients looking at single versus multiple phenol injections for the treatment of hemorrhoids in patients who have had prior medical therapy. Results from that study showed that injection sclerotherapy, whether single or multiple, is an effective form of therapy for patients with first- or second-degree hemorrhoids with improvement or cure in almost 90% of patients.<sup>76</sup> Another randomized, prospective study, however, showed no difference in bleeding rates at 6 months follow-up when comparing sclerotherapy plus bulk laxative to bulk laxative alone.<sup>77</sup>

### *Anal Dilatation or Stretch*

This method of treating hemorrhoids by manual dilatation of the anus was reported and popularized by Lord in 1968.<sup>78</sup> Although it has had its proponents, primarily in European countries, subsequent reports have shown endosonographic evidence of sphincter injury as well as high rates of associated incontinence especially with long-term follow-up.<sup>79-81</sup> In addition to its higher failure rate in comparison to surgical hemorrhoidectomy, and because of the risk of incontinence, most authorities advocate abandoning this approach for the treatment of hemorrhoids.<sup>81,82</sup>

### *Cryotherapy*

Cryotherapy is based on the concept that freezing the internal hemorrhoid at low temperatures can lead to tissue destruction. A special probe is required through which nitrous oxide at  $-60^{\circ}$  to  $-80^{\circ}\text{C}$  or liquid nitrogen at  $-196^{\circ}\text{C}$  is circulated. Initial enthusiasm with cryotherapy essentially has disappeared because of very disappointing results. The procedure is time consuming and associated with a foul-smelling profuse discharge, irritation, and pain.<sup>83-85</sup> Furthermore, improper application can lead to anal stenosis and or incontinence from sphincter destruction. The procedure should no longer be recommended for the treatment of internal hemorrhoids.

## External Hemorrhoids

### *Acute Thrombosis*

Patients with a thrombosed external hemorrhoid typically present with complaints of a painful mass in the perianal region. The pain is frequently described as burning in nature. The pain associated with the abrupt onset of an anal mass usually peaks at around 48 hours and subsides significantly after the fourth day (see Figure 11-6). The skin overlying the thrombosed hemorrhoid may necrose and ulcerate, resulting in bleeding, discharge, or infection.

FIGURE 11-6. Timing of excision of a thrombosed external hemorrhoid.

Treatment should be aimed at relief of pain. The management will depend, therefore, on the patient's symptoms at the time seen. If the pain is intense, then excision of the thrombosed external hemorrhoid should be offered. If the pain is subsiding, then conservative nonoperative management is warranted. Nonoperative treatment consists of warm sitz baths, nonconstipating analgesics, and bulk-producing fiber supplements. Anoscopy and proctoscopy to rule out associated anorectal disease are postponed to a later date when the patient is not in acute pain.

The operative treatment of a thrombosed external hemorrhoid demands excision of the entire thrombus. This can be done in the clinic, office, or emergency room under local anesthesia (0.5% lidocaine mixed with equal amounts of 0.25% bupivacaine containing 1:200,000 epinephrine). The overlying skin and surrounding area are prepped with Betadine swabs or alcohol and then anesthetized. A small radial elliptical incision is performed directly over the thrombosed hemorrhoid and the thrombus is excised in total with the aid of a fine scissors and forceps. Hemostasis is obtained with either Monsel's solution (ferric subsulfate) on cotton-tipped applicator or with silver nitrate. Although the skin edges can be reapproximated loosely with absorbable sutures, leaving the wounds open to heal by secondary intention gives greater assurance that rethrombosis will not occur in the same location. Postoperatively the patients are given a prescription for analgesics, instructed to take warm sitz baths two to three times daily, and to take bulk-producing fiber supplements.

### Operative Hemorrhoidectomy

Hemorrhoidectomy is indicated for patients with symptomatic combined internal and external hemorrhoids who have failed or are not candidates for nonoperative treatments. This would include patients with extensive disease, patients with

FIGURE 11-7. Open (Milligan-Morgan) hemorrhoidectomy. **A** External hemorrhoids grasped with forceps and retracted outward. **B** Internal hemorrhoids grasped with forceps and retracted outward with external hemorrhoids. **C** External skin and hemorrhoid excised with scissors. **D** Suture placed through proximal internal hemorrhoid and vascular bundle. **E** Ligature tied. **F** Tissue distal to ligature is excised. Insert depicts completed three bundle hemorrhoidectomy.

concomitant conditions such as fissure or fistula, and patients with a preference for operative therapy. Only about 5%–10% of patients need surgical hemorrhoidectomy.<sup>15,86</sup> Recurrence with operative hemorrhoidectomy is uncommon and hemorrhoidectomy is the most effective treatment for hemorrhoids, especially those that are third degree.<sup>87,88</sup> Hemorrhoidectomy can be performed using a variety of techniques or instruments; however, most are variants of either a closed or open technique.<sup>89,90</sup> The Milligan-Morgan technique (open) is widely used in the United Kingdom (Figure 11-7). It involves excision of the external and internal hemorrhoid components leaving the skin defects open to heal by secondary intention over a 4- to 8-week period.<sup>90</sup> The Ferguson hemorrhoidectomy (closed) involves excision of the external and internal hemorrhoid components with closure of the skin defects primarily (Figure 11-8).<sup>89</sup>

Circular excision of the internal hemorrhoids and prolapsing rectal mucosa proximal to the dentate line has also been

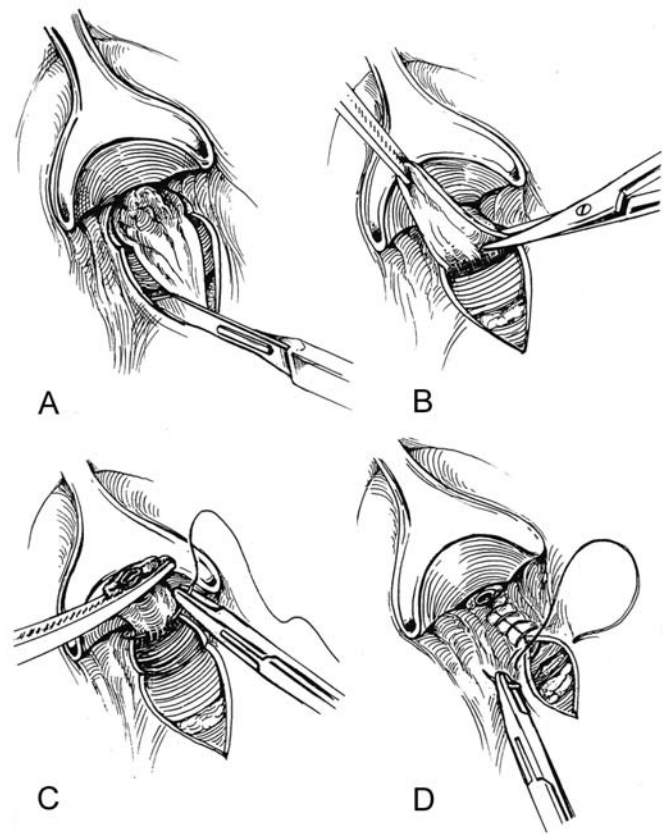

FIGURE 11-8. Modified Ferguson excisional hemorrhoidectomy. **A** Double elliptical incision made in mucosa and anoderm around hemorrhoidal bundle with a scalpel. **B** The hemorrhoid dissection is carefully continued cephalad by dissecting the sphincter away from the hemorrhoid. **C** After dissection of the hemorrhoid to its pedicle, it is either clamped, secured, or excised. The pedicle is suture ligated. **D** The wound is closed with a running stitch. Excessive traction on the suture is avoided to prevent forming dog ears or displacing the anoderm caudally.

described for the surgical management of hemorrhoids (Whitehead procedure, Figure 11-9).<sup>91–94</sup> This technique involves circumferential excision of hemorrhoidal veins and mucosa beginning at the dentate line and proceeding proximally. It was used often in Great Britain but has fallen out of favor. It is rarely used in the United States because of technical difficulties and the potential for ectropion but has attracted the attention of some surgeons using a modification of the original technique.<sup>93,95</sup>

Table 11-6 lists four randomized prospective studies comparing open versus closed hemorrhoidectomy.<sup>96–99</sup> The majority of trials showed no difference in pain, analgesic use, hospital stay, and complications, whereas complete wound healing shows mixed results. There essentially seems to be no difference in both techniques and, therefore, recommendations for either should be based on surgeon experience and patient preference.

One of the most significant obstacles to patients seeking surgical management of their hemorrhoids is postoperative pain. Narcotics are often required to control pain and patients are frequently not back to their usual activities including work for 2–4 weeks.<sup>100–103</sup> A number of trials have looked at results with a variety of different excision techniques including scissors, diathermy, laser, bipolar diathermy (LigaSure™; Valleylab, Boulder, CO), and the ultrasonically activated scalpel.<sup>104–117</sup> Although some of these newer instruments have come into vogue for performing operative hemorrhoidectomy such as the Harmonic Scalpel® or LigaSure™ device, no long-term results have been published utilizing these modalities<sup>104,105,113</sup> (see Tables 11-7 and 11-8). Furthermore, the additional costs accrued through the use of this equipment and the lack of documented superior results with these techniques precludes recommendation for routine use. The majority of randomized trials have shown no difference between diathermy or scissor excision hemorrhoidectomy<sup>106,116,117</sup> (see Table 11-7). Laser hemorrhoidectomy was initially suggested to be associated with decreased postoperative pain; however, a randomized trial comparing Nd:YAG laser versus cold scalpel did not detect any difference.<sup>107–109</sup> Furthermore, the trial reported increased costs and decreased wound healing with use of the laser.<sup>109</sup>

Other strategies or procedures developed in an attempt to reduce postoperative pain include use of limited incisions, suturing the vascular pedicle without any incisions, performing a concomitant lateral internal sphincterotomy, use of metronidazole, using anal sphincter relaxants, injecting local anesthetics, using anxiolytics, and parasympathomimetics. All these strategies, however, have had mixed results and therefore cannot be recommended for routine use.<sup>118–127</sup>

Complications associated with hemorrhoidectomy include urinary retention (2%–36%), bleeding (0.03%–6%), anal stenosis (0%–6%), infection (0.5%–5.5%), and incontinence (2%–12%).<sup>86,107,109,128–134</sup>

Another method recently developed to reduce pain and treat hemorrhoidal disease has recently come into favor. Over the past 6–7 years, stapled “hemorrhoidectomy” has been developed as an alternative to standard Ferguson or Milligan-Morgan hemorrhoidectomy mainly because of the pain associated with traditional hemorrhoid surgery. It was first alluded to by Pescatori et al.<sup>135</sup> for mucosal prolapse but refined by Longo<sup>136</sup> using a specially developed circular stapling device (see Figure 11-10). The procedure involves the use of a specially designed circular stapler (Ethicon Endo-Surgery), which performs a circumferential resection of mucosa and submucosa above the hemorrhoids and then staples closed the

Excision started at dentate line and continued to proximal bundle. **B** Internal hemorrhoidal tissue excised above ligated bundle. **C** Vascular tissue excised from underside of elevated anoderm. **D** End of anoderm reapproximated with sutures to original location of dentate line. **E** Completed procedure.

defect (see Figure 11-11). This procedure is more of a hemorrhoidopexy than a hemorrhoidectomy and is also known by other names (stapled anopexy, stapled prolapsectomy, stapled circumferential mucosectomy). None of the hemorrhoids are necessarily removed by this procedure, rather they are simply returned to their physiologic position. The preservation of the

anal cushions within the anal canal may in fact contribute to the low rate of incontinence after this operation. This procedure can be used for patients with all degrees of hemorrhoids, however is best reserved for patients with second- and third-degree hemorrhoids that do not respond to banding and fourth-degree hemorrhoids that are reducible under anesthesia.<sup>137</sup> The cost and anesthetic risks do not make stapling a practical option for grade 1 and 2 disease, which should continue to be treated with traditional methods. The stapling

device cuts and staples well above the dentate line, therefore postoperative pain is minimal, and usually absent. The stapling procedure does not create any external wounds.

A number of randomized, controlled trials comparing stapled hemorrhoidopexy with conventional hemorrhoidectomy have been published as well as reviewed and are listed in Table 11-9.<sup>100-103,138-149</sup> Cochrane review on a registered Cochrane title comparing stapled anopecty with excisional methods is pending. The majority of studies show that stapled

hemorrhoidopexy is less painful, and allows earlier return to work compared with conventional hemorrhoidectomy. A systematic review of stapled hemorrhoidopexy concluded that the procedure was as safe as conventional hemorrhoidectomy and was associated with shorter operative time, convalescence, and postoperative disability.<sup>150</sup> Senagore et al.<sup>149</sup> reported results from a U.S. multicenter, randomized, prospective study on stapled anopexy versus Ferguson hemorrhoidectomy at the American Society of Colon and Rectal Surgeons annual meeting in 2003. The results showed less pain, less pain at bowel movement, less analgesic use, and fewer re-treatments, with similar symptom control in comparison to Ferguson hemorrhoidectomy. Despite these early encouraging results and safety profile, several serious complications have been reported including rectal perforation,

retroperitoneal sepsis, and pelvic sepsis.<sup>151,152</sup> Other studies have indicated the presence of smooth muscle fibers in the excised specimens as well as a 14% incidence of internal sphincter fragmentation in those procedures in which the standard 37-mm anal dilator is used.<sup>153,154</sup> What long-term sequelae this may have remains to be seen.

The main complication of the procedure is bleeding from the staple line, which can be easily controlled by oversewing the bleeding point on the staple line.<sup>155</sup> With the second generation 33-mm hemorrhoidal circular stapler (Ethicon Endo-Surgery; PPH03) and a closed staple height of 0.75 mm, bleeding has been markedly decreased. One other disadvantage of the stapling procedure is that it does not address fibrotic external hemorrhoids or additional anorectal pathology such as fissures or skin tags.

## Stapling Technique

The stapling procedure can be done with the patient in the prone jackknife, lithotomy, or left lateral position while under local, spinal, or general anesthesia. A circular anal dilator is introduced into the anal canal, which reduces the prolapsed tissues. The obturator is removed, and the prolapsed tissue falls into the lumen of the dilator. A circumferential pursestring suture is placed 4–6 cm above the dentate line into the submucosa. The circular stapler is opened and the head is introduced proximal to the pursestring. The pursestring suture is tied and the suture threader is used to pull the free ends of the pursestring suture through a pair of holes on the lateral sides of the stapler. Traction is applied to the pursestring while the stapler is being closed, which causes the prolapsed mucosa and some hemorrhoidal tissue to be drawn into the casing. The stapler is fully tightened and then fired. The instrument should be left closed for 20 seconds after firing to enhance hemostasis. The staple line should be carefully examined for hemostasis and any bleeding areas should be oversewn. Anoscopic examination will reveal persistent internal hemorrhoids. It is important to remember that this technique does not completely excise the hemorrhoids; rather, it returns the tissues to their physiologic location. The circular specimen will contain the excised tissue and the pursestring suture.

## Strangulated Hemorrhoids

Strangulated hemorrhoids arise from prolapsed third- or fourth-degree hemorrhoids that become incarcerated and irreducible because of prolonged swelling. Patients usually have a long-standing history of prolapse and may present with complaints of severe pain and urinary retention. Examination shows a rosette of thrombosed external hemorrhoids and prolapsed incarcerated internal hemorrhoids with marked edema. This can progress to subsequent ulceration and necrosis if left untreated.

Treatment usually consists of urgent or emergent hemorrhoidectomy in an operating room. An open or closed technique can be performed unless tissues are necrotic in which case the open technique should be performed. Emergency hemorrhoidectomy in the presence of strangulation and necrosis is safe provided all necrosis is excised.<sup>134</sup>

An alternative treatment that can be performed in the office or emergency department setting consists of locally anesthetizing the area, collapsing the tissues via massage, reducing the internal hemorrhoids and performing multiple external thrombectomies, and multiple rubber band ligations. This can provide immediate relief and future hemorrhoidectomy is seldom needed.<sup>156</sup> A randomized trial comparing open hemorrhoidectomy versus incision and ligation for acute hemorrhoidal disease showed both techniques to be safe and with a trend toward earlier recovery from the incision ligation technique.<sup>156</sup>

## Hemorrhoids, Varices, and Portal Hypertension

The etiology of “hemorrhoids” in patients with portal hypertension must be distinguished from anorectal varices especially when bleeding is present. The upper anal canal (internal hemorrhoids) is drained by the middle rectal vein which drains into the iliac veins and subsequently into the systemic circulation. The inferior rectal veins drain the lower part of the anal canal (external hemorrhoids) into the internal iliac veins. Anorectal varices essentially provide a collateral pathway to decompress the portal system into the systemic circulation. Despite this communication between the portal and systemic systems, the incidence of hemorrhoidal disease in patients with portal hypertension is no greater than in the general population.<sup>157–159</sup>

Chawla and Dilawari<sup>160</sup> observed anorectal varices endoscopically in approximately 78% of their patients. Hosking et al.<sup>157</sup> observed varices in 59% of cirrhotic patients with portal hypertension. Hence, anorectal varices are actually quite common in patients with portal hypertension. However, unlike esophageal varices, anorectal varices rarely bleed and are implicated in less than 1% of massive bleeding episodes in patients with portal hypertension.<sup>161</sup> Nevertheless, bleeding from anorectal varices has been reported and may be continuous or intermittent and massive. Treatment of bleeding from anorectal varices has included a conservative medical management, direct suture ligation,<sup>162</sup> stapled anopexy,<sup>163</sup> transjugular intrahepatic portosystemic shunt,<sup>164–166</sup> ligation of the inferior mesenteric vein,<sup>167</sup> inferior mesocaval shunt,<sup>168</sup> inferior mesorectal vein shunt,<sup>169</sup> sigmoid venous to ovarian vein shunt.<sup>170</sup>

## Hemorrhoids in Pregnancy

Although hemorrhoidal symptoms often occur and are exacerbated during pregnancy, the majority that intensify during delivery usually resolve. Hemorrhoidectomy during pregnancy should only be offered for acutely thrombosed and prolapsed hemorrhoidal disease. If required, the procedure should be performed under local anesthesia with the patient in the left anterolateral position to rotate the uterus off the inferior vena cava.<sup>9,171</sup>

## Hemorrhoids and Crohn's Disease

Crohn's disease of the intestine in and of itself is not an absolute contraindication to hemorrhoidectomy. However, extreme caution and careful patient selection are warranted. In a study published from St. Mark's hospital, the rate of severe complications was high.<sup>172</sup> Approximately 30% of their Crohn's patients treated for hemorrhoids required a proctectomy for complications possibly related to the treatment. In contrast, Wolkowicz and Luchtefeld<sup>173</sup> reported a 2-month healing rate of almost 90% in Crohn's patients with

quiescent ileal or colonic disease undergoing hemorrhoidectomy. Nevertheless, hemorrhoidectomy in patients with anorectal Crohn's disease or Crohn's proctitis should not be performed because of a substantially increased risk of local complications and subsequent need for proctectomy.<sup>172</sup>

## Hemorrhoids and the Immunocompromised

Management of hemorrhoidal disease in the immunocompromised patient is challenging and fraught with difficulties secondary to poor wound healing and infectious complications. Although it does not appear that surgery increases the mortality in patients with hematologic malignancies (leukemia, lymphoma), hemorrhoidectomy should be performed as a last resort to relieve pain and sepsis.<sup>174</sup> Stapled hemorrhoidopexy may offer an alternative to excisional hemorrhoidectomy, avoiding external wounds and hence problems with wound healing; however, data in this group of patients are anecdotal at best. Although infection with the human immunodeficiency virus is not a contraindication to hemorrhoidectomy, it cannot be recommended for patients with the acquired immunodeficiency syndrome because of increased complications.<sup>175</sup>

## Posthemorrhoidectomy Hemorrhage

Severe hemorrhage after hemorrhoidectomy is a rare complication occurring in approximately 2% (0.6%–5.4%) of patients.<sup>176,177</sup> Traditionally, sepsis of the ligated pedicle has been considered an important etiological factor, although this has been challenged by a recent study by Chen et al.<sup>178</sup> who found male patients and operating surgeon as risk factors. The majority of patients will respond to packing or tamponade with a Foley catheter balloon. Approximately 15%–20% of patients may need suture ligation to control the postoperative bleed. Initial rectal irrigation has been suggested as a technique to separate patients that have stopped bleeding from those that need to go to the operating room.<sup>179</sup> Another helpful technique is to irrigate the rectum free of clots and blood at the initial hemorrhoid operation, to prevent postoperative passage of old clots that could cause clinical confusion.

## Appendix: Practice Parameters for Ambulatory Anorectal Surgery

Prepared by The Standards Task Force, The American Society of Colon and Rectal Surgeons

Drs. Ronald Place and Neal Hyman, Project Coordinators; Clifford Simmang, Committee Chairman; Peter Cataldo; James Church; Jeff Cohen; Frederick Denstman; John Kilkenny; Juan Noguerras; Charles Orsay; Daniel Otchy; Jan Rakinic; Joe Tjandra

## Ambulatory Facilities

*Anorectal Surgery May Be Safely and Cost-Effectively Performed in an Ambulatory Surgery Center.*

*Level of Evidence—Class III (Appendix A).* It has been estimated that 90% of anorectal cases may be suitable for ambulatory surgery. A wide variety of anorectal conditions including condylomata, fissures, abscesses, fistulas, tumors, hemorrhoids, pilonidal disease, and various miscellaneous conditions have been shown to be amenable to surgery on an outpatient basis. An admission rate of 2% has been reported. A reduction in hospital charges of 25%–50% has also been noted.

*Patients with American Society of Anesthesiology (ASA) Classifications I and II Are Generally Considered Suitable Candidates for Outpatient Anorectal Surgery (Appendix B). Selected ASA Category III Patients May Also Be Appropriate Candidates.*

*Level of Evidence—Class III.* Multiple factors must be considered in determining the appropriateness of performing anorectal surgery in the ambulatory setting. The ASA physical status classification is useful to determine the risk of anesthesia. The magnitude of the proposed surgery, type of anesthesia, availability of appropriate instrumentation, ability of the patient to follow instructions, distance of the patient's home from the surgical center, and home support structure all need to be considered.

## Preoperative Evaluation

*Preoperative Investigations (e.g., Laboratory Studies and Electrocardiograms) Should Be Dictated by History and Physical Examination.*

*Level of Evidence—Class III.* Multiple studies have documented that patient history and physical examination are the key elements of an appropriate preoperative evaluation. Routine preoperative investigations that are not warranted on the basis of history and physical seem to provide little further information. There is clear evidence that nonselective preoperative screening yields few abnormal results.

One study of 1200 patients undergoing ambulatory surgery revealed that the vast majority of abnormalities could have been predicted by history and physical examination. These abnormalities did not predict perioperative complications or the need for hospital admission. A separate study of 1109 patients undergoing elective surgery revealed that 47% of laboratory investigations duplicated tests performed within the previous year. Meaningful changes in the repeat laboratory values were very rare. Such abnormalities were predictable by the patient's history. A further study of 5003 preoperative screening tests revealed 225 abnormal results. Only 104 were of potential importance and the abnormality caused action in only 17 cases. It was believed that only four patients could have had a conceivable benefit from their preoperative screening test.

Similar studies have been performed to investigate the value of specific tests. A study of 12,338 patients undergoing invasive procedures was performed to examine the value of determining activated partial thromboplastin time as a routine. Ninety-two percent of the patients were believed to be at low risk (there were no clinical factors to suggest the bleeding tendency). In these patients, it was shown that no information was gained from activated partial thromboplastin time, and therefore, clotting studies had no role as a screening test in asymptomatic patients. Similarly, routine cardiac workup seems unjustified. The risk of a perioperative myocardial infarction in patients without clinical evidence of heart disease is 0.15%. This risk increases significantly in patients who had a previous myocardial infarction. History and physical examination are the cornerstones of appropriate preoperative evaluation.

## Intraoperative Considerations

*Most Anorectal Surgery May Be Safely and Cost-Effectively Performed Under Local Anesthesia; Regional or General Anesthesia May Be Used Depending on Patient or Physician Preference.*

*Level of Evidence—III.* The use of local anesthetics such as monitored anesthetic care for anorectal surgery is safer and has fewer complications than other anesthetic techniques. Perianal infiltration of local anesthetics is a simple procedure that is easily learned. Injection of the local anesthetics can be accomplished in less than 5 minutes and the operation begun immediately. However, the anesthetic technique used for any procedure should be the one that provides for maximal safety and efficacy.

## Postoperative Considerations

*Anorectal Surgery Patients May Safely Be Discharged from the Postanesthesia Care Unit.*

*Level of Evidence—II.* The time course for recovery from anesthesia includes early recovery, intermediate recovery, and late recovery. Early recovery is the time interval for anesthesia emergence and recovery of protective reflexes and motor activity. The Aldrete score has been used for 30 years to determine release from phase 1 (early) recovery to a hospital bed or phase 2 (intermediate) recovery. Intermediate recovery is the period during which coordination and physiology normalize to an extent that the patient can be discharged from phase 2 recovery in a state of “home readiness” and be able to return home in the care of a responsible adult. The Post-Anesthetic Discharge Scoring System has been shown to be efficacious for discharge.

*Multiple Modalities May Be Used to Achieve Adequate Postoperative Pain Control.*

*Level of Evidence—II.* If local anesthetics are not used as the primary anesthetic technique, their use will provide

TABLE 11-A1. Levels of evidence

Level I: Evidence from properly conducted randomized, controlled trials.
Level II: Evidence from controlled trials without randomization, or cohort or case-control studies, or multiple times series, dramatic uncontrolled experiments.
Level III: Descriptive case series or opinions of expert panels.

TABLE 11-A2. ASA physical status classification

Class I: Patient has no systemic disturbance (e.g., healthy, no medical problems).
Class II: Patient has mild to moderate systemic disturbance (e.g., hypertension, diabetes).
Class III: Patient has severe systemic disturbance (e.g., heart disease that limits activity).
Class IV: Patient has severe systemic disturbance that is life-threatening (e.g., unstable angina, active congestive heart failure).
Class V: Patient is moribund and has little chance of survival (e.g., ruptured abdominal aortic aneurysm).

prolonged postoperative analgesia. Oral narcotics may be used as primary postoperative analgesia. The use of nonsteroidal antiinflammatory drugs, particularly intramuscular or intravenous Toradol® (Roche Pharmaceuticals, Nutley, NJ) or sulindac suppositories has also shown improved analgesia, lower narcotic usage, and lower rates of urinary retention. Although the effect is unknown, oral metronidazole shows improved postoperative pain control.

*Postoperative Urinary Retention Can Be Reduced by Limiting Perioperative Fluid Intake.*

*Level of Evidence—III.* Multiple studies have shown that limiting perioperative fluid lowers the incidence of postoperative urinary retention. These same studies show conflicting evidence over the relationship between gender, age, and the quantity of narcotic medication and urinary retention. Hemorrhoidectomy and the performance of multiple anorectal procedures have higher rates of urinary retention.

*Postoperative Education Should Include Recommendations for Sitz Baths, Fluid Intake, and Activity Limitations.*

*Level of Evidence—III.* Textbooks of anorectal surgery advocate consistent instructions before discharge from ambulatory surgery. Although derived from common sense, scientific justification does not exist. With appropriate communication, ambulatory anorectal surgery may be performed with a high degree of patient satisfaction.

## Benign Anorectal: Anal Fissure

Sharon L. Dykes and Robert D. Madoff

### Epidemiology

An anal fissure, or fissure-in-ano, is an oval, ulcer-like, longitudinal tear in the anal canal, distal to the dentate line. Although the exact incidence is unknown, it is a common disorder, with equal gender distribution. Fissures can occur at any age, but are usually seen in younger and middle-aged adults. In almost 90% of cases, fissures are identified in the posterior midline, but can be seen in the anterior midline in up to 25% of affected women and 8% of affected men. An additional 3% of patients have both anterior and posterior fissures. Fissures occurring in lateral positions should raise suspicions for other disease processes, such as Crohn's disease, tuberculosis, syphilis, human immunodeficiency virus (HIV)/ acquired immunodeficiency syndrome (AIDS), or anal carcinoma (Figure 12-1).

Early, or acute, fissures have the appearance of a simple tear in the anoderm, whereas chronic fissures, defined by symptoms lasting more than 8–12 weeks, are further characterized by edema and fibrosis. Typical inflammatory manifestations of chronic fissures include a sentinel pile, or skin tag, at the distal fissure margin and a hypertrophied anal papilla proximal to the fissure in the anal canal. In addition, fibers of the internal anal sphincter (IAS) are often visible at the fissure base.

### Etiology

The cause of anal fissure has been long debated. Trauma to the anal canal secondary to the passage of a hard stool is believed to be a common initiating factor. A history of constipation is not universally obtained, however, and some patients report an episode of diarrhea before the onset of symptoms.

The persistence of a fissure after any initiating event is associated with increased resting anal pressure—an observation first reported in the mid-1970s.<sup>1,2</sup> Physiologic studies using ambulatory manometry have confirmed the presence of sustained resting hypertonia in fissure patients.<sup>3</sup> Further observations have delineated an inverse relationship between

anal canal pressure and perfusion of the anoderm. Ischemia was initially proposed as an instigator of fissure persistence by Gibbons and Read<sup>4</sup> in 1986. Later support was provided by angiographic studies of the inferior rectal artery in cadavers, which demonstrated a paucity of blood vessels in the posterior midline of the anal canal in 85% of those examined.<sup>5</sup> Schouten et al.<sup>6</sup> measured anodermal blood flow in healthy individuals using Doppler laser flowmetry, and found that the posterior midline had the lowest perfusion when compared with the other three quadrants. In addition, there was a significant inverse correlation between posterior midline anodermal blood flow and maximum resting anal pressure in a large cohort of patients that included normal controls and fissure patients. Those with fissures demonstrated the highest resting anal pressures and the lowest posterior blood flow of any group. Improvement in posterior midline blood flow was noted to occur after reduction of anal pressure with anesthesia. These same authors were able to demonstrate normalization of sphincter hypertonia and anodermal blood flow after lateral internal sphincterotomy (LIS) in anal fissure patients.

### Symptoms

The clinical hallmark of an anal fissure is pain during, and particularly after, defecation. In acute fissures, pain may be short-lived, but it can last several hours or even all day in the presence of a chronic fissure. The pain is frequently described as passing razor blades or glass shards. Understandably, patients with anal fissures may often fear bowel movements. Rectal bleeding, although not uncommon, is usually limited to minimal bright red blood seen on the toilet tissue.

### Diagnosis

Diagnosis is suggested by patient history and confirmed by physical examination. Most fissures are readily visible by simply spreading the buttocks with opposing traction of the

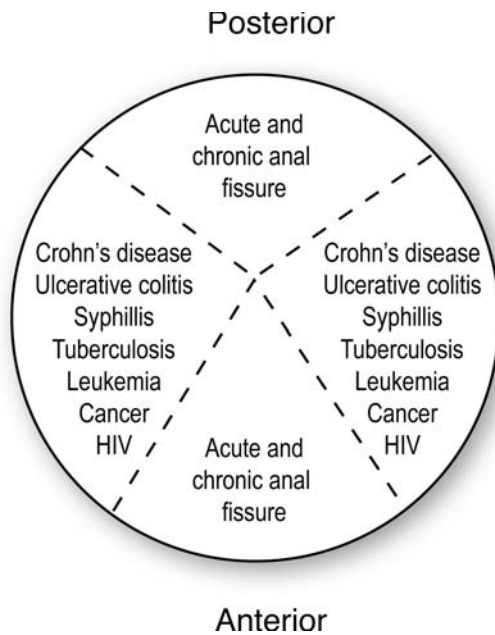

FIGURE 12-1. The location of anal fissure suggests their cause.

thumbs (Figure 12-2). Once the presence of a fissure is verified, further attempt to examine the anal canal with insertion of a finger or endoscopic instrumentation (anoscopy or proctoscopy) is not appropriate. Most patients are far too tender to justify such invasive evaluation, which should be delayed or deferred until symptoms have resolved.

Fissures may be frequently misdiagnosed as hemorrhoids by primary care providers. The differential diagnosis includes perianal abscess, anal fistula, inflammatory bowel disease, sexually transmitted disease, tuberculosis, leukemia, and anal carcinoma. Atypical fissures, such as those occurring off the midline, multiple, painless, and nonhealing fissures, warrant

FIGURE 12-2. Examination revealing an anal fissure.

further evaluation, via examination under anesthesia and possible biopsy and cultures.

## Management

### Conservative

Almost half of all patients diagnosed with an acute fissure will heal with conservative measures, i.e., sitz baths and psyllium fiber supplementation, with or without the addition of topical anesthetics or anti-inflammatory ointments. In a retrospective review, Shub et al.<sup>7</sup> were able to demonstrate healing in 44% of fissure patients using psyllium fiber, sitz baths, and emollient suppositories. During a 5-year follow-up period, there were treatment failures in 27% of patients initially reported as healed. A second retrospective review almost 20 years later demonstrated similar findings. Hananel and Gordon<sup>8</sup> reported initial healing in 44% and recurrence in 18.6% of their fissure patients. Therapy consisted of bulking agents and sitz baths.

Jensen<sup>9</sup> has conducted two randomized, controlled trials examining the effects of unprocessed bran in both initial treatment and maintenance therapy of acute fissures. In the first, 103 patients with acute posterior anal fissures were randomized to receive lignocaine ointment (33), hydrocortisone ointment (35), or sitz baths and unprocessed bran (35) for 3 weeks, with symptomatic relief and fissure healing as endpoints. After weeks 1 and 2, patients treated with sitz baths and bran were found to have significant improvement in symptomatic relief as compared with the other two groups. By the 3-week endpoint, there was no symptomatic difference between the three groups; however, healed fissures occurred most frequently in the bran/sitz bath group (87%), when compared with patients receiving hydrocortisone (82.4%) or lignocaine (60%). In a double-blind, placebo-controlled trial, fissure recurrence was measured after 1 year in three groups. Significantly fewer recurrences (16%) were seen in patients receiving 15 g of unprocessed bran daily, when compared with 60% of patients receiving 7.5 g daily or 68% of patients on placebo.<sup>10</sup>

### Operative Treatment

The primary goal in the treatment of a nonhealing anal fissure is to decrease abnormally elevated resting anal tone. Operative procedures, such as manual anal dilatation or internal sphincterotomy, have been advocated as initial modes of treatment because they produce permanent reductions in maximum resting anal pressures.

#### *Anal Dilatation*

Manual dilatation of the anus for anal fissure was first reported in 1964.<sup>11</sup> Ensuing endorsements have described a variety of means to enlarge the anal canal, such as the “four-finger method” and an assortment of instrumentation,

including rectal dilators and retractors. Inconsistencies with regard to technique, specifically extent and duration of sphincter stretch, have cast some doubt about true success rates of this procedure. Reports as recent as 1995, however, support the use of gentle anal dilatation as a “first management choice in the treatment of anal fissure.”<sup>12–15</sup> In 1992, Sohn et al.<sup>16</sup> standardized the extent of anal dilatation using either a Parks’ retractor opened to 4.8 cm or a pneumatic balloon inflated to 40 mm. These authors reported up to 93%–94% healing of anal fissures after these procedures, which were associated with relatively few complications.

Long-term outcomes of anal dilatation are sparse. Additional widespread criticism of the technique stems from reported complications of incontinence, secondary to diffuse sphincter damage. In a retrospective analysis by MacDonald et al.,<sup>14</sup> patient outcomes after manual anal dilatation were reviewed. Not only was dilatation unsuccessful in 56% of patients diagnosed with fissures, incontinence occurred in 27% of patients overall. Speakman et al.<sup>17</sup> performed endoanal ultrasound and anorectal physiology studies on 12 men with fecal incontinence after anal dilatation. Internal and external anal sphincter defects were identified in 11 and 3 patients, respectively. Sphincter defects after anal dilatation were also recognized by Nielsen et al.,<sup>18</sup> who reported minor incontinence in 12.5% of patients overall. Ultrasound was ultimately performed in 20 patients, 13 of whom had IAS defects. Deficits were identified in 61% (11/18) of the continent and 100% (2/2) of the incontinent patients.

One retrospective review comparing treatment outcomes of anal dilatation and lateral subcutaneous sphincterotomy was reported by Collopy and Ryan.<sup>19</sup> Questionnaires were sent to 160 patients who underwent either of the two procedures. Fissure recurrence and incontinence were reported less often in the sphincterotomy group. Early prospective, randomized trials did not support these findings.<sup>20–22</sup> In one study, recurrence and incontinence rates were equal between both groups<sup>20</sup>; in another, significantly worse after lateral sphincterotomy.<sup>21</sup> Four months after randomization in the trial by Marby et al., symptomatic improvement was reported in 93% after dilatation versus 78% after sphincterotomy ( $P < .05$ ). During the same time period, recurrence rates were 10% after dilatation and 29% after sphincterotomy ( $P < .02$ ). Later randomized trials demonstrated better functional results, in terms of incontinence, after lateral sphincterotomy.<sup>23</sup> Whereas recurrence rates were 3.5%–10% up to 1 year after lateral sphincterotomy, higher rates of 26%–30% were observed after anal dilatation.<sup>22,24</sup>

### *Lateral Internal Sphincterotomy*

The use of internal sphincterotomy in the treatment of anal fissure was introduced by Eisenhammer<sup>25</sup> in the early 1950s. His initial approach through the bed of the fissure in the posterior midline often resulted in a scarred groove, or “keyhole

deformity,” as often referred today. The functional impairment that ensued resulted in incontinence to gas and/or stool for many patients. Lateral subcutaneous sphincterotomy was popularized by Notaras<sup>26</sup> in 1969, and was believed to be associated with less functional impairment. In a retrospective review of 300 patients, comparing LIS to fissurectomy and midline sphincterotomy, Abcarian<sup>27</sup> reported a low recurrence rate of 1.3% and no incontinence after LIS—his procedure of choice for uncomplicated anal fissures. Several retrospective studies support the use of LIS as the preferred operative method for the treatment of anal fissures.<sup>28–30</sup> Exceptional healing and low recurrence rates have invariably been reported, and LIS has emerged as the “gold standard” for the treatment of anal fissure<sup>31</sup> (Table 12-1).

Persistent incontinence to gas and stool has emerged as a major concern after sphincterotomy. Incontinence rates of up to 36% have been reported, but these vary widely among studies.<sup>32–36</sup> Much of this variation can be attributed to differences in definition and assiduousness of follow-up. Reasons for incontinence after LIS have been related to the type and extent of sphincter muscle divided. Sultan et al.<sup>37</sup> prospectively performed endoanal ultrasonography before and 2 months after sphincterotomy in 15 patients. IAS defects were identified in 14 patients. In 90% of the women examined, the defect comprised the full length of the sphincter. Incontinence to flatus was reported in 3 of 10 women, in whom *external* sphincter defects were found in 2. The authors concluded that the complete sphincter deficits observed in women were the consequences of lack of appreciation for shorter anal canals in this population and suggested that postsphincterotomy incontinence may be further lessened if external anal sphincter deficits are recognized preoperatively.

Littlejohn and Newstead<sup>38</sup> reported a retrospective review of 287 patients who underwent tailored sphincterotomy, i.e., division of the IAS for the length of the fissure, rather than to the dentate line. There were no reports of incontinence to liquid or solid stool. The incidence of urgency was 0.7%; gas incontinence, 1.4%; and minor staining, 35%. Pescatori et al.<sup>39</sup> reported the results of a prospective, randomized study of tailored LIS on the basis of preoperative manometry. When increased resting anal tone was not demonstrated preoperatively, fissurectomy with anoplasty was performed. For elevated anal pressures (70–90 mm Hg), the extent of sphincterotomy was 0.5–1.5 cm and up to 2.5 cm for higher pressures. Continence worsened in only 11% of patients, and recurrences were limited to 4% of patients after sphincterotomy.

Inadvertent division of the external sphincter during sphincterotomy affects overall healing rates as well. In a study by Farouk et al.,<sup>40</sup> ultrasound evaluations performed in patients with persistent fissures after sphincterotomy demonstrated a lack of internal sphincter defects in almost 70% of patients. External sphincter defects were identified, however.

Other technical variations that have influenced patient outcomes after LIS have been described (Figures 12-3 and 12-4).

With regard to open or closed sphincterotomy, several retrospective analyses<sup>41</sup> and at least one randomized trial<sup>42</sup> report similar rates of initial healing and fissure recurrence. In these studies, incontinence to flatus or stool occurred in 15%–17% of patients overall. Although there was no significant difference in *acute* complications in another randomized study, long-term persistent complications were more frequent in the open (55%) than the closed (20%) sphincterotomy group in retrospective review.<sup>43</sup> In a separate study, in which the degree of continence after open versus closed sphincterotomy was assessed by questionnaire, closed internal sphincterotomy was again favored. A significant difference was reported with regard to postoperative incontinence to gas (27.6% versus 30.6%), stool (3.1% versus 11.3%), and seepage (16.1% versus 26.7%).<sup>32</sup>

Excision of hypertrophied anal papillae and fibrous anal polyps has been advocated by Gupta and Kalaskar.<sup>44</sup> In a randomized trial, patient satisfaction was rated as excellent or good after removal of these structures in 84% of patients, compared with 58% of patients whose polyps and papillae were left intact. In a separate prospective study, earlier wound healing rates were achieved with primary closure after LIS, as compared with healing by secondary intention.<sup>45</sup>

### *Advancement Flaps*

One prospective trial of the use of advancement flaps for chronic anal fissures has been conducted to date.<sup>46</sup> When patients were randomized to receive LIS or advancement flap, there was no significant difference between healing rates (100% in the sphincterotomy group versus 85% in the flap group,  $P = .12$ ). Incontinence was not observed in either group.

## Medical Management

### *Sphincter Relaxants*

Increasing concerns with long-term complications associated with the operative management of anal fissures has led to the development of “chemical sphincterotomy,” aimed at reducing mean maximum resting anal pressures, without permanent sphincter injury. Preparations have included: 1) various nitrate formulations, including nitroglycerin (NTG) ointment, glyceryl trinitrate (GTN), and isosorbide dinitrate (ISDN); 2) oral and topical calcium channel blockers, including nifedipine and diltiazem (DTZ); 3) adrenergic antagonists; 4) topical muscarinic agonists, i.e., bethanechol; 5) phosphodiesterase inhibitors; and 6) botulinum toxin (BT). However, there is increasing controversy in this area. Whereas one recent review concluded “first-line use of medical therapy cures most chronic fissures cheaply and conveniently,”<sup>47</sup> a systematic review of the literature published at the same time concluded “medical therapy for chronic anal fissure . . . may be applied with a chance of cure that is only marginally better than placebo . . . [and] far less effective than surgery.”<sup>48</sup>

### *Topical Nitrates*

The IAS is a smooth muscle whose tone is affected by both intrinsic myogenic properties and extrinsic neural influences. Nitric oxide is the predominant nonadrenergic, noncholinergic neurotransmitter in the IAS. Release of nitric oxide results in IAS relaxation. Exogenous nitrates release nitric oxide *in vivo* and have been used as nitric oxide donors.

Studies by Loder et al.<sup>49</sup> and Guillemot et al.<sup>50</sup> demonstrated decreased resting anal pressure with 0.2% GTN. This led to a series of retrospective and prospective reports, as well as randomized trials, supporting the use of various nitrate preparations in the treatment of anal fissures (Table 12-2). An early clinical trial in 1997 by Bacher et al.<sup>51</sup> randomized 35 patients with acute and chronic anal fissures to receive either 0.2% NTG ointment or 2% lidocaine gel for 4 weeks. After 1 month, the healing rate was 80% for patients receiving NTG (11 of 12 acute and 5 of 8 chronic fissures), which was significantly higher than the 40% healing rate reported for patients receiving topical lidocaine (5 of 10 acute and 1 of 5 chronic fissures). Manometry was performed on the 28th day of treatment. Overall maximum resting anal pressures were found to decrease from a mean of 110 to 87 cm H<sub>2</sub>O, although this difference was not observed for patients with chronic fissures or patients receiving lidocaine ointment. The authors postulated that the persistence and recurrence of chronic anal fissures was secondary to lack of sphincter tone reduction.

Subsequent randomized, placebo-controlled trials have attempted to determine whether higher doses of NTG ointment promote healing and lessen recurrence in chronic anal fissures. Carapeti et al.<sup>52</sup> found no difference in chronic fissure healing between patients randomized to receive an 8-week treatment of either 0.2% GTN 3 times daily or 0.2% GTN titrated in 0.1% increments (to maximum of 0.6%). Higher dosing did not result in accelerated healing. Patients treated actively with either GTN preparation demonstrated 67% healing rate, compared with 32% in those receiving placebo. Bailey et al.<sup>53</sup> and Scholefield et al.<sup>54</sup> reported similar findings when patients with chronic anal fissures were randomized to receive placebo, 0.1%, 0.2%, or 0.4% GTN ointment 2–3 times daily. In the study by Bailey et al., there were no significant differences in fissure healing among treatment groups. In fact, healing rates were approximately 50% for all groups, including placebo.<sup>53</sup> Scholefield et al. also demonstrated similar healing rates among all groups (37.5% for placebo, 46.9% for 0.1% GTN, 40.4% for 0.2% GTN, and 54.1% for 0.4% GTN) with no significant improvement over the placebo response.<sup>54</sup>

Additional randomized, placebo-controlled trials have demonstrated comparable healing rates of 46%–70% in patients with chronic anal fissures after application of 0.2% GTN ointment 2–3 times daily for 4–8 weeks. Supportive data have included statistically significant decreases in pain scores and maximal anal resting pressures in patients treated with GTN as compared with placebo. In a study by Altomare et al.,<sup>55</sup> 132 patients with chronic fissures were randomized to receive

TABLE 12-2. Randomized trials of NTG therapy

Year	Author	n	Treatment	Follow-up	Success (%)
1997	Lund et al. <sup>114</sup>	80	0.2% GTN bid placebo	8 wk	68 39

2003	Scholefield et al. <sup>54</sup>	200	0.1%, 0.2%, and 0.4% GTN bid/tid placebo	8 wk	46.9, 40.4, 54.1, 37.5

GTN, glyceryl trinitrate; NTG, nitroglycerin; LIS, lateral internal sphincterotomy; bid, twice daily; tid, three times daily.

0.2% GTN or placebo bid for 4 weeks. These authors confirmed the effects of GTN on anodermal blood flow and sphincter pressure, but unlike similarly designed trials, they demonstrated no significant difference in healing rates between GTN and placebo (49.2% versus 51.7%). They concluded that the use of GTN as a substitute for surgery should be discouraged.

Several simultaneous randomized trials whose treatment arms consisted of 0.2% GTN and LIS support the findings of Altomare et al. Although initial healing rates during 4- to 8-week evaluation periods were similar to those in placebo-based trials (and up to 83.3% in a study by Oettle<sup>56</sup>), healing rates were far superior for LIS (91.7%–100%). Evans et al.<sup>57</sup> demonstrated healing in 20 (60.6%) of 33 patients treated with GTN, in comparison to 26 (97%) of 27 patients treated with sphincterotomy. Of the patients initially treated with GTN, 12 eventually underwent sphincterotomy for persistent fissures. Of the 20 patients whose fissures healed with GTN treatment, nine developed recurrences. The authors acknowledge that GTN will heal the majority of fissures, but concluded “a significant minority have little improvement and require conventional surgical treatment.”<sup>57</sup> Richard et al.<sup>58</sup> also found LIS “superior to topical NTG . . . in the treatment of chronic anal fissure, with a high rate of healing, few side effects, and low risk of early incontinence.” After 6-week follow-up in a multi-

center, randomized, controlled trial, 89.5% of patients in the LIS group compared with 29.5% in the NTG group had complete healing of fissures. At 6 months, fissure healing had occurred in 92.1% versus 27.2% in the LIS and NTG groups, respectively. Side effects were observed more frequently in patients treated with NTG (28.9%), compared with LIS (84%).

Although findings were similar in other randomized, controlled trials, conclusions still favor the use of GTN. Libertiny et al.<sup>59</sup> randomized 70 patients with chronic anal fissure to receive 0.2% GTN or LIS. Only 16 of 35 patients initially treated with GTN healed without recurrence during 24-month follow-up, in contrast to operative cure in 34 of 35 patients treated with LIS. The authors concluded that chemical sphincterotomy with GTN should be the initial treatment in patients with chronic anal fissure, and despite its effectiveness, LIS should be reserved for treatment failures. Zuberi et al.<sup>60</sup> similarly concluded that GTN ointment and NTG patch were effective treatment options in patients with anal fissures. In their study of 42 patients, healing rates were 66.7% in patients receiving 0.2% GTN, 63.2% for those receiving a 10-mg NTG patch applied at a distance from the fissure, and 91.7% in patients who underwent LIS. Their findings support the use of GTN as a first line agent in chronic anal fissures, as the difference in healing rates was not statistically significant between groups.

Other nitrate preparations have been used in the treatment of anal fissures. A prospective, uncontrolled study by Schouten et al.<sup>61</sup> demonstrated reduction in anal pressure and improvement in anodermal blood flow in patients with chronic anal fissure treated with ISDN. The authors demonstrated an 88% fissure healing rate after 12 weeks. Two randomized, placebo-controlled trials confirmed these findings. Werre et al.<sup>62</sup> were able to achieve healing in 17 of 20 patients (85%) with chronic anal fissure treated with ISDN for 5 weeks, as compared with 6 of 17 patients (35.3%) who received placebo. Tankova et al.<sup>63</sup> subsequently reported fissure healing in 80% of patients actively treated with mononitrate for 3 weeks, compared with 22% of the control group. In a dose finding study, Lysy et al.<sup>64</sup> found that 2.5 mg of topically applied ISDN 3 times daily resulted in a greater reduction in maximum anal resting pressure than 1.25 mg. By 1 month, 34 patients (83%) were able to achieve complete healing of their fissures. During the mean follow-up period of 11 months, six healed patients had fissure recurrence, which responded to additional treatment with ISDN.

Endogenous nitric oxide donors, such as L-arginine, have also been shown to be effective in relaxation of the anal sphincter. Preliminary in vivo studies in rats have demonstrated a decline in sphincter pressure with administration of 10 mg L-arginine rectally. This effect was reversed with the use of L-arginine antagonists. In a placebo-controlled trial, 46% reduction in resting anal pressure was observed 5 minutes after topical application of L-arginine, and maintained for 2 hours. The decrease in pressure observed in the placebo group was not significant.<sup>65</sup>

Despite these encouraging results regarding initial healing rates with topical nitrates, concerns about long-term outcomes and adverse reactions have limited their use. In studies summarizing long-term follow-up, recurrence rates up to 35% have been documented. For example, in a retrospective study by Dorfman et al.,<sup>66</sup> of 31 patients treated with 0.2% GTN bid, only 67% were compliant with treatment. Although there was an overall healing rate of 56%, recurrence occurred in 27% of patients initially healed. More than 75% of patients had side effects, including headache in 63% and lightheadedness in 52% of patients. In a nonrandomized, prospective trial, Graziano et al.<sup>67</sup> demonstrated a 67% recurrence rate for chronic fissures during a 9-month follow-up period. Patients were treated with a 2-week course of 0.25% NTG, which produced headache in 77% of patients actively treated.

Side effects have invariably been reported in randomized, controlled trials as well. Mild headaches were described by Bacher et al.<sup>51</sup> in 20% of patients receiving 0.2% GTN. Altomare et al.<sup>55</sup> reported that 34% of chronic fissure patients treated with GTN had headaches and nearly 6% of patients had orthostatic hypotension. Carapeti et al. reported headaches in 72% of patients receiving GTN versus 27% of controls receiving placebo.<sup>52</sup> In the L-arginine study, no side effects were noted during the study period.<sup>65</sup>

### *Calcium Channel Blockers*

The effect of nifedipine on the anal sphincter was first evaluated by Chryso et al.<sup>68</sup> in a prospective, controlled trial in 1996. Anorectal manometry was performed on 10 patients with hemorrhoids and/or anal fissure and 10 controls before and 30 minutes after receiving 20 mg of sublingual nifedipine. Anal resting pressure was reduced by almost 30% in both groups. This study set the stage for further prospective, clinical trials examining the efficacy of nifedipine and other calcium channel blockers in treating anal fissures. Carapeti et al.<sup>69</sup> investigated the use of topical DTZ in the treatment of anal fissure, after a prior randomized trial demonstrated that the majority of fissure patients treated with GTN developed headaches. After application of 2% DTZ gel 3 times daily in 10 patients, 67% obtained healed fissures after 8 weeks of treatment. No headaches or side effects were reported.

Further prospective trials substantiated these findings. Knight et al.<sup>70</sup> also evaluated the effects of 2% DTZ gel in 71 patients and were able to achieve healing in 75%, after 9 weeks of treatment. An additional 8 weeks of treatment was administered to incompletely healed fissures in 17 patients, 8 of whom healed. Side effects were reported in five patients overall: four with perianal dermatitis and one with headache. Agaoglu et al.<sup>71</sup> demonstrated 60% healing in patients treated with 20 mg of oral nifedipine twice daily. Headache was reported in only one patient. Ansaloni et al.<sup>72</sup> reported even more encouraging results regarding efficacy of 6 mg of oral lacidipine and warm sitz baths. At 2 months' follow-up, 90.4% of patients treated healed without evidence of fissure recurrence; however, 33% of patients had side effects.

Randomized, controlled trials comparing topical nifedipine gel with a combination of topical lidocaine and hydrocortisone gels have also demonstrated superiority of nifedipine in the treatment of anal fissures. Antropoli et al.<sup>73</sup> randomized 283 patients to either receive 0.2% nifedipine gel every 12 hours or 1% lidocaine/1% hydrocortisone gels. Complete healing occurred in 95% of patients receiving nifedipine, as compared with 50% of controls. Perrotti et al.<sup>74</sup> similarly randomized 110 patients with anal fissure to receive 0.3% nifedipine gel with 1.5% lidocaine or 1.5% lidocaine with 1% hydrocortisone twice daily. Of the 52 patients treated with nifedipine, 94.5% healed completely versus 16.4% of controls. During 1-year follow-up, three of the 52 patients healed with nifedipine had recurrent fissures; two healed after additional treatment. No side effects were observed in either study.

Jonas et al.<sup>75</sup> performed a randomized, controlled trial to ascertain whether different routes of administration had similar healing rates. The authors randomized 50 patients to receive 60 mg of oral DTZ or 2% topical DTZ gel twice daily. Complete healing occurred in 38% of patients taking oral treatment versus 65% of patients using topical therapy. Side effects were reported in 33% of patients treated orally.

Although long-term follow-up studies are lacking, several randomized, controlled trials comparing calcium channel

blockers and nitrates have been performed. Kocher et al.<sup>76</sup> randomized 61 patients with chronic anal fissures to receive 0.2% GTN or 2% DTZ. After 6–8 weeks of treatment, 21 of 29 patients in the GTN group and 13 of 31 in the DTZ group experienced side effects. Therapeutic efficacy was similar between both groups. In the GTN group, 25 of 29 patients (86.2%) were healed or improved, compared with 24 of 31 patients (77.4%) in the DTZ group ( $P = .21$ ). Bielecki et al.<sup>77</sup> also found equal healing rates between topical 0.2% GTN and 2% DTZ, as well as fewer headaches with 2% DTZ (0% versus 33% with 0.2% GTN). In a prospective, double-blind trial by Ezri and Susmallian,<sup>78</sup> 52 patients were randomized to receive topical GTN or nifedipine. The healing rate was higher ( $P < .04$ ) with nifedipine (89%) as compared with GTN (58%). Side effects occurred more frequently ( $P < .01$ ) with GTN (40%) than nifedipine (5%), a finding that was similar to the other trials. Recurrences within a 6-month period were common in both groups: 31% for GTN and 42% for nifedipine. Based on these study results, topical calcium channel blockers appear to be as effective as topical nitrates, with fewer side effects. Initial data suggest that long-term recurrences may be similar between both treatment groups, but further studies are warranted. Currently, topical calcium channel blocker preparations are not commercially available in the United States.

#### *Adrenergic Antagonists*

The effect of alpha-1 adrenergic blockade on anal sphincter pressure has been studied in two prospective trials. Pitt et al.<sup>79,80</sup> administered 20 mg of indoramin, an alpha-1 blocker, to seven patients with chronic anal fissure and six healthy controls. Reduction in anal pressure was observed in both groups: 35.8% in patients with fissure and 39.9% in those without. In a placebo-controlled trial, 23 patients with chronic anal fissure were randomized to receive 20 mg of indoramin or placebo twice daily.<sup>79</sup> Although a 29.8% reduction in maximum anal resting pressure was observed 1 hour after active treatment, healing occurred in only 1 patient (7%), despite 6 weeks of therapy. That patient developed a recurrence within 3 months. In the placebo group, 22% of patients achieved healing, although no significant change in anal pressure was observed. The trial was not completed because of lack of efficacy.

#### *Cholinergic Agonists*

Carapeti et al.<sup>81</sup> documented reduced anal sphincter pressure using bethanechol in a dose-finding study. Using increasing concentrations of bethanechol gel in healthy volunteers, they demonstrated a 24% reduction in maximal anal resting pressure using 0.1% dose. In a subsequent study, they reported fissure healing in 9 of 15 patients treated with 0.1% bethanechol gel 3 times daily for 8 weeks.<sup>69</sup> Maximum resting sphincter pressure was significantly lower after treatment ( $P = .02$ ) compared with pretreatment values. No side effects were reported.

#### *Phosphodiesterase Inhibitors*

Early work by Jones et al.<sup>82</sup> has demonstrated an in vitro effect of increasing concentrations of various phosphodiesterase inhibitors on internal sphincter tone. This may spark future clinical trials in the treatment of anal fissure.

#### *Botulinum Toxin*

Botulinum Toxin (BT) is an exotoxin produced by the bacterium *Clostridium botulinum*. When injected locally, BT binds to the presynaptic nerve terminal at the neuromuscular junction, thereby preventing release of acetylcholine and resulting in temporary paralysis of skeletal muscle. Its mechanism of action on smooth muscle, such as the internal sphincter, has been evaluated in recent animal studies. In a series of experiments, Jones et al.<sup>83</sup> injected BT into porcine anal sphincters, which responded with decreased mean anal resting pressure in subsequent manometric studies. Strips of sphincter muscle were then isolated and examined in vitro. Application of electrical field stimulation and nicotinic agonists resulted in increased myogenic tone, which was blocked by guanethidine and attenuated by BT injection. These findings suggested that the predominant effect of BT on the IAS is sympathetic blockade.

BT injections can be given easily, on an outpatient basis, and are well tolerated. The commercial availability of BT has prompted several prospective trials examining its efficacy in the treatment of anal fissure (Table 12-3). An early placebo-controlled trial randomized 30 patients to receive either two injections of 20 U BT-A or saline.<sup>84</sup> After 2 months, complete healing occurred in 11 of 15 patients (73.3%) receiving BT and 2 of 15 patients (13.3%) receiving placebo. Subsequent BT injections were offered and given to 10 patients in the control group; there were seven healed fissures. Repeat BT injections (25 U) were given to four treatment failures, all of which healed after 2 months. No recurrences were observed during 16 months' follow-up. In a randomized trial comparing BT and lidocaine pomade in the treatment of anal fissure, Colak et al.<sup>85</sup> demonstrated superiority ( $P = .006$ ) of BT in 62 patients, with complete epithelialization in 70.58% of patients in the BT group versus 21.42% in the lidocaine group.

The dose of BT injected is critical to successful healing in anal fissures. Siproudhis et al.<sup>86</sup> reported that a single 20-U injection of BT was not superior to that of placebo in a randomized, double-blind trial of 44 patients with chronic anal fissure. In a dose-finding study, Brisinda et al.<sup>87</sup> randomized 150 patients to two treatment arms. Initial treatment with 20 U of BT, followed by 30 U of BT for fissure persistence, was given to the first group, and 30 U of BT, followed by 50 U of BT, was given to the second group. One month after BT injections, there were no significant differences in resting anal pressures between the two groups; however, complete healing was more frequent in the second group (87%) than the first (73%). Fissures remained unhealed in two patients in the first, and three patients in the second group, despite additional BT

TABLE 12-3. Prospective BT trials

Year	Author	n	Treatment	Follow-up	Success (%)	Side effects
1998	Maria et al. <sup>84</sup>	30	BT 20 U (2 doses) Saline	2 mo	73.3 13.3 ( $P = .003$ )	
1999	Brisinda et al. <sup>90</sup>	50	BT 20 U (2 doses) 0.2% NTG	2 mo	96 60 ( $P = .005$ )	20% headaches
2002	Colak et al. <sup>85</sup>	62	BT Lidocaine	2 mo	70.6 21.4 ( $P = .006$ )	
2002	Brisinda et al. <sup>87</sup>	150	BT 20 U, 30 U BT 30 U, 50 U	2 mo	89 96	
2003	Siproudhis et al. <sup>86</sup>	44	BT 20 U (1 dose) Saline	4 wk	22.7 22.7	
2003	Mentes et al. <sup>91</sup>	101	BT 0.3 U/kg LIS	12 mo	75.4 94 ( $P = .008$ )	16% incontinence

BT, botulinum toxin; U, units; LIS, lateral internal sphincterotomy.

injections. Temporary incontinence to flatus was reported in 6.6% of the second group only.

Optimal dosing of BT therapy was evaluated in a separate study by Madalinski et al.<sup>88</sup> Fourteen patients with chronic anal fissures resistant to topical nitrates and a subsequent 25-U BT injection were offered a second application of topical nitrates, which resulted in healing in only one patient. A higher dose of BT (50 U) was given to the 13 remaining patients and healing achieved in seven. The use of BT injections for GTN treatment failures was further supported in a prospective trial conducted by Lindsey et al.<sup>89</sup> Forty patients with chronic anal fissures despite GTN therapy were treated with 20 U of BT. Initial success, which included patients with symptomatic relief in the presence of an unhealed fissure, was observed in 29 patients (73%). Less than one-third of patients eventually underwent a surgical procedure. Transient incontinence was noted in 18% of patients. The authors concluded that BT should be considered as a second-line, and perhaps a first-line, agent in the treatment of chronic anal fissures before pursuing surgical options.

In a prospective, randomized trial, Brisinda et al.<sup>90</sup> directly compared BT injection and topical NTG as first-line agents in the treatment of chronic anal fissures. BT injections (20 U) were given on each side of the IAS and 0.2% NTG ointment was applied twice daily for 6 weeks. Fissures healed in 96% of the patients in the BT group and 60% of the patients in the NTG group. Moderate to severe headaches were reported in 20% of the NTG group, whereas no side effects were observed after BT injections. Regarding nonsurgical treatment of chronic anal fissure, the authors concluded that BT was more effective than NTG therapy.

There has been only one prospective, randomized trial to date comparing BT to LIS in the treatment of chronic anal

fissures. Mentés et al.<sup>91</sup> reported the results of 61 patients receiving a total of 0.3 U/kg BT in two divided doses and 50 patients who underwent sphincterotomy. Fissure healing was evaluated at 1 and 4 weeks postprocedure, as well as at 2-, 6-, and 12-month intervals. Patients in the BT group had a second injection if healing was incomplete after 2 months. After 1 month, fissures were completely healed in 62.3% of patients in the BT group versus 82% of patients in the LIS group ( $P = .023$ ). By 2 months, healing rates were 73.8% in the BT group and 98% in the LIS group ( $P < .0001$ ). Six months after treatment, 86.9% of patients in the BT group had healed fissures. In the LIS group, two patients developed recurrences, decreasing the healing rate to 94%, not significantly different from the BT group. By 12 months, however, fissure recurrence in seven patients in the BT group resulted in a decrease in the overall healing rate to 75.4%, significantly lower than 94% rate still observed in the LIS group ( $P = .008$ ). Anal incontinence, predominantly to flatus, was reported in 16% of patients in the LIS group. No side effects were observed with BT injections. Although initial success and fewer complications were found with BT therapy, long-term results were not as encouraging when compared with LIS.

Late recurrence rates 42 months after BT treatment of chronic anal fissures have been reported in a prospective trial by Mínguez et al.<sup>92</sup> Only patients with complete healing 6 months after BT injections were included for reassessment in 6-month intervals. Fissure recurrence was demonstrated in 41.5% of patients. Stratification by various clinical parameters revealed that higher risks of recurrence were associated with anterior location, chronicity of disease (longer than 12 months), multiple injections, and dosage greater than 21 U. They comment that lack of recurrence cited in earlier reports by Maria et al. and Brisinda et al. may have been influenced

by their use of strict exclusion criteria, such as patients with anterior fissures. Furthermore, standard doses of BT were not used in all trials. Optimal dosing and appropriate patient selection remain uncertain.

Complications reported after BT injections of anal fissures have included perianal hematomas in 2 of 10 patients treated by Tilney et al.<sup>93</sup> and perianal thrombosis in early reports by Jost et al.,<sup>94</sup> although this has not been reproduced in his recent experience.<sup>95</sup>

## Special Situations

### Low Pressure Fissures

Unlike the classic anal fissures described previously, low pressure fissures are not appropriate candidates for operative sphincterotomy. Patients within this category include those with impaired continence and fissure recurrence after sphincterotomy. Anal fissures sustained after childbirth are also associated with reduced anal canal pressures. Corby et al.<sup>96</sup> prospectively studied 209 primigravid women with anal manometry 6 weeks before and after childbirth. Of those women, 9% developed postpartum fissures. Manometric evaluations demonstrated similar antepartum resting and squeeze pressures in women who developed fissure and those who did not. In addition, postpartum resting and squeeze pressures were decreased in both groups. For this group of patients, “surgical interference with the anal sphincter mechanism should be avoided.”<sup>96</sup>

Optimal treatment of low-pressure fissures is unclear. Nyam et al.<sup>97</sup> reported the results of an island flap in 21 patients with preoperative median resting anal pressures and squeeze pressures significantly lower than controls or patients with high-pressure fissures. Sphincter defects were recognized ultrasonographically in 15 of 21 patients (71%). During an 18-month follow-up, all fissures healed and incontinence was not observed. The authors concluded that the island advancement flap “provides a useful alternative” for recurrent anal fissures, or low-pressure anal fissures, in which sphincterotomy “might jeopardize continence.”<sup>97</sup>

### Crohn’s

The incidence of perianal Crohn’s fissures varies widely among reports. In one retrospective review by Platell et al.,<sup>98</sup> symptomatic anal disease was documented in 42.4% of patients with Crohn’s disease. More than one-quarter of those patients (27.6%) had anal fissures. In a separate analysis in which 3.8% of patients with Crohn’s disease required surgery for perianal symptoms, Sangwan et al.<sup>99</sup> found that 31.8% had anal fissures. Fleshner et al.<sup>100</sup> specifically examined fissures in Crohn’s disease and found 84% were symptomatic. Multiple fissures were noted in one-third of patients and only 66% were located in the posterior midline. Sweeney et al.<sup>101</sup>

reviewed the natural history of Crohn’s fissures in 61 patients, in whom anal fissure was the only anal pathology. Fissure healing occurred in 42 of 69 patients (60.8%) during medical treatment for Crohn’s disease. Ten patients developed additional anal lesions. Six patients (9.8%) eventually underwent anorectal surgery.

Traditionally, anorectal surgery in patients with Crohn’s disease has been approached with caution. Complications resulting in proctectomy and fears regarding postoperative incontinence, exacerbated by preexisting diarrhea, have precluded perianal operations in these patients (although impairment of continence after such operations has not been studied in this population). As a result, most authorities argue that initial treatment of Crohn’s fissures should be focused on controlling diarrhea. If fissure persists despite conservative measures, examination under anesthesia and limited sphincterotomy should be performed. Currently, there are no data to support the use of topical sphincter relaxants or BT in the treatment of fissures in Crohn’s disease.

Outcomes after surgery in patients with Crohn’s fissures have been reported, albeit in small retrospective series. Wolkomir and Luchtefeld<sup>102</sup> reported uncomplicated wound healing in 22 of 25 patients. In the series by Fleshner et al.,<sup>100</sup> 88% of patients healed after anorectal surgery, compared with 49% of patients after medical treatment and 29% after abdominal surgery. Of treatment failures, perianal abscess or fistula was observed in 26% of patients.

Anal dilatation for Crohn’s fissures has also been reported with some success. Isbister and Prasad<sup>12</sup> reported that “three patients with anal fissures and Crohn’s disease were successfully managed by anal dilatation.” Allan and Keighley<sup>103</sup> described improvement in 4 of 7 patients, in whom 1 became incontinent.

### Human Immunodeficiency Virus

Distinction between HIV-associated fissures and HIV-associated ulcers is necessary for optimization of fissure management in this patient population. Fissures in HIV-positive patients have a typical appearance, whereas HIV ulcers are deep and broad based and can occur anywhere within the anal canal.<sup>104,105</sup> Early pessimistic reports of poor wound healing and high rates of incontinence after sphincterotomy for HIV-associated fissures may have been skewed by inclusion of HIV ulcers in the fissure group.<sup>105</sup> In addition, these data preceded the era of highly effective antiviral therapy. In fact, there is a paucity of current information on HIV-associated fissures, and no available data about risk of postoperative incontinence or use of topical sphincter relaxants or BT as treatment options.

Barrett et al.<sup>106</sup> reported fissure prevalence in 32% of HIV-positive patients. Although sphincterotomies were performed in 18 patients, specific outcomes were not reported. Viamonte et al.<sup>104</sup> compared alternative treatments for anal fissures in 33 HIV-positive patients. Ten patients were lost to follow-up.

Improvement was noted in 10 patients treated nonoperatively and in 12 of 13 patients who underwent LIS. Actual healing rates were not provided, but no cases of incontinence were observed.

## Conclusions

Anal fissure is a common, symptomatic disorder. Diagnosis is often established by history alone, but is easily confirmed by physical examination without the need for additional instrumentation. After instigation by anal trauma, anal fissure is sustained by elevated resting anal pressure. Treatment of anal fissure has consequently been aimed at reducing anal tone.

Surgery has been highly effective, although alterations in continence have been documented. Although proponents of anal dilatation exist, LIS has been advocated as the operation of choice. Regarding nonoperative treatment options, the early GTN literature has been promising, but varies significantly with regard to rates of healing, relapse, and side effects. Topical calcium channel blockers have shown similar efficacy to GTN, but fewer side effects have been reported. In at least one randomized trial, BT demonstrated superiority to GTN, but long-term outcomes of BT have uncovered high fissure recurrence rates. In general, the success of medical therapies has been controversial, with lack of consensus demonstrably evident after dichotomous analyses in the recent literature: a review by Lindsey et al.<sup>47</sup> that determines that most chronic anal fissures are successfully treated by inexpensive medical therapies and a systematic evaluation by Nelson<sup>48</sup> that concludes that medical therapy offers only a slight advantage when compared with placebo, but is significantly inferior to surgery.

## Benign Anorectal: Abscess and Fistula

Carol-Ann Vasilevsky and Philip H. Gordon

Anorectal abscesses and fistula-in-ano represent different stages along the continuum of a common pathogenic spectrum. The abscess represents the acute inflammatory event whereas the fistula is representative of the chronic process.

### Abscess

#### Anatomy

Successful eradication of anorectal suppuration and fistula-in-ano requires an in-depth understanding of anorectal anatomy. Essential is an understanding of the existence of potential anorectal spaces<sup>1</sup> (Figure 13-1A). The perianal space is located in the area of the anal verge. It becomes continuous with the ischioanal fat laterally while it extends into the lower portion of the anal canal medially. It is continuous with the intersphincteric space. The ischioanal space extends from the levator ani to the perineum. Anteriorly it is bounded by the transverse perineal muscles; the lower border of the gluteus maximus and the sacrotuberous ligament form its posterior border. The medial border is formed by the levator ani and external sphincter muscles; the obturator internus muscle forms the lateral border. The intersphincteric space lies between the internal and external sphincters and is continuous inferiorly with the perianal space and superiorly with the rectal wall. The supralelevator space is bounded superiorly by peritoneum, laterally by the pelvic wall, medially by the rectal wall, and inferiorly by the levator ani muscle. The deep postanal space is located between the tip of the coccyx posteriorly and lies below the levator ani and above the anococcygeal ligament (Figure 13-1B).

At the level of the dentate line, the ducts of the anal glands empty into the anal crypts. Some 80% of the anal glands are submucosal in extent, 8% extend to the internal sphincter, 8% to the conjoined longitudinal muscle, 2% to the intersphincteric space, and 1% penetrate the internal sphincter.<sup>2</sup>

### Pathophysiology

#### *Etiology*

Ninety percent of all anorectal abscesses result from nonspecific cryptoglandular infection whereas the remainder result from the causes as listed in Table 13-1. According to the cryptoglandular theory championed by Parks,<sup>3</sup> abscesses result from obstruction of the anal glands and ducts. Obstruction of a duct may result in stasis, infection, and formation of an abscess. Persistence of anal gland epithelium in part of the tract between the crypt and the blocked part of the duct results in the formation of a fistula. Predisposing factors include diarrhea and trauma in the form of a hard stool. Associated factors may be anal fissures, infection of a hematoma, or Crohn's disease.

#### *Classification*

Abscesses are classified according to their location in the aforementioned potential anorectal spaces: perianal, ischioanal, intersphincteric, and supralelevator (Figure 13-2). Perianal abscesses are the most common type whereas supralelevator abscesses are the rarest. Pus can also spread circumferentially through the intersphincteric, supralelevator, or ischioanal spaces, the latter via the deep postanal space, resulting in a horseshoe abscess.

### Evaluation and Treatment

#### *Symptoms*

Pain, swelling, and fever are the hallmarks associated with an abscess. The patient with a supralelevator abscess may complain of gluteal pain.<sup>4</sup> Rectal bleeding has been reported. Severe rectal pain accompanied by urinary symptoms such as dysuria, retention, or inability to void may be suggestive of an intersphincteric or supralelevator abscess.

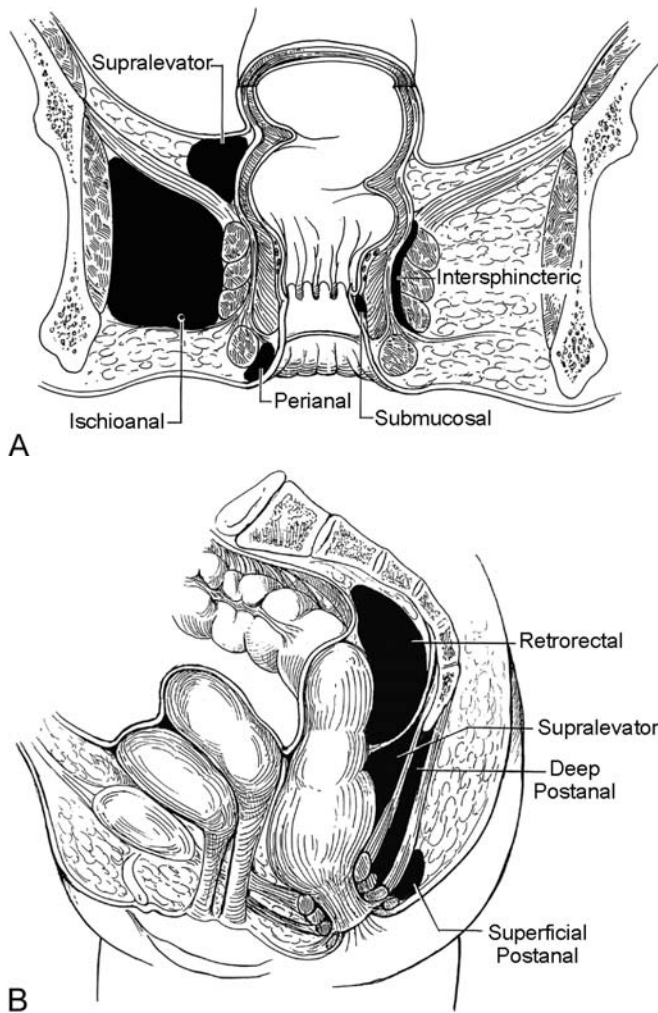

FIGURE 13-1. Anorectal spaces. **A** Coronal section. **B** Sagittal section. (From Vasilevsky CA. Anorectal abscess and fistula-in-ano. In: Beck D, ed. Handbook of Colorectal Surgery. 2nd ed. Copyright 2003 by Taylor & Francis Group LLC (B). Reproduced with permission of Taylor & Francis Group LLC (B) in the format Textbook via Copyright Clearance Center.)

*Physical Examination*

Inspection will reveal erythema, swelling, and possible fluctuation. It is crucial to recognize that no visible external manifestations will be present with the intersphincteric or supralevator abscesses despite the patient’s complaint of excruciating pain.<sup>1</sup> Although digital examination may not be possible because of extreme tenderness, palpation, if possible, will demonstrate tenderness and a mass. With a supralevator abscess, a tender mass may be palpated on rectal or vaginal examination.<sup>4</sup> Anoscopy and sigmoidoscopy are inappropriate in the acute setting.

Leukemia
Lymphoma
Radiation

*Treatment*

General Principles

Essentially, the treatment of an anorectal abscess involves incision and drainage. Watchful waiting under the cover of antibiotics is ineffective and may allow the suppurative process to progress resulting in the creation of a more complicated abscess and thus possible injury to the sphincter mechanism. Rarely, delay in diagnosis and management of anorectal abscesses may result in life-threatening necrotizing infection and death.<sup>5</sup>

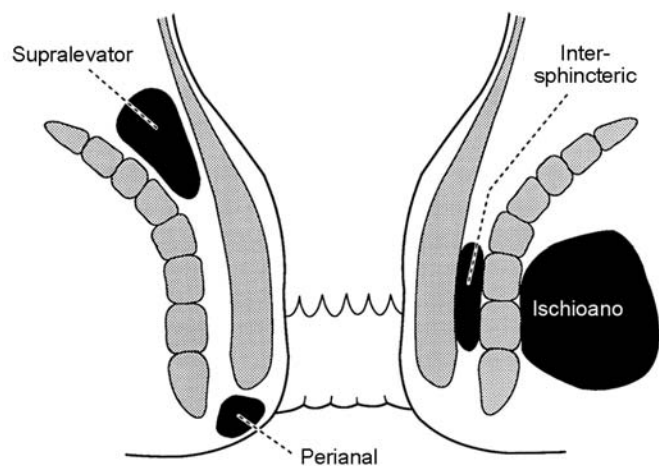

FIGURE 13-2. Classification of anorectal abscess. (Reprinted from Vasilevsky CA. Fistula-in-ano and abscess. In: Beck DE, Wexner SD, eds. Fundamentals of Anorectal Surgery. London: WB Saunders, copyright 1998, with permission from Elsevier.)

## Operative Management

### Incision and Drainage

Perianal abscesses can be effectively drained under local anesthesia.<sup>4,6</sup> After the most tender point has been determined, the area is infiltrated with 0.5% lidocaine with 1:200,000 epinephrine. A cruciate or elliptical incision is made and the edges are trimmed to prevent coaptation which may result in poor drainage or recurrence (Figure 13-3). No packing is required.

Most ischioanal abscesses can be incised and drained in a similar manner with the site of incision shifted close to the anal side of the abscess, minimizing the complexity of a subsequent fistula. Large ischioanal or horseshoe abscesses often require drainage with the patient under a regional or general anesthetic and in the prone jackknife or left lateral (Sim's) position. The location of infection is often in the deep

FIGURE 13-3. Drainage of abscess. **A** Injection of local anesthesia. **B** Cruciate incision. **C** Excision of skin. **D** Drainage cavity.

postanal space. Access to this space may be achieved by a midline incision between the coccyx and anus, spreading the superficial external sphincter to enter the space. An opening is made in the posterior midline and the lower half of the internal sphincter is divided to drain the anal gland in which the infection originated.<sup>4</sup> Counter-incisions are made over each ischioanal fossa to allow drainage of the anterior extensions of the abscess (Hanley procedure)<sup>5,7</sup> (Figure 13-4).

Because the diagnosis of an intersphincteric abscess is entertained when the patient presents with pain out of proportion to the physical findings, an examination under anesthesia is mandatory to completely assess the cause of the pain. Once the diagnosis is established, either by palpation of a protrusion into the anal canal or by needle aspiration in the intersphincteric plane, treatment consists of dividing the internal sphincter along the length of the abscess cavity. The wound is then marsupialized to allow adequate drainage and quicker healing.

Before the treatment of a supralelevator abscess, it is essential to determine its origin because it may arise from an upward extension of an intersphincteric or an ischioanal abscess, or downward extension of a pelvic abscess.<sup>1,4</sup> The treatment in each case will be different. If the origin is an intersphincteric abscess, it should be drained through the rectum by dividing the internal sphincter and not through the ischioanal fossa, because this will result in the creation of a suprasphincteric fistula. However, if it arises from an ischioanal abscess, it should be drained through the perineal skin and not through the rectum; otherwise, an extrasphincteric fistula will occur (Figure 13-5). If the abscess is of pelvic origin, it may be drained through the rectum, ischioanal fossa, or abdominal wall via percutaneous drainage depending on the direction to which it is pointing.

### Catheter Drainage

An alternative method of treatment for selected patients is catheter drainage. Patients suitable for this technique should not have severe sepsis or any serious systemic illness.<sup>8</sup> The patient is placed in the prone jackknife position or left lateral

FIGURE 13-4. Drainage of horseshoe abscess.

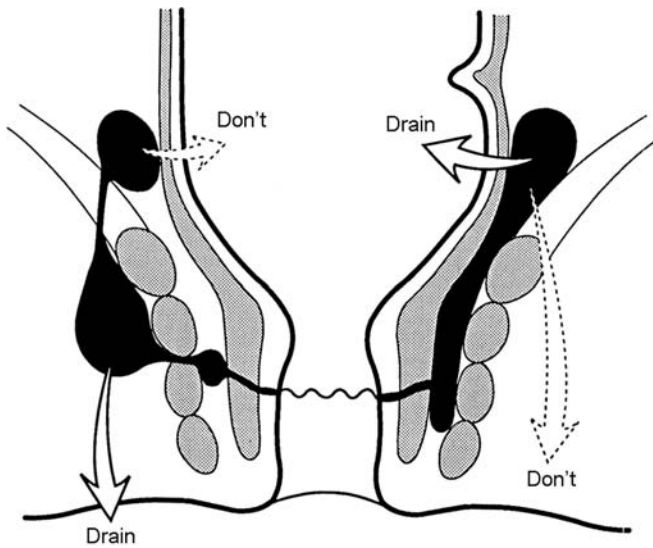

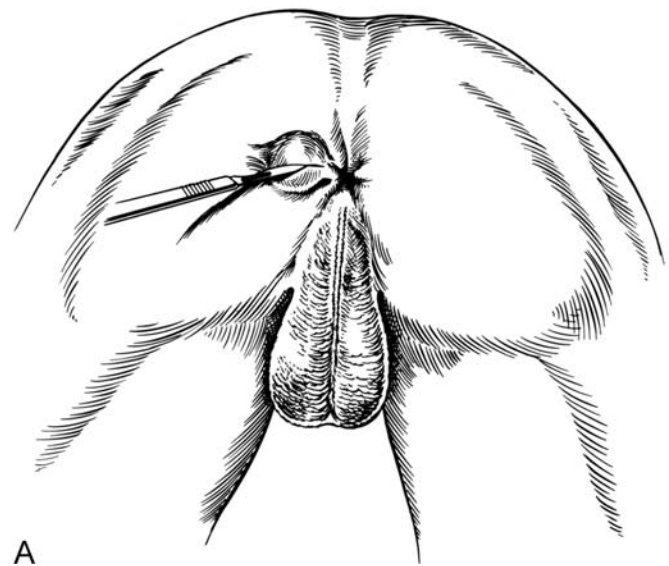

FIGURE 13-5. Drainage of a supralelevator abscess.

(Sim's) position. The skin is prepared with a providone-iodine solution and the fluctuant point of the abscess is selected. Local anesthesia consisting of 0.5% lidocaine with 1:200,000 epinephrine is injected in a 1-cm area of skin and a stab incision is made to drain the pus. The lidocaine should be injected into the skin around, rather than immediately over, the point of maximal fluctuation because the acid environment may otherwise preclude adequate anesthesia (Figure 13-6A). A 10- to 16-French soft latex mushroom catheter is inserted over a probe into the abscess cavity. When released, the shape of the catheter tip will hold the catheter in place, obviating the need for sutures. The external portion of the catheter is shortened to leave 2–3 cm outside the skin with the tip in the depth of the abscess cavity (Figure 13-6B). This reduces the chances of the catheter falling out of or into the abscess cavity. A small bandage is placed over the catheter.

Several portions of this technique deserve further comment. First, the stab incision should be placed as close as possible to the anus, minimizing the amount of tissue that must be opened if a fistula is found after resolution of inflammation (Figure 13-6A). Second, the size and length of the catheter should correspond to the size of the abscess cavity (Figure 13-7A). A catheter that is too small or too short may fall into the wound (Figure 13-7B). Third, the length of time that the catheter should be left in place requires clinical judgment. Factors involved in this decision should include the size of the original abscess cavity, the amount of granulation tissue around the catheter, and the character and amount of drainage. If there is doubt, it is better to leave the catheter in place for a longer period of time.

#### Primary Fistulotomy

A point of controversy is whether primary fistulotomy should be performed at the time of initial abscess drainage. Proponents<sup>5,9-11</sup> believe that in the acute phase one can better

A

B

FIGURE 13-6. Catheter drainage of an abscess. **A** Stab incision. **B** Catheter in abscess cavity.

trace the suppurative process because of the presence of pus. Primary fistulotomy eliminates the source of infection and decreases the rate of recurrence, obviating the need for subsequent surgery with the potential to decrease disability and morbidity. Fucini<sup>11</sup> reported no recurrences in 51 of 58 primary

A

B

FIGURE 13-7. Catheter in an abscess cavity. **A** Correct size and length of catheter. **B** Catheter too short.

fistulotomies when internal openings could be identified. No major incontinence was reported, but impaired control of flatus was seen in 17%. In eight patients in whom only incision and drainage were performed because of failure to identify an internal opening, recurrences were reported in 87%.<sup>11</sup>

Opponents<sup>6,12</sup> are reluctant to perform primary fistulotomy in the presence of acute inflammation because the search for an internal opening may lead to creation of false passages resulting in neglect of the main source of infection. Failure to identify an internal opening has been reported to occur in as high as 66% of patients.<sup>10</sup> In addition, 34%–50% of patients who present with an abscess for the first time will not develop a fistula.<sup>6,12</sup> Thus, primary fistulotomy in these patients would be unnecessary and may result in needless disturbances of continence. Of those patients whose abscesses are drained, 11% may develop a fistula whereas 37% may develop a recurrent abscess.<sup>6</sup> This is most often observed in conjunction with ischioanal abscesses.<sup>6</sup> The search for an internal opening converts the operative procedure from one that can be performed under local anesthesia to one that requires regional or general anesthesia. A prospective, randomized trial of drainage alone versus drainage and fistulotomy for acute perianal abscesses with proven internal openings revealed that incision and drainage alone demonstrated no statistical significance in recurrence compared with concurrent fistulotomy although there was a tendency to recurrence in the former group.<sup>13</sup> Another prospective study advocated a conservative approach in the treatment of anorectal abscess, reserving fistulotomy as a second-stage procedure if necessary.<sup>14</sup>

If the internal opening of a low transsphincteric fistula is readily apparent at the time of abscess drainage, primary fistulotomy is feasible with the following exceptions: 1) patients with Crohn's disease, 2) patients with acquired immunodeficiency syndrome (AIDS), 3) elderly patients, 4) patients with high transsphincteric fistulas, and 5) women with anterior fistulas and episiotomy scars.

The decision to perform a primary fistulotomy should be individualized but should only be attempted by a surgeon with a sound knowledge of the regional anatomy. Insistence upon finding a fistula may encourage creation of a false passage and unnecessary division of sphincter muscle.<sup>11</sup>

As will be seen in the discussions of the use of fibrin glue anal plug in the treatment of fistula-in-ano further on in this chapter, many of the former proponents of primary fistulotomy have abandoned this approach and have instead elected to await the appearance of a fistula after drainage only to treat it with fibrin glue anal plug so as to avoid cutting any sphincter muscle.

#### Antibiotics

There is little if any role for antibiotics in the primary management of anorectal abscesses except as an adjunct in patients with valvular heart disease or prosthetic valves, extensive soft tissue cellulitis, prosthetic devices, diabetes, immunosuppression, or systemic sepsis.

#### Postoperative care

Patients are instructed to continue with a regular diet and to take a bulk-forming agent, non-codeine-containing analgesic, and sitz baths. Patients are generally seen in follow-up in 2–4 weeks or for intersphincteric or supralelevator abscesses, 2 weeks postoperatively. Those patients in whom catheter drainage has been performed are seen within 7–10 days after the procedure. If the cavity has closed around the catheter and drainage has ceased, the catheter is removed. If the cavity has not healed, the catheter is left in place or replaced with a smaller one. In all cases, patients are observed until complete healing has occurred.

#### Complications

##### Recurrence

After incision and drainage, ischioanal and intersphincteric abscesses are associated with the development of recurrent abscesses or fistulas in as many as 89% of patients.<sup>6,14,15</sup> Recurrence is more likely to occur in patients with a history of abscess drainage<sup>6,14,15</sup> perhaps because the natural barriers to infection have been destroyed.

Reasons for recurrence of anorectal infections include missed infection in adjacent anatomic spaces, the presence of an undiagnosed fistula or abscess at initial abscess drainage, and failure to completely drain the abscess.<sup>5</sup>

If a patient waits too long for follow-up after catheter drainage, the skin may seal and a second incision may be required to retrieve the catheter or redrain a recurrent abscess.

Failure to detect a primary opening at the time of primary fistulotomy and abscess drainage may result in persistence of the infection.

##### Extra-anal Causes

Extra-anal disease should be considered once the usual causes of recurrence have been ruled out. Hidradenitis suppurativa and downward extension of a pilonidal abscess should be considered.<sup>1</sup> A prospective review of recurrent anorectal abscesses by Chrabot et al.<sup>16</sup> reported hidradenitis in one-third of patients with recurrent abscesses. In addition, the possibility of Crohn's disease should be suspected.

##### Incontinence

Incontinence may result after incision and drainage of an abscess either from iatrogenic damage to the sphincter or inappropriate wound care. Continence may be compromised if the superficial external sphincter is inadvertently divided during drainage of a perianal or deep postanal abscess in a patient with preoperative borderline continence. Drainage of a supralelevator abscess may lead to incontinence if the puborectalis is inappropriately divided.<sup>17</sup> Prolonged packing of a drained abscess may impair continence by preventing the development of granulation tissue and promoting the formation of excess scar tissue.<sup>18</sup>

Although advocated to decrease recurrence rates, primary fistulotomy may result in unnecessary division of sphincter muscle in acutely inflamed tissue. Schouten and van Vroonhoven<sup>14</sup> reported a 39% rate of continence disturbances in a prospective, randomized trial.

### Special Considerations

#### Necrotizing Anorectal Infection

Rarely, anorectal abscesses may result in necrotizing infection and death. Factors thought to be responsible include delay in diagnosis and management, virulence of the organism involved, bacteremia and metastatic infections, or underlying disorders such as diabetes, blood dyscrasias, heart disease, chronic renal failure, hemorrhoids, and previous abscess or fistula.<sup>5</sup>

#### Symptoms and Signs

Spreading soft tissue infection of the perineum can be classified into two groups.<sup>19</sup> The first group includes anorectal sepsis in which the infection extends superficially around the perineum resulting in necrosis of skin, subcutaneous tissue, fascia, or muscle. Perianal crepitation, erythematous, indurated skin, blistering, or gangrene may be present (Figure 13-8). A black spot may appear early and indicates a widespread necrotizing infection.<sup>20</sup> The second group includes sepsis in which the preperitoneal or retroperitoneal spaces have become involved.<sup>19</sup> Subtle signs may be present which include abdominal wall induration, tenderness, or a vague mass. It is important to realize that systemic symptoms such as fever, tachycardia, and vascular volume depletion may precede the appearance of overt signs of infection.<sup>21</sup>

#### Treatment

Treatment consists of vigorous intravenous fluid hydration, restoration of electrolyte balance, and insertion of a Foley catheter. Accompanying coagulopathy, respiratory insufficiency, and

FIGURE 13-8. Necrotizing anorectal infection.

renal failure must be aggressively treated. Invasive monitoring and ventilatory support may be necessary.<sup>22</sup> Pus or necrotic tissue from the infected region must be cultured for aerobes and anaerobes. A Gram stain can be used to distinguish between the presence of clostridial and nonclostridial organisms.<sup>23</sup> Empiric broad-spectrum antibiotic therapy should be instituted regardless of Gram stain and culture results. The chosen antibiotic regimen should be effective against staphylococci and streptococci, Gram-negative coliforms, *Pseudomonas*, *Bacteroides*, and *Clostridium*. For Gram-positive rods seen on Gram stain, antibiotics administered should include sodium penicillin G in doses of 24–30 million units per day and an aminoglycoside. Tetanus toxoid should also be administered.<sup>22</sup>

Surgical treatment consists of wide radical debridement until healthy tissue is encountered. The goals of surgical debridement are to remove all nonviable tissue, halt the progression of infection, and alleviate the systemic toxicity.<sup>21</sup> It is crucial to realize that the preoperative skin changes may be minimal compared with the operative findings which may include edema, liquefactive necrosis of subcutaneous tissues, watery pus formation, and extensive necrosis of underlying fascia.<sup>22</sup> Reexamination under anesthesia is usually necessary because this is the only manner by which adequate wound examination can be conducted.<sup>22</sup> The need for colostomy is a debatable issue and has been recommended if the sphincter muscle is grossly infected, if there is colonic or rectal perforation, if the rectal wound is large, if the patient is immunocompromised, or if incontinence is present.<sup>19,21</sup> Whereas some authors<sup>23</sup> believe that colostomy is seldom necessary, fecal diversion may also be accomplished with the use of a “medical colostomy” consisting of enteral or parenteral nutrition. Controversy also exists with regard to the need for urinary diversion by suprapubic catheterization. It has been suggested that this may be indicated in the presence of known stricture and urinary extravasation with phlegmon.<sup>24</sup>

Although antibiotics and adequate surgical drainage are thought to be sufficient, the use of hyperbaric oxygen (HBO) has been advocated as an adjunct to treatment, particularly in patients with diffuse spreading infections who do not have chronic obstructive pulmonary disease.<sup>25</sup> It is postulated that HBO has a direct antibacterial effect on anaerobic bacteria by diminishing the effect of endotoxins and optimizing leukocyte phagocytic function.<sup>20</sup> HBO may also promote wound healing by facilitating fibroblast proliferation.<sup>25</sup> HBO is delivered as 100% oxygen through an oronasal mask or endotracheal tube at 3 atm for one or two cycles each lasting 2 hours. If HBO is to be used as an adjunctive therapy, appropriate surgical intervention with wide debridement cannot be compromised because ischemic tissue cannot be salvaged by HBO.<sup>21</sup>

Despite aggressive surgical and multidisciplinary management of anorectal sepsis, mortality rates ranging from 8% to 67% have been reported.<sup>19,21</sup> This high mortality rate is attributable in part to the aggressive nature of the infection and to the underlying comorbid diseases that are present in these

patients.<sup>21</sup> Mortality rates are 2–3 times higher in diabetics, in elderly patients, and in patients in whom treatment is delayed.<sup>21</sup>

### Anal Infection and Hematologic Diseases

Acute anorectal suppuration poses an interesting and often life-threatening problem in patients with acute hematologic diseases. In patients with acute leukemia, mortality rates of 45%–78% have been reported.<sup>26</sup> There is a definite relationship between the number of circulating granulocytes and the incidence of perianal infection in patients with hematologic diseases. In one study, patients with neutrophil counts below 500 per cubic millimeter had an incidence of anorectal infections of 11% whereas those with counts greater than 500 per cubic millimeter had an incidence of 0.4%.<sup>27</sup> Glenn et al.<sup>28</sup> reported that 63% of anorectal infectious episodes occurred when fewer than 500 neutrophils were present per cubic millimeter. The risk of developing anorectal infection in this patient population has been found to be related to the severity and duration of the neutropenia.<sup>26</sup> The most important prognostic indicator was the number of days of neutropenia during the infectious episode.<sup>28</sup>

The most common presenting symptoms include fever which precedes pain, and urinary retention. Point tenderness and poorly demarcated induration constitute the earliest signs,<sup>26</sup> whereas external swelling and fluctuation often appear late in the course of infection.<sup>28</sup>

Controversy surrounds the treatment of acute anorectal infections in patients with hematologic malignancies. Surgery has generally been avoided because what may seem to be simple incision and drainage may produce scant or no pus and may instead cause hemorrhage, poor wound healing, or expanding soft tissue infection.<sup>28</sup>

Any patient with perianal pain is assumed to have a perianal complication and is started on precautionary measures which consist of no digital rectal examinations, suppositories, or enemas.<sup>29</sup> Sitz baths, stool softeners, bulk agents, and analgesia are advised. On aspiration of most abscesses in this group, the most common organisms have been found to be *Escherichia coli* and group D streptococcus.<sup>28</sup> Consequently, infections are successfully controlled with a third-generation cephalosporin combined with anaerobic coverage or an extended spectrum penicillin in combination with an aminoglycoside and an anti-anaerobic antibiotic. This combination has been associated with an 88% success rate.<sup>28</sup>

Barnes et al.<sup>26</sup> recommend an aggressive surgical approach. Through this approach, 13 of 15 patients who were severely neutropenic with neutrophil counts of fewer than 100 per cubic millimeter recovered with incision and drainage. It must be noted that these patients were found to have extensive soft tissue infection. Because appropriate antibiotic coverage has been found to control infection successfully, surgery has generally been recommended only if there is obvious fluctuation, progression of soft tissue infection, or persistent sepsis after a trial of antibiotic therapy.<sup>28</sup>

With severe neutropenia of fewer than 500 neutrophils per cubic millimeter, low-dose radiation therapy of 300–400 rads for a period of 1–3 days has been suggested. Spontaneous drainage or subsidence of induration has been found to occur in 3–5 days.<sup>29</sup> A randomized, controlled study, however, has failed to confirm the utility of this approach.<sup>30</sup>

### Anorectal Sepsis in the Patient Positive for the Human Immunodeficiency Virus

Patients who are human immunodeficiency virus (HIV) positive and present with abscesses require drainage either by incision and drainage or use of catheter drainage. Because these patients are immunosuppressed, adjunctive antibiotics should be used. Efforts should be directed at keeping wounds small because these patients are at risk of poor wound healing.<sup>31</sup> An increased incidence of perianal sepsis<sup>32</sup> may be observed in HIV-positive patients. Serious septic complications or uncommon presentations of anorectal sepsis were found in 13% of patients who initially presented with anorectal suppuration in one study.<sup>31</sup> In another study, perianal sepsis was associated with in situ neoplasia.<sup>33</sup>

## Fistula-in-ano

Familiarity of the surgeon with the anatomy of the anorectal area and with the pathogenesis and classification of fistulas is essential for their adequate management.

## Pathophysiology

### *Etiology*

A fistula is defined as an abnormal communication between any two epithelium-lined surfaces. A fistula-in-ano is an abnormal tract or cavity communicating with the rectum or anal canal by an identifiable internal opening. Most fistulas are thought to arise as a result of cryptoglandular infection.

### *Classification*

The most helpful yet complicated classification of fistula-in-ano is that described by Parks et al. (Table 13-2). It has been suggested that its use is particularly applicable to the treatment of recurrent fistulas.<sup>10</sup>

### *Intersphincteric Fistula-in-ano*

This fistula is the result of a perianal abscess. The tract passes within the intersphincteric space (Figure 13-9A). This is the most common type of fistula and accounts for approximately 70% of fistulas.<sup>34</sup> A high blind tract passing from the fistula tract to the rectal wall may occur; in addition, the tract may also pass into the lower rectum. The infectious process may pass into the intersphincteric plane and terminate as a blind tract. There is no downward extension to the anal margin, and

Secondary to pelvic inflammation

thus no external opening is present. Infection may also spread in the intersphincteric plane to reach the pelvic cavity to lie above the levator ani muscles. Lastly, an intersphincteric fistula may originate in the pelvis as a pelvic abscess but manifest itself in the perianal area.

#### *Transsphincteric Fistula-in-ano*

In its usual variety, this fistula results from an ischioanal abscess and constitutes approximately 23% of fistulas seen.<sup>34</sup> The tract passes from the internal opening through the internal and external sphincters to the ischioanal fossa (Figure 13-9B). A high blind tract may also occur in this situation in which the upper arm of the tract may pass toward the apex of the ischioanal fossa or may extend through the levator ani muscles and thereby into the pelvis. One form of transsphincteric

FIGURE 13-9. Classification of fistula-in-ano. **A** Intersphincteric. **B** Transsphincteric. **C** Suprasphincteric. **D** Extrasphincteric.

fistula is the rectovaginal fistula. This is discussed further in Chapter 14.

#### *Suprasphincteric Fistula-in-ano*

This fistula results from a supralelevator abscess and accounts for approximately 5% of fistulas in some series.<sup>34</sup> The tract passes above the puborectalis after arising as an intersphincteric abscess. The tract curves downward lateral to the external sphincter in the ischioanal space to the perianal skin (Figure 13-9C). A high blind tract may also occur in this variety and result in a horseshoe extension.

#### *Extrasphincteric Fistula-in-ano*

This constitutes the rarest type of fistula and accounts for 2% of fistulas.<sup>34</sup> The tract passes from the rectum above the levators and through them to the perianal skin via the ischioanal space (Figure 13-9D). This fistula may result from foreign body penetration of the rectum with drainage through the levators, from penetrating injury to the perineum, or from Crohn's disease or carcinoma or its treatment. However, the most common cause may be iatrogenic secondary to vigorous probing during fistula surgery.<sup>4</sup>

### Evaluation and Treatment

#### *Symptoms*

A patient with a fistula-in-ano will often recount a history of an abscess that has been drained either surgically or spontaneously. Patients may complain of drainage, pain with defecation, bleeding caused by the presence of granulation tissue at the internal opening, swelling, or decrease in pain with drainage. Additional bowel symptoms may be present when the fistula is secondary to proctocolitis, Crohn's disease, actinomycosis, or anorectal carcinoma.<sup>35</sup> Systemic diseases such as HIV, carcinoma, and lymphoma should be entertained.<sup>35</sup>

#### *Physical Examination*

The external or secondary opening may be seen as an elevation of granulation tissue discharging pus. This may be elicited on digital rectal examination. In most cases, the internal or primary opening is not apparent. The number of external openings and their location may be helpful in identifying the primary opening. According to Goodsall's rule (Figure 13-10), an opening seen posterior to a line drawn transversely across the perineum will originate from an internal opening in the posterior midline. An anterior external opening will originate in the nearest crypt. Generally, the greater the distance from the anal margin, the greater the probability of a complicated upward extension. Cirocco and Reilly<sup>36</sup> found that Goodsall's rule was accurate in describing the course of anal fistulas with a posterior external opening. It was inaccurate in describing the course of anal fistulas with an anterior external opening because 71% of these fistulas tracked to a midline anterior primary opening. This

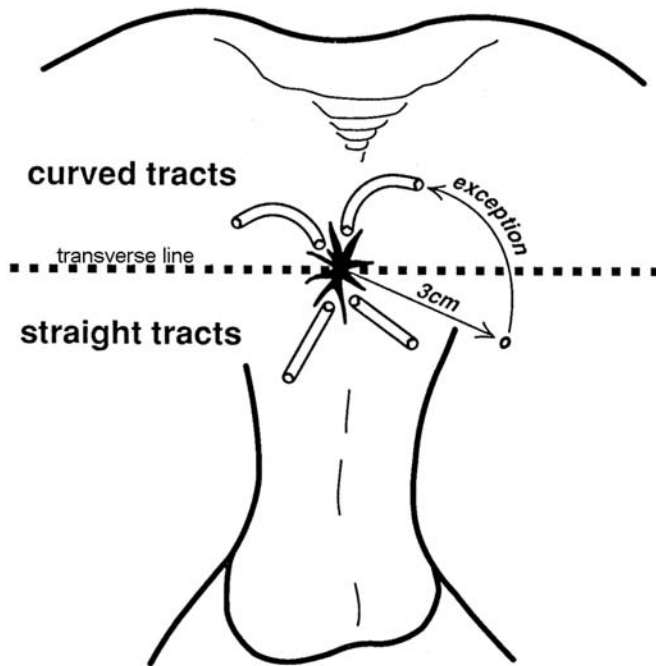

FIGURE 13-10. Goodsall's rule.

was especially true in women in whom fistulas with anterior external openings tracked in a radial manner in only 31%.<sup>36</sup>

Digital rectal examination may reveal an indurated cord-like structure beneath the skin in the direction of the internal opening with asymmetry between right and left sides. Internal openings may be felt as indurated nodules or pits leading to an indurated tract.<sup>36</sup> Posterior or lateral induration may be palpable indicating fistulas deep in the postanal space or horseshoe fistulas.<sup>35,36</sup> Bidigital rectal examination will define the relationship of the tract to the sphincter muscles and provides information as to preoperative sphincter tone, bulk, and voluntary squeeze pressure which need to be assessed preoperatively because of a possible risk of incontinence.<sup>17,35</sup>

### Investigations

Anoscopy should be done before operation in an attempt to identify the primary opening. Sigmoidoscopy should be performed to locate a proximal internal opening and to exclude underlying pathology such as proctitis or neoplasia. Colonoscopy or barium enema and a small bowel series are indicated in patients who have symptoms suggestive of inflammatory bowel disease and in patients with multiple or recurrent fistulas. Although anal manometry is not generally required, it may be useful as an adjunct to planning the operative approach in women with previous obstetric trauma, in an elderly patient, a patient with Crohn's disease or AIDS, or in a patient with a recurrent fistula.<sup>37</sup>

The role of preoperative imaging is to demonstrate clinically undetected sepsis, to serve as a guide at the time of the

initial surgery, to determine the relationship of the fistula tract to the sphincter mechanism, and to reveal the site of sepsis in a recurrent fistula, all serving to decrease recurrence rates associated with fistula surgery. Imaging may take the form of fistulography, computed tomography (CT) scan, endoanal ultrasound, and magnetic resonance imaging (MRI).

### Fistulography

Fistulography, which involves cannulation of the external opening with a small feeding tube and injection of water-soluble contrast may be useful in the evaluation of recurrent fistulas or in Crohn's disease where previous surgical forays or disease may have altered anorectal anatomy<sup>38</sup> (Figure 13-11). Contrast is introduced at low pressures for fear of tissue disruption. This may not allow secondary tracts to fill with contrast. It is difficult to distinguish between an abscess located high in the ischioanal fossa and one located in the supralelevator space. In addition, the level of the internal opening may be difficult to see because of the absence of precise landmarks. Contrast may reflux into the rectum wrongly suggesting an extrasphincteric tract with a rectal opening thus resulting in injudicious probing. Accuracy rates in identifying the internal openings and extensions in one study were found to be 16%, whereas a subsequent study found fistulography to be useful in 96%.<sup>38,39</sup> Its use resulted in altered surgical management or revealed other surgical pathology in 48%.<sup>38</sup> It was found, for reasons outlined previously, to have a false-positive rate of 12%.<sup>39</sup> Fistulography is invasive and potentially may result in the dissemination of sepsis.

FIGURE 13-11. Fistulogram. Arrowheads indicate fistula tract.

### CT Scan

CT scanning performed with intravenous and rectal contrast is a noninvasive method used to assess the perirectal spaces. Its use may be to distinguish an abscess requiring drainage from perirectal cellulitis. It does not permit visualization of tracts in relation to the levators.

### Endoanal Ultrasound

The role of endoanal ultrasound is to establish the relation of the primary tract to the anal sphincters, to determine if the fistula is simple or complex with extensions, and to determine the location of the primary opening. It may aid in the identification of complex suppuration to assess the adequacy of drainage<sup>40</sup> (Figure 13-12a). A prospective study that compared this modality to digital examination found that although endosonography was able to detect a large portion of intersphincteric and transsphincteric tracts, it was unable to detect primary superficial, extrasphincteric and suprasphincteric tracts or secondary supralelevator or infralevator tracts.<sup>41</sup> A study conducted 10 years later<sup>42</sup> using a 10-mHz probe along with injection of hydrogen peroxide into the tract, was able to identify the internal opening in 93%. Although this investigative modality is rapid and well tolerated, it is operator dependent and scars or defects caused by previous sepsis, surgery, or trauma will confuse ultrasonographic interpretation and make delineation of fistula tracts difficult.<sup>41</sup> The concomitant use of hydrogen peroxide (Figure 13-12b) or Levovist<sup>TM</sup><sup>43</sup> at the time of ultrasound examination has been found to improve its accuracy.

### Magnetic Resonance Imaging

MRI in the form of endoanal coil, body coil, and phase array coil (Figure 13-13) may be of value in the assessment of

patients with complex fistulas and in those with anatomic distortion resulting from previous surgery. Because MRI can provide multiplanar visualization of the sphincter muscles, differentiation of supralelevator from infralevator lesions is easier.<sup>44</sup> MRI has been found to accurately delineate the presence and course of a primary fistulous tract but also demonstrates the site and presence of any secondary extensions.<sup>45</sup> It also provides the most accurate imaging technique of localizing the site of the internal opening because its location can be inferred from the proximity of the tract in the intersphincteric space.<sup>45</sup> A prospective study that compared the accuracy of MRI in the preoperative assessment of anal fistulas to operative findings found concordance rates of 88% for the presence and course of the primary tract, 91% for the presence and site of secondary extensions or abscesses and 97% for the presence of horseshoeing, and 80% for the position of the internal openings.<sup>45</sup> In the same study, failure of healing in 9% was found to be related to pathology missed at the time of surgery which had been documented on preoperative MRI.<sup>45</sup> Difficulties in interpretation, however, may occur because neural and vascular structures could be mistaken for fistulas and chemical shift artifacts may simulate a fistula filled with fluid.<sup>46</sup> The use of the endoanal coil has been found to be superior to external MRI for the identification of complex sphincter anatomy especially in the demonstration of the morphology of the internal and external sphincters<sup>47</sup>; however, definition may fall off outside the sphincter and may fail to show the tracts that lie beyond its range. It is also painful. A prospective study comparing hydrogen peroxide endoanal ultrasound to endoanal MRI found good agreement for the classification of the primary fistula tract and the location of the internal opening. These results also demonstrated good agreement with the surgical findings enabling both to be reliable for the preoperative evaluation of fistulas.<sup>48</sup>

FIGURE 13-12. **A** Anal endosonogram; arrows indicate fistula tract; **B** with hydrogen peroxide; arrows indicate better delineation of fistula tract. (Courtesy Dr. Julio Faria.)

FIGURE 13-13. Phase array MRI. **A** White arrowhead indicates levators; black arrowhead indicates fistula tract to rectum; black arrow shows tract crossing levator. **B** Arrowhead indicates tract going to skin.

A prospective trial comparing the use of the endoanal coil to the body coil found that surgical concordance for the endoanal coil was 68% versus 96% for the body coil, presumably because of field of view limitations.<sup>49</sup> This can be overcome with the use of the phase array coil which has a larger field of view and may be useful in Crohn's disease and recurrent fistulas.<sup>50</sup>

Buchanan et al.,<sup>51</sup> in a prospective study to determine the impact of MRI with primary fistulas, found that MRI changed the surgical approach in 10%. In another study with respect to recurrent fistulas, recurrence rates were found to be higher for those surgeons who never used MRI.<sup>52</sup> They concluded that MRI-guided surgery can decrease recurrence rates by 75% in surgery for recurrent fistulas.

## Treatment

### General Principles

The principles of fistula surgery are to eliminate the fistula, prevent recurrence, and preserve sphincter function. Success is usually determined by identification of the primary opening and dividing the least amount of muscle possible.

Several methods have been proposed to identify the primary opening in the operating room<sup>1,4</sup>:

1. Passage of a probe or probes from the external opening to the internal opening or vice versa.
2. Injection of a dye such as dilute solution of methylene blue, milk, or hydrogen peroxide, and noting their appearance at

the dentate line. Although methylene blue may stain surrounding tissues, diluting it with saline or hydrogen peroxide will obviate this problem.

3. Following the granulation tissue present in the fistula tract.
4. Noting puckering of an anal crypt when traction is placed on the tract. This may be useful with simple fistulas but is less successful in the more complicated varieties.

## Operative Management

### Lay-open Technique

For the treatment of simple intersphincteric and low transsphincteric fistulas, the patient is placed in the prone jack-knife position after induction of a regional anesthetic. Local anesthesia consisting of 0.5% lidocaine or 0.25% bupivacaine hydrochloride with 1:200,000 epinephrine is injected along the fistula tract for hemostasis after insertion of an anal speculum. Use of bupivacaine provides analgesia of longer duration than most regional anesthetics. A probe is inserted from the external opening along the tract to the internal opening at the dentate line. The tissue overlying the probe is incised and the granulation tissue curetted and sent for pathologic evaluation. A gentle probe is used to identify any high blind tracts or extensions, which are unroofed, if found. If desired, the wound may be marsupialized on either edge by sewing the edges of the incision to the tract with a running locked absorbable suture. There is no need to insert packing if an adequate unroofing has been accomplished (Figure 13-14A-C).

FIGURE 13-14. Technique of laying open. **A** Insertion of probe and incision of tissue overlying probe. **B** Curettage of granulation tissue. **C** Marsupialization of wound edges.

### Seton

The problem of preserving anal continence and treating the fistula is more complicated when managing high transsphincteric fistulas. If the tract is seen to cross the sphincter muscle at a high level, the use of the lay-open technique in combination with insertion of a seton is safer. A seton may be any foreign substance that can be inserted into the fistula tract to encircle the sphincter muscles. Materials frequently used include silk or other nonabsorbable suture material, Penrose drains, rubber bands, vessel loops, and silastic catheters.<sup>17</sup> The lower portion of the internal sphincter is divided along with the skin to reach the external opening and a nonabsorbable suture or elastic suture is inserted into the fistulous tract. The ends of the suture or elastic are tied with multiple knots to create a handle for manipulation (Figure 13-15). This form of seton, known as a cutting seton, is tightened at regular intervals to slowly cut through the sphincter. This allows the tract to become more superficial, converting a high fistula into a low one. The proximal fistulotomy subsequently heals by stimulating fibrosis behind it reestablishing continuity of the anorectal ring to prevent separation of the sphincter muscle at a second-stage repair 8 weeks later when the remaining external sphincter is divided. The seton also allows delineation of the amount of remaining muscle thus enabling improved postoperative assessment by outlining the tract. A seton may also be used as a drain which is left loosely in place to facilitate prolonged drainage. Specific indications for seton use include the following:<sup>53</sup> 1) to identify and promote fibrosis around a complex anal fistula that encircles most or all of the sphincter mechanism; 2) to mark the site of a transsphincteric fistula in cases of massive anorectal sepsis where the normal anatomic landmarks have been distorted; 3) anterior, high transsphincteric fistulas in women. Because the

FIGURE 13-15. Seton.

puborectalis is absent in this area and the external sphincter is quite tenuous, primary fistulotomy may result in incontinence; 4) the presence of a high transsphincteric fistula in a patient with AIDS in whom healing is known to be poor; 5) to avoid premature skin closure and formation of recurrent abscesses and promote long-term drainage in patients with Crohn's disease. In these patients, a silastic catheter can be left in place for a prolonged period of time to promote epithelialization of the fistula tract or tracts; 6) when there is suspicion that primary fistulotomy will result in incontinence such as in those patients with multiple simultaneous fistulas, patients who have undergone multiple prior sphincter operations such as fistulotomy or internal sphincterotomy, and in elderly patients with weakened sphincter muscles.

Another option available to treat transsphincteric fistulas without division of muscle involves the use of a dermal island flap.<sup>54</sup> Division of muscle was able to be avoided in 90%; however, a 23% failure rate was reported. This was found to be more likely in males, patients who had previous treatment of their fistulas, patients with large fistulas requiring combined flaps, and patients who underwent simultaneous fibrin glue injection.

Treatment of suprasphincteric fistulas requires an appreciation that the tract involves the entire external sphincter complex as well as the puborectalis muscle. Laying open the entire tract would render the patient incontinent. Thus, several methods have been proposed to manage this fistula without the ensuing devastating consequences. The use of a seton has been advocated in combination with division of the internal sphincter and the superficial portion of the external sphincter to the external opening. The seton is placed around the remaining external sphincter as was previously described.<sup>55</sup>

A modification of this approach has been proposed by Kennedy and Zegarra<sup>56</sup> in which an internal sphincterotomy is performed, followed by opening of the tracts outside the external sphincter without division of any portion of the external sphincter which is encircled by a seton to promote fibrosis and assure adequate drainage. Complete healing using the latter approach has been reported in 66% with posterior fistulas and in 88% with anterior fistulas.<sup>56</sup> Parks and Stitz<sup>55</sup> obtained healing in 63%. Another method that has been proposed to treat this type of fistula is the anorectal advancement flap which will be described.

The horseshoe variety of the suprasphincteric fistula also presents the problem of complete sphincter involvement combined with the presence of multiple external openings a great distance from the cryptoglandular source. Treatment consists of identification of the internal opening and proper drainage of the postanal space as was previously described. The horseshoe extensions are enlarged for counter-drainage and the granulation tissue is curetted.

The treatment of an extrasphincteric fistula depends on its etiology. If the fistula arises secondary to an anal fistula, a secondary opening above the puborectalis is thought to be iatrogenic because of extensive probing of a transsphincteric

fistula. The lower portion of the internal sphincter is divided and the rectal opening is closed with a nonabsorbable suture. A temporary colostomy may be necessary but a medical colostomy consisting of preoperative mechanical and antibiotic bowel preparation followed by enteral feeding may suffice. If the fistula is the result of entrance of a foreign body, it must be removed, drainage must be established, the internal opening closed, and a temporary colostomy constructed to decrease rectal pressure. This type of fistula may also be a manifestation of Crohn's disease. Treatment will depend on the nature of the anorectal mucosa and drainage may be assisted by placement of a seton. Finally, the fistula may be the result of downward tracking of a pelvic abscess which must be drained so that the fistula can heal.

#### Anorectal Advancement Flap

When the traditional laying-open technique may be inappropriate, for example, in anterior fistulas in women, in patients with inflammatory bowel disease, in patients with high transsphincteric and suprasphincteric fistulas, as well as in those with previous multiple sphincter operations, multiple and complex fistulas, the use of an anorectal advancement flap has been advocated<sup>57</sup> (Figure 13-16A-D). Advantages of this technique include a reduction in the duration of healing, reduced associated discomfort, lack of deformity to the anal canal, as well as little potential additional damage to the sphincter muscles because no muscle is divided.<sup>17</sup>

After full mechanical and antibiotic bowel preparation, the patient is placed in the prone jackknife or left lateral position. Under a regional or general anesthetic, after insertion of a Foley catheter, the fistula tract is identified with a probe and either cored out or curetted. The internal opening is identified and excised. The external opening is enlarged to allow for drainage. A full-thickness flap of rectal mucosa, submucosa, and part of the internal sphincter is raised. The residual internal opening is closed with absorbable suture. The flap is then advanced 1 cm below the internal opening. The tip of the flap containing the fistulous opening is excised and the flap is sewn into place with absorbable sutures ensuring that the mucosal and muscular suture lines do not overlap. The base of the flap should be twice the width of the apex to maintain good blood supply. Successful results have reported in more than 90% of patients.<sup>58</sup> Factors associated with poor outcomes include Crohn's disease and steroids.<sup>59</sup> Cigarette smoking was found to be another significant variable in another study.<sup>60</sup>

#### Fistulectomy

Although excision of the fistula or fistulectomy was thought to be a satisfactory method of treatment of fistula-in-ano, its use is no longer recommended. Larger wounds are created significantly prolonging wound healing time.<sup>61</sup> A greater separation of muscle ends occurs<sup>1</sup> and there is greater risk of injuring or excising underlying muscle<sup>57</sup> thereby increasing the risk of incontinence. Schouten and van Vroonhoven<sup>14</sup>

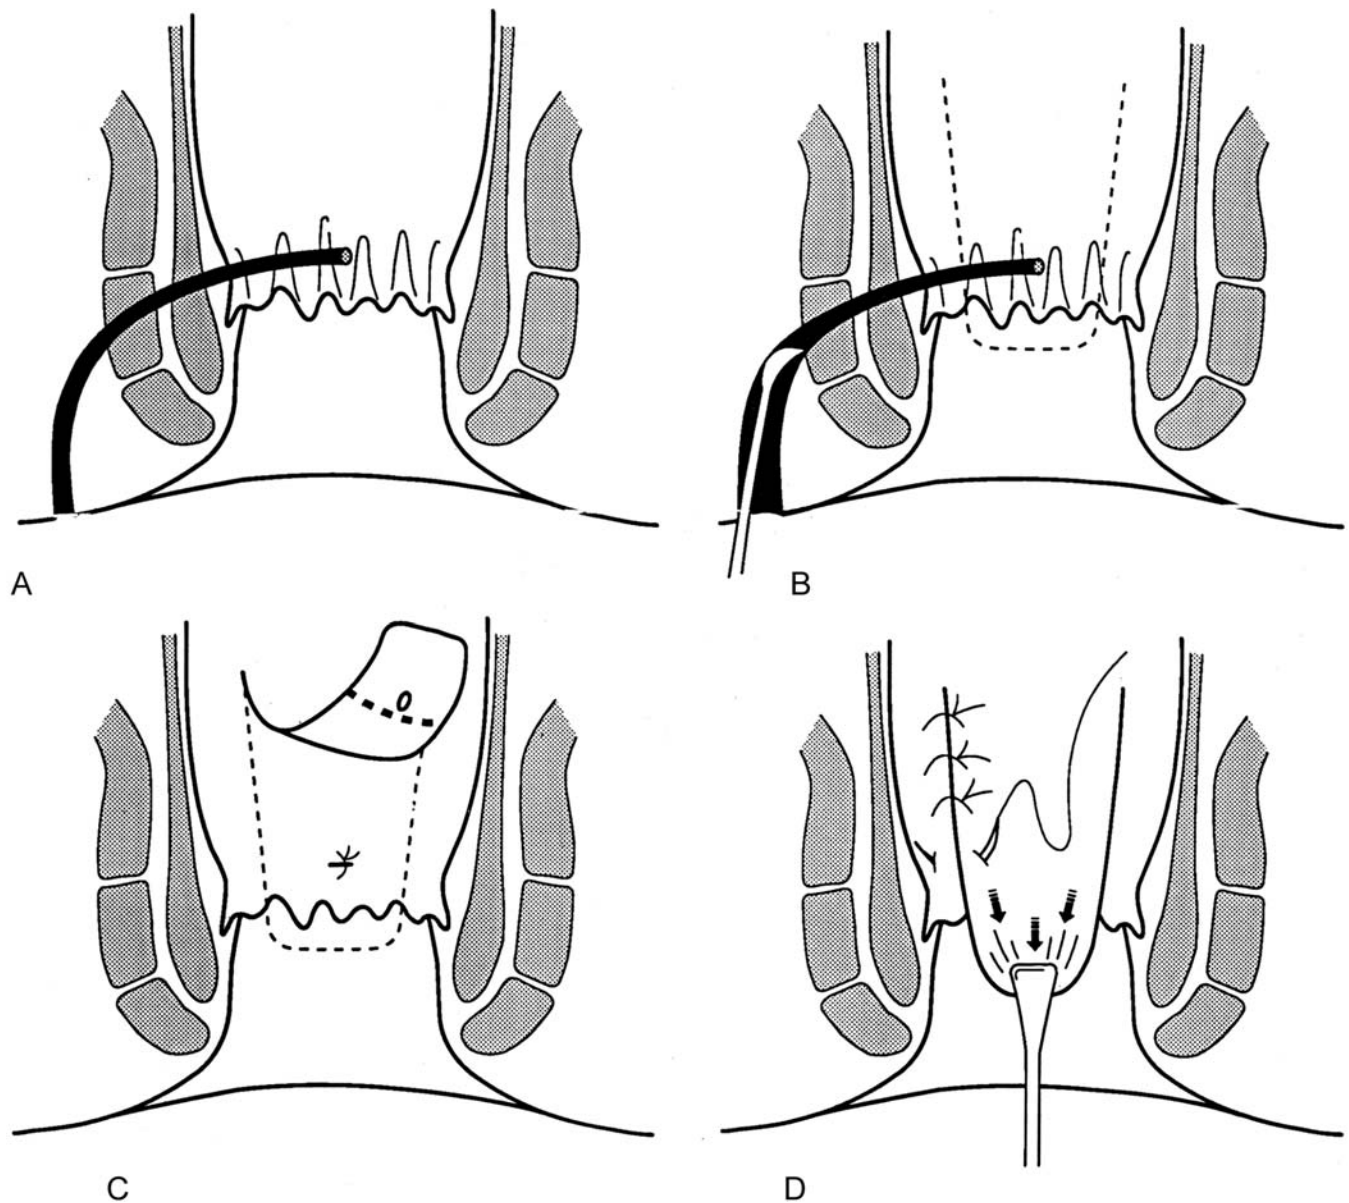

FIGURE 13-16. Anorectal advancement flap. **A** Transsphincteric fistula-in-ano. **B** Enlargement of external opening and curettage of granulation tissue. **C** Mobilization of flap and closure of internal opening. **D** Suturing of flap in place covering internal opening.

have found that fistulectomy, whether primary or secondary, was associated with a clinically significant disturbance in anal function.

#### Fibrin Glue

The use of fibrin glue as a primary treatment alone or in combination with an advancement flap has come into vogue. This treatment modality is appealing because it is a noninvasive approach that avoids the risk of incontinence associated with fistulotomy. In the case of failure, it may be repeated several times without jeopardizing continence. The technique involved is simple. As with fistulotomy, the fistula tract along

with its internal and external openings is identified and curetted (with curettes or flexible brushes). Fibrin glue is injected into the fistula tract through a Y connector so that the entire tract is filled and the glue can be seen emerging from the internal opening. The injecting catheter is slowly withdrawn so that the entire tract is filled. Petrolatum jelly gauze may be placed over the external opening.

Enthusiasm generated because of short-term success rates of 70%–74%<sup>62,63</sup> has been tempered because of delayed fistula recurrence despite initial apparent healing.<sup>64</sup> With longer follow-up, 60% of fistulas were found to have healed in a recent study<sup>65</sup> although patients underwent a two-stage approach consisting of seton placement followed by glue

injection at a second stage. Patients who failed underwent repeat injection which allowed 69% to heal. The 29% who failed to heal underwent either fistulotomy or advancement flap. Late recurrences (6%) occurred more than 6 months postoperatively and were treated with reinjection. Buchanan et al.<sup>66</sup> found fibrin glue injection to be useful in 14% with complex anal fistulas without extensions.

Although the exact mechanisms responsible for failure have not been entirely appreciated, it has been suggested that curettage may not adequately remove all granulation or epithelialized tissue thus failing to provide the correct environment for the glue to work.<sup>66</sup> Other adverse factors shown to influence healing include the presence of a short tract which may make it easier for the fibrin glue plug to become dislodged as well as the presence of a cavity on endoanal ultrasound.<sup>67</sup> The latter was associated with a complication of perianal abscess because the tract may not have been entirely filled with glue.<sup>68</sup> It has been suggested that fibrin glue be considered as first-line treatment for complex anal fistulas in appropriately selected patients.

### Bioprosthetic Fistula Plug

Recently, the use of a bioprosthetic plug made from lyophilized porcine intestinal submucosal has been described for complex anal fistulas.<sup>117</sup> This porcine fistula plug (Surgis anal fistula plug) is commercially available from Cook Surgical Inc, Bloomington, IN. Following rehydration of the plug, the following technique is used. The fistula tract is identified but not debrided. A solution of peroxide may be used to gently clean the tract. A fistula probe is placed through the tract and a 2-0 suture is placed through the tapered end of the plug and the ends of this suture are attached to the fistula probe at the primary opening. The suture is pulled from the primary opening, through the fistula tract to exit at the secondary opening. For patients with a "horseshoe" fistula, an incision is made over the fistula tract distal to the anal verge to create a secondary opening that the ends of the suture are brought through. With gentle traction on the suture, the porcine plug is pulled into the primary opening of the fistula until "wrinkling" of the superficial layer of the plug is first seen. The plug is not forced tightly. Excess plug is removed by transecting the plug at the level of the primary opening. The plug is secured in the primary opening using a 2-0 absorbable suture placed in a figure of 8 fashion with the suture crossing through the center of the plug and incorporating a generous portion of the sphincter mechanism on both sides. Any plug protruding through the secondary opening is also excised. The distal end of the plug is not sutured to the fistula tract and the distal opening is left open for drainage. Patients are advised to avoid vigorous physical activity for two weeks after plug placement to minimize the chance of plug dislodgement.

The prospective study by Johnson, et al., compared the porcine plug to fibrin glue in twenty-five patients with high transsphincteric or deeper fistulas.<sup>117</sup> Patients with Crohn's dis-

ease or superficial fistulas were excluded. Ten patients underwent fibrin glue closure, and 15 used a fistula plug. Patient's age, gender, fistula tract characteristics, and number of previous closure attempts was similar in both groups. In the fibrin glue group, six patients (60 percent) had persistence of one or more fistulas at three months, compared with two patients (13 percent) in the plug group ( $p < 0.05$ , Fisher exact test). The authors concluded that closure of the primary opening of a fistula tract using a suturable biologic anal fistula plug is an effective method of treating anorectal fistulas.

The technique has appeal for its simplicity and avoidance of sphincter injury. The technique seems to work best with long tracts without active sepsis. It is not suitable for short rectovaginal fistulas. An additional limitation has been the relatively high cost of the plug and the lack of large scale controlled multi-center trials. Although the early has been positive, further prospective, long-term studies are warranted.

### Postoperative Care

After the lay-open technique, patients are placed on regular diets, bulk agents, and non-codeine-containing analgesia. Patients are instructed to take frequent sitz baths to ensure perianal hygiene. Patients are evaluated at 2-week intervals to ensure that healing has occurred from the depths of the tract. Granulation tissue can be cauterized using silver nitrate sticks and cotton-tipped swabs are often used to probe the depths of the incision to ensure that adequate healing is occurring.

After the advancement flap technique, the Foley catheter is removed on the following day. The authors prefer to maintain patients on intravenous therapy and no oral nutrition for 5 days to allow adequate healing of the flap. After elapse of this time, the diet is progressed and routine management is instituted. The editor (D.E.B.) prefers to feed patients as soon as they can tolerate a diet.

### Complications

#### Incontinence

Minor disorders of continence after fistulotomy have been reported to range from 18% to 52% whereas soiling and insufficiency have been reported in as many as 35% to 45%<sup>69</sup> (Table 13-3). The occurrence of continence disorders has been found to be related to the complexity of the fistula and to the level and location of the internal opening.<sup>69</sup>

Patients with complicated fistulas, high openings, posterior openings, and fistula extensions have been found to be at higher risk.<sup>69</sup> In the treatment of complicated fistulas and those with high openings, more muscle is divided, thus decreasing anal pressures whereas posterior fistula wounds have been associated with higher rates of incontinence because of their more circuitous routes.<sup>69</sup> Drainage of extensions may accidentally damage small nerves and create more scar tissue around the anorectum.<sup>69</sup> If the edges of the

fistulotomy wound do not approximate precisely, the anus may be unable to properly close, resulting in intermittent leakage of gas and stool.<sup>53</sup> In addition to these factors, impaired continence was associated with increasing age<sup>70</sup> and female gender.<sup>69,70</sup> The latter is probably the result of partial anal sphincter disruption and/or traction injury to the pudendal nerves sustained during vaginal delivery.<sup>70</sup>

Although excellent results using a seton have been reported,<sup>77</sup> its use does not protect against the development of impaired continence.<sup>69</sup> Minor continence disorders were reported in 73%<sup>69</sup> whereas Williams et al.<sup>78</sup> reported minor disturbances in 54%. Parks and Stitz<sup>55</sup> found that minor incontinence occurred in 39% with the two-stage approach versus 17% when only the first stage was performed and the seton was removed rather than dividing the muscle. Major fecal incontinence was reported in 6.7%<sup>53</sup> after a review of several series (Table 13-4). The degree of incontinence is thought to be influenced by the patient's preoperative state of control as well as to how the anal wound heals.<sup>53</sup> Excellent results with respect to continence have been reported with the use of the advancement flap<sup>59</sup> although recent reports have observed disturbances in continence in 9%–35%.<sup>82,83</sup>

### Recurrence

Recurrence rates after fistulotomy range from 0% to 18%.<sup>72</sup> Results from selected references are cited in Table 13-3. Causes include failure to identify a primary opening or recognize lateral or upward extensions of a fistula.<sup>71,72</sup>

TABLE 13-4. Results of staged fistulotomy using a seton

Author	Year	Recurrence (%)	Incontinence (%)
Ramanujam et al. <sup>77</sup>	1983	1/45 (2)	1/45 (2)
Fasth et al. <sup>79</sup>	1990	0/7 (0)	0/7 (0)
Williams et al. <sup>78</sup>	1991	2/28 (8)	1/24 (4)
Pearl et al. <sup>53</sup>	1993	3/116 (3)	5/116 (5)
Van Tets <sup>69</sup>	1994	—	15/29 (54)
Graf et al. <sup>80</sup>	1995	2/25 (8)	11/25 (44)
Garcia-Aguilar et al. <sup>73</sup>	1996	6/63 (9)	39/61 (64)
Hasegawa et al. <sup>81</sup>	2000	8/32 (25)	15/32 (48)

Inability to locate the primary opening may imply a circuitous tract,<sup>72</sup> spontaneous closure of the primary opening,<sup>71</sup> or a microscopic opening.<sup>72</sup> The presence of secondary tracts<sup>71</sup> which can be easily missed accounted for early recurrence in 20%.<sup>72</sup> Premature closure of the fistulotomy wound can be obviated by producing an external wound twice the size of the anal wound resulting in proper healing of the internal wound before the external wound.<sup>72</sup> Diligent postoperative care can also reduce recurrence rates by avoiding bridging and pocketing of the wound.<sup>84</sup> Epithelialization of the fistula tract from internal or external openings rather than chronic infection of an anal gland has also been suggested as the cause of a persistent anal fistula.<sup>85</sup>

Recurrence rates after staged repairs using a seton range from 0% to 29%.<sup>53</sup> Results from selected references are cited in Table 13-4.

Although recurrence rates after anorectal advancement flaps were initially reported to be low, with long-term follow-up, recurrence rates of 40% have been reported.<sup>83</sup> Recurrence can be minimized provided that care has been taken to avoid necrosis or retraction of the flap. The use of full-thickness rectal wall has been advocated to prevent ischemic necrosis of the flap.<sup>86</sup>

Early postoperative complications that have been reported after fistula surgery include urinary retention, hemorrhage, fecal impaction, and thrombosed external hemorrhoids, which were found to occur in less than 6% of cases.<sup>18</sup> Later complications such as pain, bleeding, pruritus, and poor wound healing have been reported in 9% of patients.<sup>57</sup> Anal stenosis may occur and is usually the result of loose stools allowing healing of the anal canal by scar contracture.<sup>35</sup> Mucosal prolapse caused by extensive division of sphincter muscle may also occur and can be treated by band ligation, sclerosis, or excision.<sup>57</sup> With attention to both operative detail and postoperative follow-up, these complications can be reduced to a minimum.

### Special Considerations

#### Crohn's Disease

Anal fistulas are the most difficult and challenging complication of Crohn's disease to manage. They constitute the most

common perianal manifestations, occurring in 6%–34% of patients.<sup>87</sup> The location of Crohn's disease in the bowel has an impact on the frequency of fistulas. Patients with colonic Crohn's have a higher incidence with the rate approaching 100% in those with rectal Crohn's.<sup>88</sup>

As discussed previously, patients with Crohn's disease should undergo sigmoidoscopy, colonoscopy, and small bowel follow through to determine the extent of disease. Delineation of the fistulous tract is especially important in Crohn's disease because many fistulas may be complex in nature. In this context, endoanal ultrasound has been found to be as useful as MRI. MRI has been found to detect abscesses that were clinically unsuspected on clinical examination<sup>89</sup> and has been helpful in determining the relationship of the fistulous tract to the sphincter muscles.

Therapeutic goals in managing anorectal fistulas in Crohn's disease remain the alleviation of symptoms and preservation of continence. Surgical treatment of fistulas is associated with poor and delayed wound healing and with the risk of sphincter injury. Alexander-Williams stated that "incontinence is likely to be the result of aggressive surgeons, not of aggressive disease." A conservative approach has therefore been advocated, especially because 38% of such fistulas have been reported to heal spontaneously without any surgical intervention.<sup>90</sup> Medications used in the treatment of fistulas include antibiotics such as metronidazole and ciprofloxacin and immunomodulators such as corticosteroids, 6MP, azathioprine, and infliximab. Although several studies have reported spontaneous closure of fistulas in 34%–50% of patients treated with metronidazole,<sup>88</sup> improvement is usually seen after 6–8 weeks of treatment with relapses common once the medication is discontinued. A recent study that looked at the long-term effects of 6MP and azathioprine found that these medications were efficacious in only one-third of patients with fistulizing perianal disease.<sup>91</sup> These effects seemed unrelated to their effects on intestinal disease. The authors concluded that their results did not support the use of these medications solely for the improvement of perianal disease. The use of infliximab has been associated with a 62% reduction in draining fistulas.<sup>92</sup> The combination of infliximab and 6MP may prolong the effect of initial infliximab treatment on fistula closure.<sup>93</sup> Selective seton placement combined with infusion of infliximab and maintenance therapy with azathioprine or methotrexate resulted in complete healing in 67% with Crohn's fistulas in a recently reported retrospective study.<sup>94</sup> Maintenance therapy with infliximab has been reported to result in absence of draining fistulas in 36% of patients compared with 19% in placebo patients at 54-week follow-up.<sup>95</sup>

Although fistulas may occur in as many as 73% of patients after previous abscess drainage,<sup>87</sup> it is imperative that primary fistulotomy not be performed because of the high risk of creating false passages and injuring the sphincter mechanism. Asymptomatic fistulas require no treatment. Low fistulas with simple tracts can be managed with the standard lay-open

method in the absence of active proctitis. Successful outcome as gauged by healing has been reported to occur in 42%–100%, mostly in the 70%–80% range of procedures.<sup>96</sup>

The advent of fibrin glue has certainly offered another option in the armamentarium of treating fistulous Crohn's disease. A closure rate of 60% has been reported in one study.<sup>97</sup> This may also be combined with an endorectal advancement flap in the absence of rectal involvement.

Fistulotomy has been associated with prolonged healing.<sup>98</sup> Factors associated with delayed healing are rectal involvement,<sup>10,73</sup> anorectal complications (especially strictures),<sup>98</sup> and the presence or absence of an internal opening.<sup>99</sup> Successful healing has occurred in patients with a classic internal opening at the dentate line and in those without rectal involvement<sup>99</sup> although Halme and Sainio<sup>98</sup> found that delayed healing occurred in 80% of patients despite the presence of a normal rectum; Van Dongen and Lubbers<sup>100</sup> found no difference in healing even in the presence of rectal involvement. Nonetheless, initial therapy should be directed at resolving inflammation in the rectum. This can be accomplished with the use of topical steroid or 5-acetylsalicylic enemas or suppositories. In addition, oral medication may be necessary.

Incontinence has been reported in patients with proctitis who have not undergone anal surgery.<sup>100</sup> A patient with severe rectal involvement and even a simple low fistula is not a candidate for fistulotomy. Division of any sphincter muscle in this situation may result in frank incontinence because the noncompliant rectum acts as a conduit rather than as a reservoir. Continence problems have been reported in 25% of patients after simple incision and drainage of abscesses during which the sphincter mechanism has not been touched.<sup>100</sup> Allan and Keighley<sup>101</sup> reported a 50% frequency of major fecal incontinence and minor incontinence has been described in 33% of patients who have undergone only simple drainage or local surgery.<sup>98</sup> It is thought that diarrhea from either associated intestinal involvement or multiple previous small bowel resections is important in control disorders in these patients.<sup>87,98,100</sup> Appropriate medical therapy should be used to control the diarrhea.

Complex fistulas with high rectal openings might best be managed conservatively, because impaired continence may certainly result if the sphincter muscle is divided. Eradication of the fistula in this situation may not be possible because of the complexity of the tracts. Seton placement has been advocated to promote drainage, limit recurrent suppuration, and preserve sphincter function.<sup>102</sup> Rectal advancement flaps have been used in the absence of severe rectal disease.<sup>103</sup> These have been found to succeed in patients without concomitant small bowel Crohn's.<sup>104</sup>

The importance of quiescent intestinal disease for successful outcome of local fistula surgery has been suggested<sup>105</sup> but not generally accepted and practical. Proximal fecal diversion has also been suggested as an option to ameliorate severe perianal disease because diversion of the fecal stream may reduce perianal inflammation. However, improvement is

temporary because fistulas will reactivate after restoration of intestinal continuity.<sup>106</sup>

Complicated fistulas are more likely to recur because of the reluctance of the surgeon to divide sphincter muscle. The use of a long-term in-dwelling seton as a drain is therefore recommended.<sup>102</sup> Fistula recurrence may be as high as 39% after removal of the seton and may necessitate the use of concomitant medical therapy.<sup>87</sup> The use of a rectal advancement flap has been successful; however, breakdown is possible because of sepsis.<sup>103</sup> In patients with mild proctitis, a 20% success rate has been reported.<sup>103</sup> The presence of a protective stoma in this situation does not guarantee success, with failure reported in 55% of patients.<sup>103</sup> A covering stoma may be beneficial in the patient who has undergone multiple unsuccessful repairs.<sup>103</sup> Many fistulas may require repeat fistulotomy to achieve complete healing<sup>98</sup> or repeat injections of fibrin glue. For severe intractable disease, an intersphincteric proctectomy may ultimately become necessary. The intersphincteric technique reduces the size of the resulting wound and reduces the incidence of unhealed sinuses.

#### Fistula-in-ano in the HIV-positive Patient

Anal fistulas are prevalent in the anoreceptive HIV-positive individual.<sup>107</sup> Disturbed locoregional defenses may allow infection to occur.<sup>107</sup> Although anal fistulas in HIV-positive patients arise from the dentate line similar to those in HIV-negative patients, they are more likely to have incomplete anal fistulas leading to blind sinus tracts.<sup>108</sup> Concern for wound healing has tempered enthusiasm for operative intervention. However, selective operative management will result in a high rate of complete or partial wound healing with symptomatic relief without excessive morbidity or mortality.<sup>107</sup> Severity of illness must be assessed before operative intervention because patients with more advanced disease are less likely to heal their wounds. Data are conflicting as to whether preoperative CD4+ lymphocyte counts can be related to poor wound healing<sup>107</sup>; however, Consten et al.<sup>31</sup> found that low CD4+ lymphocyte counts in patients with perianal sepsis were a risk factor for disturbed wound healing. Use of Highly Active Antiviral therapy (HAART) may reduce the incidence of opportunistic infections and anorectal disease and aid healing.<sup>109</sup>

Asymptomatic fistulas require no treatment. Perioperative antibiotic therapy over a 5-day course has been recommended because of the high risk of infectious complications.<sup>107</sup> Care should be exercised to avoid creation of large wounds and to preserve as much sphincter muscle as possible because these patients may be prone to diarrhea which may overwhelm a partially divided sphincter.<sup>107</sup> In patients who are good operative risks, fistulotomy is appropriate in patients with intersphincteric or low transsphincteric fistulas. For high or complex fistulas as well as for those patients who are poor operative risks, liberal use of draining setons is recommended.<sup>35,107</sup> It is important to realize that cellulitis may be seen with a fistula without

concomitant underlying exudate.<sup>107</sup> Metastatic abscesses to other organs including brain, liver, and mediastinum have been reported with asymptomatic perianal fistulas.<sup>31</sup> Healing has been reported in 55%–80% of patients.<sup>31,107</sup>

## Rectourethral Fistulas

### Pathophysiology

Rectourethral fistulas are rare but devastating complications that may occur after radical prostatectomy, radiation treatment for prostate cancer, trauma, recurrent perineal abscess, or after treatment with radiofrequency hyperthermia for benign prostatic hypertrophy. It may occur after trauma, as a result of Crohn's disease.

The prostatic urethra is the most common site for fistulization to occur because this portion of the urethra is adjacent to the rectal wall.

### Evaluation and Treatment

#### *Symptoms*

The most common symptoms include leakage of urine through the rectum during voiding, pneumaturia, and fecaluria. These symptoms will tend to occur during the early postoperative period after prostatectomy. In addition, recurrent urinary tract infections resistant to antibiotic treatment after one of the aforementioned causes should suggest this diagnosis.

#### *Investigations*

Prostate-specific antigen determination should be done to rule out recurrence of carcinoma. Digital rectal examination should always be performed to determine if there is any anorectal pathology that could be the cause. Sigmoidoscopy will show the fistula opening which is located on the anterior rectal wall and in addition rule out rectal pathology as a source. Cystoscopy and retrograde urethral cystography should be performed to determine the presence of a urethral stricture. Assessment of urinary continence should be done before any attempt at surgical repair.

#### *Operative Treatment*

Operative repair of rectourethral fistulas is challenging because of technical difficulties that are often encountered as a result of difficult exposure. Multiple repairs have been developed but there is no consensus as to which is best. Traditionally, it has been suggested that the first attempt at repair is the best and that subsequent repairs become more difficult.<sup>110</sup>

Treatment consisting of fecal diversion with either colostomy or ileostomy and urinary diversion with suprapubic

catheterization under cover of antibiotics has been described in the management of rectourethral fistulas secondary to radiation when the urethral defect has been found to be too large to repair. This has been associated with bouts of recurrent sepsis and persistent symptoms.<sup>111</sup>

#### Transabdominal Approach

The transabdominal approach combines the use of abdominoanal pullthrough in combination with omental interposition. Difficulties with this procedure include limited exposure deep in the male pelvis making closure of the urethral defect very difficult. A fenestrated splinting catheter apposed to the omentum has been used when leaving the prostatic defect open. Complications associated with this approach include impotence and urethral stricture.<sup>110</sup>

#### Perineal Approach

Perineal approaches using the gracilis muscle, dartos, or Martius flap have been described. Access through scarred tissue limits exposure and may result in limited space available for the muscle to be placed. Important repair principles include excision of the fistula, development of layers on the urinary and rectal sides if the fistula and closure of nonoverlapping suture lines with interposition of the levators when possible. Zmora et al.<sup>112</sup> retrospectively reported on the effectiveness of the gracilis transposition in healing all rectourethral fistulas with minimal morbidity. Complications with this procedure include urinary incontinence and stricture as well as complications associated with the muscle harvest.

#### Anterior Trans-anorectal Approach

In this approach, a midline perineal incision is deepened by incising all structures superficial to the prostatic capsule which include the superficial perineal fascia, the central tendon of the perineum, and the internal and external sphincters.<sup>110</sup> This approach allows better access in the repair of complicated membranoprostic fistulas with preservation of continence and erectile function.

#### Per-anal Approach

This approach has the theoretical advantages of minimal scarring and fewer wound infections although it suffers from limited exposure. Initially described by Parks and Motson,<sup>113</sup> it involves the use of a full-thickness advancement of anterior rectal wall protected by diverting colostomy. Success rates of 83% have recently been reported when combined with fecal diversion, urinary diversion, both, or none at all.<sup>114</sup> Success rates have been found to be higher when the flap was done for fistulas secondary to iatrogenic causes or trauma as opposed to Crohn's disease.<sup>114</sup> Advancement flap repair can be achieved with minimal morbidity and good postoperative quality of life without compromise to future interventions if needed.

#### Kraske Laterosacral Approach

This approach provides excellent exposure without division of the sphincter mechanism. The need to excise two to three sacral segments as well as the nerves, muscles, and ligaments around them pose a disadvantage.<sup>110</sup>

#### York Mason (Trans-sphincteric) Approach

This approach affords a rapid, bloodless exposure through fresh territory and allows for complete separation of the urinary and fecal streams. It avoids the neurovascular bundles and pelvic floor structures essential in maintaining continence and sexual function. It may be performed in combination with a diverting colostomy or a so-called medical colostomy consisting of mechanical preparation and postoperative elemental diet.

It has been associated with longer operative times and more postoperative pain than the other procedures mentioned but has a reported 100% success rate.<sup>115</sup>

#### Transanal Endoscopic Microsurgery

This highly specialized technique allows for a meticulous two-layer closure of the rectal wall and may be combined with transurethral fulguration of the opposite urethral opening of the fistula.<sup>116</sup> There has been no reported morbidity associated with this procedure although experience is very limited.

#### Cystectomy and Ileal Conduit

Cystectomy and ileal conduit may be considered for those patients with a low probability of success in resolving the fistula or in maintenance of urinary continence.<sup>110</sup>

## Appendix: Practice Parameters for Treatment of Fistula-in-ano

Prepared by The Standards Task Force, American Society of Colon and Rectal Surgeons

### Acute Suppuration (Abscess)

#### Presentation and Management

An abscess should be drained in a timely manner; lack of fluctuance is not a reason for delay in treatment. If the abscess is superficial, it may be drained in the office setting using a local anesthetic. If the patient is too tender to permit examination and drainage, then these measures should be undertaken in the operating room. Antibiotics may have a role as adjunctive therapy in special circumstances, including valvular heart disease, immunosuppression, extensive cellulitis, or diabetes. Location of the abscess should be documented. If

possible, anoscopy should be performed to reveal the primary site of infection. Patients should notify the physician if pain recurs after abscess drainage.

## Chronic Suppuration (Fistula)

### Physical Examination

Inspection and palpation form the basis of the initial evaluation. Specifically, external (secondary) openings are sought, because their relationship to the anal canal provides a clue to the origin of the abscess-fistula. Anoscopy may be useful to identify an internal opening. If clinically indicated, proctosigmoidoscopy or colonoscopy may be suggested to exclude more proximally located inflammatory disorders with which fistulas can be associated.

### Radiographic Evaluation

Ultrasound, fistulography, computed tomography, and magnetic resonance imaging are not routinely indicated in the initial evaluation of fistulas but may be helpful in identifying an occult cause of recurrent fistula.

### Treatment

**Simple Fistulas May Be Treated by Fistulotomy.** Fistulotomy is preferred to fistulectomy, because the former technique does not involve excision of the sphincter. Primary fistulotomy is appropriate in cases of intersphincteric and low transsphincteric fistulas. Exceptions may include an anteriorly based transsphincteric fistula in a female, a diabetic patient, or a patient with a weakened sphincter. Patients with irritable bowel syndrome or increased stool frequency may require staged fistulotomy with a seton.

**Recurrent Abscess-Fistula/Incontinence.** Repeat fistulotomy can be used in treatment of recurrent fistula. If the patient with a recurrent fistula has symptomatic incontinence, then a physiologic investigation may be warranted.

**Selective Complex Fistulas May Require Treatment Other Than Fistulotomy.** These indications include: 1) high transsphincteric fistula, 2) extrasphincteric fistula, 3) anterior fistulas in females, 4) patients with coexisting inflammatory disease, 5) patients with immunosuppressive disease such as human immunodeficiency virus, 6) elderly patients with poor sphincter function, 7) uncertainty by the surgeon of level of fistula in relation to sphincter, 8) multiple simultaneous fistulas, and 9) patients with multiple prior sphincter surgeries or injuries. Either seton placement or advancement flap closure should be considered. The seton may be used in either a cutting or draining manner, depending on the clinical situation and the patient's underlying condition.

## Special Considerations

### Rectovaginal Fistulas

For a traumatic (postobstetric) fistula, a 3- to 6-month waiting period after injury is generally useful to promote fibrosis of the injured muscle. A fistulotomy is not generally used if it results in undue amounts of sphincter division. Treatment alternatives include transanal or transvaginal advancement flap closure, closure of the rectovaginal septum, conversion to a complete perineal laceration with layered closure, sphincteroplasty, and muscle interposition.

### Radiation-associated Fistulas

Interposition flap or transabdominal approaches have the highest success rates, depending on the level of the fistula.

### High Fistulas

For some surgeons, the transabdominal approach is more familiar and involves division of the fistula with layered closure and interposition of omentum. Alternatively, an anterior resection or coloanal anastomosis may be considered.

### Suprasphincteric Fistulas

Treatment requires an appreciation that the tract involves the entire external sphincter complex and the puborectalis muscle. Useful treatment options include division of the internal sphincter with concomitant seton placement, excision and drainage of the tract with closure of the internal opening, and advancement flap closure.

### Horseshoe Fistula

The internal opening and postanal (or deep anterior anal) space should be drained with or without a seton. The horseshoe portion of the fistula should be curetted and counterdrained rather than unroofed.

### Human Immunodeficiency Virus Infection

Large open wounds and sphincter division should be avoided. In general, minimally immunocompromised patients can undergo standard fistulotomy, whereas patients with higher degrees of immunosuppression should undergo placement of a noncutting (draining) seton.

### Crohn's Disease

Initial management should be directed at resolving rectal inflammation. Such medical management may include antidiarrheals, topical enemas, antibiotics, suppositories, or

systemic steroids and/or immunosuppressive agents. Fistulotomy is a reasonable alternative in most cases of intersphincteric or low transsphincteric fistulas. More complex fistulas can be treated with drainage, seton placement, or flap closure based on the patient's level of continence or extent of concomitant intestinal disease. Ultimately, a temporary or permanent stoma may be indicated.

## Benign Anorectal: Rectovaginal Fistulas

Ann C. Lowry and Barton Hoexter

Although typically small in size and seemingly simple, rectovaginal fistulas are an aggravation to the patients and surgeons. Passing flatus or stool through the vagina is understandably distressing to patients; the lack of a uniformly successful repair is frustrating to surgeons.

### Etiology

Obstetric injury is the most frequent cause of acquired rectovaginal fistulas but infection and other forms of trauma may also result in these fistulas. After an obstetric injury, the fistula may be manifest immediately but more frequently appears 7–10 days after delivery. Fistulas occur most often after a third- or fourth-degree laceration. Inadequate repair, breakdown of the repair, or infection may result in fistula formation. In developed nations, rectovaginal fistulas occur after 0.06%–0.1% of vaginal deliveries.<sup>1–3</sup> In developing countries, however, the incidence of rectovaginal and vesicovaginal fistula after childbirth is almost 3 times higher, with more than half of these fistulas being larger than 4 cm in diameter.<sup>4,5</sup> In these countries, prolonged labor, causing necrosis of the rectovaginal septum, leads to the formation of a fistula.

Disease processes may also cause rectovaginal fistulas. Cryptoglandular infection may result in an abscess spontaneously draining into the vagina resulting in a fistula. Rectal and gynecologic malignancies may result in fistulas as a result of local extension of the tumor or secondary to treatment with radiotherapy. Women with inflammatory bowel disease, Crohn's disease more frequently than ulcerative colitis, may develop rectovaginal fistulas. In a 23-year population-based study of patients with Crohn's disease in Olmsted County, MN, 88 fistulas developed in 59 patients.<sup>6</sup> Eight (9%) of the fistulas were rectovaginal fistulas. Over a period of approximately 30 years, 90 of the 886 women seen at St. Mark's Hospital with Crohn's disease and an intact rectum developed a rectovaginal fistula.<sup>7</sup>

Operative trauma may also result in a rectovaginal fistula. Complications of rectal or vaginal surgery usually result in

fistulas opening low in the rectum. High fistulas are most frequently complications of low stapled colorectal or ileoanal anastomoses. In one series of 140 patients undergoing low anterior resection for rectal carcinoma, four (2.9%) developed a rectovaginal fistula.<sup>8</sup> The mechanism is usually that a portion of the posterior vaginal wall is included in the anastomosis or that an abscess secondary to an anastomotic leak drains into the vagina. Pouch vaginal fistulas are reported in 3%–12% of patients.<sup>9–12</sup> Rectovaginal fistulas are also a complication of neovaginal construction for congenital abnormalities or as sex-change procedures.<sup>13</sup>

Fistulas have also been reported after vaginal dilatation of a radiated vaginal cuff, fecal impaction, viral and bacterial infection in human immunodeficiency virus patients and sexual assault.<sup>14–17</sup> Congenital rectovaginal fistulas occur but are outside the scope of this chapter.

### Evaluation

There are two primary goals in the evaluation of women with possible rectovaginal fistulas: identification of the fistula site and assessment of the surrounding tissue. The type of investigation required varies with the underlying etiology of the fistula.

#### Identification of Fistula Site

In most women with complaints consistent with a rectovaginal fistula, the site can be readily identified on examination. Visual examination may show the dark red rectal mucosa contrasting with the pale mucosa of the vagina. A dimple may be palpable in the anterior midline on rectal examination. The rectal opening is frequently visible on anoscopy. In some women, the diagnosis may be elusive. A methylene blue test may confirm the presence of a communication and aid in locating the site. During this test, a vaginal tampon is inserted and then the patient is given an enema colored with methylene blue. If the patient retains the enema, staining on the

tampon is highly suggestive of a rectovaginal fistula. Alternatively, saline can be instilled in the vagina with the patient in the lithotomy position. The rectum is then insufflated with air and the vagina observed for bubbles.

Radiographic tests may help identify an elusive fistula. One option is vaginography. The examination is performed by instilling contrast into the vagina through a Foley catheter with the balloon inflated to occlude the vaginal opening. The technique has a sensitivity of 79%–100% for the detection of the fistula tract. Vaginography is most helpful for colovaginal and enterovaginal fistulas; it is less useful for low rectovaginal fistulas.<sup>18,19</sup> Computed tomography scans may identify the fistula tract and characterize the surrounding tissue. Contrast material in the vagina after oral or rectal administration is diagnostic of a fistula. Suggestive evidence includes air or fluid in the vagina if there is no history of recent instrumentation.

Both magnetic resonance imaging (MRI) and ultrasound are used to identify fistulas. Small studies of endoanal ultrasound with and without contrast, MRI with and without endoluminal coils, and transperineal and transvaginal ultrasounds are available. One study comparing MRI with a coil to endoanal ultrasound found the same positive predictive value for identification of the fistula site for both tests.<sup>20</sup> Accuracy could not be determined in this retrospective study. In an earlier study of endoanal ultrasound, positive predictive value was good but ultrasound only identified 28% of rectovaginal fistulas.<sup>21</sup> Fistulas above the dentate line were more frequently identified than ones at or below the dentate line. Contrast enhanced ultrasound using hydrogen peroxide seems to be more accurate than nonenhanced studies.<sup>22</sup> Contrast enhanced ultrasound has not been directly compared with MRI. Another group reported the use of transperineal and transvaginal ultrasound in the assessment of fistulas. The examinations successfully identified fistulas.<sup>23</sup> The accuracy of the technique could not be determined because only 56% of patients underwent surgery. At present it is not clear which radiologic examination is optimal to detect elusive fistulas.

### Assessment of Local Tissue

The second goal of evaluation is to determine the etiology and to assess the surrounding tissue. The necessary tests are determined by the suspected etiology of the fistula. Symptoms of incontinence should be elicited during the history. If the mechanism of injury is childbirth, the patient with a fistula is at significant risk of a sphincter defect. In a review by the University of Minnesota, 48% of women with rectovaginal fistulas complained of incontinence preoperatively.<sup>24</sup> Ultrasound or MRI should be done to assess the anal sphincter. One study found that 100% of women presenting with a rectovaginal fistula after a delivery had a sphincter defect.<sup>21</sup> In another study, only 3 of 34 women with rectovaginal fistulas had an isolated rectovaginal fistula without abnormality in the perineal body or sphincter muscles.<sup>25</sup> Symptoms of the fistula

frequently mask anal incontinence; failure to study the sphincter may lead to a poor choice of repair and persistent incontinence postoperatively.<sup>24,26</sup> Endoanal ultrasound and MRI are reported to be essentially equivalent in detection of a sphincter defect.<sup>20</sup>

Multiple perianal fistulas suggest Crohn's disease as the etiology. Evaluation of the intestinal tract by colonoscopy and contrast studies is indicated in patients with known or suspected inflammatory bowel disease. One must be careful to consider the patient's obstetric history even if she carries the diagnosis of Crohn's disease.

Biopsy of a detectable mass should be done for suspected malignancy. The presence of a known malignancy may dictate a workup for metastatic disease. It is critical that recurrent carcinoma be distinguished from irradiation injury. In patients with a history of malignancy treated by radiation, examination under anesthesia with biopsies is often necessary. Two series report an approximately 50% incidence of recurrent cancer on biopsies of these fistulas.<sup>27,28</sup>

### Classification

A variety of classification systems exist for rectovaginal fistulas. Most systems classify by size, location, and etiology. Daniels<sup>29</sup> classified fistulas by their location along the rectovaginal septum as low, middle, or high. The rectal opening is at the dentate line and the vaginal opening just inside the vaginal fourchette in low fistulas. The vaginal opening is at or near the cervix in high fistulas. Middle fistulas are located between high and low fistulas. This system is useful in that high fistulas are more likely to require laparotomy; perineal approaches are appropriate for most low and middle fistulas. However, beyond that, these categories are not very useful in guiding treatment decisions. In addition, this terminology is not applied consistently because some authors would term the low fistulas anovaginal fistulas. Others state that the rectal opening is below the dentate line in anovaginal fistulas.

Another system classifies fistulas into simple and complex categories.<sup>30</sup> Simple fistulas are small (<2.5 cm), low, and secondary to trauma or infection. Complex fistulas are large, high, caused by inflammatory bowel disease, radiation, or malignancy, or persistent despite multiple failed repairs. This system separates fistulas amenable to local repairs and ones likely to require resection or the interposition of well-vascularized tissue. Simple fistulas tend to have healthy surrounding tissue and complex fistulas occur in diseased tissue which dictates the type of repair necessary.

Saclarides<sup>31</sup> argues that a classification system based on etiology is the most useful for the treating physician. A system determined by etiology would take into consideration the state of the surrounding tissue both anatomically and functionally as well as the health of the patient.

None of these systems have been tested to see whether they are predictive of outcome but a strong case can be made that etiology is the best guide to patient management. Research in

this area would benefit from standardized terminology and a valid classification system.

## Conservative Management

For women with small fistulas and minimal symptoms, medical management is appropriate. Optimizing the patient's bowel function, particularly controlling diarrhea, is beneficial. Unfortunately, for the majority of women with rectovaginal fistulas, the symptoms are intolerable.

## Surgical Techniques

### Local Repairs

#### *General Considerations*

A local repair is appropriate for the first or second repair in women with rectovaginal fistulas and intact sphincter muscles. The type of repair is determined by surgeon expertise and size of the fistula. Colorectal surgeons typically prefer an endorectal or perineal approach whereas gynecologists favor a transvaginal approach.

Patients undergo mechanical and antibiotic preparation preoperatively. General anesthesia is used in most cases although the repairs may be performed under regional anesthesia. A urinary catheter is inserted. Prone jackknife position provides the best exposure for transanal and perineal approaches whereas lithotomy position is better for transvaginal repairs. Exposure is optimized by the use of a headlight, taping of the buttocks, and a Lone Star retractor. A Pratt bivalve anoscope will be helpful in repair of low fistulas; Wylie renal vein retractors, narrow Deaver, or malleable retractors are preferable for higher fistulas.

Simple fistulotomy is reported as an option but should be avoided because of the risk of incontinence. It is not acceptable to divide a significant portion of intact sphincter muscle and leave it to heal by secondary intention.

#### *Fibrin Sealant*

Fibrin glue instillation has been used for fistula-in-ano with some success. The technique does not differ when fibrin glue is applied to rectovaginal fistulas. Most studies that include rectovaginal fistulas report discouraging results of 0%–33% success in very small numbers of patients.<sup>32–34</sup> The one exception is a study by Venkatesh and Ramanujam<sup>35</sup> who report that six of eight patients with rectovaginal fistulas were cured with fibrin glue.

#### *Advancement Flaps*

Advancement flaps may be approached transrectally, vaginally, or through the perineum. An advantage of the transanal approach is direct access to the rectal side of the fistula which

is the high pressure side. Several variations of the technique for endorectal advancement flaps have been reported but the general principles are the same. With the patient in the prone jackknife position and adequate exposure, a U-shaped flap is outlined with the distal end below the fistula opening. The flap should have a base 2–3 times wider than the apex. A flap of mucosa, submucosa, and circular muscle is raised for a distance sufficient to allow a tension-free repair, usually 4–5 cm. The fistula tract is debrided but not excised. Anoderm is elevated off the internal sphincter and circular muscle laterally. The muscles are approximated over the fistula opening with long-acting absorbable suture in one to two layers. The distal end of the flap including the fistula site is excised and the flap sutured in place with absorbable suture. The vaginal side is left open for drainage (Figure 14-1). Patients are typically observed overnight. They resume a normal diet with fiber supplements to prevent constipation. Diarrhea must also be controlled because it will affect healing as much as constipation. There is usually minimal discomfort and a brief recovery period. Patients are cautioned to avoid intercourse and the use of tampons for 6 weeks.

The literature contains many case series of endorectal advancement flaps<sup>24,26,36–50</sup> (Table 14-1). The reported outcome measure is usually successful repair of the fistula; continence is rarely included. The explanation of the wide range of results is not clear. Perhaps it is the surgeon's technique or patient selection that explains the reports with high success rates. Other considerations are that some studies include patients with concomitant sphincter repairs. One would expect that group to have a higher closure rate than patients undergoing an endorectal advancement flap alone. Some series include fistulas of multiple etiologies which may influence outcome. Even within a group of patients whose etiology is all obstetric injury, early series mix patients with and without sphincter defects. The presence of scar rather than healthy muscle under the flap intuitively would decrease the success of the repair. A recent series of endorectal advancement flaps in women with intact sphincter muscles supports that view. Eleven of 12 fistulas healed.<sup>38</sup> In addition, some series report ultimate closure rates combining patients with one attempt at repair and those with repeated attempts. Watson and Phillips<sup>50</sup> reported a primary success rate in 7 of 12 patients and an ultimate success in 10 of 12 patients illustrating the difference that would occur depending on the reporting method. Not all authors include both data. The number of previous repairs has been reported to affect the success rate and is not always reported.<sup>51</sup> Lowry and colleagues<sup>40</sup> reported a success rate of more than 80% in first and second repairs but only 55% in patients with two prior repairs. Follow-up techniques vary and may influence the accuracy of the data.

Recent investigations sought explanations for the failure rate. One group presented a retrospective study of 116 consecutive endorectal advancement flaps done for both fistulas-in-ano and rectovaginal fistulas. Recurrence was not associated with prior attempts at repair, type of fistula,

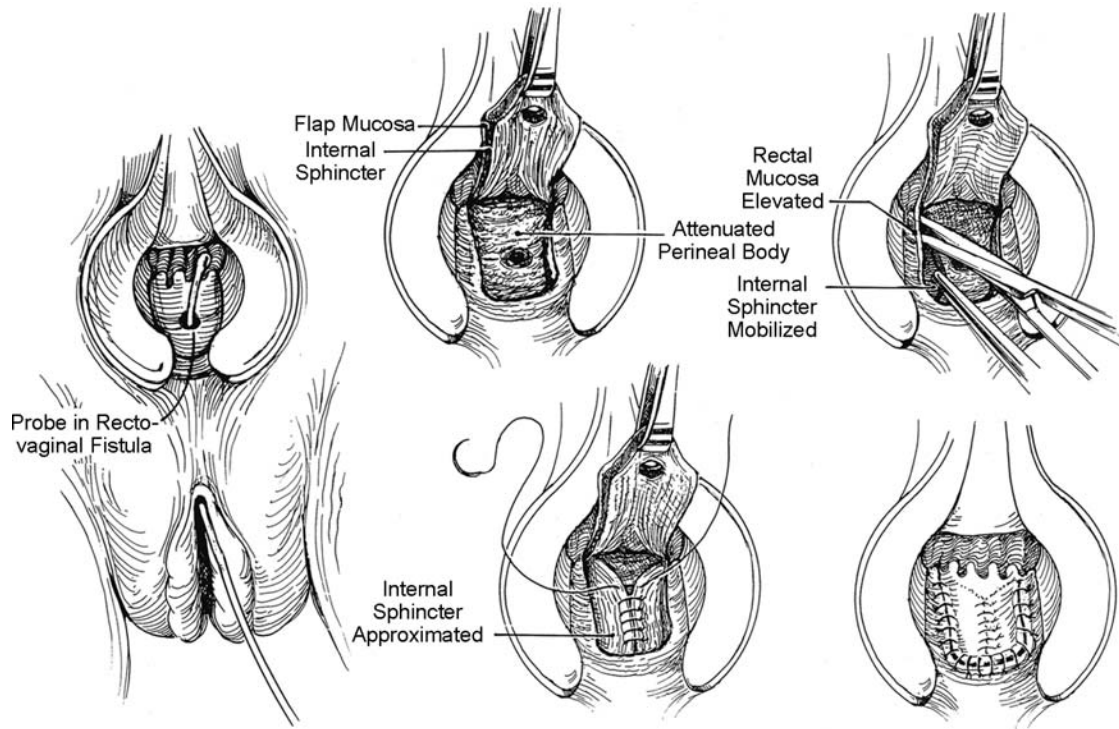

FIGURE 14-1. Endorectal advancement flap.

origin, steroid use, antibiotic usage, bowel confinement, or presence of a diverting stoma.<sup>41</sup> There was a higher rate of recurrence in patients with Crohn's disease. Sonoda and colleagues<sup>43</sup> also found that a diagnosis of Crohn's disease was associated with a higher failure rate in their study of 105 endorectal advancement flaps. In distinction to the first study, however, patients with rectovaginal fistulas secondary to obstetric injury also had a lower success rate. Smoking was linked to failure of endorectal advancement flap in another study.<sup>52</sup> In an attempt to improve the results, that group added labial fat transposition to endorectal advancement flap.<sup>45</sup>

Unfortunately, the results were no different from an advancement flap alone.

Sliding flaps may also be performed on the vaginal side. An incision is made in the posterior vaginal wall near the introitus and a flap of vaginal wall is raised. Dissection is extended laterally to the ischial tuberosities to provide adequate mobility. The vaginal and rectal defects are closed with absorbable sutures. The levator ani muscles are approximated in the midline; this portion of the repair is believed to be critical to its success. The vaginal flap is then sutured in place. Success rates of 84%–100% are reported with vaginal flaps.<sup>50,53–57</sup>

Anocutaneous flaps are an option for distal rectovaginal or anovaginal fistulas. A flap of anoderm and perineal skin is raised and advanced into the anal canal. After the fistula tract is debrided, the flap is sutured into place.<sup>58</sup> A diamond-shaped cutaneous flap has also been used on the vaginal side in conjunction with an endoanal advancement flap.<sup>59</sup> Only a few cases have been reported with either technique.

### *Rectal Sleeve Advancement*

An alternative transrectal approach is a rectal sleeve advancement involving mobilization of the distal rectum and advancement to cover the fistula. A circumferential incision is made at the dentate line and deepened through the submucosa. This plane is continued in a cephalad direction exposing internal sphincter muscle. Above the anorectal ring the dissection becomes full thickness. The mobilization continues until healthy, nonscarred tissue is reached and that tissue can be pulled down to the dentate line without tension. The rectum is pulled through the anal canal, the diseased portion excised, and healthy tissue sutured to anoderm below the dentate line. This technique is reported in patients with a rectovaginal fistula and inflamed anal canal and distal rectum from Crohn's disease. In a series of five patients with rectovaginal fistulas and Crohn's disease reported by the Cleveland Clinic, three of the patients with fecal diversion healed.<sup>60</sup> One patient required two rectal sleeve advancements before healing occurred. Of the two patients without fecal diversion, one healed. Simmang et al.<sup>61</sup> emphasized that this technique is useful for someone with a rectovaginal fistula and a stricture because both problems will be corrected with the procedure.

A variation is the modified Noble-Mengert-Fish technique.<sup>25</sup> With this procedure, the full thickness of the anterior rectal wall is mobilized. A curvilinear incision is made at the mucocutaneous junction over the anterior 180 degrees of the anal canal. The dissection continues until the rectovaginal septum is entered. The superior limit is the vault of the vagina; the lateral margin is the full width of the rectovaginal space. There needs to be adequate dissection to ensure that the flap will reach the area of the external sphincter without tension. The flap is then anchored to the external anal sphincter and the perineal skin, forming a new mucocutaneous junction. Older reports of this technique documented successful repair of rectovaginal fistulas in 86%–100%. Minor incontinence troubled 25% of patients.<sup>42,62,63</sup> The only recent report combined this repair with sphincter reconstruction or perineal body repair in the majority of patients.<sup>25</sup> The overall anatomic success was 94%; the results for the anterior rectal wall advancement alone were not reported separately.

### *Excision of Fistula with Layered Closure*

Another option is excision of the fistula tract and layered closure. Layered closure may actually be performed through the rectum, vagina, or perineum. If done through the rectum or vagina, an elliptical incision is made around the fistula and

mucosal flaps are raised for 2–3 cm. The fistula tract is excised. Vaginal mucosa, rectovaginal septum, rectal muscle, and rectal mucosa are closed in succession. Plication of the levator muscles is added by some surgeons. If done through the perineum, a transverse incision is made and extended down to the fistula tract. The fistula is then cored out of the rectal and vaginal walls and a layered closure performed.

Using layered closure, successful repair is reported in 88%–100% of patients in the small series published.<sup>53–56</sup>

### *Perineo-proctotomy*

Perineo-proctotomy or conversion to a fourth-degree laceration is usually performed with the patient in the lithotomy position; this approach begins with the identification of the fistula and division of the bridge of skin, subcutaneous tissue, sphincter muscle, rectal and vaginal walls overlying the fistula. The tract is excised and both the rectal and vaginal walls are dissected away from the muscle. After repair of both the rectal and vaginal defects, the external sphincter muscle is reapproximated. The muscle must be adequately mobilized to avoid tension on the repair. The perineal body is reconstructed and the skin closed (Figure 14-2).

The use of perineo-proctotomy or conversion to a fourth-degree laceration for rectovaginal fistulas is reported in women with intact sphincter muscles as well as ones with a sphincter disruption. Success rates for fistula closure range from 87% to 100% in small series.<sup>35,49,56,64</sup> In most series, postoperative continence is not documented. Mazier and colleagues<sup>49</sup> did report that none of 38 women undergoing this repair were incontinent postoperatively.

### *Inversion of Fistula*

Inversion of the fistula is a simple technique usually performed through the vagina. The vaginal mucosa is mobilized circumferentially around the fistula. The tract is excised and a pursestring suture used to invert the fistula into the rectum. The vaginal wall is then closed over the inversion.<sup>65</sup> One small series reports success in 8 of 11 patients<sup>66</sup>; a more recent series reports a 100% success rate in 47 women.<sup>67</sup>

## **Complex Repairs**

The complex repairs involve the interposition of well-vascularized tissue between the rectum and the vagina; that tissue may be muscle, omentum, or healthy bowel. With the exception of transposition of the rectus muscle, the initial dissection for muscle interposition is typically through the perineum. The interposition of omentum or healthy bowel requires an abdominal procedure.

### *Tissue Interposition: Muscle*

The most common tissue interposition technique is a sphincteroplasty utilized when a defect in the external sphincter is

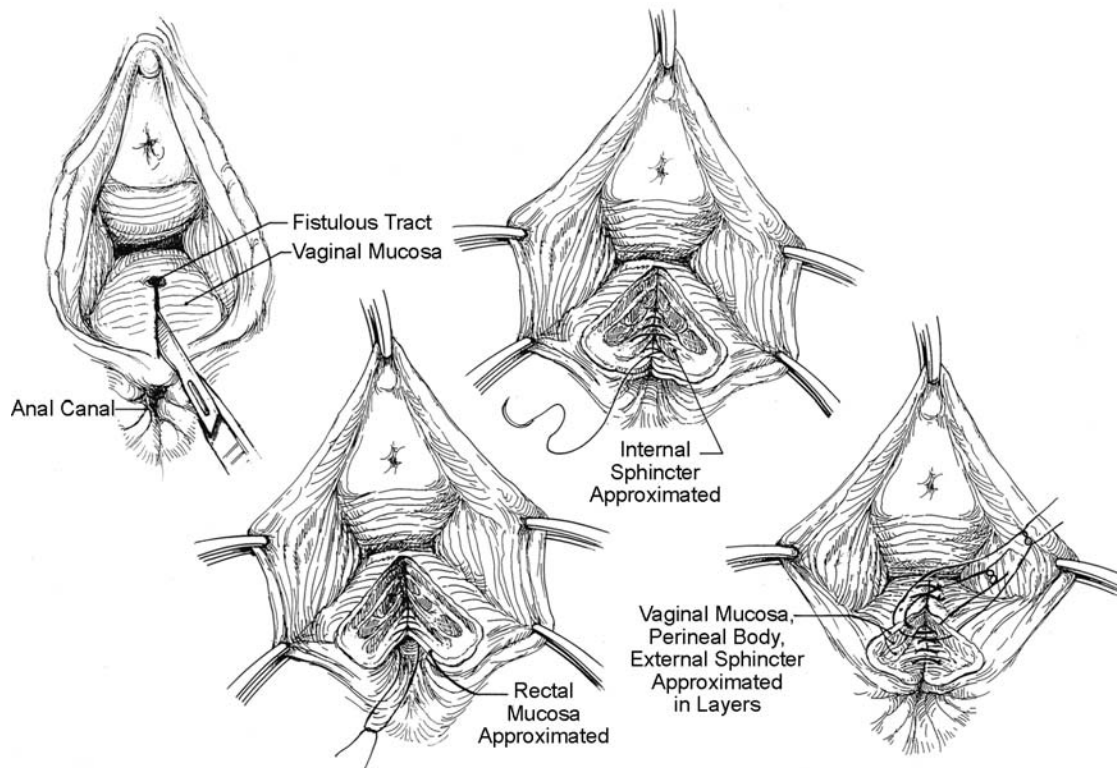

FIGURE 14-2. Perineo-proctotomy.

present with the rectovaginal fistula. In that situation, an overlapping sphincteroplasty will correct the fistula and the incontinence. The technical details are described and illustrated in Chapter 46 on incontinence. Successful closure of rectovaginal fistulas with this operation is reported in 65%–100% of patients (Table 14-2).<sup>21,26,42,44,48,68,69</sup>

When the sphincter muscle is intact or the fistula is above the sphincter muscles, rectus, bulbocavernosus, gracilis, gluteus, and sartorius muscles have been used to repair rectovaginal fistulas.<sup>4,70–82</sup> The perineal dissection is similar regardless of the muscle used. Preoperatively, the patients undergo a full mechanical bowel preparation and receive preoperative antibiotics. For these dissections, a Lone Star retractor and a headlight are very useful for exposure. With the patient in the prone jackknife position, a transverse perineal incision close to the vaginal introitus is made. The posterior

vaginal wall is separated from the anal sphincter and anterior rectal wall until soft, pliable tissue is reached. This dissection is often difficult because of dense scarring. Care must be taken to avoid entering the rectum; a finger or anoscope in the rectum is helpful to identify the appropriate plane. The rectal and vaginal walls are closed with absorbable sutures. It is generally not necessary to trim the vaginal or rectal wall and doing so often only makes a significantly larger defect. The mobilized muscle is then inserted between the rectum and the vagina and tacked to the posterior vaginal wall. The incision is loosely closed often with a drain in place. For transposition of the rectus muscle, a midline abdominal incision is also made to allow dissection between the rectum and vagina from above as well as from the perineal side.

If the labial fat pad is chosen for transposition, the patient is placed in modified lithotomy position. Once the perineal dissection is completed, a longitudinal incision is made over the labial majora. Skin flaps are raised laterally and medially. There is often a plane similar to Scarpa's fascia for this portion of the dissection. The dissection is continued to the periosteum of the pubis posteriorly. Superiorly the tissue is mobilized to the pubic symphysis. Once the entire fat pad with the bulbocavernosus muscle is mobilized, the superior end is divided. The posterior pedicle is left intact to preserve the perineal branch of the pudendal artery. A subcutaneous, subvaginal tunnel is created from the base of the pedicle to the perineal incision. The flap is pulled through this tunnel and

sutured to the posterior vaginal wall above the vaginal and rectal closures. The labial incision is closed in two layers over a suction drain. The perineal incision is closed loosely often over a drain (Figure 14-3). When vaginal stenosis is a concern, inclusion of an island of skin from the inner thigh with the pedicle is an alternative.<sup>4</sup> The use of the Martius graft is reported primarily in fistulas secondary to radiation. Aartsen and Sindram<sup>83</sup> reported 100% success in 14 patients initially; they do caution, however, that after a 10-year follow-up, 8 of the 14 patients required diversion for progressive radiation damage. Others report success in 78%–84%.<sup>74,75,84</sup>

The details of mobilization of the rectus, gracilis, and sartorius muscles are beyond the scope of this chapter.

#### *Tissue Interposition: Bowel*

Healthy bowel may be interposed in one of two ways. An extended low anterior resection may be done with excision of the rectum containing the fistula and an anastomosis below. The vaginal defect is closed and if possible separated from the new anastomosis with omentum. Parks and associates<sup>85</sup> described a sleeve coloanal technique when the fistula is very low. The rectum is mobilized to a level below the fistula and divided. From a perineal approach, a distal rectal mucosectomy is performed. The proximal healthy colon is pulled through the muscular sleeve covering the fistula. A hand-sewn coloanal anastomosis is then completed. Technical success is reported in 78%–100% of patients.<sup>85–87</sup> In a review of functional results after stoma closure, 64% of patients were completely continent at 6 months and 75% at 1 year.<sup>87</sup>

An alternative is a procedure described by Bricker and Johnston.<sup>88</sup> Through an abdominal incision the fistula is divided. The sigmoid colon is mobilized and divided. The

proximal end is used for a temporary colostomy; the distal end is rotated upon itself and sutured in an end to side manner to the debrided edges of the defect in the rectal wall. When healing is confirmed with a contrast study, the proximal sigmoid colon is sutured to the loop of colon used in the repair (Figure 14-4). Bricker and colleagues<sup>89</sup> reported excellent or satisfactory results in 19 of 26 patients.

## Choice of Treatment

For any patient with a rectovaginal fistula, conservative management is an option if the symptoms are tolerable. In addition, fibrin glue instillation may reasonably be attempted particularly in low, small fistulas. The success rate is unproven but the procedure is very well tolerated and carries minimal risk. For fistulas resulting in significant symptoms, the choice of treatment largely depends on the etiology of the fistula.

### Rectovaginal Fistulas Secondary to Obstetric Injury

Rectovaginal fistulas may close spontaneously in the early postpartum period<sup>67,90</sup>; all others require surgery to close. It is important that the surrounding tissue be free of infection and induration before proceeding with surgery. For most patients, treatment of infection and time will allow the surrounding tissue to soften. Once the surrounding tissue is amenable to repair, timing of the repair may be chosen by the patient. Patients with significant symptoms need not wait until their childbearing is complete, although depending on the choice of repair, subsequent babies should be delivered by Cesarean section.

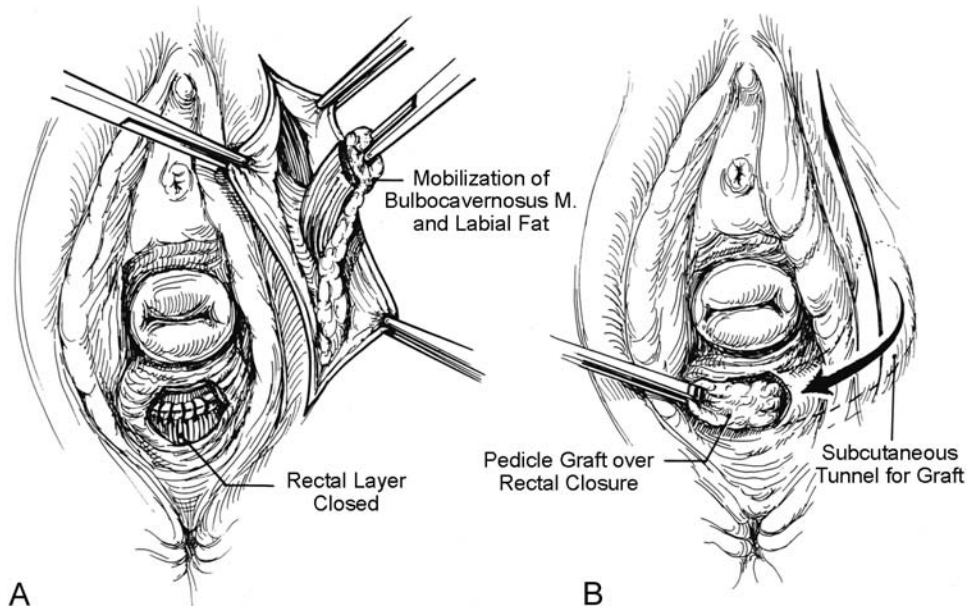

FIGURE 14-3. Martius graft. **A** Perineal dissection and mobilization of graft. **B** Interposition of labial graft.

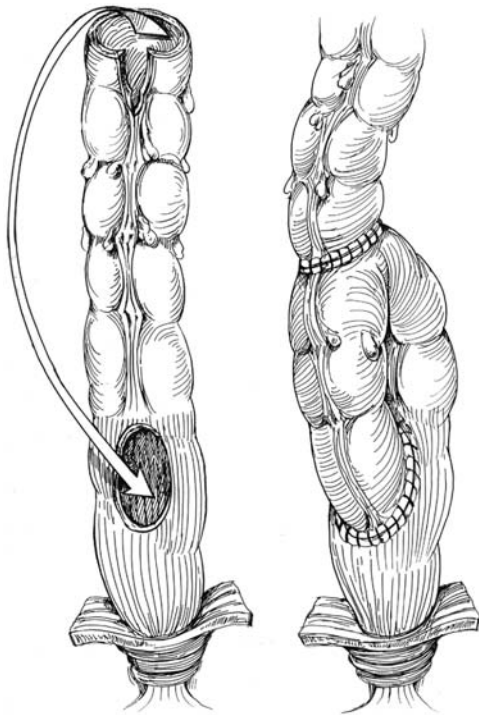

FIGURE 14-4. Onlay patch (Bricker procedure).

As mentioned above, an important part of the evaluation of women with rectovaginal fistulas caused by obstetric injury is assessment of anal sphincter anatomy and function. In multiple studies, the incidence of associated sphincter defect is close to 100% in this subset of patients.<sup>21,24,26</sup> Therefore, both closure of the fistula and continence should be considered important outcome measures.

For women with intact sphincters and a rectovaginal fistula after childbirth, a simple local repair is recommended. Because data comparing the various repairs do not exist, the choice of the repair should be based on the surgeon's experience. In most practices, these women represent only a small portion of the patients with rectovaginal fistulas because the majority will have a concomitant sphincter defect.

For women with sphincter defects, sphincteroplasty closes the fistula and repairs the sphincter defect. A perineoproctotomy is also appropriate. The advantage of this technique is the excellent exposure it provides; the disadvantage is the risk of incontinence if intact sphincter muscle is divided. No direct comparison of this approach and sphincteroplasty exists but sphincteroplasty is more widely accepted.

### Rectovaginal Fistulas Secondary to Cryptoglandular Disease

When rectovaginal fistulas secondary to cryptoglandular disease are reported, they represent only a small portion of most series. Evaluation must include a search and treatment of associated local sepsis with the possible use of a seton.

Endoanal ultrasound should be performed to exclude an occult sphincter defect. If none is found, an endorectal advancement flap is the most frequently used procedure. Fistula closure rate is rarely documented separately for cryptoglandular fistulas so the success rate is not well established. In some series, it seems that these fistulas heal less well than other types. Insertion of fibrin glue, a vaginal advancement flap, and an anocutaneous flap would be reasonable alternatives but no data exist regarding their efficacy in this specific situation. In addition, there are no data comparing any two procedures.

### Rectovaginal Fistulas Secondary to Crohn's Disease

The treatment of patients with rectovaginal fistulas secondary to Crohn's disease differs from other patients with rectovaginal fistulas in several ways. Given the nature of Crohn's disease, control of symptoms becomes the primary goal as opposed to elimination of the fistula in this subset of patients. In addition, the treatment is in more flux than any other subset of patients.

Medical management with antibiotics and immunosuppressive medication was able to control symptoms but rarely close fistulas. Surgical therapy often required proctectomy because of associated proctitis and was not uniformly successful even in the absence of inflammation.<sup>7,91</sup> Over a period of approximately 30 years, Radcliffe and colleagues at St. Mark's Hospital identified 90 women with Crohn's disease and a rectovaginal fistula.<sup>7</sup> Eight were diverted, 34 underwent early proctectomy, and another 12 required proctectomy later. The indications for proctectomy were severe colitis or proctitis or an associated anal lesion in the majority of patients. Twelve were managed conservatively and 24 underwent a local repair. Heyen and colleagues<sup>91</sup> traced the course of 28 women with Crohn's disease and a vaginal fistula. Five required early proctectomy and seven underwent proctectomy later. Of the 16 fistulas managed conservatively, none healed. Malignancy developed in the fistula tract of two patients.

The introduction of infliximab is a recent addition to the treatment options for Crohn's perianal fistulas. A randomized, controlled trial found that infliximab was significantly better than placebo in healing fistulas in Crohn's disease.<sup>92</sup> Subsequent studies have confirmed a 24%–55% healing rate by assessment of clinical symptoms.<sup>93,94</sup> Most of these studies reported healing rates after a course of three infusions. Data are accumulating that some patients will require a longer course, perhaps maintenance therapy, to control symptoms. In addition, several studies using follow-up ultrasound or MRI revealed that the radiologic healing rate is lower than the clinical healing rate.<sup>95</sup> One recent study showed that there was continued radiologic healing with a longer course of therapy.<sup>96</sup> It also seems that a combination of surgery and infliximab is necessary in a substantial portion of patients. Results are better when drainage of local sepsis and placement of a

seton are done before initiating infliximab.<sup>93</sup> If the goal is complete healing, the seton must be removed before the completion of the course of infliximab. Another unresolved detail is whether the addition of immunosuppressive medication improves the response rate or maintenance of a response. Although this therapy is promising for perianal fistulas, it is not clear that rectovaginal fistulas respond as well. One study reported that only one of eight patients with a rectovaginal fistula had a complete response<sup>93</sup> whereas another study reported no difference between simple and complex fistulas.<sup>96</sup>

At the present time, the following treatment program seems reasonable. Each patient should be assessed to determine the presence of associated proctitis and undrained local sepsis. Patients with associated proctitis require appropriate medical or surgical management for that condition. In either case, any local sepsis should be drained, all tracts identified, and setons placed if appropriate. Until more definitive data are available, a trial of infliximab should be considered. Setons should be removed before the last infusion. If symptoms resolve or are minimal, then conservative therapy is appropriate. No clear recommendation regarding maintenance infliximab or immunosuppressive medication is possible at this time.

If a persistent fistula results in significant symptoms and any associated proctitis resolves, then surgical intervention is appropriate. A multitude of repairs is reported. Vaginal flaps succeeded in 13 of 14 patients in one series.<sup>97</sup> All patients had diverting stomas at the time of the repair. Eradication of the fistula with an endorectal advancement flap is reported in 30%–70% of patients.<sup>43</sup> Kodner reported an initial healing rate of 71% which increased to 92% with additional procedures.<sup>47</sup> The Cleveland Clinic surgeons tailor the advancement flap according to the height and length of the fistula and the presence of rectal ulceration or inflammation. They report an initial healing rate of 54% and an overall success rate of 68% including repeat repairs. The necessity of diversion is controversial but it is often performed in this subset of patients. All of these results predate the introduction of infliximab. Whether the use of infliximab or other new medications will result in improved outcomes remains to be seen.

### Rectovaginal Fistulas Secondary to Malignancy

The treatment of these fistulas is dictated by the type of underlying malignancy. For rectal cancer invading the vagina, resection with or without reconstruction is required. If preoperative adjuvant therapy is given, diversion before initiation of treatment may be necessary for the patient's comfort. If reconstruction is possible, interposition of tissue between the colorectal anastomosis and closure of the vagina may prevent a postoperative fistula if a pelvic abscess or anastomotic leak occurs. For squamous cell carcinoma of the anus, a preexisting fistula or one that develops during chemoradiation often requires diversion for symptom control. If there is complete resolution of the tumor after chemoradiation, repair of the fistula with interposition of the bulbocavernous or gracilis

muscle is indicated after a waiting period to allow for resolution of any acute radiation changes. It is unlikely that a local repair would be successful. If tumor persists after chemoradiation, an abdominal perineal resection is necessary. Low rates of perineal wound healing in this situation have led to the use of primary muscle flaps for wound closure. Presumably those muscles flaps would be particularly indicated if a rectovaginal fistula exists. The same principles apply when invasion of the rectum by gynecologic malignancy occurs.

### Rectovaginal Fistulas Secondary to Radiation Therapy

The evaluation of patients with fistulas secondary to radiation must be more intensive than most other patients with rectovaginal fistulas. Because of their usual age, they are more likely to have significant medical conditions. In addition, it is paramount that the fistula site be biopsied to exclude recurrent cancer. Diversion for a minimum of 6 months is recommended to allow inflammation in the surrounding tissue to resolve. Decisions about surgical intervention center on the patient's overall medical condition, the degree of symptoms caused by the fistula and any associated abnormalities, and the risk of a proposed corrective procedure. Not uncommonly, the combination of those factors makes a colostomy alone the most reasonable choice. This is particularly appropriate if the patient is experiencing significant fecal incontinence. If, however, the patient's condition allows, a variety of surgical options exist. If the fistula is low and the rectum is relatively normal, muscle interposition through the perineum is a reasonable choice. If the fistula is high, tissue interposition through the abdomen is preferable. If a stricture or severe radiation damage exists in the rectum, rectal resection with reconstruction would eliminate that problem and the fistula. However, the morbidity can be high, e.g., 24% in one series.<sup>99</sup> A Bricker procedure is less morbid and can relieve a stricture but does not avoid the potential bleeding, pain, or malignant transformation associated with leaving the rectum in place. Patient selection and operative choice must be made based on clinical experience because comparative studies do not exist.

### Iatrogenic Rectovaginal Fistulas

The choice of treatment for an iatrogenic fistula is based on the causative operation. Fistulas developing after rectal resection almost always arise at the anastomosis. They have been reported after both hand-sewn and stapled anastomoses.<sup>100,101</sup> Radiation and prior or concomitant hysterectomy increase the risk of fistula formation. Incorporation of the vaginal wall in the stapler is probably the most common explanation but necessitation of pelvic infection into the vagina may also occur. Obviously, prevention with adequate dissection of the rectum from the vagina before inserting the stapler and careful attention to the separation of the rectum and vagina as the stapler is fired is optimal. Once a fistula

occurs, temporary diversion is often necessary to control pelvic sepsis. Some fistulas will close spontaneously although this is less likely if the patient has received pelvic radiation.<sup>102</sup> Repair is determined by the level of the fistula. High fistulas usually require repeat resection with anastomosis or interposition of omentum or muscle. Low fistulas may be amenable to rectal or vaginal advancement flaps. Large fistulas or one failing initial attempts at repair will require tissue interposition.

### Persistent Rectovaginal Fistulas

There are few data regarding fistulas that persist after an attempted repair. Repeat repairs after one attempt seem to have a reasonable success rate.<sup>40,50,51</sup> However, several studies report a higher failure rate after two or more procedures so subsequent options should be chosen carefully.<sup>40,51</sup> Two reports specifically address the issue of persistent fistulas. MacRae and colleagues<sup>48</sup> retrospectively reviewed 28 patients who had at least one previous attempt at repair. The etiology was obstetric injury in 14, Crohn's disease in 5, and miscellaneous in 9. Five of the last group had fistulas considered simple; one fistula was caused by radiation. In the 14 patients with a history of obstetric injury, advancement flaps, sphincteroplasty, or coloanal anastomoses were performed. Eleven flaps were performed in nine patients with four resulting in healed fistulas. All five of the patients undergoing sphincteroplasty had successful outcomes as did the two patients undergoing coloanal anastomoses. Overall, 5 of 23 advancement flaps (29%) in 17 patients were successful. Sphincteroplasty succeeded in six of seven patients (86%); four of six coloanal anastomoses (67%) and both of two gracilis muscle interpositions succeeded.

In a report from the Cleveland Clinic, Halverson et al.<sup>69</sup> retrospectively reviewed 35 patients with recurrent rectovaginal fistulas. Causes of the fistulas included obstetric injury in 15, Crohn's disease in 12, pouch vaginal fistulas in 5, cryptoglandular disease in 2, and iatrogenic after low anterior resection in 1. Advancement flap, sphincteroplasty, rectal sleeve advancement, insertion of fibrin glue, and ileal pouch revision were used. The results are presented by etiology and by type of repair but not stratified by both. All 15 obstetric patients were ultimately healed after 23 repairs. Two of the four cryptoglandular fistulas were eradicated. Nine of the 30 mucosal advancement flaps (30%) and 9 of 14 sphincteroplasty procedures (65%) successfully closed the fistulas. Rectal sleeve advancement resulted in healing in two of three fistulas. Crohn's disease, the presence of a diverting stoma, and decreased time interval from a prior repair were associated with a poor outcome regardless of the technique used. The authors commented that the presence of a stoma likely was a marker for more complex disease.

From the data available, it seems that a reasonable approach to recurrent rectovaginal fistulas would begin with a planned waiting period of a minimum of 3 months. In the

interval, the status of the sphincter muscle and surrounding tissue should be evaluated. Any areas of sepsis must be drained. For low fistulas, the treatment choice depends on the status of the sphincter and the number of prior repairs. If the sphincter muscle is intact and the patients had undergone only one or perhaps two previous repairs, a repeat advancement flap or rectal sleeve advancement would be appropriate. Insertion of fibrin glue is a safe alternative but there are few data regarding the expected success rate. If there is a defect in the sphincter muscle, sphincteroplasty is the appropriate choice. Conversion to a fourth-degree laceration followed by a layered repair may be chosen by some surgeons. If the muscle is intact and two or more repairs have failed, a tissue interposition technique should be considered. Tissue interposition may also be required for recurrent fistulas with anatomically intact sphincter wraps. The insertion of bulbocavernous muscle is the least morbid transposition method but there are no comparative data regarding outcomes of the various interposition methods. The role of diversion is not established but seems to be primarily control of symptoms except perhaps in patients with Crohn's disease.

Recurrent fistulas involving the middle of the vagina almost always require tissue interposition. The choice depends on the level of the fistula and the body habitus of the patient. The bulbocavernous muscle may not reach if the patient is obese or the fistula is in the upper middle third of the vagina. Gracilis muscle would be a good alternative in those situations. High fistulas require resection or tissue interposition through an abdominal approach.

### Conclusion

The literature on rectovaginal fistulas documents a wealth of clinical experience. However, there is a definite lack of uniform terminology, standardized evaluation, and comparative studies. Given the multitude of etiologies and the varying nature of the anatomy and condition of surrounding tissue, improving the quality of research will be challenging. However, continued work is necessary to determine appropriate patient selection and optimal surgical repair.

# Pilonidal Disease and Hidradenitis Suppurativa\*

Jeffery M. Nelson and Richard P. Billingham

## Pilonidal Disease

### Background and Incidence

“Pilonidal disease” refers to a subcutaneous infection occurring in the upper half of the gluteal cleft. It may present as an acute “pilonidal abscess,” or as an indolent wound, resistant to spontaneous healing, and causing drainage and discomfort. It typically presents in the second decade of life, but also occurs in teenagers and in patients in their thirties.<sup>1</sup> It afflicts men more often than women at a ratio of three or four to one, and is more common in individuals with more body hair.<sup>1</sup> It is not known to be more common in any one racial group. During World War II, soldiers filled up whole hospital wards to convalesce from the large excisional operations used at the time to treat pilonidal disease.<sup>2</sup> It became such a problem that the Surgeon General forbade wide local excision as primary therapy, because this treatment had hospitalized 79,000 soldiers for an average hospital stay of 55 days.<sup>3</sup> Akinci et al.<sup>4</sup> reported an 8.8% incidence of pilonidal disease in Turkish Army recruits and found associations with family history, obesity, being a vehicle driver, and having a history of a furuncle at another site on the body. Sondenaar et al.<sup>5</sup> studied 322 patients with pilonidal disease prospectively and calculated the incidence of the disease at 26 per 100,000 persons. It occurred 2.2 times more often in men than in women. He also found the following significant associations: family history in 38%; obesity in 37%; preceding local irritation or trauma in 34%; and a sedentary occupation in 44%. Since World War II, a paradigm shift has occurred in favor of conservative measures, mainly in the form of shaving and hygiene.

Patients typically present initially with pain, redness, and swelling in the midline gluteal cleft region overlying the sacrum and coccyx. Many patients will spontaneously drain

their abscesses, which will temporarily relieve the symptoms. This may set up a chronic cycle of drainage and recrudescence of the abscess before the patient eventually seeks medical attention. Thus, some patients may already have a chronic condition at the time of their initial presentation. Patients may also present with a history of having had many different surgical procedures performed in the past for their disease. They may have a persistent wound from a midline excision or a failed flap procedure. Those patients with long-standing disease typically have multiple sinuses that usually extend cephalad from where the midline pits lie. Uncommonly, this process can be quite destructive with large sinus cavities extending out into the lateral gluteal regions.

Pilonidal disease first appeared in the medical literature in 1833 when William Mayo published his first descriptions of this problem.<sup>6</sup> The term “pilonidal,” which means “hair nest,” however, was first used by Hodges in 1880.<sup>7,8</sup> The term pilonidal “cyst” is a misnomer, because no epithelialized wall exists in the cavities this disease creates. Pilonidal “sinus” or “disease” are the more accurate terms. Pilonidal disease itself, and the surgical and medical treatment related to it, can be a source of disability. This disease disables patients primarily because of pain and its inconvenient location in the gluteal cleft.

### Pathogenesis

Empiric data currently support the theory that pilonidal disease is an acquired condition. Pilonidal disease has been observed in the hands of barbers and sheep shearers, implying that shed hairs may initiate the condition.<sup>6</sup> In addition, pilonidal lesions appear to have the pathologic characteristics of a foreign body reaction, presumably from burrowed hair and debris.<sup>1</sup> Pilonidal disease likely results from problems that attack epidermis in the gluteal cleft, rather than from a problem in the deep tissues, or problems with midline skin itself.<sup>3</sup> John Bascom believes that the skin in the natal cleft is perfectly normal, but that conditions that exist there may predispose a patient to pilonidal disease.<sup>3,9</sup> Treatment, therefore, should be directed at changing those conditions. Bascom sur-

\*The opinions or assertions contained herein are the private views of the authors and are not to be construed as official or as reflecting the views of the Department of the Army or the Department of Defense.

mises that the natal cleft is probably a hypoxic environment, and cites as empiric evidence the fact that anaerobic bacteria can be cultured from pilonidal wounds and abscesses.<sup>3,10</sup> However, no experiments have directly shown that the natal cleft is hypoxic at all, or even to what degree it may be hypoxic. In addition, Bascom theorizes that vacuum forces and negative suction in the natal cleft draws hair and debris into the midline pits, which are stretched and ruptured hair follicles, resulting in obstruction.<sup>6</sup> These stretched follicles, he believes, stretch and eventually rupture into the subcutaneous tissue, causing the classic pilonidal abscess.<sup>10</sup> The midline “pits” communicate with chronic abscesses containing trapped hair and debris via sinus tracts. If these sinus tracts become epithelialized, excision is the only option for cure. Presently, the ideas of Bascom and others about the pathogenesis of pilonidal disease are based on empiric evidence. No published experiments exist that directly prove or refute the current theories about how pilonidal disease occurs.

### Initial Presentations: Pilonidal Abscess

The presenting symptoms for many patients include pain, swelling, and erythema near the top of the natal cleft, with or without spontaneous drainage. A few definitions at this point are in order. An *acute pilonidal abscess* is no different from an acute abscess in any other location on the body. It requires incision and drainage before considering any other definitive therapy. A *chronic abscess* is really an established pilonidal sinus cavity, which chronically drains and fails to heal because of retained hair and foreign material. A *recurrent abscess* is an acute abscess, which occurs after apparent complete healing of pilonidal disease in the past. Excision in a patient in the presence of acute inflammation and swelling is ill advised. Many times the midline pits will not be visible until after the inflammation subsides. Abscesses should be drained with an incision parallel to the midline and at least 1 cm lateral to it (if possible) to facilitate healing of the wound (Figure 15-1). It is prudent to remove a small ellipse of skin from the wound to prevent the skin edges from sealing and reforming the abscess. Packing of such wounds serves no good purpose, is painful, and potentially interferes with drainage and healing. Antibiotics are only necessary in the patient with significant cellulitis. Simply cover the wound with a dressing and have the patient do sitz baths or use a hand-held shower 2–3 times a day. The patient should return to the office every week or two until the wound heals. Any hair that has grown back within 2 inches of the entire gluteal cleft is shaved at each visit (Figure 15-2).

### Initial Presentation: Draining Pilonidal Chronic Abscess

Pilonidal disease has been treated in many different ways, but no treatment has proved completely satisfactory. The ideal treatment would at least meet the following criteria: ease of

FIGURE 15-1. Incision placement for acute pilonidal abscess.

performance; short or no hospitalization; low recurrence rate; minimal pain and wound care; fast return to normal activity; and cost effectiveness. No current treatment meets all these criteria.

### Nonsurgical Approach

#### Shaving

For the initial treatment of chronic disease (which can be a chronic sinus that has never been treated or any persistent disease that has failed to heal despite treatment), shaving alone has been advocated as the sole alternative treatment for pilonidal disease. In 1994, Armstrong and Barcia<sup>9</sup> tested the hypothesis that wide, meticulous shaving was equal or superior to surgical therapy of any kind. They performed a pilot

FIGURE 15-2. Shaving technique.

nonrandomized cohort study, which also included a follow-up retrospective study, which remains one of the largest studies to date looking at any aspect of pilonidal disease. One group of patients was treated with weekly strip shaving (5 cm circumferentially around the entire gluteal cleft) until healing occurred and the other with surgery (midline excision with or without marsupialization, closure or partial closure, and open packing; rotational flaps; Z-plasty; and skin grafting). The article does not clarify if the patients treated with surgery received one or more of these procedures. They then followed the patients for 3 years, comparing the groups as to the number of occupied bed days and number of operations needed. They found a highly statistically significant difference in favor of the group that received only shaving. This study received criticism for several reasons. First, they did not control for the type of surgery the nonconservative group received, or for the severity of disease. They also did not look at healing or recurrence rates. One might surmise that even though the conservatively treated patients were not occupying hospital beds, they still could have been suffering for long periods from their disease. They may have also sought treatment elsewhere. Despite these limitations, this study provides evidence that conservative nonsurgical treatment, when applied with a dedicated effort, can work. Physicians should consider shaving as the initial therapy in all patients without an acute or chronic abscess and localized disease. However, no one knows how long one should continue shaving in order to prevent recurrence. Currently, we recommend shaving until complete healing has occurred. Recently, several authors have described laser hair removal as an alternative to shaving.<sup>11-13</sup>

## Surgical Approaches

### *Midline Excision*

The most frequently performed operation for pilonidal disease is midline excision, with or without primary closure of the wound, because most chronic or recurrent disease presents while localized to the midline. In this procedure, only the clearly abnormal tissue in the midline is excised. It is not necessary to always excise down to presacral fascia. Surprisingly, the literature contains only four randomized, prospective studies comparing open excision to excision and primary closure. In 1985, Kronborg et al.<sup>14</sup> randomized 88 patients to one of three treatment groups: excision, leaving the wound open; excision and wound closure; and excision and closure with postoperative clindamycin coverage. This article is important because it was the first to look at the utility of using antibiotics after pilonidal excision. The authors then looked at recurrence and healing rates. They followed each patient for 3 years. Healing rates among each of the primary closure groups were not statistically significant, and there was no benefit shown from the addition of clindamycin (14 versus 11 days,  $P > .10$ ). Healing took a substantially longer amount of time in the open group compared with the primary closure

groups (64 versus 15 days,  $P > .001$ ). Recurrence rates were not significant in any of the groups ( $P > .40$ ); however, there was a tendency toward more recurrences in the primary closure group (7 versus 0 at 3 months and 7 versus 4 at 3 years).

Fuzun et al.<sup>15</sup> randomized 91 patients to either excision without closure or excision with primary closure. The authors then followed the patients for a minimum of 4 months. They primarily looked at infection and recurrence rates. In the two patients who experienced infection in the closed group, this was treated with simple suture removal and healing by secondary intent without the need for further hospitalization. They used no antibiotics. Patients whose wounds were left open had a lower infection rate (1.8% versus 3.6%,  $P < .01$ ) and no instances of recurrence, whereas the recurrence rate for those undergoing wound closure was 4.4% ( $P < .01$ ). They did not specify the duration of healing for either group. The only patients that had delayed healing were those few patients who developed a wound infection. Despite the statistically significant differences in favor of open excision, the authors concluded that either method is acceptable.

Sondenaa et al.<sup>16</sup> randomized 153 patients to midline excision and primary closure with or without cefoxitin prophylaxis. After following the patients for 4 weeks, they found no differences in healing or recurrence. Based on these data, the authors did not recommend cefoxitin prophylaxis. In a follow-up article a year later, the same authors published the results of a study that randomized 120 patients to either open excision or excision with primary closure.<sup>17</sup> They followed the patients for a median of 4.2 years. The authors detected no significant difference between the groups, and concluded that either method was acceptable.

Based on the results of these studies, no clear benefit exists for the use of primary closure after midline excision. Proponents of primary closure cite the accelerated healing rate in patients in whom this approach is successful. However, this comes with the price of a significantly increased chance of more wound infections.

### *Unroofing and Secondary Healing*

Midline excision without primary closure leaves a large wound, which is associated with long healing times. If wound closure is not indicated (i.e., with an associated abscess), a smaller wound with much shorter healing times can be achieved with unroofing or laying open of the pilonidal sinus (Figure 15-3A). Open wounds require dressing changes and wound care, but unroofing is associated with half the healing time of wide and deep excision.<sup>18,19</sup> The recurrence rate is less than 13% with this technique.

### *Bascom's Chronic Abscess Curettage and Midline Pit Excision (Bascom I)*

Bascom bases this procedure on the premise that efforts to help patients with pilonidal disease should be directed at changing the gluteal cleft conditions rather than excising a

FIGURE 15-3. **A** Bascom procedure. Lateral incision and debridement of cavity. **B** Bascom procedure. Removal of a midline pits with small incisions after lateral debridement, and closure of midline wounds without closure of the lateral incision.

large amount of normal tissue associated with the diseased areas. In patients who present initially with a chronic abscess, this procedure has given excellent results. He does this by making a generous, vertically oriented incision through the site of the abscess cavity more than 1 cm off the midline (in some cases more than one chronic abscess is present) and then curetting it out, without excising the fibrous abscess wall. The connecting tracts to the midline pits are also identified and the overlying skin undermined so that they drain to the site of the incision. The midline pits are then excised using a small diamond-shaped incision to circumferentially remove each of them.<sup>3,10</sup> According to Bascom,<sup>10</sup> the excised pit should be about the size of a grain of rice. The undermined flap of skin, between the incision and drainage site and the excised midline pits, is then tacked down, and the pit excision sites are closed with either subcuticular or vertical mattress, nonabsorbable suture (4-0 or 3-0) (Figure 15-3B). Once this has been accomplished, meticulous shaving of the gluteal cleft should continue at least once a week until the wound has healed. Shaving can be done in the physician's office, or at home by a family member or friend who has been given the proper instruction.

Senapati et al.<sup>20</sup> published a prospective series of 218 patients treated with Bascom's operation described above. The patients had a mean age of 27 years, and a mean duration of symptoms of 2.4 years. The mean duration of follow-up was 12.1 months (range, 1–60). Follow-up consisted of phone calls, office visits, and mailed questionnaires. All but one patient healed his or her pit excision sites. The lateral wound in one patient failed to heal and required further excision. All the other wounds healed after a mean of 4 weeks (range, 1–15 weeks). Four percent of patients experienced bleeding that required either external pressure or cautery to stop. Eight percent of patients reformed their abscesses when the lateral skin

wound healed before the underlying cavity completely healed. This required reopening the lateral wound. Ninety percent of patients healed completely with only 21 patients (10%) ultimately requiring further surgery for recurrent pilonidal disease. Given the overall good results and the fact that patients who failed to heal or recurred were not any worse off than when they initially presented, they recommended the use of this technique. To date, no trials compare Bascom's procedure with another approach to chronic abscess.

### Treatment: Recurrent Disease and Severe Disease

Controversy exists over how to treat and follow patients who heal, but continue to present with multiply recurrent disease despite attempts at limited surgery and the other conservative measures discussed above. In addition to midline excision, the surgical options often used today, after initial shaving and hygiene methods have failed, include rhomboid flaps, Z-plasty (Figure 15-5), the Karydakis procedure, Bascom's cleft lift procedure, V-Y plasty, gluteus maximus myocutaneous flaps, and skin grafting (Table 15-1). Some level-one evidence exists regarding flap-based or asymmetric closures off the midline

TABLE 15-1. Complex Pilonidol Procedure Results

Procedure	% Healing (mean)	% Complications (mean)	% Recurrence (mean)
Rhomboid flap <sup>21,22</sup>	100	13.5	4.9
Karydakis <sup>24</sup>	—	8.5	1
Bascom cleft lift <sup>3</sup>	100	—	0
V-Y plasty <sup>25</sup>	100	8	0
Z-plasty <sup>26</sup>	100	—	0
Myocutaneous flap <sup>287</sup>	100	100	0
Skin graft <sup>29</sup>	96.6	—	1.7

for pilonidal disease, but most data come from patient series reports. The major disadvantages with flaps are longer operative times, greater blood loss, potential flap loss, and infection. However, these flaps do offer a quicker time to healing than midline excision, with no increase in infection rate.

### Rhomboid Flap

The rhomboid, or Limberg flap, is a cutaneous rotational flap used to fill soft tissue defects and is ideally suited for this purpose with regard to pilonidal disease (Figure 15-4A–D). One large recent prospective series used the rhomboid flap on 102 patients regardless of the severity of their disease.<sup>21</sup> All of the patients healed eventually, but they did not specify a time frame. They reported a 6% complication rate consisting of three seromas, two partial wound dehiscences, and one wound infection. The recurrence rate was 4.9%. The authors also used the rhomboid flap to treat recurrences. Patients returned to normal activity by 7 days, on average. Although this study is not level-one evidence, it does show us that the majority of patients treated with this method generally do

well in the short term. Abu Galala et al.<sup>22</sup> randomized 46 patients with chronic sinuses to either the rhomboid flap, or to midline excision with primary closure, and followed them for healing and recurrence. Patients with acute abscesses or recurrent sinuses were excluded. All of the rhomboid flap patients healed versus only 77% healing in the midline closure group ( $P > .02$ ). After 18 months of follow-up, 9% of the midline suture group had recurred. No one in the rhomboid flap group recurred. Another randomized, prospective trial regarding the rhomboid flap method evaluated the use of drains after surgery. Erdem et al.<sup>23</sup> randomized 40 patients and used a drain in half of them. The study found no difference in wound healing or recurrence ( $P > .05$ ). The drain group, however, had a longer hospital stay ( $P < .001$ ).

Despite the overall good results with use of the rhomboid flap for recalcitrant pilonidal disease, this technique necessitates excision of a large amount of normal tissue and subsequently creates a large scar at the flap site (Figure 15-4D). Also, many patients with chronic abscesses have their abscesses located so lateral and cephalad to the midline area containing the pits, that it makes the use of this technique

FIGURE 15-4. Rhomboid flap technique for recurrent pilonidal disease. **A** Initial excision of the sinus cavity. Counter incisions are created as shown. **B** Flaps are raised and maneuvered as shown to close defect. **C** Final surgical result. **D** Result at 1 month postoperatively.

more morbid because of the size of the flap required to cover the excised area. With disease localized more or less to the midline, however, any abscess cavities and all the pits are easily excised. In addition, this technique works particularly well for flap coverage of chronic wounds (as a result of midline excisions) in the gluteal cleft that have failed to heal over a prolonged period of time.

### Karydakis Flap

The Karydakis operation has been used by Dr. Karydakis in Athens, Greece since 1965. The two goals of this procedure are: 1) to eccentrically excise "vulnerable" tissue in the midline, or laterally displace it; and 2) to laterally displace the surgical wound out of the midline gluteal cleft. An elliptical incision is made parallel to the midline at a distance at least 1 cm from the midline. Skin and gluteal fat are then excised down to the sacral fascia eccentrically (Figure 15-5). By necessity, some normal tissue needs to be excised to create a flap. This flap is then sutured down to the sacral fascia. The closed incision should be entirely lateral to the cleft.

In 1992 Karydakis reported the results of this approach in 7471 patients over a period of 24 years from 1966 to 1990, which is one of the largest series in the surgical literature.<sup>24</sup> Follow-up ranged from 2 to 20 years, and was possible in 95% of cases. He reported a recurrence rate of 1% in the first 6545 cases, finding that new disease occurred from new midline pits. The overall complication rate was 8.5%, mainly from infections and fluid collections. Antibiotics were not routinely used, but a drain was always placed at the upper end of the wound for 2–3 days.

The large numbers of patients that have received this operation along with the good reported results make this an attractive

FIGURE 15-5. Karydakis advancing flap operation.

option to consider. However, no one else has ever studied this or reported their results, nor are there any comparative trials.

### Bascom Cleft Lift (Bascom II)

Bascom developed this procedure, which may be the most technically challenging of all the techniques dealing with multiply recurrent and severe pilonidal disease. It also may prove to be the most revolutionary technique to come along since the Karydakis procedure. The key difference between the cleft lift procedure and other flap-based procedures is that the cleft lift procedure excises no normal subcutaneous tissue. As described above, the Karydakis procedure does excise normal fat to create the flap. The only tissue excised during the cleft lift is a portion of skin. The goal of the cleft lift procedure is to undermine and completely obliterate the gluteal cleft in the diseased area. This procedure detaches the skin of the gluteal cleft from the underlying subcutaneous tissue as a flap. A portion of this flap containing the diseased skin is then excised from the side of the buttocks to which the flap will be sutured (Figure 15-6A). When the flap is pulled across the midline, the gluteal subcutaneous tissue is approximated underneath the flap, thus obliterating the gluteal cleft. Any open chronic wounds or sinus cavities are simply curetted out, but not excised. The raised skin flaps cover these prior wound sites in addition to coapting the normal gluteal fat. The final suture line lies parallel to, but well away from, the midline, and is free from tension (Figure 15-6B). Bascom<sup>3</sup> studied 28 consecutive patients with recurrent, festering wounds who

FIGURE 15-6. **A** Cleft-lift technique as described by Bascom for non-healing midline wounds. **B** Final result after flaps are raised and underlying gluteal fat is approximated.

received this treatment. Twenty-two patients healed their wounds immediately and had their sutures removed at 1 week. Six patients took longer to heal because of small wound separations. Three patients required operative revision to achieve healing. Finally, one obese patient took 13 months to heal. The median follow-up was 20 months (range, 1 month to 15 years) and all patients remained healed. This procedure has enjoyed spectacular results in Dr. Bascom's hands, but it awaits duplication elsewhere.

### V-Y Plasty

Schoeller et al.<sup>25</sup> retrospectively investigated the use of the V-Y advancement flap in 24 patients with a mean follow-up of 4.5 years. They reported two wound dehiscences, but achieved healing in all cases. They noted no recurrences. Overall, they found the method to be satisfactory, but demanding, and recommended a simpler approach. However, it may have applicability in some situations in which other flaps have failed, such as the rhomboid flap.

### Z-plasty

Hodgson and Greenstein<sup>26</sup> published the only other randomized, prospective study on flap closure for pilonidal disease in 1981. This study looked at Z-plasty versus midline excision with or without marsupialization. The Z-plasty group required no further surgery, but 40% of the open excision group did go on to have repeat operations. This study gives us the best available evidence that even open excision, although not prone to wound breakdown, does not completely rectify a patient's wound issues, at least in the short term.

Petersen et al.<sup>27</sup> reviewed these asymmetric closure techniques, which utilize cutaneous flaps, examining the results of 74 articles published in the last 35 years. Wound infections occurred in up to 38.5% of all patients undergoing any surgery for pilonidal disease. However, they found no consistent trend that all flap procedures had significantly lower infection rates than midline excision. Similarly, wound failure occurred in up to 52.4% of all patients. No individual technique showed consistently better results in this regard, compared with all flap procedures as a group. Pilonidal recurrence proved to be the only area in which the flap techniques showed a consistent advantage. Recurrence occurred in up to 26.8% of all the patients. The midline pits recurred less often in the asymmetric closure/flap group compared with midline excision. Overall, they concluded that asymmetric closures and flap techniques were superior to midline excision despite the limitations of the study. Also, they recommended that an asymmetric closure, such as the Karydak, be considered initially before using the rotational flap procedures, because these may be unnecessarily complex.<sup>27</sup>

### Myocutaneous Flaps

Larger areas of disease with large, deep wounds may require myocutaneous flaps. Rosen and Davidson<sup>28</sup> treated five patients with severe disease with gluteus myocutaneous flaps.

They were all young males and had received an average of six previous procedures. All patients healed with an average follow-up of 40 months and 13 hospital days. Most surgeons reserve this technique for the most severe cases, usually after failure of simpler techniques.

### Skin Grafting

No study looking at skin grafting for pilonidal disease has been published since 1983 when Guyuron et al.<sup>29</sup> published their retrospective study of 58 patients so treated. Seventy-two percent of these patients initially presented to the authors' institution with recurrent disease. The patients all underwent excision of their pilonidal disease with split-thickness skin grafting. They noted a 1.7% recurrence rate and a 3.4% graft failure rate. The authors recommended use of this method for recurrent or extensive pilonidal disease.

### Summary

The algorithm in Figure 15-7 delineates an approach to pilonidal disease based on the evidence presented in this section. Conservative treatment ought to form the cornerstone of therapy—specifically, wide, meticulous shaving and hygiene. The best evidence available suggests that shaving should be done until healing is complete, either in patients treated primarily this way, or those treated with surgery. When patients present initially with simple midline pits, sinuses, and various symptoms, such as pain and occasional drainage, but no acute abscess, shaving can again be offered as the initial treatment. A patient who presents with an acute pilonidal abscess should have incision and drainage, ideally making the incision lateral to the midline whenever possible. At the same time, one should do a 2-inch strip shave circumferentially around the affected area. Anyone familiar with the procedure (doctor, medical assistant, significant other, etc.) repeats the shaving

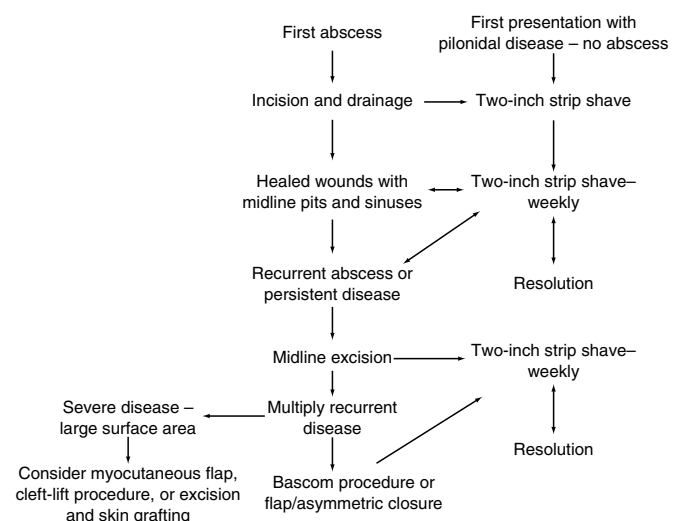

FIGURE 15-7. Pilonidal disease algorithm.

weekly. Continue dressing changes and sitz baths without packing until the wound has healed. If this is the initial presentation of the patient's pilonidal disease, then simply continue shaving. This shaving must be meticulous and ritualistic to be successful. One single hair protruding from a midline pit will keep it open. The majority of patients do not recur after conservative treatment consisting of incision and drainage and shaving. For these reasons, we do not recommend continued shaving once healing is complete.

Patients who present with multiply recurrent pilonidal disease, meaning disease occurring sometime after healing of prior episodes (i.e., abscesses, new pits) are more challenging. The usual case is the patient with a chronic abscess that persists despite shaving and other conservative measures. Continued shaving in this situation is unlikely to succeed, because the abscess cavity and the epithelialized tracts connecting it to the midline pits will contain a great deal of burrowed hair. In this case, we prefer to move on to the Bascom chronic abscess curettage and midline pit excision, or a cutaneous flap procedure. For the initial management of the chronic abscess, virtually all cases can be done as an outpatient in the operating room under local anesthesia with conscious sedation. Sungurtekin et al.<sup>30</sup> found no benefit to the use of spinal anesthesia over local anesthesia in the outpatient surgical treatment of pilonidal disease. They randomized 60 patients receiving the rhomboid flap operation to either spinal anesthesia or local anesthesia. The local group also received intravenous midazolam for sedation. They found no differences regarding patient satisfaction, side effects, or pain scores. However, two spinal patients suffered urinary retention. In addition, both the amount of time spent recovering before discharge, and the total cost of the spinal anesthetic patients' care were significantly higher ( $P < .05$ ).

Neither antibiotics nor drains have been shown to be helpful on a routine basis. However, when taking on complex flap procedures or skin grafts, antibiotics may be used perioperatively based on evidence from other arenas of surgery proving their benefit. The evidence presented here also shows that more complications and recurrences occur with midline excision and primary closure than with open excision alone. However, time to healing is greater with open excision. Despite the good results reported with the flaps and asymmetric closures for pilonidal disease, midline excision or unroofing does seem to work most of the time, and has the advantage of simplicity. Cutaneous rotational flaps and asymmetric closures may best be reserved for the patient with a laterally located chronic abscess, multiply recurrent disease, a large area of involvement, or a nonhealing wound.

In response to the question, "Which procedure should be tried first for the new pilonidal patient?" the answer is, "It depends." If the patient presents with a draining sinus, alternately known as a chronic abscess, the surgeon first needs to note the location of the sinus relative to the midline. In the case in which all the disease, sinuses, and pits are located near and in the midline, then a conservative midline excision

is a reasonable first-line treatment. A Bascom procedure for a chronic abscess/sinus is also reasonable. Many times, however, multiple draining sinuses exist and can be located far enough away from the midline that a simple midline excision becomes impractical because of the larger wound created. In this case, we typically make a choice between a Bascom I and a rhomboid flap. For patients who have failed midline excisions, a rhomboid flap or a Bascom I are our procedures of choice for the patient whose disease is easily encompassed within the rhomboid excision specimen. If this is not the case, then another Bascom I is again a good option for this type of presentation, primarily because it is nonexcisional in nature (except for the midline pits). As always, shaving should continue with the proper vigilance until healing is complete. For a small, chronic nonhealing wound from a prior operation for pilonidal disease, a rotational flap is ideal. We prefer the rhomboid flap for this purpose. For extensive recurrence in the midline with abscesses and multiple nonhealing wounds, the Bascom II procedure has shown great promise.

## Hidradenitis Suppurativa

### Background

Hidradenitis suppurativa is a cutaneous condition that involves skin containing apocrine sweat glands. Areas of the body where this often occurs include the perineum, the axilla, and the groin. It presents initially as an abscess, but is typically multiply recurrent in the affected area and ultimately can lead to severe scarring and disability for the patient. This section will focus on disease that presents perianally. Velpeau first described this entity in 1839 as an inflammatory process causing superficial skin abscesses affecting the axillary, mammary, and perineal regions. It was not until 1854, however, that Verneuil ascribed this process specifically to sweat glands. Verneuil also named the disease "hidradenitis suppurativa," although it has also been called Verneuil's disease, as well as "the follicular occlusion triad," "acne inverse," and "acne vulgaris." Schieffendecker classified sweat glands as eccrine or apocrine in 1922. He then localized hidradenitis suppurativa to the apocrine glands of the perineal, mammary, axillary, inguinal, and umbilical areas.<sup>31</sup> Finally, Lane in 1933 and Brunsting in 1939, defined the histology of this disorder and implicated luminal obstruction of the apocrine sweat glands as the inciting event.<sup>32,33</sup>

### Incidence and Etiology

The exact incidence of hidradenitis suppurativa in general is unknown. However, one in every 300 individuals may be affected in some way.<sup>32</sup> African-Americans seem to be affected more often than Caucasians, and perianal disease seems to be more common in males.<sup>31,32</sup> Almost all patients present after puberty and before the age of 40, implicating

hormones and the development of secondary sexual characteristics as causative.<sup>32</sup> Other endocrine associations include diabetes mellitus, hypercholesterolemia, and Cushing's disease. It can theoretically occur in any skin that contains apocrine glands, but the most common locations are axillary and inguinal-perineal. Obesity has been implicated as a predisposing factor presumably from shearing forces in the affected areas.<sup>32</sup> In a series from the Lahey clinic, 70% of affected patients were smokers, but no causal relationship could be shown.<sup>32</sup> Perianal hidradenitis affects males twice as often as females, but hidradenitis in all locations may be more common in females and African-American persons.<sup>32</sup> Fortunately for sufferers of perianal hidradenitis, it seems to recur less often after surgical treatment (<0.5%) than does inguinal-perineal disease (37%–74%).<sup>31,33</sup>

### Bacteriology

Wound cultures from hidradenitis patients have grown *Staphylococcus epidermidis*, *Escherichia coli*, *Klebsiella*, *Proteus*, alpha *Streptococcus*, anaerobic bacteria, and diphtheroids, although negative cultures are common. Lapins et al.<sup>34</sup> showed that *S. epidermidis* was the most frequently cultured bacteria from deep portions of hidradenitis suppurativa lesions in 25 patients. *Chlamydia trachomatis*, often associated with lymphogranuloma venereum, and *Bilophila wadsworthia* infection have also been implicated, but the clinical significance is not known.<sup>31,32</sup>

### Pathogenesis

Most authors agree that hidradenitis suppurativa originates from obstruction of apocrine sweat glands by keratin. However, it is unknown why this occurs in some people and not in others (females, African-Americans, etc). Attanoos et al.<sup>35</sup> examined 118 pathologic hidradenitis specimens and found some degree of keratin plugging in all cases along with an active deep folliculitis. They concluded that plugging of the hair follicle itself led to apocrine inflammation making the actual apocrine gland destruction of hidradenitis suppurativa a secondary process. These glands secrete a milky, odorless fluid that only becomes malodorous after it interacts with bacteria on the skin. The apocrine glands secrete into the hair follicle as opposed to directly onto the skin like eccrine sweat glands. The function of apocrine secretion is unknown. Nevertheless, obstruction leads to secondary bacterial infection and rupture of the gland into the dermis and subcutaneous tissue, thus causing cellulitis, abscess, and draining sinuses. This process then leads to the characteristic "pit-like" scars from chronic fibrosis of the destroyed glandular unit. With time, this disease can become not only disfiguring, but debilitating. Microscopically, the pathognomonic serpentine epithelialized sinus tracks with giant cells and granulomas are typically seen.<sup>31,32,36,37</sup>

### Differential Diagnosis

Differentiating hidradenitis suppurativa from other inflammatory conditions of the perianal region can be difficult, and many of them may coexist. Cutaneous infections such as furuncles, carbuncles, lymphogranuloma venereum, erysipelas, epidermoid or dermoid cysts, and tuberculosis can be particularly troublesome. In particular, it must be distinguished from other fistulizing or sinus-forming processes of the perineum. Crohn's disease typically affects the anus and rectum with fistulas arising from the dentate line or higher in the rectum. Ordinary perianal abscesses and fistulas of cryptoglandular origin will arise from the dentate line and traverse the sphincter mechanism. In contrast, hidradenitis does not affect the rectum, because apocrine glands only exist in the lower two-thirds of the anal canal and do not penetrate into the sphincter complex. Thus, patients will not have sinus or fistula tracks to or from the rectum.<sup>31,32</sup> If fistulas are present, then the surgeon should perform anoscopy to rule out the possibility of fistula-in-ano from a cryptoglandular source. Fistulas from hidradenitis should only connect areas of involved skin, and not penetrate the anal sphincters. If they do, then another, or concomitant, diagnosis should be entertained. Several case reports have been published describing the association of Crohn's disease and hidradenitis, but no definitive link between the two conditions has ever been proven.<sup>38–42</sup> Nonspecific granulomas (required for a pathologic diagnosis of Crohn's disease) are seen in pathologic specimens in both diseases and may be confused with one another.

Several cases of squamous cell carcinoma in chronic hidradenitis wounds have also been published.<sup>43–46</sup> A retrospective review of a Swedish database of hospital discharge diagnoses from 1965 to 1997 revealed a 50% increased risk of developing *any* cancer in patients with hidradenitis suppurativa over the general population. Specifically, the authors observed significant increases for nonmelanoma skin cancers, buccal cancer, and primary liver cancer.<sup>47</sup> The association seems to be rare with affected patients, who usually have had untreated disease for longer than 20 years. One report found a 3.2% incidence in 125 patients with perianal hidradenitis lasting 20–30 years.<sup>46</sup> One should at least keep a high index of suspicion for this entity in patients with long-standing disease and extensive scarring in the affected areas.

### Treatment: Initial

Hidradenitis suppurativa typically presents with pain, erythema, and swelling in the affected area. Patients with cellulitis and no definable clinical abscess may be successfully treated with antibiotics that cover skin flora, such as staphylococcus species, over 1–2 weeks. The safest course of action with any patient who presents with an obvious abscess is incision and drainage. No evidence exists supporting the use of prophylactic antibiotics beyond the initial treatment course. Jemec and Wendelboe<sup>48</sup> conducted the only double-blinded

randomized, prospective study looking at antibiotic use for hidradenitis suppurativa (or any other aspect of this disease). They evaluated 46 patients with mild hidradenitis (not more than 10 lesions; no extensive sinus tracts) after 3 months of therapy with either systemic tetracycline or topical clindamycin. The patients also received a placebo of the other agent. Patients selected for the study did not undergo incision and drainage. The authors found no benefit of topical clindamycin versus systemic tetracycline for treatment of acute disease. The study did not include a control arm, which received no antibiotics, so we cannot conclude that these topical antibiotics provide no benefit or some benefit versus no topical antibiotic treatment at all.

Sadly, 83% of patients will have recurrent localized sepsis of some sort after initial incision and drainage or limited excision. Our preference is to leave the wounds open to heal by secondary intent, after excising the involved area. Pathologic examination may show apocrine involvement providing histologic confirmation of hidradenitis.<sup>31</sup>

### Treatment: Chronic

Chronic disease is simply any hidradenitis disease persisting or recurring after initial treatment. This could present as recurrent abscesses, nodules, sinuses, fistulas, cellulitis, or any combination of these problems. Unroofing of all sinus tracts is a simple method that may control the hidradenitis, but disease remains, by definition, and recurrence is highly likely for this reason. More specifically, unroofing of abscesses does not control the underlying problem in patients who get hidradenitis. It is a problem with the apocrine glands located in susceptible perianal skin. Unless the surgeon excises all this skin, the patient will technically be at risk for recurrence, although not every patient eventually goes on to radical excision.

Excision with healing by secondary intention is probably the most widely used surgical treatment. The literature reports various recurrence rates after removal of a portion, or all, of the apocrine gland bearing skin. Only the grossly involved apocrine bearing skin (but all of it) in the perianal area should be excised full thickness into the uninvolved gluteal fat. No evidence exists supporting any need for a wide excisional margin, however. This method is simple and almost never requires fecal diversion. It also allows completion of the procedure as an outpatient. Perioperative antibiotics are unnecessary. Patients with large areas of involvement may undergo staged excision. The extent of excision should remain outside the anal verge as long as there is no obvious involvement or history of involvement in the anal canal. If excision is necessary near the anal canal, because of extensive involvement at the anal verge, it should be limited, or staged, in order to prevent a stricture. The major disadvantage of this method is that the wounds take 1 month or much longer to heal, and they require daily wound care. The disability associated with this treatment, however, is minimal. With either of the methods mentioned above, the patient should do sitz baths, or use a

handheld shower, at least twice daily along with dressing changes.

Recently, reports on the use of negative pressure dressings have appeared as a way to promote healing and shorten the time to wound closure.<sup>49</sup> The purported benefits of these dressings, which have never been validated, include increased wound oxygen tension, decreased bacterial counts, better control of fluid produced by the wound, increased granulation tissue formation, and decreased shear forces. Negative pressure dressings have been used successfully on open wounds and on skin grafts.<sup>49,50</sup> However, the expense and mechanical difficulties inherent with all dressings placed in the perianal area are rarely justified. These dressings require an air-tight seal at all times, which is difficult to achieve near the anal verge.

Patients with chronic disease, extensive scarring, and sinus tracts rarely respond to conservative measures. The gold standard of care remains wide excision of all skin bearing involved apocrine glands. Reconstruction then can follow a number of paths—unroofing of sinus tracts with or without marsupialization, cutaneous flap closure, myocutaneous flap closure, or excision and simple healing by secondary intent. Cutaneous or myocutaneous flaps are typically taken from the posterior thigh, gluteus muscle, or lumbosacral region. They are analogous to those used for pilonidal disease. Flaps are almost never necessary, however. Which of these options to choose, however, depends on the extent of involvement around the anus and the severity of disease. Patients who might benefit from diversion are those who cannot take care of their wounds long term and those who have both hidradenitis and Crohn's disease, although this is rarely needed.<sup>32,51</sup>

### Summary

The algorithm in Figure 15-8 depicts our suggested approach to treating patients with perianal hidradenitis suppurativa. Patients who present initially with an acute abscess, and a

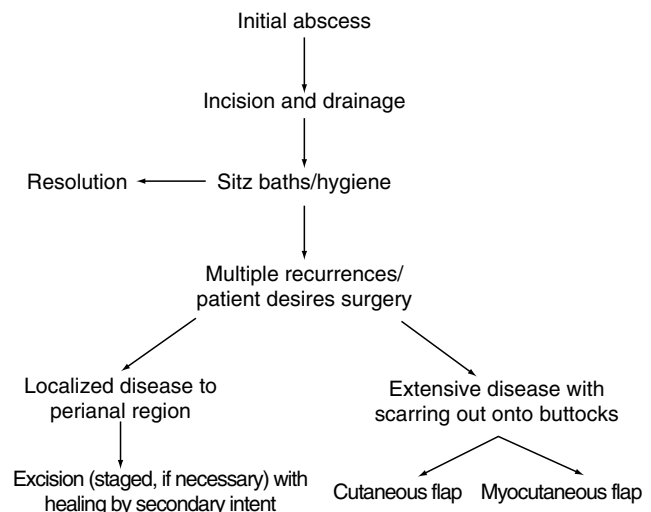

FIGURE 15-8. Perianal hidradenitis suppurativa algorithm.

history and examination consistent with hidradenitis, should have incision and drainage, ideally in an office setting.<sup>52</sup> Physicians should reserve antibiotics for those patients with a component of cellulitis as discussed above, or those who are immunocompromised. This process can be repeated as many times as is necessary. It is important to rule out other causes of perianal sepsis in the early stages of the disease, such as Crohn's disease or perirectal abscesses from a cryptoglandular source. For those patients with chronic and/or recurring disease, we proceed to definitive excision, as long as the diagnosis is not in doubt and we have exhausted the simpler alternatives. Flap procedures are reserved for patients with extensive scarring and tissue damage out onto skin distant from the anus, such as the buttocks. By the time a patient reaches the point at which they desire surgery, they have usually suffered for many years with recurrent abscesses in the affected area.

Even relatively large open wounds around the anus heal remarkably well in the absence of Crohn's disease and other inflammatory, malignant, or infectious processes, compared with how similar wounds typically heal in other areas of the body. Because of this, it is usually not necessary to use flaps after skin excisions for hidradenitis around the anus, especially when using a staged approach. If circumferential disease is present and requires excision, we excise half of the involved perianal skin down to subcutaneous fat and allow the wound to heal by secondary intent, which may take up to 3 months. We excise the other half after complete healing of the first wound. If circumferential excision of perianal skin is considered in a single procedure, we take care not to excise the skin at or inside the anal verge. This diminishes the risk of anal stricture. For patients whose disease does not extend out more than 5 or 6 cm from the anal verge, this approach works very well. We consider a flap-based procedure for those patients with much wider involvement extending out onto the buttocks. Negative pressure dressings are only rarely of potential help.

## Perianal Dermatology and Pruritus Ani

Charles O. Finne

Perianal skin is subject to virtually all of the diseases that affect skin in other areas of the body. The differential diagnosis of perianal skin is presented in Table 16-1. This list includes a variety of diagnoses, which almost never present as isolated perianal disease, but there are common diseases such as psoriasis that may present in isolation without obvious ties to other areas of the body unless a careful search is made. Successful treatment of perianal disease requires accurate diagnosis to eliminate diseases that have specific cause and treatment (e.g., psoriasis, candida, Bowen's disease). Recognition of important treatable causes requires a disciplined, organized approach to diagnosis with frequent use of biopsy. This chapter's objective is to lay out a strategy to facilitate accurate diagnosis and successful treatment of perianal and anal skin conditions. Implicit in this strategy is the ability to properly examine the anus with appropriate instruments and bright light and to understand diseases peculiar to the anal area, hence, the importance of the colorectal surgeon who has the skills to accomplish this task. The importance of complete, accurate evaluation is emphasized by a St. Louis University series in which a study of 209 patients with the presenting symptom of pruritus over a 2-year period revealed that 75% of patients had coexisting anal or colorectal pathology. The diagnoses included 11% with rectal cancer, 6% with anal canal cancer, and 2% with colon cancer, although the majority of patients had hemorrhoids or fissure.<sup>1</sup>

### Definitions

Pruritus ani is a term of Latin derivation, which means itchy anus. Not only is it a symptom, but the term is a Medline MeSH searchable diagnosis and is also used to designate a specific condition of disputed etiology recognized since antiquity.<sup>2,3</sup> Pruritus used alone simply means itchy: there is no distinction between it and itch, an unpleasant sensation that provokes the desire to scratch.<sup>4</sup> To avoid confusion in this chapter, the syndrome will always be referred to as pruritus ani. Pruritus ani has been classified into primary and second-

ary. The primary form is the classic syndrome of idiopathic pruritus ani, whereas the secondary form implies an identifiable cause or a specific diagnosis.

Accurate description of the morphology of skin lesions can aid in the diagnosis and follow-up of patients with pruritic complaints. Macules are flat spots. Papules are elevated circumscribed solid lesions, raised spots. Vesicles are separations of the epidermis and dermis filled with serum. Bulla are larger vesicles or blisters. Pustules contain pus. Ulcers are surface lesions with loss of continuity of the skin and may result from rupture of vesicular lesions, infection, or trauma. Intertrigo is inflammation seen between two opposing skin surfaces, often the result of mixed bacterial, fungal infection associated with moisture, obesity, and poor hygiene.

### Physiologic Considerations

Itch is a surface phenomenon mediated by pain fibers in the epidermis that may have a lower threshold for stimulation than pain. Itch receptors may be located more superficially than those dedicated to pain. Because receptors are superficial, innocuous, nondamaging stimuli such as wearing wool, or other minor mechanical stimuli may induce itching. In addition to histamine, kallikrein, bradykinin, papain, and trypsin experimentally produce itching, but these substances do not respond to blockade with histamine antagonists such as diphenhydramine, hence topical antihistamines are not always effective against itching.<sup>5</sup> The phenomenon of hyperesthesia with chronic pain may have a parallel with itching, whereas minimal stimulation of the skin may induce itching; scratching with subsequent injury may produce an enlarging patch of itchy skin. Scratching produces inadequate feedback to inhibit itching; more scratching occurs with cutaneous injury, which provides an additional stimulus to scratch in a self-defeating loop. Substituting heat, cold, painful or stinging stimulus for the itch by applying alcohol or pepper extract may provoke an inhibitory feedback not supplied by scratching alone and lead to inhibition of the urge to scratch.<sup>5</sup> Itching

TABLE 16-1. Differential diagnosis of anal dermatoses

Inflammatory disease	Nonsexual infectious disease
Pruritus ani	Pilonidal disease
Psoriasis	Hidradenitis suppurativa
Lichen planus	Fistula-in-ano
Lichen sclerosis et atrophicus	Crohn's disease
Atrophoderma	Tuberculosis
Contact (allergic) dermatitis	Actinomycosis
Seborrheic dermatitis	Herpes zoster
Atopic dermatitis	Vaccinia
Radiation dermatitis	Fournier's gangrene
Behçet's syndrome	Tinea cruris
Lupus erythematosus	Candidiasis
Dermatomyositis	"deep" mycoses
Scleroderma	Amebiasis cutis
Erythema multiforme	Trichomoniasis
Familial chronic pemphigus (Hailey-Hailey)	Schistosomiasis cutis
Pemphigus vulgaris	Bilharziasis
Cicatricial pemphigoid	<i>Oxyuris</i> (pinworm)
	Creeping eruption (larva migrans)
	Larva currens
	Cimicosis (bed bugs)
	Pediculosis (lice)
	Scabies
Sexually transmitted disease	Premalignant and malignant disease
Gonorrhea	Acanthosis nigricans
Syphilis	Leukoplakia
Chancroid	Mycosis fungoides
Granuloma inguinale	Leukemia cutis
Lymphogranuloma venereum	Basal cell carcinoma
Molluscum contagiosum	Squamous cell carcinoma
Herpes simplex	Melanoma
Condyloma acuminata	Bowen's disease (AIN)
	Extramammary Paget's disease

Source: Modified from Corman.<sup>2</sup>

attending the healing of surgical wounds and scars probably results from the combination of histamine release, release of other kinins and prostaglandins involved in the inflammatory phase of healing, and regeneration of nerves that may be

thinly myelinated in immature scars. Antihistamines, topical anti-inflammatory agents (steroids), topical anesthetics, and aloe preparations (prostaglandin inhibitors) all have beneficial effects on the itching of healing wounds.<sup>5</sup>

## Etiology of Pruritus

Because pruritus is a symptom that may have protean causes, it is useful to consider diagnoses that have been associated with pruritus ani. Table 16-2 is a list of diagnoses and conditions modified from Stamos and Hicks.<sup>6</sup> Specific causes are considered below.

## Localized Itch Syndromes

Notalgia paresthetica is a defined syndrome with itching or pain of the upper mid back to either side of the scapular region. This has been attributed to spinal nerve damage or entrapment, but an inherited form with eight affected family members has been described. Skin biopsies have shown increases in sensory innervation in the area, and other changes that could be attributed to repeated rubbing and scratching. Treatment by application of pepper cream (capsaicin 0.025%) has been effective. Such treatment may exacerbate the symptoms during the first week of application, but thereafter both the symptoms and the side effects of the treatment subside. Topical application of EMLA® (2.5% lignocaine + 2.5% prilocaine), a topical anesthetic cream, has also been effective.<sup>5</sup> Dermographism has been reported as a cause of anogenital pruritus.<sup>7,8</sup> It is not unreasonable to propose that the idiopathic form of pruritus ani may be a related disorder, and that the skin changes are the sole result of skin trauma. The effectiveness of the anal tattooing procedures, discussed later, lends some support to this hypothesis.

TABLE 16-2. Proposed etiologies of idiopathic pruritus ani

Anatomic factors	Obesity, deep clefts, hirsutism, tight clothing
Anorectal disease	Fissure, fistula, tags, prolapsing papilla, hemorrhoids, mucosal prolapse, sphincter insufficiency, deforming scars
Antibiotics	
Contact dermatitis	Chemicals in topical preparations, toilet paper, wet wipes, alcohol, witch hazel, "caine" anesthetics, fecal soiling
Dermatoses	Psoriasis, seborrheic dermatitis, atopic dermatitis, lichen planus, lichen simplex, LS, dermatographism
Diet	Coffee (caffeinated and decaffeinated), chocolate, spicy foods, citrus fruits, tomatoes, beer, dairy products, vitamin A and D deficiencies, fat substitutes, consumption of large volumes of liquids
Diarrhea	Infectious diarrhea, irritable bowel syndrome, Crohn's disease, ulcerative colitis
Drugs	Quinidine, colchicine, intravenous steroids
Gynecologic conditions	Pruritus vulvae, vaginal discharge of infection
Idiopathic	
Infection	Viruses: herpes simplex, cytomegalovirus, papillomavirus; bacteria: <i>S. aureus</i> , beta hemolytic strep, mixed infections; fungi: dermatophytes, <i>Candida</i> species; parasites: pinworms, scabies, pediculosis; spirochetes: syphilis
Neoplasms	Bowen's disease (AIN), extramammary Paget's disease, squamous cell carcinoma variants, secreting villous tumors
Personal hygiene	Poor cleansing habits, over-meticulous cleansing producing mechanical trauma, use of soaps
Psychogenic/neurogenic	Anxiety, neurosis, psychosis, neurodermatitis, neuropathy, "itch syndromes"
Radiation	Radiation dermatitis, sphincter compromise or leakage caused by radiation proctitis
Systemic disease	Jaundice, diabetes mellitus, chronic renal failure, iron deficiency, thyroid disorders, lymphoma, polycythemia vera

Source: Modified from Stamos and Hicks, 1998.<sup>6</sup>

## Fecal Contamination

Systematic, rigorous studies of anal pruritus are rare, but good evidence supports fecal contamination as one cause of symptoms. Caplan<sup>9</sup> performed a study in 27 Caucasian men in which fresh autologous feces was applied as a patch test both perianally and on the inner arm, and perianal skin was also cultured for fungi. There were 10 control subjects where feces samples were collected; the skin was spatulated but feces not applied to the skin. The patch-tested subjects had several pH-adjusted samples applied to the skin in addition to the unadulterated samples. Twelve of the 27 had a history of pruritus ani. pH of the perianal skin varied from 5.0 to 7.0 and was not different between the two groups. Five of 12 pruritus subjects (42%) grew yeast (non-*Candida albicans*) but no dermatophytes, whereas 4 of 15 nonpruritus subjects (27%) grew *C. albicans* (3) or *Geotrichum*. Twelve of 27 (44%) with feces applied to the skin developed symptoms from the feces. Four of 12 (33%) of the pruritus group developed symptoms, 8 of 15 (53%) of the nonpruritus group developed symptoms, whereas none of the control group developed symptoms. Symptoms occurred within 1–6 hours in all but one subject and were relieved by washing the skin. Only one of the 27 subjects reacted to feces on the arms patch test, suggesting that the skin in different locations reacts differently. The prompt appearance of symptoms and relief with cleansing was believed to indicate an irritant effect rather than an allergic effect.

Smith and colleagues<sup>10</sup> in a rigorous study of 75 patients with pruritus found that half of their patients had poorly formed stools and 41% of their patients complained of soiling from daily to several times a week. Seepage of liquid and mucous was believed to be an important factor in the etiology of the symptoms. Coffee was demonstrated to lower anal resting pressure in 8 of 11 patients.

Allan et al.<sup>11</sup> showed that leakage during a saline infusion test occurred sooner in patients with pruritus ani than in nonpruritic controls (median leak point 600 mL versus 1300 mL in controls). This is consistent with findings by Farouk et al.<sup>12</sup> and Eyers and Thomson<sup>13</sup> who both found that the anal inhibitory reflex was more pronounced in patients with pruritus ani. Rectal distension, because the decrease in anal pressure from baseline is greater in patients with pruritus ani, makes these patients more prone to leak and soil.

## Viral Infection

Condylomata acuminata are a common cause of itching, but the diagnosis is easily recognizable and should not be confused with idiopathic pruritus ani. Condylomata, papilloma virus infection, and anal intraepithelial neoplasia (AIN) will be discussed extensively elsewhere. Herpes syndromes are usually accompanied by pain rather than itching and the clinical course is accompanied by a characteristic eruption consisting of red macules, which progress to vesicles that

rupture, ulcerate, and may become secondarily infected. Culture or biopsy shows specific diagnostic findings. Likewise, molluscum contagiosum produces characteristic lesions, papular, 2- to 5-mm diameter, with central umbilication, usually clustered. Human immunodeficiency virus-associated lesions are rarely associated with chronic itching except for secondary fungal infections. No credible evidence exists for a viral etiology in idiopathic pruritus ani.

## Fungal Infection

Smith et al.<sup>10</sup> found no instances of fungal infection in their investigation of pruritus in which each of 75 patients had scrapings and fungus cultures. In contrast, Dodi et al.<sup>14</sup> found *C. albicans* had no relationship to pruritus (culture positive in 23% of control subjects, 26% of those with pruritus, and 28% of those without pruritus), but 10 patients who cultured dermatophytes all had itching. None of these patients had exposure to steroids or antibiotics. Their conclusion was that *C. albicans* was saprophytic in the absence of steroids, but that dermatophytes were always pathogenic. Prolonged courses of steroids are said to enhance pathogenicity of *C. albicans* and to mask *Candida* infection.<sup>15</sup>

Verbov<sup>3</sup> found 7 of 47 patients (15%) with pruritus ani whose itching was attributed to *Candida* out of a review of his dermatologic practice (3000 patients surveyed on the basis of their primary complaint). Pirone et al.<sup>16</sup> claim that surgical treatment of anal disorders (hemorrhoids, fissure, spasm, mucosal prolapse) eliminated *Candida* and dermatophyte infections in all but 3 of 23 patients who were culture positive and symptomatic with itching before surgery. Two of these three failures responded to antifungal treatment, but the final patient continued to itch.

In another study of 200 patients evaluated by colorectal surgeons and dermatologists, thrush was found in 28 (14%), only one of whom was diabetic. Fourteen patients had local steroid therapy, and 6 occurred after a course of systemic antibiotics. Only one case of dermatophyte infection was found.<sup>17</sup>

Perianal dermatophyte infection, all *Trichophyton rubrum*, was reported to be infrequent by Alexander<sup>15</sup> (4 of nearly 300 cases). Topical steroids may render direct scrapings negative for hyphae.

## Bacterial Infection

Several non-sexually transmitted bacterial infections are reported to cause longstanding pruritus. Weismann et al.<sup>17A</sup> reported that 19 patients (16 males and 3 females) with pruritus of duration 1–20 years had beta hemolytic streptococci cultured (four also had *Staphylococcus aureus*) from the perianal area but not from nasal or throat swabs. Treatment with various regimens resulted in cure of 42% and amelioration of symptoms in the others.

Erythrasma was reported to cause pruritus in 15 of 81 patients (18%) who had failed to respond to routine

treatment.<sup>18</sup> Wood's light fluorescence (coral pink) was the most reliable diagnostic maneuver, being positive in every case, but cultures of *Corynebacterium minutissimum* were positive in only four cases. Groin, thighs, and toes were also involved in every case and cure was achieved in all patients with erythromycin. Smith et al.<sup>10</sup> found erythrasma in only 1 of their 75 patients, each of whom had Wood's light examination. *C. minutissimum* is probably present in normal skin flora, but the moisture, diabetes, and obesity predispose to infection which is usually found in the body folds (axilla, groin, intergluteal, inframammary) and toe webs.<sup>19</sup> The St. Mark's series found erythrasma in 16% of their 200 cases, but 27% of the group were symptomatic for more than 5 years.<sup>17</sup> Their patients had disease in more than one site, in common with other quoted series.

*S. aureus* has been anecdotally implicated as a cause of treatable pruritus.<sup>20</sup> Intertrigo was reported in 27% of the St. Mark's series and was highly treatable with topical agents.<sup>17</sup>

## Contact Dermatitis

Contact dermatitis has been reported from a wide variety of preparations including topical anesthetics, topical antibiotics, topical antiseptics, topical antihistamines, and nickel.<sup>17,21</sup> Common sensitizing agents identified in the dermatologic literature are listed in Table 16-3. The role of feces and seepage as a contact agent has been emphasized in almost every article devoted to pruritus ani. Contact dermatitis may have an irritant or allergic basis, but is recognized by being an eczematous inflammation characterized by erythema, scale, and vesicles.<sup>22</sup> Avoidance of contact with the inciting agent is the obvious treatment, and topical steroids may be useful unless secondary infection is present. It is preferable to avoid soaps. Bath oils and emollient creams may be useful for cleansing. The cause of contact dermatitis may be obscure. Dasan et al.<sup>21</sup> reported one patient who had pruritus associated with bathing in a tub of water in which his wife shampooed her hair with para phenyl diamine, a dye. When the patient's wife stopped shampooing her hair in the tub, his symptoms resolved.

A large study of patch testing in 80 patients with pruritus ani in Sheffield, England, emphasized the importance of

contact dermatitis as an aggravating factor. Fifty-five patients tested positive. Thirty-eight of the positives were to medications or their constituents including neomycin, fragrance mix, Peru balsam, and cinchocaine. After counseling, two-thirds of these 55 patients experienced improvement or resolution of their symptoms.<sup>23</sup> These authors disputed the recommendation to use "wet wipes" for cleansing because of possible sensitization. Bruynzeel<sup>24</sup> corroborates the potential sensitization from use of moist wipes containing methyl-dibromoglutaronitrile. Rohde believes that excessive exposure to water and the act of excessive cleansing itself may incite symptoms, and recommends the use of oils for cleaning.

Alexander<sup>15</sup> found lanolin, neomycin, procaine, and parabens to be offending agents and emphasized the difficulty of identifying these types of products when incorporated with a local anesthetic or steroid because the anesthetic suppresses the itching and the steroid suppresses the inflammation giving paradoxical temporary relief. Temporary relief leads to increasing application of the offending agent over a wider area, escalating the process.<sup>15</sup>

## Psoriasis

Psoriasis has been an important underlying cause of pruritus in every series on this subject. In a combined colorectal dermatologic clinic established to prospectively evaluate patients with pruritus, 22 of 40 patients were found to have psoriasis.<sup>21</sup> Alexander<sup>15</sup> confirms that psoriasis may present as an isolated lesion in the perianal area, and emphasizes that lesions in this location do not appear as typical because of maceration. Smith et al.<sup>10</sup> found 6 cases (8%) of psoriasis in his series, 5 of which had not been previously diagnosed. The St. Marks-Guy's hospital series found 5.5% of their 200 patients had psoriasis.<sup>17</sup> They also emphasized the nontypical appearance of the perianal lesions. Lochridge<sup>25</sup> claimed the diagnosis of perianal psoriasis in 81 patients, all of whom responded to fluocinolone acetonide 0.025% (Synalar®) with normalization of the skin. He recommended a search for lesions elsewhere including elbows, knees, ankles, extensor surfaces of the forearm, base of the scalp, ear canals, eyelids, nipples, penis, vulva, or navel. Biopsy was rarely diagnostic because of secondary changes as a result of drugs or trauma and limited experience of pathologists with diagnosis of perianal skin.

## Lichen Sclerosis

Lichen sclerosis (formerly lichen sclerosus et atrophicus) (LS) is a chronic disease of unknown cause, almost always occurring in women (female/male 10:1, usually seen on the penis in the male) which in females has a predilection for the vulva and perianal area. The skin has a characteristic appearance that is white, atrophic, and wrinkled.<sup>22,26-29</sup> Involvement of the labia gives this condition a characteristic distribution that makes recognition easy once the diagnosis is considered. Biopsy is characteristic and may be especially indicated in

(benzocaine, dibucaine)
Turpentine oil

a lesion not responding to treatment because of rare occurrence of squamous cell carcinoma.<sup>30–32</sup> Treatment of LS with a potent topical steroid (clobetasol propionate 0.05%, Temovate®) for 6–8 weeks is highly successful, often resulting in normalization of the skin.<sup>5,27,29</sup> Other recent reports suggest that tacrolimus ointment may avoid the skin atrophy that may accompany potent steroid use.<sup>33,34</sup> Patients with LS in the vulva probably have a 4%–5% incidence of squamous cell carcinoma arising in or adjacent to the LS.<sup>31</sup> These patients should be followed periodically for raised lesions or ulcers that fail to heal. The exact role LS has in the development of cancer is not certain, but is thought to be independent of human papilloma virus.<sup>30</sup>

### Food Factors

No controlled trials have been done to examine food stuffs or diet as a cause for itching, but strong opinions have garnered a revered place in the literature. Friend<sup>35</sup> states that virtually all patients with idiopathic pruritus and consume enormous quantities of liquids, are almost never constipated, and usually have loose stools. Because it helps their symptoms, patients with severe pruritus usually maintain good anal hygiene. Friend states that there are six common foods that unequivocally cause idiopathic pruritus: coffee, tea, cola, beer, chocolate, and tomato (ketchup) and that total elimination will result in remission of itching in 2 weeks. After a 2-week elimination period, the food may be reintroduced to determine the threshold above which consumption causes symptoms. Thresholds are typically between 2–3 cups of coffee, 4 cups of tea, and less than 2 cans of beer.

Smith et al.<sup>10</sup> demonstrated that coffee lowered anal resting pressure in 8 of 11 patients tested. An elimination diet gave partial or complete relief in 27 of 56 (48%) of their patients. Specific dietary items identified by elimination as a cause were coffee (8), alcohol (5), peanuts (3), chocolate (2), milk products (3), cola (1), and citrus (1). Alcohol was an equivocal factor in this study because 41% did not consume alcohol and only a third of patients drank more than 1 ounce per day. Smith et al. confirm the importance of poorly formed stool and coffee which may contribute to seepage and recommend a bulk agent taken at the same time of day to promote regular, complete emptying of stool.

Daniel et al.<sup>1</sup> reported that average coffee intake in patients with primary pruritus and averaged 6 cups per day, compared with those with secondary pruritus who averaged about 3.5 cups per day.

Akl<sup>36</sup> reported an 8-year-old boy with asthma, intolerant of milk with abdominal pain, whose pruritus and disappeared after elimination of yogurt.

### Coexisting Anal Disease

Coexisting surgical anal conditions (hemorrhoids, fissure, fistulas) may of themselves produce itching or aggravate any

tendency to itch. Most authors agree that correcting these disorders in selected patients is indicated. Smith et al. reported that 8 of his 75 patients required treatment of hemorrhoids (four operations, four Barron ligations) which by virtue of prolapse may induce soiling.<sup>10</sup> These authors note, however, that correction of the hemorrhoids eliminated itching in only one patient. Another with scars from previous fissure surgery also had soiling not amenable to surgical correction. Murie et al.,<sup>37</sup> in a study of 82 hemorrhoidal patients with and without pruritus, believe that pruritus is more common in patients with hemorrhoids than in age- and sex-matched controls without hemorrhoids and that correction of the hemorrhoids usually eliminates itching along with the other symptoms of bleeding, pain, soiling, and protrusion. Bowyer and McColl<sup>17</sup> reported that hemorrhoids were the sole cause of itching in 16 of their 200 patients, contributory in 27 others, and that correction of fissure was required in five patients before symptoms were relieved. Five others had skin tags which when removed eliminated symptoms. These patients could point to the skin tag as the source of the itching. Dasan et al.<sup>21</sup> in a study of 40 patients with pruritus found two that required surgery, one to remove complex skin tags and the other to correct a fistula. The St. Louis University group found that 52% of 109 patients with the sole presenting complaint of itching had anorectal disease as the cause.<sup>1</sup> The diagnoses included hemorrhoids, fissure, idiopathic proctitis, condyloma, ulcerative proctitis, abscess, and fistula.

Pirone et al.,<sup>16</sup> as mentioned above, believe that correction of hemorrhoids, fissure, mucosal prolapse, and spasm can resolve fungal infection and the consequent pruritus.

### Psychologic Factors

Smith et al.<sup>10</sup> studied 25 of their patients who completed an MMPI (Minnesota Multiphasic Personality Inventory). They found no deviations on the clinical scales but a trend toward inhibition of aggression, and denial of feeling of social and emotional alienation. Anxiety, stress, and fatigue added to personality, coping skills, and obsessive compulsive disorders probably have a role in the exacerbation of pruritus and.<sup>38</sup> Because of this, psychiatric drugs may have a role in its management in isolated cases, but the preponderance of evidence suggests, in my opinion, that idiopathic pruritus and does not have a psychiatric basis except as a form of neurodermatitis. The fact that it responds to simple topical treatment with resolution of physical findings in most cases and is so common argues against an obscure etiology.

### Steroid-induced Itching

Anogenital itching has been reported after bolus administration of intravenous dexamethasone.<sup>39</sup> More often, itching occurs as a rebound phenomenon after withdrawal of steroids leading to their reinstitution and chronic use because symptoms always exacerbate after withdrawal. This syndrome has

been characterized as steroid addiction<sup>40</sup> and can lead to permanent deformity and dependence.<sup>41</sup> Experimental application of potent steroids under occlusion for as little as 3 weeks has been shown to produce an acute dermatitis resembling that seen with a blister that has been unroofed and exposed to air.<sup>40</sup> In my view, steroids should always be viewed as potentially dangerous and should be used to achieve specific effects. Potency and dosing should be tapered in a planned manner with the goal of eliminating steroids altogether from a maintenance regimen. If elimination is not possible, alternate day therapy or intermittent therapy once or twice a week is to be preferred.

### Skin Trauma

Trauma can arise from physiologic processes such as diarrhea or frequent stools which may be associated with frequent wiping and maceration. Scratching either consciously or nocturnally while asleep may result in the classic lesion of lichen simplex chronicus. Alexander-Williams<sup>42</sup> puts it nicely: "Perianal dermatitis is a cross between a nappy rash, athlete's foot, and a self inflicted injury. In most patients the problem is due either to inadequate cleansing of the anus or to over vigorous attempts to polish it clean." There is controversy about the best way to clean the anus. Rohde<sup>43</sup> takes issue with the standard method using water or wet wipes and advocates a smooth, dry article with olive oil if necessary, believing that water breaks down the barrier function of the skin. Most authors agree that contact dermatitis is a contributing cause of perianal irritation and that attempts to discontinue over-the-counter preparations (OTCs), perfumed, or scented products including toilet paper, should be made because of potential sensitizing agents (Table 16-3). Bland emollients, Acid Mantle®-based creams, and waterless cleansing agents are reasonable substitutes that may be used with tissue paper or cotton balls for cleansing and left on the skin. My own experience suggests that dilute white vinegar (1 tablespoon in 8 ounces of water) and Burow's solution (Domeboro®) are effective cleansing agents associated with little adverse reaction. Burow's solution and acetic acid have been found to be an effective antibacterial in chronic otitis with little toxicity.<sup>44-47</sup>

### Neoplasms

Perianal Paget's disease is rare and large series do not exist, but more than half of patients in most series have itching, often for longer than 3 months.<sup>48-50</sup> Perianal Bowen's disease (intraepithelial squamous cell carcinoma in situ) is also rare, but in a series of 47 patients reviewed at the Cleveland Clinic, 28 (60%) had perianal itching as a presenting complaint.<sup>51</sup> AIN is the sequel to human papillomavirus infection (associated with itching) and refers to premalignant change in the area of the dentate line and anal transitional zone. Although pruritus has not been described in large series looking at AIN<sup>52,53</sup> (because of their study design), it

would seem prudent to be alert for neoplastic change in any patient with a history of warts who presents with pruritus. Higher-grade tumors such as melanoma or squamous cell cancer usually present with bleeding or pain, not with pruritus.<sup>54-56</sup> Further discussion of anal neoplastic disease is found in Chapter 35.

## Diagnosis of Perianal Disease

Given the variety of possible diagnoses as cataloged so far, it is important to identify the specific diagnoses that are treatable for cure, and to engage a strategy that will avoid mistakes. It is often helpful in the differential diagnosis of anal and perianal disease processes to divide them into the general classifications of mass (inflammatory or neoplastic), rash, or fissure (primary or secondary). The morphology of a lesion is a starting point for diagnosis, but may not be specific, and the same disease may have several different appearances (Table 16-4). As an example, candidiasis may be present as an erythematous lesion, a papular lesion, or as an ulcerative lesion. Specific techniques are necessary, therefore, to establish or eliminate a diagnosis. Bacterial culture is a time-honored technique for identification of organisms, but proper media and collection techniques must be used to avoid killing certain species.<sup>57</sup>

Nits: crab lice	
Hypertrophic: donovanosis	

## History and Physical Examination

History and physical examination, often overlooked in our technologic arrogance, is still the most basic maneuver for diagnosis of any disease (see Table 16-5). Inquiry about other skin diseases, allergic conditions such as asthma or urticaria, or sites of involvement may be the first clue to diagnosis of unrecognized psoriasis or atopic dermatitis. Patients may not relate the itch on their elbow to the itch around their anus. Erythrasma usually involves the groin and toes, usually is chronic, and is often associated with hyperpigmentation. Patients frequently do not consider OTC or nonprescription preparations as medicines, but these may modify the appearance of a condition or even cause it. Specific questions about the use of these products are necessary to uncover their use and exposure to unsuspected ingredients. Knowledge of a patient's allergies is important not only for avoidance, but may aid in uncovering an unsuspected exposure to an occult ingredient. Patients sometimes have had patch testing and allergy consultation, and will not volunteer that information unless specifically asked. Patch testing, dermatologic consultation, and withdrawal of medication may be in order. Specific questions about infections, colds, or diarrheal illnesses treated with pills may be necessary to uncover antibiotic use. Patients sometimes will not list prednisone in their list of medications until asked a question pertinent to an illness such as arthritis or asthma or myalgias. A condition that has come and gone for years or that has seasonal exacerbation may be a clue to anal fissure, but could reflect dietary changes, type of clothes worn, or laundry practices.

Physical examination should specifically look for other sites of involvement. The groin is a classic intertriginous area that is easily accessible in the prone jackknife or the lateral position and should be the first place one looks to confirm a suspected yeast or fungus diagnosis. Hyperpigmentation in the buttock cleft or other intertriginous area is a clue to a chronic inflammatory condition or the presence of chronically

infected drainage or secretion. Effective treatment of a patient with changes in the groin as well as the cleft requires attention to each area of involvement. If a condition is infectious, steps to eliminate the infection will be more successful if the environment of the host is made inhospitable to the organism in each area of involvement. A sharply defined border usually points to a definable diagnosis such as tinea, especially when accompanied by scale (Figure 16-1). Psoriasis usually has a sharply defined border, but in the cleft may lack the classic scale seen in skin that is exposed to air. In the confined, occluded area of the cleft, there usually is no scale (Figure 16-2). Neoplastic changes may appear sharply marginated, but margins may be microscopically involved, especially around the dentate line, even if grossly normal (Figure 16-3, Bowen's disease). Infiltrative processes may be less well defined as in Paget's disease of the anus with the same caveat about margins (Figure 16-4). Inflammatory changes of idiopathic nature often have borders that are indistinct and nondescript (Figures 16-5 and 16-6). Bright red erythema often is seen with perianal yeast (Figure 16-6). Erythema may be seen with chronic steroid use (Figure 16-7). Patient A had used hydrocortisone daily for 20 years or more and came in with recurrent warts and carcinoma in situ when the cortisone failed to control his symptoms. Treatment of his warts, carcinoma in situ, and withdrawal of his steroids resulted in resolution of his symptoms and normalization of his skin. Patient B had used Mycolog® cream daily for several years, having had radiation therapy for prostate cancer. He was also treated with withdrawal of steroids. Acute severe injury from prolonged diarrhea with frequent wiping produced the picture of lichen simplex chronicus (Figure 16-8), which was treated by specific treatment of the patient's diarrhea, cleansing with Burow's solution, and topical silver sulfadiazine to which

FIGURE 16-1. Dermatophyte infection. Note the sharp border, the scale at the edges, and its involvement of the groin crease. As this type of infection moves into the anal cleft, the characteristic edge at the border of the cleft and involvement of the groin may be the only clues.

FIGURE 16-2. Psoriasis often appears atypical in the cleft and around the labia, lacking the silvery scale that is so characteristic. Isolated areas of involvement in the cleft occur and require biopsy confirmation by a competent skin pathologist.

FIGURE 16-3. Anal Bowen's disease or squamous cell carcinoma in situ may have a varied appearance and be indistinguishable from Paget's Disease (Figure 5) by clinical examination. The white pearls on the red background are often present and are a clue to the diagnosis. Despite sharp-appearing edges, the process often involves normal-looking skin and requires frozen section to confirm negative margins.

FIGURE 16-4. Perianal Paget's disease may present as a nondescript rash that itches. This clinical appearance is not specific and requires biopsy to confirm the diagnosis. Unlike Paget's of the breast, there is rarely an underlying invasive adenocarcinoma, and local excision with clear margins is the treatment of choice. Margins of excision require frozen section confirmation because clinically normal skin may be involved.

cortisone was added. Chronic infected discharge may lead to hyperpigmentation in the cleft (Figure 16-9) in this case caused by chronic pilonidal disease, but may also occur with fistulas, chronic yeast or fungus infection, or hidradenitis. Treatment complications can result in a rash in this patient with a contact dermatitis from clotrimazole (Figure 16-10). Severe symptoms, especially paresthesias, coupled with scattered lesions may be a clue to herpes virus infection (Figure 16-11). LS characteristically involves the perineum and labia in the female and has a distinctive appearance with wrinkling of the skin (Figure 16-12). Biopsy is characteristic.

Groin adenopathy, and whether or not the nodes are tender, can have specific relevance to diagnosis of perianal and anal disease (Table 16-6), especially sexually transmitted disease.

### Laboratory Examination

Ideally, infected material should be aspirated with a syringe and expelled into a sterile container. Next best is a swab of exudate collected from a deep portion of the lesion. Bacterial and fungal cultures should be placed into a bacterial transport medium and refrigerated if any delay in transport to the laboratory occurs. Anaerobic specimens require transport in a special anaerobic medium, and should not be refrigerated. Viral

FIGURE 16-5. Classic severe pruritus ani is marked by lichenification (leathery thickening of the skin), accentuation of folds, fissuring of the skin, and erosions and an indistinct border. Changes this severe require short-term aggressive therapy with high-potency steroids for 4–8 weeks which then are rapidly tapered to a maintenance program, if possible without steroids. It is important to rule out secondary infection, which requires specific treatment.

cultures require a viral transport medium and should be kept on ice. Vesicular lesions should be unroofed and cultures taken from the base of the vesicle. Microscope slides can be pressed against the base of the lesion for Tzanck smears, but inoculation of the fluid or exudate from the lesion base onto cell culture is more sensitive (viral culture).<sup>57</sup>

The office should have arrangements with a laboratory, which will supply culture swabs with transport media appropriate for aerobic, anaerobic, fungal, and viral culture. These become outdated and can result in rejection of specimens for processing. The practitioner should check the appropriateness of the media and its date before using it. Because staph and strep have been documented as causal agents, it is prudent to culture for pathogens in almost all cases in which treatment is not obvious. Conventional water-soluble lubricant is bactericidal for some organisms (*Neisseria gonorrhoeae*). Swabs should be lubricated with saline if lubricated at all. Ulcerated lesions should have the base vigorously swabbed. Biopsy should be accomplished early with a representative lesion and should include an area of adjacent normal skin. Specific query should be made to the pathologist about suspected diagnoses, and if possible a pathologist with skin expertise should be consulted. Highly reliable histologic criteria exist for viral lesions, pyoderma, syphilis, and neoplastic lesions. EMLA® cream, applied as a lubricant at the time of examination, may facilitate injection of local anesthetic, and biopsy may conveniently be done with either an 11 blade or skin punch blades that come in numerous sizes in separate sterile packages (Figure 16-13). Bleeding from punch biopsy holes is readily controlled with silver nitrate sticks or GELFOAM® packing.

FIGURE 16-6. Perianal yeast may present as a bright red rash without the cheesy exudate sometimes seen elsewhere and may follow treatment with antibiotics for some other condition. This infection is easy to treat but has a tendency to recur. Rendering the cleft environment inhospitable by drying with a hair dryer after bathing and using athlete's foot powder to coat the skin and absorb moisture can help maintain remission.

**A**

**B**

FIGURE 16-7. Chronic steroid use may cause itching or mask other processes. **A** An elderly man who had used 1% cortisone daily for more than 20 years, but had worsening of his symptoms despite increasing use. Treatment of his warts and carcinoma in situ along with withdrawal of steroids resolved his symptoms. The erythema has disappeared and he had remained free of symptoms for over a year. **B** A similar erythema superimposed on radiation dermatitis from treatment of prostate cancer. Withdrawal of Mycolog®, which had been used for years without interruption and substitution of a barrier cream with menthol relieved his symptoms.

FIGURE 16-8. This man has classic lichen simplex chronicus with inflammation and erosion resulting from unremitting diarrhea of 3 weeks' duration with wiping five times a day. Treatment of the patient's diarrhea and topical silver sulfadiazine with 2% cortisone achieved rapid healing and relief of symptoms.

FIGURE 16-9. Hyperpigmentation may result from chronic inflammatory changes in the skin for whatever reason. In this particular case, infected drainage from a chronic pilonidal sinus was the cause, but fistula disease, chronic dermatophyte infection, erythrasma may produce the same picture. This finding should emphasize the need to modify environmental conditions within the cleft and surrounding area as an adjunct to healing.

FIGURE 16-10. This patient had a reaction to topical clotrimazole in use for 1 week.

Skin scrapings may be submitted for fungus culture, and if available examined by KOH prep for hyphae. Most colorectal offices are not set up for KOH prep and rarely are we trained in this technique, therefore culture is probably more reliable.

## Treatment of Pruritus Ani

A general strategy is presented in Table 16-7. Directed treatment for a specific, curable diagnosis is the ideal, and diagnostic efforts should be directed to avoid overlooking curable disease.

Many investigators have alluded to the importance of controlling seepage and fecal contamination of the skin. Diet may directly contribute to itching and it is prudent to give patients a list of potential foods implicated in itching for an elimination trial. Patients with loose stools may benefit from the addition of fiber to absorb moisture and add bulk and improve emptying with defecation. Many patients who have tried fiber without benefit may benefit from judicious use of Imodium® or Lomotil® to lessen frequency and firm up stools. Questran®, in varied doses, has been helpful in my practice to firm loose stools.

FIGURE 16-11. Scattered lesions, especially when accompanied by severe symptoms suggest herpes virus infection. Herpes simplex type 1 was cultured from the base of these ulcerations that were 9 days old at the time of this picture. Treatment caused prompt resolution of symptoms.

Environmental factors should be altered as much as possible with removal of irritants such as soaps, perfumes, dyes in clothes or wiping tissues, alcohol- or witch hazel-containing agents, and moisture. Dove® is free of conventional soap and is the preferred bathing agent. Bidets are not common in the United States, but detachable shower heads are common and inexpensive and when equipped with long tubing and handle may be a useful item for cleansing the perianal skin and anal canal and eliminating soap residues by flushing with water in the squatting position. Subsequent drying with a hair dryer can eliminate moisture, and application of an athlete's foot powder or barrier cream will lubricate and prevent maceration of the skin in the cleft and anal canal. Zeasorb® is an alternate lubricating, drying agent in powder form. Cornstarch is to be avoided because it is culture medium for yeast. Cornmeal agar is used to identify different species of yeast in the laboratory.<sup>57</sup> Dilute white vinegar (1 tablespoon in an 8-ounce glass of water) on a cotton ball is a cheap effective nonsoapy cleanser that can be kept at the toilet when bathing is not handy. Burow's solution, 1:40 (Domeboro® tablet one in 12 ounces of water, or one in 6 ounces for 1:20) is another nonirritating cleanser that can be kept refrigerated in a plastic squeeze bottle and used in lieu of soap or plain water. Burow's

FIGURE 16-12. LS has a distinctive appearance with cigarette paper thinning and wrinkling of the skin. It almost always involves the labial skin and perineum, making it easy to recognize. Biopsy is characteristic and is especially indicated for any areas that are raised, ulcerated, or unresponsive to treatment because of a 5% risk of squamous cell carcinoma developing within its distribution.

may be used as an antibacterial soak for 5–15 minutes and then dried. Balneol® is a commercially available mineral oil-based preparation that can be kept in a pocket and squeezed onto toilet paper to make a soothing cleansing agent when using public facilities. Breaks in the skin caused by scratching or over-vigorous cleansing efforts must be avoided, so an attempt to control symptoms with application of topical anesthetics, menthol, phenol, camphor, or a combination of ingredients may be appropriate. These agents may be used in combination with topical steroids, topical antifungal agents, and topical antibacterials. Doxepin (Sinequan®

FIGURE 16-13. Skin punch biopsy tools come in various sizes up to 1 cm in diameter (2, 3, and 5 mm pictured). They may be purchased as autoclavable sets which may be sterilized and reused, or for the occasional user, disposable punches are supplied in individually wrapped sterile packages. One advantage of the disposable instruments is that they are always sharp.

orally) is available topically as an effective antihistamine (Zonalon®), but orally is 1000 times more potent than diphenhydramine (Benadryl®) for elimination of itching and may be a useful adjunct at bedtime to avoid nocturnal scratching. Nocturnal scratching, of which the patient may be unaware, is probably a significant contributing factor in most cases of idiopathic pruritus ani. Patients who are awakened by the urge to scratch should be instructed to gently cleanse the area to eliminate any fecal seepage and reapply their steroid or barrier cream (whichever is in effect at the time) but not to scratch. Pepper creams may be useful in breaking the overwhelming urge to scratch by substituting a more powerful temporary burning stimulus.

No data exist on the influence of clothes or other fomites on pruritus, but from a practical standpoint, loose underwear that

TABLE 16-7. Treatment of pruritus ani

1. Specific directed treatment for a diagnosis
2. Eliminate offending agent [contact irritant (perfume, soap, toilet paper), organism]
3. Eliminate scratching (especially nocturnal)
4. Control symptoms
5. Hygienic measures (Dove® soap, detachable shower head, hair dryer to dry)
6. Withdraw inappropriate steroids
7. Treat infection (silver sulfadiazine cream, gentamicin or clindamycin topically, nystatin, clotrimazole)
8. Protect skin [barrier creams, powders (especially athlete's foot powder)]
9. Correct anal disease (fissure, hemorrhoids)
10. Judicious use of appropriate steroids
11. Emphasize control as a chronic condition
12. Reassess diagnosis if response to treatment is not appropriate
13. Anal tattooing in extreme cases

allows air circulation and promotes dryness makes sense. Fresh clothes should be used daily that have been laundered without perfume, perhaps with the addition of a small amount of chlorine bleach to secure lowered bacterial counts.

Patients who come to the office with acute moderate to severe changes of the skin are treated by application of Berwick's dye (combination of gentian violet and brilliant green) which has alcohol content and stings, often relieving the itch. The dye is dried with compressed air or a hair dryer. Benzoin tincture is applied over top of this as a barrier and dried similarly. This preparation will stay in place for several days if only water is used to cleanse and gives excellent temporary relief of symptoms and allows reepithelialization of broken skin. Berwick's is suitable as an office applied remedy but is generally not for home application.

Patients who have mild to moderate symptoms with minimal skin changes will often respond to topical 1% hydrocortisone cream which can be combined with menthol, 0.5%–1.0%, and topical antibiotics (gentamicin, clindamycin, or bacitracin) or antifungals (clotrimazole, nystatin). This preparation is applied at night and in the morning after bathing, being used daily until symptoms subside. Thereupon a tapering regimen is instituted, ending with substitution of a barrier cream such as Calmoseptine® to keep the skin covered. Elimination of the steroids and substitution of an innocuous agent to maintain attention to the hygiene is an important goal. Patients with thickened skin and chronic moderate or severe changes should be approached with higher intensity therapy, with a medium or high potency steroid for a limited, defined period of time (Table 16-8; nonsteroidal topical therapies are listed in Table 16-9). My preference is to prescribe brand names when dealing with topical steroids because of the vehicle in which it is delivered, and the particular salt matter as to potency (Table 16-8). For instance, betamethasone as Diprolene® is more than 1000 times more potent than Valisone® cream, with Valisone® ointment

TABLE 16-8. Relative potency of topical steroids (descending order)

Group 1 (most potent)	Group 4
Betamethasone dipropionate 0.05% (Diprolene®)	Desoximetasone 0.05% (Topicort LP®)

Macrolide topical agents (Tacrolimus and Pimecrolimus)
Menthol (0.125%–1%)
Phenol (0.125%–2%)
Pramoxine
Shake lotions (calamine + additives)
Topical "caines"

somewhere in between. These differences can lead to a great deal of confusion when prescribing by generic name without spelling out every tiny detail. Emphasize to patients that a high-potency steroid should be used for a limited period of time, generally 4–8 weeks. When normalization of the skin has been achieved, switch them to a mild steroid such as hydrocortisone 1% or Locoid® 0.1% with tapering frequency of application down to once or twice a week or to total elimination. Patients who have frankly eroded or denuded skin may benefit from topical antibiotics. Silver sulfadiazine cream to which hydrocortisone or triamcinolone and menthol have been added may be soothing and promote regrowth of epidermis over ulcerated areas while suppressing the inflammation that can cause fissuring in the skin.

Skin atrophy is a serious problem with prolonged use of potent steroids, but each of the steroid preparations differs in its tendency to cause trouble. Creams cause comparatively greater atrophy than ointment preparations containing identical ingredients.<sup>58</sup> Newer, double-ester, nonfluorinated steroids may prove to be less atrophogenic than the older preparations,<sup>58,59</sup> but the package stuffers for prednicarbate and mometasone furoate still quote 8% and 6% incidence of mild skin atrophy for these compounds. Macrolide topical immune modulators (tacrolimus and pimecrolimus) seem to be free of the problem of skin atrophy, a fact that enhances their appeal for use on the apposed skin of the cleft.<sup>60</sup> These compounds may have some intrinsic antifungal activity as well.<sup>61</sup> I have had a very limited, good anecdotal experience with these compounds, but there are currently no published data on topical macrolide use in pruritus ani. Table 16-10 lists the

TABLE 16-10. Adverse reactions to topical steroids

Skin atrophy with telangiectasia, pseudoscars, purpura, striae, spontaneous bleeding
Tinea, impetigo, scabies incognito
Allergic contact dermatitis
Systemic absorption with adrenal suppression
Burning, itching, dryness from vehicle
Rebound worsening after withdrawal

potential complications of topical steroids, which are not to be taken lightly, and are all the more important because they are preventable complications of treatment excess.

### Anal Tattooing

Every practice has a small number of patients who respond poorly to treatment and whose symptoms are severe enough to alter life and happiness. These refractory patients may benefit from a technique originally described by a Russian surgeon, but espoused in the United States by Wolloch and Dintsman<sup>62</sup> who described nine patients, eight of whom got relief after one treatment, one requiring a second injection to obtain a good result. Eusebio et al.<sup>63</sup> reported 23 patients: 13 with complete relief, 8 with incomplete relief but much improved, and 2 who were not improved, but who had presented with burning, not itching. Three cases of skin necrosis resulted in modification of their technique, and treatment of 11 subsequent patients was without complication with good result.<sup>64</sup> The modified technique consists of the intradermal and subcutaneous injection of the following solution with the patient under intravenous sedation in the prone jackknife position: 10 mL 1% methylene blue + 5 mL normal saline + 7.5 mL 0.25% bupivacaine with epinephrine (1/200,000) + 7.5 mL 0.5% lidocaine. Farouk and Lee<sup>65</sup> reported six patients treated with a similar volume to the modified technique of Eusebio et al. Five patients got substantial relief of symptoms with follow-up of 2–5 years. Three of the six required a repeat injection at 1, 3, and 5 years after the initial treatment.

I have personally used this technique on four patients, infiltrating the skin with the same solution as Eusebio et al. using a modified technique. I use a 30- or 27-gauge needle and infiltrate the skin as I would for cutaneous anesthesia with multiple injection sites sufficient to cover the perianal-involved skin up to the dentate line (Figure 16-14). All four of my patients have gotten results lasting at least 1 year, during which time all have had relative cutaneous hypoesthesia. They describe the sensation as having the side of one's face numb after a dental block. Certain individuals have found this sensation very disagreeable, so I am careful to warn them in detail before treatment. The skin changes of severe pruritus in all cases rapidly and dramatically regressed and resolved. In one case with return of skin sensation at about a year, the pruritus returned and required topical therapy to be reinstated, but was milder and did not require repeat injection. The response of these patients during the time of hypoesthesia lends some credence to the idea of skin trauma from nocturnal scratching of which patients are not aware.

### Conclusion

Skin conditions around the anus are common and often poorly diagnosed and treated. The appearance of a lesion is rarely pathognomonic, but may place it into a diagnostic category

FIGURE 16-14. Tattooing with methylene blue is a simple technique to treat intractable itching that does not respond to traditional vigorous therapy. Patients experience hypalgesia and numbness of the perianal skin that can be bothersome, but rapid resolution of itching occurs and the chronic skin changes normalize quickly.

that can be either treated or investigated in a systematic way to arrive at a logical successful outcome. Follow-up of treatment plans, reevaluation of patients with chronic conditions, and reconsideration of ongoing prescriptions should be standard practice and help to avoid the pitfall of misdiagnosis.

## Sexually Transmitted Diseases

Charles B. Whitlow and Lester Gottesman

There are more than 25 diseases spread primarily by sexual means with an annual incidence of approximately 15 million cases in the United States.<sup>1</sup> In 1994, the overall cost related to major sexually transmitted diseases (STDs) was estimated to be 17 billion dollars. In the United Kingdom, the incidence of STDs has increased substantially over the past 6 years and has led to a new government strategy to counteract these increases.<sup>2,3</sup>

Site and route of infection determine the symptoms caused by STDs. Infections of the distal anal canal, anoderm, and perianal skin are similar to lesions in other parts of the genitalia and perineum caused by the same organisms. These are typically the result of anal receptive intercourse but in some instances represent contiguous spread from genital infections. Proctitis from sexually transmitted organisms is almost always from anal intercourse. Direct or indirect fecal-oral contact produces infection with organisms that cause proctocolitis or enteritis but are generally thought of as food or waterborne diseases instead of STDs. Included in this group are *Entamoeba histolytica*, *Campylobacter*, *Shigella*, *Giardia lamblia*, and hepatitis A. Although it seems that male homosexual activity and the use of the anorectum for sexual gratification is increasing, data regarding the frequency of these behaviors both past and present are limited. Current estimates are that less than 2% of adult males regularly practice anal receptive intercourse and between 2% to 10% participate in homosexual activity at any point in their life.<sup>4</sup> Between 5% and 10% of females engage in anal receptive intercourse "with some degree of regularity" and females seem to be more likely than men to have unprotected anal intercourse.<sup>4</sup>

Difficulty in correct diagnosis and appropriate treatment of STDs of the anorectum is caused by several factors. 1) The signs and symptoms of infection are more organ related than organism related so that no symptom or symptom complex or physical finding is diagnostic for many STDs. 2) The presence of more than one organism is not uncommon, especially with anogenital ulcerations. 3) Determining true pathogen from colonizing organisms may be difficult. 4) Lastly, there is

a lack of rapid sensitive diagnostic tests for many STDs so that empiric treatment is frequently required.

This chapter discusses the STDs that are most often seen by colorectal surgeons. Entire texts are devoted to the STDs; however, we will confine most of our comments to the diagnosis, treatment, and prevention of the anorectal component of these infections. Infections, which manifest as one of the colitides, are covered in Chapter 43.

### Overview of Anorectal Immunology

The optimal state of health of the anus requires the integrity of the skin which acts as the primary protection against invasive pathogens. The mucosa shed from the rectum contains immunoglobulin A which traps foreign antigens and expels them with stool, preventing them from reaching the anorectal crypt cells.<sup>5</sup> Cellular immunity is controlled by the Langerhans, or dendritic cells which communicate with the T cells through a complicated mechanism and essentially prime the T cells to identify foreign cells.<sup>6</sup> This then allows the entire complement of cell-mediated immunity to destroy that which is alien. Although study of anal immunology is still in its infancy, it seems that certain pathogens may alter the balance of cellular elements. It is known that whereas human papilloma virus (HPV) increases Langerhans cells, human immunodeficiency virus (HIV) may damage their effectiveness. In addition, pathogens such as HPV and herpes simplex virus (HSV) invade into the host cell, combining with cellular elements or the genome, thus evading surveillance mechanisms. In addition, in the case of HPV, the identifying foreign antigens are placed onto the frame of the new virus near the epidermis, where the virus normally sheds and where an attack by the host has little value.<sup>7</sup>

HIV is known to deplete cell-mediated immunity by depletion of T cells and destruction of Langerhans cells. This allows, through unknown mechanisms, propagation of oncogenic processes such as HPV to become dysplastic. The exact switches are not understood but seem to be related to the

coexistence of perhaps HSV and the highly active antiretroviral therapy (HAART) drugs.

Breakdown of the mucous complex protecting the rectum is seen in various diseases contracted through anal intercourse. The physical act of intercourse abrades the mucous lining and delivers pathogens directly to the crypt and columnar cells allowing for easy entry. Depending on their mechanism of action, they may burrow into the cells (ameba) or proliferate on the cells without damaging them (*G. neisseria*). Invasive pathogens (*LGV*) unleash nefarious cytokines that can destroy the cell. The immune response is usually too late to contain an acute attack. In the case of recurrent viral attacks (HPV, HSV), it seems that the level of functioning T cells may have an impact on recurrence of warts or herpes outbreaks. The mechanics of anoreceptive intercourse, as compared with vaginal intercourse, almost always results in denuding of the protecting cellular and mucous layer of the anus and rectum.

Latex allergies, with condom use, may also be seen causing severe invasive and erosive proctitis and should be in the differential of a caustic burn to the rectum after sexual anoreceptive intercourse.

## Diagnosis and Management of Bacterial Pathogens

### Gonorrhea

*Neisseria gonorrhoeae*, the Gram-negative diplococcus (Figure 17-1) responsible for gonorrhea, was first described by Albert Neisser in 1879 from exudates from urethritis and cervicitis.<sup>8</sup> It is probably the most common bacterial STD affecting the anorectum. Whereas gonorrhea rates decreased over the last several decades, in the mid-1990s the incidence slowly increased to the current rate of about 650,000 cases per year. Similar recent increases have been noted in Canada and the United Kingdom.<sup>9</sup> Peak incidence for all forms of gonorrhea

is in the late teens for females and early 20s for males. African-Americans have a 30-fold higher rate of infection than white Americans.

Infection from *N. gonorrhoeae* occurs in columnar, cuboidal, or noncornified epithelial lined cells of the urethra, endocervix, rectum, and pharynx and is frequently asymptomatic. The incubation period ranges from 3 days to 2 weeks. Untreated infection may lead to disseminated gonococcal infection with transient bacteremia, arthritis, and dermatitis. Rare but severe sequelae include endocarditis and meningitis.

Anorectal transmission in homosexual males and some females is by anoreceptive intercourse with an infected partner. Thirty-five to fifty percent of women with gonococcal cervicitis have concomitant rectal infection which is believed to be from contiguous spread from the genital infection.<sup>10</sup> Oral-anal sex has been suggested as another mode of anorectal gonococcal infection.<sup>11</sup> A large percentage of patients who culture positive for rectal gonorrhea are asymptomatic—up to 50% of males and 95% of females. Asymptomatic rectal infection constitutes the main reservoir of gonococcal disease in homosexual men.

Symptomatic anorectal gonococcal infection results in pruritus, tenesmus, bloody discharge, mucopurulent discharge, and/or severe pain. External inspection of the anus is generally unremarkable; however, nonspecific erythema and superficial ulceration may occur (Figure 17-2). Anoscopy reveals a thick purulent discharge, which classically is expressed from the anal crypts as pressure is applied externally on the anus. Nonspecific proctitis may be present with erythema, edema, friability, and pus. Diagnosis is confirmed by culture on selective media (Thayer-Martin or Modified New York City) incubated in a CO<sub>2</sub>-rich environment and Gram's stain of directly visualized discharge.<sup>12</sup> The use of lubricants other than water may introduce antibacterial agents during anoscopy and decrease diagnostic yield. Nonculture detection of gonorrhea is being used more frequently especially in urethral and cervical infections. Nucleic acid amplification tests (NAATs) such as polymerase chain reaction

FIGURE 17-1. Gram-negative intracellular diplococcus.

FIGURE 17-2. Anorectal gonorrhea.

(PCR) and ligase chain reaction (LCR) and nonamplified DNA probes provide sensitivities of greater than 95% but do not provide antibiotic susceptibility data. There are no NAATs currently licensed for detection of rectal gonorrhea.<sup>13</sup>

Because of the prevalence of penicillinase-producing *N. gonorrhoeae* starting in the 1970s, penicillin G is no longer the drug of choice for gonorrhea. The most current recommended treatment regimens from the Centers for Disease Control (CDC) were published in 2002 and are listed in Table 17-1. Since publication of these guidelines, cefixime has become unavailable in the United States. Alternative regimens include spectinomycin (2 g as a single intramuscular injection), other cephalosporins (ceftizoxime, cefoxitin, and cefotaxime), and other quinolones. Only a few isolates reported by the Gonococcal Isolate Surveillance Report in the past 10 years showed decreased susceptibility to the cephalosporins listed in Table 17-1.<sup>15</sup> Quinolone-resistant *N. gonorrhoeae* (QRNG) have been detected in the past decade with increasing frequency in Asia and the Pacific. In the United States, this is particularly important in Hawaii (where QRNG may account for as much as 14% of gonorrhea isolates) and California. In the United Kingdom, the overall rate of QRNG was reported at 9.8% for 2002.<sup>16</sup> Concurrent HIV infection does not alter treatment for anorectal gonorrhea. Because of the high rate of concomitant infection with chlamydia, patients treated for gonococcal infections should be given appropriate treatment for chlamydia at the same visit or measures to rule out chlamydial infection should be taken.

Routine follow-up at 3 months is no longer necessary because current treatment provides near 100% efficacy. Patients with persistent symptoms after treatment should be followed and cultured as should those treated with nonstandard antibiotics. Sexual partners from the past 60 days should be treated and patient should abstain from intercourse until treatment is completed and symptoms resolved.

### Chlamydia/Lymphogranuloma Venereum

*Chlamydia trachomatis* is an obligate intracellular bacterium that is sexually transmitted and results in clinical infections that are similar to those caused by *N. gonorrhoeae*. Simultaneous infection with both organisms is common. Chlamydia is the most frequently reported STD in the United States with an annual incidence of about 3 million cases per year.<sup>17</sup> Aggressive screening programs are credited with the decline of the chlamydia infection rate from its peak of more than 4 million per year in the early 1970s.

TABLE 17-1. Treatment of anorectal gonococcal infection<sup>14</sup>

One of the following as a single dose:	
Ceftriaxone	125 mg intramuscularly
Ciprofloxacin	500 mg orally
Ofloxacin	400 mg orally
Levofloxacin	250 mg orally
Cefixime	400 mg orally

Anorectal transmission of chlamydia is through anoreceptive intercourse although secondary involvement can occur as a late manifestation of genital infection. Different serovars of *C. trachomatis* produce differing clinical illness. Serovars D through K [non-lymphogranuloma venereum (LGV)] are responsible for proctitis and common genital infections. Lymphogranuloma venereum is caused by LGV serovars L1–L3. The incubation period for chlamydia is 5 days to 2 weeks. Non-LGV serovars are less invasive and cause mild proctitis (manifested by tenesmus, pain, and discharge) but asymptomatic infection is common. LGV serovars produce a much more aggressive infection with perianal, anal, and rectal ulceration. The proctitis produced can be difficult to distinguish from Crohn's disease (including microscopic findings of granulomas) with resulting rectal pain and discharge. Anoscopy and sigmoidoscopy demonstrate friable rectal mucosa, which is more severe in appearance (and extends above the rectum in some cases) in LGV strains.<sup>18–20</sup> Perianal abscesses, fistulas, and stricturing may also occur. Lymphadenopathy develops in draining nodal basins—iliac, perirectal, inguinal, and femoral—several weeks after initial infection. Large indurated matted nodes (Figure 17-3) and overlying erythema may produce a clinical picture similar to syphilis.

Diagnosis of chlamydia as the causative agent in proctitis can be difficult. Proper specimen collection increases diagnostic yield and consists of a cotton or Dacron swab with an inert shaft (plastic or metal). Specimen for tissue culture should be transported on specific medium and kept refrigerated or on ice until inoculated onto culture plates. Specimens that are to be tested by a nonculture technique are transported and stored in accordance with the test manufacturer's guidelines. In patients with a clinical presentation consistent with chlamydia proctitis, rectal Gram's stain showing polymorphonuclear leukocytes without visible gonococci is presumptive for a diagnosis of chlamydia.<sup>20</sup> Tissue culture for chlamydia is relatively insensitive and is not widely available because of cost and technical requirements.<sup>21</sup>

FIGURE 17-3. Inguinal adenopathy of LGV.

Antigen detection by direct fluorescent antibody (DFA) or enzyme immunoassay DFA is highly specific, widely available, and does not require rapid transportation or refrigeration. A trained microscopist is needed for interpretation. As with gonorrhea, newer NAATs are available. Their use is increasing in genital infection but unproven for anorectal chlamydia. A pilot study using both PCR and LCR techniques showed that these techniques can be effective for making this diagnosis but there are few additional data on the use of NAATs in anorectal chlamydia.<sup>22</sup>

The two recommended treatment regimens for rectal chlamydia (non-LGV) are azithromycin, 1 g orally as a single dose or doxycycline, 100 mg orally, twice a day for 7 days.<sup>14</sup> Alternative regimens include erythromycin (less effective, more gastrointestinal side effects), ofloxacin (7-day course, more expensive), or levofloxacin (7-day course, no data on efficacy). Treatment of LGV is with doxycycline or erythromycin for 21 days. In patients with HIV and LGV, prolonged therapy may be required. Management of sexual contacts is the same as for gonorrhea. Abstinence from sexual intercourse should last until 7 days after treatment with azithromycin or completion of 7 days of doxycycline.

## Syphilis

Syphilis is an STD caused by the spirochete *Treponema pallidum* that can present in one of several progressive stages—primary (chancre or proctitis), secondary (condyloma lata), or tertiary. The incidence of syphilis had its recent peak of 107 cases per 100,000 people in the United States in 1991, but decreased to 2.2 per 100,000 in 2001, meaning that only 6103 cases were reported. A slight increase in primary and secondary syphilis cases reported occurred in 2002.<sup>23</sup> These low rates have led to a national plan for eliminating syphilis.<sup>24</sup>

The primary stage of anorectal syphilis appears within 2–10 weeks of exposure via anal intercourse. The chancre begins as a small papule that eventually ulcerates. Anal ulcers are frequently painful (in contrast to genital ulcers) and without exudates. They may be single or multiple (Figures 17-4 and 17-5) and located on the perianal skin, in the anal canal, or distal rectum. Differentiation from idiopathic anal fissures may be difficult. Painless but prominent lymphadenopathy is common. Proctitis from syphilis may occur with or without chancres.<sup>18</sup> Untreated lesions in this stage will usually heal in several weeks.

Hematogenous dissemination of untreated syphilis leads to a secondary stage that occurs 4–10 weeks after primary lesions appear. Nonspecific systemic symptoms from this infection include fever, malaise, arthralgias, weight loss, sore throat, and headache. A maculopapular rash is seen on the trunk and extremities. Condyloma lata, another secondary manifestation, are gray or whitish, wart-like lesions that appear adjacent to the primary chancre and are laden with spirochetes. Untreated, the symptoms of syphilis usually resolve after 3–12 weeks—of these patients, approximately one-fourth will have a relapse of symptoms in the first year. This is called early latent syphilis.

FIGURE 17-4. Solitary anal chancre.

Diagnosis in the primary or secondary stage is made by visualization of spirochetes on dark-field microscopic examination of scrapings from chancres (Figure 17-6). Alternatively, spirochetes may be demonstrated on Warthin-Starry silver stain of biopsy specimens. A direct fluorescent antibody test for *T. pallidum* (DFA-TP) is performed by some laboratories.<sup>18,25</sup> Serologic tests, rapid plasma reagin (RPR) and Venereal Disease Research Laboratory (VDRL), have a false-negative rate of up to 25% in primary syphilis and are

FIGURE 17-5. Multiple anal chancres.

FIGURE 17-6. Spirochetes demonstrated on dark-field microscopy.

called nontreponemal tests because they are not specific for *T. pallidum* infection. Positive nontreponemal tests should be confirmed by a treponemal test such as the fluorescent treponemal antibody absorption test (FTA-ABS), which remains positive for life.

A single intramuscular injection of 2.4 million units of benzathine penicillin G is the treatment for primary and secondary syphilis. Penicillin-allergic patients are treated with doxycycline (100 mg orally, twice daily for 14 days) or tetracycline (500 mg orally, four times a day for 14 days). Follow-up serology (VDRL or RPR) should be checked at 6 months after therapy for HIV-negative patients and every 3 months for HIV-positive patients.<sup>14</sup> Treatment failures are re-treated with the same dose of penicillin but at weekly intervals for a total of 3 weeks. Partner notification, testing, and treatment depends on stage at diagnosis of the index case. At-risk partners include sexual contacts a) within the prior 3 months plus duration of symptoms for patients with primary syphilis; b) within the prior 6 months plus duration of symptoms for patients with secondary syphilis; and c) within the prior year for those with early latent syphilis.<sup>26</sup>

## Chancroid

Chancroid is an ulcerating STD caused by the Gram-negative, facultative anaerobic bacillus *Haemophilus ducreyi*. Whereas there were approximately 5000 cases reported per year in the late 1980s and early 1990s in the United States, there were fewer than 200 cases reported in 1999.<sup>1</sup> It is much more common in developing countries with a global incidence estimated at 6 million.<sup>27</sup>

Transmission of *H. ducreyi* is strictly via sexual contacts through breaks in the skin during intercourse and results in genital ulcers. The initial manifestation (hour to days after exposure) is as infected tender papules with erythema that subsequently develop into pustules and then (days to weeks) become ulcerated and eroded. Multiple ulcers are common and are generally painful, especially in males. Although chancroid ulcers are most frequently located on the genitalia,

perianal abscesses and ulceration may occur. Anal ulcerations in females may be the result of drainage from adjacent genital infections. Differentiation of other ulcerating STDs cannot be made on gross appearance in most cases.<sup>28</sup> Painful inguinal adenopathy accompanies half of cases in males and is usually unilateral. Females are less likely to develop adenopathy from *H. ducreyi* infection.<sup>29</sup> Abscess formation may result, necessitating drainage. Besides causing genital ulcers, *H. ducreyi* facilitates transmission of HIV and vice versa.

Diagnosis of chancroid is made by Gram stain and culture of *H. ducreyi* (on selective medium agar) from the base of ulcers. Gram stain is only 40%–60% sensitive relative to culture and demonstrates nonmotile Gram-negative rods in small groups. *H. ducreyi* is difficult to culture and many laboratories in the United States are not equipped to perform this test. PCR is more sensitive than culture for detecting *H. ducreyi* but is not commercially available at this time.<sup>30</sup> Treatment for *H. ducreyi* is single-dose treatment with azithromycin (1 g, orally) or ceftriaxone (250 mg, intramuscularly). Alternatively, regimens include ciprofloxacin, 500 mg orally twice a day for 3 days or erythromycin 500 mg three times a day for 1 week.<sup>14</sup>

## Granuloma Inguinale (Donovanosis)

Donovanosis is an ulcerating infection of the genitalia and anus caused by *Calymmatobacterium granulomatis* (also called *Donovania granulomatis*). Transmission is believed to occur from both sexual and nonsexual contact. It is rarely seen in the United States but is common in parts of Africa, South America, and Australia. Morphologic manifestations include an ulcerogranulomatous form (nontender, fleshy, beefy red ulcers), hypertrophic or verrucous lesions, necrotic ulcers, or cicatricial. Genital involvement is most common but contiguous involvement of the anorectum occurs. Development of sclerotic lesions causes anal stenosis.<sup>31</sup>

*C. granulomatis* cannot be cultured by routine techniques. Diagnosis can be made by tissue smear or biopsy that reveals Donovan bodies (small inclusions) within macrophages. Several antibiotic regimens have been recommended. The most recent CDC guidelines are doxycycline (100 mg orally, twice daily for 1 week) or trimethoprim-sulfamethoxazole (one 800 mg/160 mg tablet orally, twice a day for at least 3 weeks).<sup>14</sup> Alternative treatments include at least 3 weeks of ciprofloxacin, azithromycin, or erythromycin. Some authors believe azithromycin to be the preferred treatment.<sup>31</sup>

## Diagnosis and Management of Viral Pathogens

### Herpes Simplex Virus

HSV is a DNA virus of the family *Herpesviridae* that includes varicella-zoster virus, Epstein-Barr virus, and Cytomegalovirus. Herpes is the most prevalent STD in the United States

with the current seroprevalence rate for HSV-2 estimated to be 20% for the general population.<sup>32</sup> Black females are the subgroup with the highest seroprevalence at 55%. Two serotypes of HSV are described. HSV-2 has been most associated with anogenital herpes infections. HSV-1 infection most often presents as labial, oral, or ocular lesions but accounts for about 30% of genital infections. Several recent reports have shown an increasing percentage of genital infections caused by HSV-1.<sup>33,34</sup> Asymptomatic infection with HSV is common.

Transmission is via close contact with an individual who is shedding the virus and infection results from penetration of mucosal surfaces or breaks in the skin. Productive infection causes viral replication within cells and cell death. Clinical infection presents first with systemic symptoms (fever, headache, myalgias), followed by local symptoms (pain, pruritus). Vesicles appear over the anogenital area, increase in number and size, and eventually ulcerate and coalesce (Figures 17-7 and 17-8). Vesicles and ulcerations heal over a mean time of 3 weeks.

Anorectal involvement by HSV-2 is acquired by anorectal intercourse and is second only to gonorrhea as a cause of proctitis in homosexual men. Herpetic infection of the anorectum results in severe anal pain, tenesmus, hematochezia, and rectal discharge. The proctitis seen is typically limited to the distal 10 cm of the rectum with diffuse friability. Simultaneous with infection, HSV moves through peripheral sensory nerves to sensory or autonomic nerve root ganglia. Sacral radiculopathy of the lower sacral roots from this infection causes sacral paresthesias and neuralgias, urinary retention, constipation, and impotence. Tender inguinal adenopathy occurs in half of patients with HSV proctitis.<sup>35</sup>

Herpes has the ability to persist in their host because of latency—the viral genome maintained in a stable condition in host cell nuclei. For HSV, the site of latent infection is the sensory ganglia of nerves innervating the site of infection. Reactivation of latent virus results in recurrent infection but the stimuli for this process are poorly understood.<sup>36</sup>

FIGURE 17-7. Perianal herpes.

FIGURE 17-8. Perianal herpes.

Recurrent attacks are generally milder, shorter in duration, and without the constitutional symptoms that occur with initial infection.

Diagnosis is frequently made on clinical grounds alone. Cultures taken from ulcerations, rectal swabs, or biopsies confirm the diagnosis. Multinucleated giant cells with intranuclear inclusion bodies (ground-glass appearance) on Pap smear or Tzanck prep are less sensitive than viral culture. Direct immunofluorescence has also been used for diagnosing HSV.<sup>18</sup> For cases in which cultures are not available, paired type-specific serology demonstrating seroconversion is diagnostic. In the past 5 years, the Food and Drug Administration (FDA) has approved several commercially available HSV serology tests. These tests have specificities and sensitivities of greater than 90% and are sure to become more frequently used in the diagnosis of HSV.<sup>37,38</sup> It should be noted that seroconversion may take several weeks after initial infection and repeat testing intervals are dependent on the particular serology kit used.<sup>39</sup>

Treatment of patients with anorectal herpes includes comfort measures such as warm soaks and oral analgesics. The only prospective, randomized trial of antiviral treatment for herpes proctitis demonstrated a shortened duration of symptoms and period of viral shedding with oral acyclovir 400 mg, five times a day for 10 days.<sup>40</sup> A three times per day dosing has been shown to be effective for genital herpes but has not been evaluated for herpes proctitis.<sup>41</sup> Other antiviral agents (valacyclovir and famciclovir) used for genital herpes are most likely effective for HSV proctitis at the same doses used for genitourinary infection but also lack clinical studies for this indication. Severe mucocutaneous HSV infection in which the patient cannot tolerate oral medication warrants intravenous acyclovir. Topical acyclovir has limited efficacy and is not recommended. Treatment of initial episodes of HSV do not prevent latency, asymptomatic viral shedding, or the course of subsequent episodes. Recurrent episodes may be treated with oral antiviral agents. Valacyclovir (500 mg twice a day) and acyclovir (200 mg five times a day) have

demonstrated equal efficacy in treating genitourinary HSV recurrences.<sup>42</sup> Prompt initiation of treatment at onset of symptoms of HSV recurrence reduces duration of symptoms and healing times. Patients who experience more than five recurrences per year are considered for suppressive treatment. Valacyclovir, acyclovir, and famciclovir have all demonstrated 70% or greater reduction compared with placebo.

As with all STDs, counseling of patients with HSV is an important part of treatment and prevention.<sup>41,42</sup> Specific items that should be addressed are: 1) infectivity is not isolated to symptomatic outbreaks; most sexual HSV transmission occurs during asymptomatic periods; 2) latent infection and the risk of recurrence; suppressive therapy does not eliminate latent infection or viral shedding; 3) abstinence is recommended while lesions are present. Condoms are advised for all other times although they likely provide incomplete protection. Most recently, once-daily administration of valacyclovir has been shown to reduce the risk of HSV-2 transmission between HSV-2-seropositive patients and their seronegative sexual partners.<sup>43</sup>

### Human Papilloma Virus

HPV is a DNA papovirus. Although HPV is not a reportable STD, it is probably the most common STD in the United States with an estimated incidence of more than 5 million cases per year (in contrast to chlamydia, being the most common of the reportable STDs).<sup>1</sup> There are more than 80 subtypes of HPV, almost one-third of which cause anogenital warts. Subtypes 6 and 11 are the most common of the low-risk HPV subtypes, whereas subtypes 16 and 18 have the greatest associated risk of anal dysplasia and anal cancer. Transmission is via sexual contact with infected individuals with or without gross lesions, and asymptomatic infection is common. Perianal involvement can occur in the absence of receptive anal intercourse.

Presenting complaints of perianal or anal condyloma acuminata include presence of a growth, pruritus, bleeding, chronic drainage, pain, and difficulty with hygiene. Physical examination is generally all that is required for diagnosis and shows the characteristic gray or pink fleshy, cauliflower-like growths of variable size in the perianal region (Figure 17-9). Anoscopy is an integral part of the evaluation. In the anal canal, the lesions tend to be small papules and involvement above the dentate line is rare. Examination should include the genitalia (including vaginal speculum examination and Pap smear), perineum, and groin folds.

The goal of treatment of condyloma acuminata is destruction or removal of all gross disease while minimizing morbidity, although this does not ensure eradication of infection. Tangential excision, cryotherapy, or fulguration of small lesions can be performed as an office procedure with a local anesthetic with little discomfort or inconvenience to the patient. Larger lesions are treated by electrodesiccation. The patient is placed in the lateral or prone jackknife position.

FIGURE 17-9. Perianal condyloma.

Depending on the size and number of lesions, local, spinal, or general anesthesia is used. The superficial-most layer of the condyloma is fulgurated with the electrosurgery tip until the lesion takes on a gray-white appearance. This is followed by curettage or simply abrading the fulgurated tissue with gauze. The process is repeated until the condyloma is completely removed without burning into the deep dermis or subcutaneous fat. Pedunculated warts are simply transected at their base. Tissue from HIV+ patients, recurrent lesions, flat lesions, or those that are suspicious (ulcerated, friable, hypervascular) should be sent for histopathologic evaluation. Topical 5% lidocaine is helpful in decreasing postoperative pain. Oral analgesics and daily cleansing with mild soap and water are all that is required for postoperative care in most patients. Silver sulfadiazine or mupirocin are applied in cases in which postoperative bacterial infection is suspected. Overall condyloma clearance rates for surgical techniques range from 60% to 90% with recurrence rates of 20% to 30%.<sup>44</sup>

The patient can apply topical agents such as podofilox and imiquimod but neither is approved for use in the anal canal.

Podofilox is the purified active component of the antimitotic plant resin podophyllin and is available as a 0.5% gel or solution. A treatment cycle consists of twice-daily application for 3 days followed by no treatment for 4 days. This is repeated for up to 1 month. Toxicity concerns are less than those with podophyllin and clearance rates for condyloma of 35%–80% have been reported. Recurrence rates in patients treated with podofilox are 10%–20%.<sup>44–48</sup> Imiquimod is an immune response modifier that increases local production of interferon. Complete response can be expected in 50% of patients treated with imiquimod with 11% of patients experiencing a recurrence.<sup>44,49–51</sup> It is applied at bedtime three times a week, left in place for 6–8 hours, and then removed by washing. Treatment may take up to 16 weeks. One study demonstrated no benefit to increased dosing frequency (from once to two or three times daily).<sup>52</sup> Side effects of imiquimod include pain, burning, itching, and ulceration which may require cessation of therapy. Imiquimod is used 1) as initial treatment with electrodesiccation reserved for those who have incomplete response, or 2) after destructive treatment and epithelial healing to treat remaining disease or decrease recurrence. Although there are no published randomized data to support this use, one of the authors (L.G.) has noted substantial diminution of wart recurrence (unpublished data). Currently, imiquimod is not approved for anal canal use but this application is being investigated.<sup>53</sup> Trichloroacetic acid is applied topically and is useful for treating small lesions in the anal canal. Topical and intralesional interferon have been used to treat condyloma acuminata with mixed results. Other agents that have been used to treat anogenital condyloma but are not in widespread use include 5-FU cream, cidofovir, and autologous vaccine.

Bushke and Loewenstein first described giant condyloma acuminata (GCA) in 1925. They are most associated with HPV types 6 and 11 but histologically demonstrate some differences from ordinary condyloma—marked papillomatosis, acanthosis, thickened rete ridges, and increased mitotic activity. The substantial percentage of cases with in situ or invasive squamous cell cancers have led to speculation that GCA represents part of a continuum from condyloma to invasive squamous cell cancer.

Wide local excision with a 1-cm margin is the treatment of choice for these lesions. Local tissue flaps or grafted skin may be required to repair surgical defects. Abdominal-perineal resection has been used for GCA involving the anal sphincters. Chemoradiation is also an option in the treatment of GCA, especially in those patients who are poor surgical candidates or in whom clear surgical margin are not attainable.<sup>54</sup> Complete regression of GCA with chemoradiation has been reported.<sup>55</sup>

### HPV, Anal Intraepithelial Dysplasia, and Anal Cancer

Although it is clear that HPV has a significant role in the development of cervical cancer, its significance in the development of anal cancer and its presumed precursor (anal

FIGURE 17-10. Anal cancer in an HIV-positive patient.

intraepithelial dysplasia) are not as well defined (Figure 17-10). Histologic and epidemiologic similarities between the two exist. Histologically, the anal canal resembles the cervix in that they are both transition zones from columnar epithelium to squamous epithelium. Epidemiologic studies before the HIV infection epidemic showed the incidence of anal cancer in homosexual males to be 12.5–37 per 100,000 in the United States.<sup>56</sup> This is similar to the incidence of cervical cancer prior to routine Pap testing. The risk of anal cancer developing in an HIV+ homosexual male is estimated to be 38 times that of the general population and twice the risk of an HIV–homosexual male.<sup>56,57</sup> HPV infection has been reported in 93% of HIV+ homosexual males compared with 60% of HIV–homosexual males.<sup>54</sup>

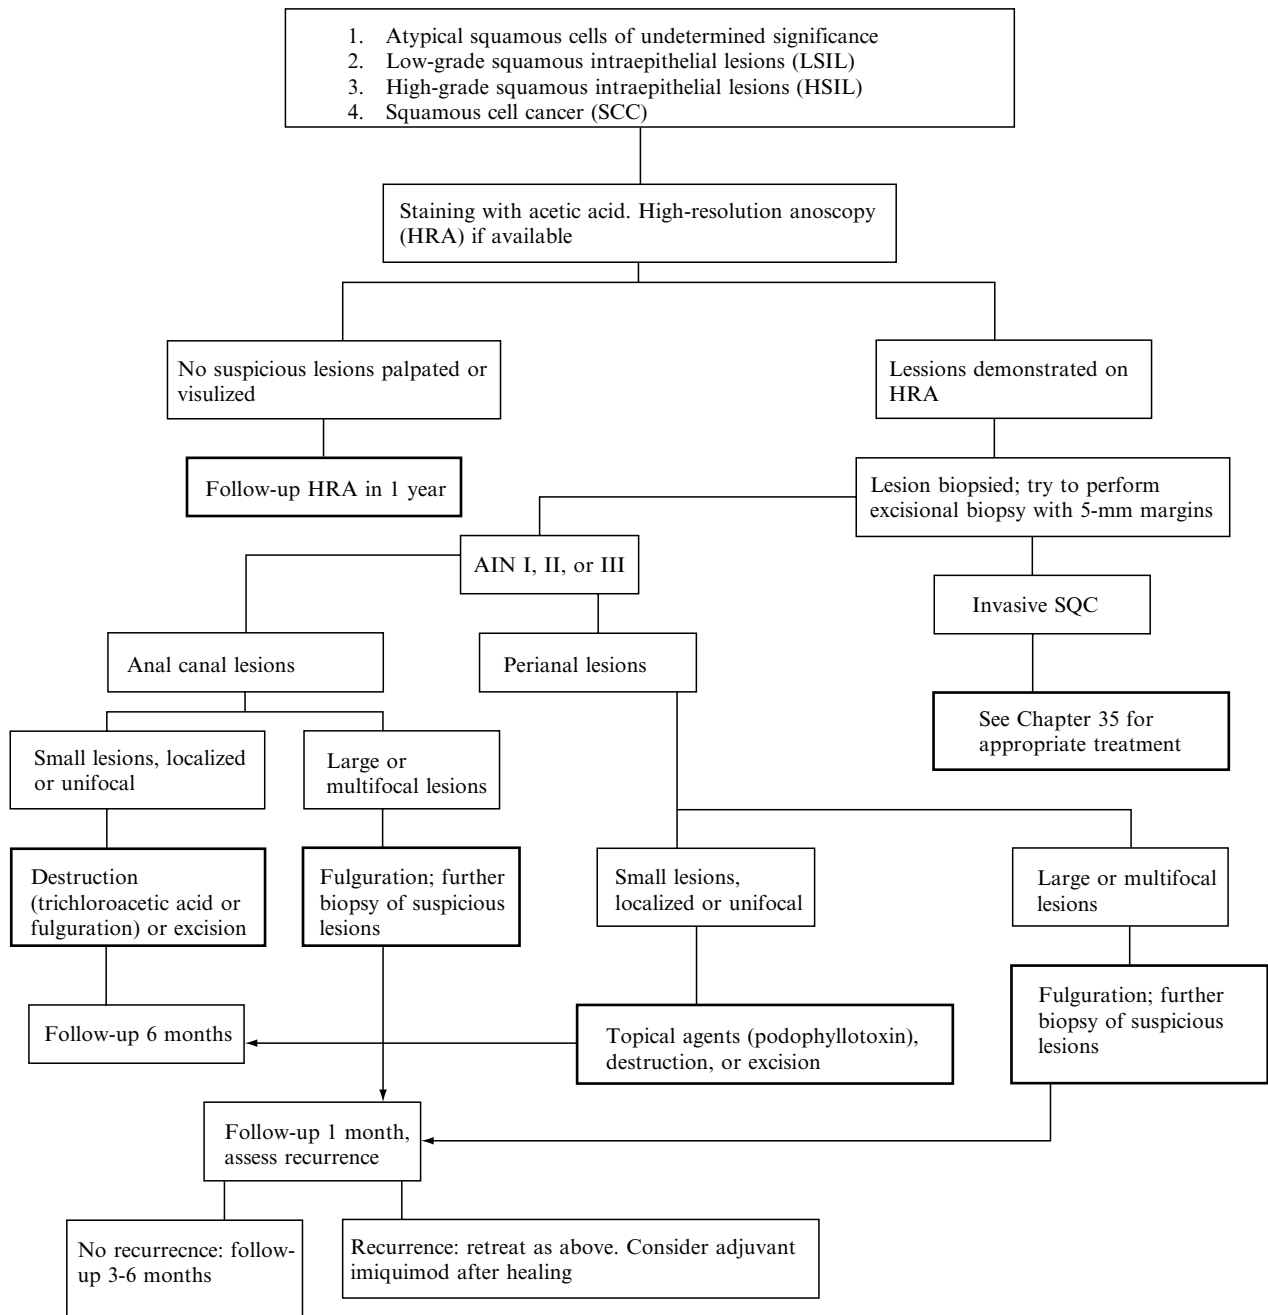

Anal cytology has been suggested as a screening tool for detecting patients with anal dysplasia. Applying the current cervical cytology terminology, specimens are designated normal, atypical squamous cells of indeterminate significance (ASCUS), low-grade squamous intraepithelial lesions (LSIL), or high-grade squamous intraepithelial lesions (HSIL). The benefit and best timing of this screening are undetermined. Evaluation and treatment algorithms as well as recommended testing schedules have been reported.<sup>58,59</sup> One such evaluation and treatment algorithm recommends high-resolution (with acetowhitening and staining with Lugol's solutions) anoscopy with biopsy.<sup>59</sup> Subsequent treatment is based on histologic findings which are typically reported as normal or AIN (anal epithelial neoplasia) I, II, or III. Options for treatment include local destruction (with topical agents, cryotherapy, or fulguration), excision, or observation. However, there are limitations of our understanding of the relationship among HPV, AIN, and anal cancer that prevent the dogmatic recommendation and widespread acceptance of such an approach. First, the incidence and predictability of the progression of AIN to invasive cancer is unclear.<sup>60,61</sup> The lack of inter- and intraobserver agreement in the interpretation of AIN no doubt contributes to this lack of understanding.<sup>62</sup> Second, data

demonstrating efficacy (defined as long-term removal of AIN, prevention of anal cancer) of treatment is lacking. There is no evidence that destroying AIN III has any impact on survival. Chang et al.<sup>63</sup> reported 37 patients with HSIL who underwent incisional biopsy and fulguration. Staged procedures were performed in patients with circumferential disease. Morbidity was mostly uncontrolled pain that lasted a mean of 2.9 weeks. Recurrence of HSIL at 12 months was 79% in HIV+ patients. The absence of established benefit combined with the morbidity of treatment lead us and others to the recommendation that AIN (regardless of grade) be observed unless there are

gross or ulcerated lesions present. Clinical trials are needed to establish and justify the benefit of more aggressive treatment. It is our belief that because the acquisition of anal cytology specimens require no particular expertise, this procedure should remain the domain of the patients' primary managing physicians who are most likely to have frequent contact with these patients (internist, general practitioner, infectious disease specialist). Patients with abnormal cytology should be referred to the colon and rectal surgeon who should evaluate patients with staining and magnification if possible to determine if biopsy or excision is required (Table 17-2).

TABLE 17-2. Algorithm for management of patients with abnormal anal cytology

Two additional comments with regard to the association of HPV, HIV, and AIN should be made. First, the use of HAART (discussed in more detail later in the section on HIV) does not reduce the incidence of AIN.<sup>64</sup> The clinical implications of this fact are: a) anal cytology screening should not be stopped just because a patient is treated with HAART; and b) with HIV patients living longer secondary to HAART, the incidence of anal cancers may increase. Second, the prevalence of HPV and AIN is high in HIV-positive males with CD4+ counts less than  $500 \times 10^6$  cells/L even in the absence of a history of anal intercourse.<sup>65</sup> These patients should also be considered for cytologic screening.

## Molluscum Contagiosum

The molluscum contagiosum virus is a member of the poxvirus family and causes a benign papular condition of the skin. Transmission is by sexual and nonsexual contact. The incubation period is 1–6 months, followed by development of 2- to 6-mm flesh-colored, umbilicated papules.<sup>66</sup> Symptoms are uncommon although pruritus or tenderness may occur. Immunocompromised hosts such as those with HIV are more prone to infection with molluscum contagiosum (compared with HIV negative) and may have a more severe form of the disease with hundreds of lesions. Diagnosis is usually made on clinical grounds but excisional biopsy demonstrates enlarged epithelial cell with intracytoplasmic molluscum bodies. Treatment is generally through eradication with curettage, electrodesiccation, or cryotherapy. Podophyllotoxin (0.5%) and imiquimod (5%) have both been used as self-applied topical preparations with success.<sup>67,68</sup> Neither is FDA approved for this use.

## HIV and the Acquired Immunodeficiency Syndrome

Infection from the HIV (at that time called human t-lymphotropic virus) related to acquired immunodeficiency syndrome (AIDS) was first described in 1983.<sup>69</sup> The most current data available show that in 2001 there were approximately 344,000 people in the United States with AIDS and another 162,000 with HIV infection not meeting the criteria for AIDS.<sup>70</sup> Cumulative totals showed 807,075 cases of AIDS in the United States through 2001 and a death rate of 57% in this group. Whereas the incidence of HIV infection has apparently leveled, the numbers of new AIDS cases and deaths from AIDS have decreased. This is in large part attributable to HAART—combinations of potent anti-HIV drugs that are nucleoside analogs, non-nucleoside reverse transcriptase inhibitors, or protease inhibitors. Table 17-3 shows the current classification system for patients who are HIV positive.

Surgery for anorectal diseases is the most common indication for surgery in HIV-infected patients and in 5% of patients whose anorectal complaints are the presenting symptom of their HIV infection.<sup>72</sup> Most of the indications for surgery are common to the population at large but some are unique to

TABLE 17-3. Revised classification system for HIV and AIDS<sup>71</sup>

CD4+ T lymphocyte categories			
Category 1: $\geq 500$ cells/ $\mu$ L			
Category 2: 200–499 cells/ $\mu$ L			
Category 3: $< 200$ cells/ $\mu$ L			
Clinical categories			
Category A: HIV positive; asymptomatic; persistent generalized lymphadenopathy			
Category B: Symptomatic conditions not listed in clinical category C; are conditions that are attributed to HIV infection; or conditions that have a clinical course or require management that is complicated by HIV infection. Examples include: bacillary angiomatosis, oropharyngeal or vulvovaginal candidiasis, cervical dysplasia, diarrhea (more than 1 month in duration), more than one episode of herpes zoster, pelvic inflammatory disease, peripheral neuropathy			
Category C: Diagnoses included in the AIDS surveillance case definition—candidiasis (pulmonary or esophageal), invasive cervical cancer, Coccidiomycosis, extrapulmonary cryptococcosis, chronic intestinal cryptosporidiosis, Cytomegalovirus disease (other than liver, spleen, nodes) or retinitis, HIV-encephalopathy, HSV (chronic ulcers, pulmonary, or esophageal), histoplasmosis (disseminated or extrapulmonary), isosporiasis (chronic intestinal), Kaposi's sarcoma, Burkitt's lymphoma, immunoblastic lymphoma, primary brain lymphoma, <i>Mycobacterium avium</i> complex or any mycobacterium species other than <i>M. tuberculosis</i> (extrapulmonary or disseminated), <i>M. tuberculosis</i> , <i>Pneumocystis carinii</i> pneumonia, progressive focal leukoencephalopathy, recurrent <i>Salmonella septicemia</i> , toxoplasmosis of the brain, HIV wasting syndrome.

Bolded groups are defined as AIDS.

AIDS patients. Several studies demonstrate poor wound healing and increased morbidity in the surgical treatment of anorectal disease in AIDS patients.<sup>72–74</sup> Delayed or failed wound healing has been associated with presence of AIDS, decreased absolute leukocyte count, and decreased CD4 count. Morandi et al.<sup>73</sup> found that at 32 weeks after hemorrhoidectomy, 50% of AIDS patients had incompletely healed wounds. The overall complication rate was significantly higher in the AIDS group than in HIV+ patients without AIDS. Lord<sup>75</sup> reported decreased wound healing in HIV+ patients with T lymphocyte count of less than 50. Others have shown longer interval and decreased complete wound healing in HIV+ patients with CD4+ T lymphocyte counts of less than 200.<sup>74</sup> The studies reviewed above describe patients who were not treated with HAART. There is a lack of data describing wound healing in anorectal surgery since the widespread use of HAART; however, the observation of the authors is that compensated HIV+ patients are at no significant risk of increased complications from anorectal surgery. Other factors to be considered in selecting appropriate treatment include any untreatable diarrheal conditions, degree of existing fecal incontinence, and the effect of the proposed surgical procedure on incontinence.

Anal fissures that occur in HIV+ patients must be distinguished from idiopathic AIDS-related anal ulcers (Figure 17-11) and ulcerating STDs such as HSV or syphilis. Anal

FIGURE 17-11. AIDS anal ulcer.

fissures in this patient population are indistinguishable from those in the general population and their treatment is similar—initial conservative management with surgery for treatment failures.<sup>76,77</sup> Treatment of fissures in HIV+ patients is modified by the factors described above and include controlling diarrhea when possible and encouraging abstinence from anoreceptive intercourse.

Although data on the incidence of AIDS-related anal ulcers are lacking, it seems that they are less common with HAART because the lesions are most frequently associated with clinical AIDS and lower CD4+ counts. These ulcers can be distinguished from typical anal fissures because they are more proximal in the anal canal (frequently above the dentate line or anorectal ring), broader based, deeply ulcerating with destruction of sphincter planes, and may demonstrate mucosal bridging. Debilitating pain is a common presenting symptom of these ulcers. Surgical debridement allows for adequate drainage of feculent or purulent material trapped in the ulcer and removal of necrotic debris. Biopsy and culture identify potentially treatable causes for ulceration—malignancy, acid-fast bacilli, HSV, *H. ducreyi*, *T. pallidum*. Cytomegalovirus has been cultured from these ulcers by some authors but is apparently not causal and therefore does not require treatment. Intralesional injection with steroids (methylprednisolone 80–160 mg, in 1 cc 0.25% bupivacaine) provides relief in the majority of patients but not healing.<sup>78</sup> Those who have persistent pain are reinjected.

Perianal suppurative diseases are common conditions in AIDS patients. Abscesses should be drained using small incisions, and placement of a mushroom catheter will lessen recurrent sepsis. Broad-spectrum antibiotics should be given in immune-compromised patients especially if cellulitis is present. Culture (to include mycobacterium) and histopathologic evaluation will help identify infection from atypical organisms and malignancy.

Nadal et al.<sup>74</sup> reported on fistulotomies performed in 31 HIV+ patients. Seven patients had failure of wound healing and all had clinical AIDS, CD4+ counts of less than 200, and

absolute leukocyte counts of less than 3000/mm<sup>3</sup>. Based on this, the authors treat anal fistulas in AIDS patients with high viral loads and low CD4+ counts similar to Crohn's patients. Draining setons are placed liberally with selective use of fistulotomy for low uncomplicated fistulas. Fistulotomy in HIV+ patients with AIDS and normal CD4+ counts is based on criteria similar to HIV– patients.

Thrombosed external hemorrhoids in patients with AIDS are treated the same as for HIV– patients. Acute thrombosis (24–48 hours after onset of symptoms) is treated with excision. Subacute thrombosis (longer than 48 hours from symptom onset) is treated conservatively with sitz baths and oral analgesics.

Internal hemorrhoids present with symptoms of bleeding or prolapse. Initial treatment in patients with AIDS is with a high fiber diet and bulking agents. Proximal colonic sources of bleeding should be excluded via colonoscopy. Patients who fail initial conservative measures are treated with rubber band ligation or infrared coagulation. Other nonoperative techniques such as bipolar coagulation, cryotherapy, or injection sclerotherapy are acceptable. There are conflicting recommendations for operative treatment of hemorrhoids published within the last decade. In a retrospective study, Hewitt et al.<sup>79</sup> found no difference in wound healing between HIV+ and HIV– patients. The mean CD4+ count was 301 but they classified 81% of patients as having AIDS based on symptoms or CD4 count less than 200. In the discussion, the authors comment that the majority of their patients were well nourished and otherwise healthy. They conclude that HIV status should not alter the indications for surgery in patients with symptomatic hemorrhoids. In contrast, as mentioned above, Morandi et al.<sup>73</sup> prospectively evaluated healing time after hemorrhoidectomy. Functional status and presence of AIDS were the two factors that correlated with poor wound healing. AIDS patients with nonhealing had a mean CD4+ count of 79. Unfortunately, they do not comment on relief of hemorrhoid symptoms. It seems that asymptomatic HIV+ patients who do not meet the clinical or CD4+ count diagnostic criteria for AIDS (see Table 17-2) can be treated with hemorrhoidectomy with the expectation that they will have good symptomatic relief and normal wound healing. AIDS patients with more advanced disease (clinical category C) or low CD4+ counts (especially less than 100) are at increased risk for wound healing problems. The benefit of symptomatic relief may still warrant performing surgical treatment in this group.<sup>76</sup>

## Benign Colon: Diverticular Disease

Alan G. Thorson and Stanley M. Goldberg

The term “diverticular disease” of the colon represents a continuum of anatomic and pathophysiologic change within the colon related to the presence of diverticula. These changes most often occur in the sigmoid colon. The continuum can range from the presence of a single diverticulum (a sac or pouch in the wall of an organ) to many diverticula (which may be too numerous to count). It can refer to an asymptomatic state (diverticulosis) or any one of a number of diverse combinations of inflammatory symptoms, changes, and complications (diverticulitis).

Symptoms may variably result from simple physiologic changes in colonic motility related to altered neuromuscular activity in the sigmoid colon, varying degrees of localized inflammatory response, or complex inflammatory interactions leading to diffuse peritonitis and septic shock. These more complex symptoms and resulting complications arise from breaches in the integrity of the wall of one or more diverticula. Diverticula may be true, containing all layers of the bowel wall (congenital), or false, lacking the muscular layer (acquired or pulsion diverticula).

This chapter will deal with inflammatory diverticular disease and its associated complications. Bleeding from diverticular disease is discussed in Chapter 20 (Lower Gastrointestinal Hemorrhage).

### Incidence

Diverticulosis was first described in the mid-19th century as more of a curiosity than a significant disease entity. However, since the early 20th century, an increasing prevalence of the disease has been recognized in industrialized countries. The incidence increases with age and the adoption of a diet high in red meat, refined sugars, and milled flour but low in whole grain breads, cereals, and fruits and vegetables. Although the exact incidence is not well established, numerous autopsy, radiographic, and endoscopic series have shown that the incidence has increased dramatically over the past 75 years,<sup>1-4</sup>

from around 5% near the turn of the century to 50% or more by 1975.<sup>2,3</sup>

It is now estimated that the risk of developing diverticular disease in the United States approximates 5% by age 40 and may increase to more than 80% by age 80.<sup>5</sup>

This increase in observed incidence was originally attributed to new imaging techniques [the introduction of the barium enema (BE) in the early 20th century] and bias inherent to estimates based on a population presenting with symptoms requiring an investigation.<sup>6</sup> It is now clear that not only diverticulosis but the incidence of related complications are increasing. This is exemplified by increasing costs in the treatment of diverticular disease which accounts for nearly 450,000 hospital admissions, 2 million office visits, 112,000 disability cases, and 3000 fatalities each year in the United States.<sup>7</sup> It is estimated that costs will continue to increase as the population continues to age in the next several decades.

Proportionately few people become symptomatic from the presence of diverticula. An estimated 10%–20% of people with diverticula develop symptoms of diverticulitis, and only 10%–20% of these will require hospitalization. Of those that require hospitalization, 20%–50% will require operative intervention. The percentage of hospitalized patients requiring operation has been increasing as outpatient management becomes more common and those admitted as inpatients are more seriously ill.<sup>8</sup> Overall, less than 1% of patients with diverticula will ultimately require surgical management.<sup>9</sup>

There is some evidence that males are more frequently affected at a younger age and females at an older age; however, significant bias may influence this impression. Young females may frequently be underdiagnosed because of confusion with gynecologic diseases in the young. Older females may be overdiagnosed because of confusion with irritable bowel syndrome (IBS). There also seems to be a dichotomy in age and sex with regard to complications of diverticular disease, particularly perforation. The incidence of perforation is higher in males younger than age 50 but in females older than 50.<sup>10</sup>

## Pathophysiology

Diverticulosis is associated with high intraluminal pressures. Pressures in patients with diverticular disease have been found as high as 90 mm Hg during peak contraction. This represents a value nearly 9 times higher than seen in patients with normal colons.<sup>11</sup> It is theorized that such pressures lead to segmentation. Segmentation refers to a process whereby the colon effectively functions as a series of separate compartments rather than a continuous tube.

The high pressures that each compartment is capable of producing are directed toward the colonic wall rather than as propulsive waves. These pressures predispose to herniation of mucosa through the muscular defects that exist where blood vessels penetrate to reach the submucosa and mucosa (*vasa recta brevia*). Most of these penetrations occur between the mesenteric and anti-mesenteric tinea where, not coincidentally, most diverticula occur. As the mucosa herniates, it does so without dragging the muscular layer along, leaving the diverticula denuded of muscle and consistent with the definition of an acquired process. Thus, the most common diverticula are acquired or pulsion diverticula.

These high pressures are consistent with the sigmoid colon being the most common site of involvement. This can be explained by the law of Laplace which states that the tension in the wall of a hollow cylinder is proportional to its radius times the pressure within the cylinder. Because of segmentation, the sigmoid generates pressures so high that the effect of a smaller radius is overcome resulting in total tension in the wall of the sigmoid colon being higher than the rest of the colon and thus the sigmoid has the highest risk of diverticulum formation. It is hypothesized that at least a part of fiber's protective effect is a result of stool bulking which maintains a larger lumen, prevents segmenting contractions, and decreases high pressures.

Complementary to these theories of pathogenesis is the consistent colonic wall muscle abnormality associated with sigmoid diverticular disease. Both the circular and longitudinal muscle wall is typically thickened resulting in a reduction in the size of the lumen and a shortening of the sigmoid. The reduced lumen size may be further enhanced by secondary pericolic fibrosis.

The source of this muscular thickening is not clear. It has been observed that in the normal process of left colon peristalsis, smooth muscle in the rectosigmoid will relax in response to a stimulus, causing contraction of the colon above and the rectum below. A combination of poor diet, aging, and constipation could lead to malfunction of this relaxation response leading to a functional obstruction and the hypertrophy seen in the muscle.<sup>12</sup> Cellular hypertrophy, cellular hyperplasia, and elastosis have all been described. Elastosis seems to precede the development of diverticulosis. It is not found in any other inflammatory conditions of the colon.

Several alternative concepts have been advanced to explain the differences in presentation of diverticular disease. Although the most common finding in diverticular disease is

the muscular changes already discussed, some patients fail to demonstrate this characteristic. These patients are more likely to have diffuse diverticula throughout the colon, and are noted to have a higher incidence of bleeding. They may have an underlying connective tissue abnormality. This would explain the development of diverticula in the absence of high intraluminal pressures. The high incidence of bleeding in these patients could be related to associated inadequate vascular support in the diverticular wall.

Pain associated with diverticular disease may be related to muscle spasm as well as inflammation. Perforation can occur in the absence of inflammation and may be secondary to the extremely high intraluminal pressure.<sup>13</sup>

## Etiology

The etiology of diverticulitis remains complex and relatively poorly understood. Pathophysiologic studies reveal that complications do not occur until there is microperforation through the wall of a diverticulum into the pericolic tissue. A single diverticulum experiences a change in the permeability of its isolated mucosa from physical, biochemical, or physiologic means. It is postulated that a free perforation then occurs leading to a characteristic response and progressing to varying degrees of inflammation. The perforation might be small and cause a microabscess, develop into a phlegmon, or form into a large abscess. Free perforation occurs rarely, but fistulization does frequently occur, most often to the bladder.<sup>14</sup>

The original communication with the lumen of the bowel is usually rapidly obliterated by the inflammatory process. Occasional failure of the diverticular neck to obliterate may lead to a free communication between the bowel and the peritoneal cavity with resultant fecal peritonitis. Rupture of a noncommunicating abscess may lead to purulent peritonitis.<sup>15</sup>

Low-grade inflammation of colonic mucosa, induced by changes in bacterial microflora, can affect the enteric nervous system and alter gut function, leading to symptom development. This explanation has been postulated as a source of symptoms in IBS. The same explanation can be easily extrapolated to symptoms in diverticular disease because some patients with diverticular disease demonstrate bacterial overgrowth.<sup>16</sup> This common source of symptoms reinforces the difficulty in sorting through the differential in patients with symptoms of bowel disease.

Recent clinical investigations have shown that disturbances in cholinergic activity may contribute to diverticular disease. Cholinergic stimulation in patients with diverticular disease leads to unsynchronized slow waves of relatively low frequency as opposed to bursts of action potentials normally associated with peristalsis.<sup>17,18</sup> This suggests a possible role for cholinergic denervation hypersensitivity in colonic smooth muscle with upregulation of smooth muscle muscarinic receptors.<sup>19</sup>

The colon with diverticular disease has more cholinergic innervation than normal colon. In addition, there is less

noncholinergic, nonadrenergic inhibitory nerve activity. This increased cholinergic activity and the relative paucity of inhibitory activity may contribute to the high intraluminal pressures and segmentation seen in the diverticular colon.<sup>20</sup>

## Epidemiology

### Diet

Large cohort and case-control studies in the United States and Greece have shown that diets high in red meat and low in fruit and vegetable fiber increase diverticular symptoms by as much as threefold.<sup>21,22</sup> Vegetables and brown bread have been shown to be protective.<sup>22</sup> Fiber may be protective by increasing stool weight and water content which decrease colonic segmentation pressures and transit times.<sup>23</sup> Fiber, through the process of fermentation, also provides short-chain fatty acids to the colonic epithelial cells, an important source of fuel and mucosal health.<sup>24–26</sup> Red meat has been associated with heterocyclic amines, a factor in colon mucosal apoptosis.<sup>27</sup> Dietary heme has been shown to be highly cytotoxic to rat colons.<sup>28</sup>

### Age and Sex

Population-based studies have reported differences in disease presentation according to age and sex. However, it is not clear that all of these associations would remain valid in the global population of diverticular disease. McConnell et al.<sup>29</sup> reported that female patients present with complications requiring surgery an average of 5 years later than males. Men have a higher incidence of bleeding and women a higher incidence of fistula. Younger men present with fistula and older men bleeding. Young females present with perforation whereas older females with chronic disease and stricture. Overall, patients younger than age 50 present more often with chronic or recurrent diverticulitis.<sup>29</sup> Finally, more patients at younger and younger ages are being diagnosed with diverticular disease.

### Nonsteroidal Inflammatory Drugs

Nonsteroidal inflammatory drugs (NSAIDs) have been linked to increased rates of complications related to diverticular disease. The plausible mechanism of action is indirect through known inhibition of cyclooxygenase and resultant decreased prostaglandin synthesis in the gut. Prostaglandins are important in the maintenance of mucosal blood flow and an effective colonic mucosal barrier. A direct mechanism also exists through mucosal damage caused by NSAIDs which leads to increased translocation of toxins and bacteria.<sup>30–32</sup>

### Immunocompromise

The use of corticosteroids is associated with a higher risk of perforation and more severe inflammatory complications. The

postulated mechanism is immunosuppressive and antiinflammatory effects hinder confinement of perforation in its early stages. The use of other immunosuppressive drugs has also been associated with such increased risks. The main risk seems to be more virulent complications once complications occur.<sup>33</sup>

### Opiates

The use of opiate pain medications has been shown to increase intracolonic pressure and slow intestinal transit, both risks for complications of diverticular disease. Case series have shown high percentages of patients with perforation taking opiate analgesics.<sup>30,34</sup>

### Smoking

A recent large case-control study showed that smokers had 3 times the risk of developing complications from diverticular disease than did nonsmokers.<sup>35</sup> However, a large cohort study involving more than 46,000 men in the United States did not find this same association.<sup>36</sup>

### Alcohol

A Danish cohort study showed the risk of diverticulitis was 3 times higher in female alcoholics than the general population and 2 times higher in male alcoholics. However, the data may be biased because of dietary and smoking habits associated with alcoholics.<sup>37</sup>

## Clinical Manifestations

### Clinical Patterns

Diverticular disease may be classified into diverticulosis (asymptomatic) and diverticulitis (symptomatic) (Table 18-1). Diverticulosis refers to the presence of diverticula with no related symptoms. This applies to the vast majority (80%–90%) of patients with diverticular disease. Diverticulitis can be subclassified into noninflammatory, acute (simple or

TABLE 18-1. The classification of diverticular disease

Diverticulosis	Asymptomatic
Diverticulitis	
Noninflammatory	Symptoms without inflammation
Acute	Symptoms with inflammation
Simple	Localized
Complicated	With perforation
Chronic	Persistent, low grade
Atypical	Symptoms without systemic signs
Recurring, persistent	Symptoms with systemic signs (may be intermittent)
Complex	With fistula, stricture, obstruction
Malignant	Severe, fibrosing

complicated), chronic (atypical or recurring/persistent), and complex disease. The term “malignant diverticulitis” has been used to describe a particularly severe form of fibrosing disease with phlegmonous inflammation extending below the peritoneal reflection, frequent fistula formation, obstruction, and high postoperative morbidity and mortality.<sup>38</sup> Many consider this form to be misdiagnosed Crohn’s disease.

### Noninflammatory Diverticular Disease

Noninflammatory diverticular disease describes those patients with symptoms of diverticulitis but without associated inflammation.<sup>39</sup> The diagnosis is made at the time of elective operation when no inflammatory changes are found in the specimen. This has been reported in 15%–35% of resections.<sup>39</sup> Some would consider this a missed diagnosis (IBS). However, if that were always the case, then one would expect a very low resolution of symptoms after resection. In fact, although a lack of inflammatory changes in the resected specimen has been associated with lesser degrees of symptom relief, the success rate is not zero.<sup>40–42</sup> One could conclude that resections are being performed for the right indication but the wrong pathology, delays in surgery may lead to complete resolution of previous inflammation, or noninflammatory diverticular disease is a real entity that sometimes requires surgical intervention. Careful follow-up on the long-term outcomes in these patients could go a long way in answering this question.

The term atypical has been applied to patients with chronic symptoms who never develop the necessary clinical and laboratory criteria to be judged as having acute diverticulitis. Up to 24% of these patients are found to lack inflammatory changes in the resected specimen thus fulfilling the criteria for noninflammatory diverticular disease. The remaining members of this group could be considered as having had acute diverticulitis based on histologic findings of inflammation. A high percentage of atypical patients (88%) become pain free at least on short-term (12 months) follow-up.<sup>42</sup>

### Acute Diverticulitis

Acute diverticulitis is heralded by signs and symptoms of acute inflammation and may be simple (limited to the colonic wall and adjacent tissues) or complicated (with perforation). Simple acute disease is usually accompanied by systemic signs of fever and leukocytosis whereas complicated acute disease may have the added signs of tachycardia and hypotension.

Complicated acute diverticulitis can be classified according to the extent of spread of the inflammatory process. A common classification for diverticulitis with perforation was first described by Hughes et al.<sup>43</sup> in 1963 and slightly revised and popularized by Hinchey et al.<sup>44</sup> in 1978. Stage I diverticulitis is a localized pericolic or mesenteric abscess, stage II is a confined pelvic abscess, stage III is generalized purulent peritonitis, and stage IV is generalized fecal peritonitis (Figure 18-1).

FIGURE 18-1. Diagrammatic representation of classification system for diverticular abscesses in which the cylinders represent the colon, the circles an abscess, and the arrows perforation. **A** Hinchey stage I: localized pericolic or mesenteric abscess. **B** Hinchey stage II: confined pelvic abscess. **C** Hinchey stage III: generalized purulent peritonitis resulting from perforation of an abscess. **D** Hinchey stage IV: generalized fecal peritonitis secondary to free colonic perforation.

### Chronic Diverticulitis

Patients with chronic diverticulitis remain symptomatic (left lower quadrant pain) despite standard treatment. It is considered atypical if systemic signs never develop. With systemic signs, chronic disease may manifest as recurring, intermittent episodes of acute disease or as persistent, symptomatic low-grade disease. This is frequently associated with the presence of a phlegmon. If resection is performed, there will be evidence of inflammatory changes within the specimen.

### Complex Diverticular Disease

Complex diverticulitis refers to disease in those patients who manifest sequelae of chronic inflammation including fistula, stricture, and obstruction. Each of these complications will be addressed later in this chapter.

### Natural History

The natural history of diverticular disease is one of increasing risk with increasing age and a diet low in fiber and high in red meat. The number and size of diverticula may increase with age; however, progression from one segment of bowel to another does not typically occur. The most common location for complications is in the sigmoid colon. It is unusual for complications to develop in the proximal colon after resection of the diseased sigmoid colon.

Most patients who develop a first episode of symptomatic diverticulitis have been asymptomatic until 1 month before presentation. Most will respond to bowel rest and antibiotics as an outpatient. It is difficult to reliably estimate how many outpatients will have recurrent episodes because outpatient data are generally not reflective of a primary care population. However, it has been reported that up to 10% of patients with a first episode who have responded to outpatient management will develop recurrent or persistent symptoms which will require hospitalization.<sup>45</sup>

Data are more readily available on recurrence for patients who were initially treated as inpatients. But our understanding of the natural history continues to evolve as antibiotics become more effective and inpatient status means increasingly severe disease. These changes make historical data regarding these issues of less value. In today's world, inpatients might be expected to be at a greater risk of recurrence. In fact, 10%–20% or more of these patients will develop a recurrence.<sup>45</sup> Some, but not all of these patients, will require a second hospitalization. The interval between acute events may be prolonged (median 5 years).<sup>46</sup> After a second hospital admission, up to 70% will continue with symptoms and more than half of those that require a third admission will do so within 1 year. The more complicated the attack, the higher the risk of recurrence.<sup>4,14,47–50</sup>

It has been estimated that up to 1% of all patients with diverticulosis will eventually require operative intervention.<sup>9</sup> However, with an increasing overall number of individuals affected with diverticulosis and better antibiotics for managing infections, this estimate may now be too high.

## Presenting Symptoms

Patients with acute diverticulitis typically complain of left lower quadrant abdominal pain. However, in a patient with a redundant sigmoid colon, an inflamed segment might present with pain in the right lower quadrant, thus complicating the differential diagnosis with appendicitis. The pain is generally constant in nature, not colicky. Radiation may occur to the back, ipsilateral flank, groin, and even down the leg. The pain may be preceded or accompanied by episodes of constipation or diarrhea. It often is progressive in nature if appropriate treatment is not instituted.

Historically, age was used as a primary determinant in distinguishing the most likely etiology of such pain. However, as increasing numbers of young people are found to have diverticular disease, the overlap between age groups has broadened and the need for diagnostic acumen has significantly sharpened. Classically, there is no prodromal epigastric pain with diverticulitis as one might expect to see with appendicitis.

Nausea and vomiting are unusual in the absence of obstruction, although secondary ileus with abdominal distention is common in more severe cases. Bleeding is not a typical associated finding, and, if present, suggests an alternative diagnosis (e.g., cancer). Symptoms of dysuria or urgency

suggest possible bladder involvement because of an adjacent inflammatory mass or a colovesical fistula. Pneumaturia, fecaluria, or passage of gas and stool through the vagina suggest a colovesical or colovaginal fistula, respectively. Fever is common and proportional to the amount of inflammatory response present. A high fever suggests a perforation with abscess or peritonitis.

Occasionally, diverticular disease will present in unusual ways. These include lower extremity (hip) joint infections of a chronic nature that culture positive for enteric bacteria. Other unusual presentations include female adnexal masses on the left; inflammation/necrosis of the perineum and genitalia including complex anal fistula and Fournier's gangrene; subcutaneous emphysema of the lower extremities, neck, and abdominal wall; isolated hepatic abscess caused by enteric organisms; brain abscess caused by enteric organisms and cutaneous lesions mimicking pyoderma gangrenosum.<sup>51</sup>

## Physical Findings

Patients presenting with acute diverticulitis will be tender to palpation in the left lower quadrant and left iliac region. There may be limited rigidity or localized guarding to deeper palpation. With resolution of the acute phase, palpation may reveal a mass in the left lower quadrant. A positive psoas sign and/or obturator sign may reflect retroperitoneal and/or pelvic involvement of the inflammatory process.

In the event of a gross perforation with development of fecal or purulent peritonitis, the area of tenderness will spread throughout the abdomen. Guarding will become prominent and the abdominal wall will become rigid.

## Complications

### Bleeding

Bleeding is not recognized as a feature of diverticulitis. Bleeding related to diverticulosis is discussed in Chapter 20 (Lower Gastrointestinal Hemorrhage).

### Perforation

Gross perforation can occur at two levels. If an abscess forms and then ruptures, purulent peritonitis is the result. If a large perforation occurs through the diverticulum directly into the peritoneum, fecal peritonitis is the result. Mixed fecal and purulent peritonitis may result from the rupture of an abscess which has an ongoing communication with the bowel lumen. Clinically, the presentation is that of either abrupt onset of abdominal pain for a free perforation or an abrupt exacerbation of progressive localized pain in the case of a ruptured abscess. A pneumoperitoneum is typically seen on abdominal films or computed tomographic (CT) scan. Rapid progression to diffuse abdominal pain and rigidity can be expected.

## Abscess

An abscess most often results from the mechanism described above. Small abscesses less than 1 cm in diameter will frequently resolve with antibiotic therapy. Larger abscesses may require drainage. CT-guided percutaneous drainage is the preferred approach when possible because it can convert the high risks of an urgent operation to a much safer elective operation.

## Fistula

The incidence of fistulization reported in the literature ranges from 5% to 33% depending largely on the type of referral center making the report.<sup>52</sup> Colovesical fistula is the most common fistula associated with diverticular disease and diverticular disease is the most common cause of colovesical fistula. Other relatively common fistulas associated with diverticular disease are colocutaneous, colovaginal, and coloenteric. Most patients who develop a colovaginal fistula have had a previous hysterectomy. Other fistulas have rarely been described and include colocolic, ureterocolic, colouterine, colosaphingeal, coloperineal, sigmoido-appendiceal, colovenous, and even fistulas to the thigh (a variant of a colocutaneous fistula).

The diagnosis of a diverticular fistula is generally clinical. Many fistulas will not be directly identifiable by imaging studies. Thus, excess efforts should not be undertaken to try to radiographically or otherwise demonstrate a fistula. Gas seen in the bladder on a CT scan in a patient who has not had their urethra or bladder instrumented is the most sensitive/common finding with a colovesical fistula. The primary aim of a diagnostic workup is not to see the fistula but to determine the etiology [diverticulitis, cancer, inflammatory bowel disease (IBD), etc.] so that appropriate therapy can be initiated.

## Stricture

The development of a phlegmon with repeated attacks of acute disease or long-term persistent disease may result in a stricture. Although a relatively uncommon complication, patients will present with constipation, abdominal pain, and bloating. It is necessary to rule out carcinoma as the true cause of the stricture. Colonoscopy is the first choice to help make this distinction; however, it is not uncommon for associated bowel angulation and fixation to prevent endoscopic visualization. Contrast studies may assist the evaluation in such instances but resection may be necessary to make a diagnosis.

## Obstruction

On rare occasions, complete obstruction may occur. If caused by diverticular disease, most patients will respond to initial medical management allowing an elective resection at a later date. Persistence of an obstruction may require a Hartmann's procedure or primary anastomosis with proximal diversion

for management. The successful use of colonic stents to relieve obstruction secondary to diverticulitis has been described.<sup>53,54</sup> In this setting, the stent is used as a bridge to surgery with later elective resection. However, the use of stents in benign disease is controversial. Some investigators have found a high incidence of complications leading to emergency surgery for removal of the stent and management of complications when a stent is used in this setting.<sup>55</sup>

## Ureteral Obstruction

The ureter is infrequently involved with diverticular disease. When involved, it is most frequently the left ureter. Rarely diverticular disease has been reported as fistulizing to the ureter. A stricture may occur but compression is more common. This can result from retroperitoneal fibrosis secondary to diverticular inflammation. Most often, this resolves with resolution of the underlying inflammatory process although rarely ureterolysis has been advised.<sup>56</sup>

## Phlegmon

A phlegmon represents an inflammatory mass. It may or may not be associated with a central abscess. A phlegmon can significantly complicate the technical aspects of resection. Many phlegmons will resolve with antibiotic therapy. If resection is planned because of recurrent episodes of disease, it is best to treat the acute phlegmon, to resolution if possible, before resection. On occasion, operation becomes necessary in the face of an acute phlegmon. This situation may be the source of some descriptions of "malignant" diverticulitis as earlier described.

## Saint's Triad

Saint's triad is a described association of diverticulosis, cholelithiasis, and hiatal hernia. Although it has been suggested that the triad occurs in 3%–6% of the general population,<sup>47</sup> it is of unknown clinical significance and likely represents the normal concomitant distribution of these common maladies.

## Diagnostic Tests

### Endoscopy

Endoscopy in the face of acute diverticulitis must be undertaken with extreme caution because of risk of gross perforation and decreased chance of success for complete colonic evaluation. It can provide important information before operation but will change acute management in less than 1% of cases.<sup>57</sup> Generally, in the absence of an urgent indication, colonoscopy should be delayed until resolution of the acute episode is complete.

In the case of elective colonoscopy, the unexpected finding of acute diverticulitis (manifested as erythema, edema, pus, or granulation tissue at a diverticula opening) is distinctly unusual, occurring in just 0.8% of patients. Treatment with antibiotic therapy for such findings is generally unnecessary because follow-up has shown that symptoms of diverticulitis do not develop after the colonoscopy.<sup>58</sup>

### Abdominal X-rays

When used, plain films of the abdomen should be done supine and upright/left lateral decubitus because the primary value is to rule out pneumoperitoneum or to assess for a possible obstruction. However, either of these two complications can also be assessed with CT scan, so in many centers, the plain abdominal film is rarely used.

### Contrast Studies

Barium or water-soluble contrast studies have proponents for their use but CT scan offers an examination of much broader scope in one evaluation making it the preferred imaging study in many centers. However, because of costs, some clinicians will use CT scan only if there is clinical suspicion of an abscess or other complicating feature for which an alternative to standard bowel rest and antibiotics might be applied. A water-soluble contrast study can evaluate the lumen of the bowel if there is concern about distal bowel obstruction. It may be an important part of the assessment for the possible use of a stent if malignant disease is suspected.

Contrast studies have been shown to identify fistulas, most often colovaginal or coloenteric. Some clinicians prefer the anatomic view of the entire colon provided by BE because it distinguishes the extent of diverticulosis throughout the colon and can assess for stricture and colonic length. In most centers, contrast studies, if used at all, are used in a limited manner to evaluate the anatomy of the colon before an operation.

### CT Scan

An important advantage to a CT scan is the ability to document diverticulitis, even if uncomplicated, when the diagnosis is in doubt. Studies using CT scan as the initial diagnostic test have shown that up to 5% of patients admitted for acute diverticulitis have been hospitalized for the incorrect clinical diagnosis.<sup>59</sup>

It has been demonstrated that CT can recognize and stratify patients according to the severity of their disease. It can distinguish uncomplicated disease with predictably short length of stay from complicated disease as defined by abscess, fistula, peritonitis, or obstruction and a predictably long length of stay. It also provides information about extracolonic pathology and anatomic variation useful for surgical planning. Early CT-guided drainage of abscesses allows downstaging of complicated diverticulitis to convert an otherwise urgent or emergent operation with attendant increases in

morbidity and mortality to the safety of an elective operation.<sup>59</sup> In some selected cases, there may be no need for elective resection.

### Ultrasonography

Transrectal ultrasound (TRUS) has been used in the evaluation of diverticular disease in conjunction with transabdominal ultrasound (TAUS). Combining TRUS with TAUS reveals complications not visualized on TAUS alone including inflamed diverticula. TRUS may be an accurate adjunct for confirming clinically suspected acute colonic diverticulitis when the rectosigmoid or perirectal tissues are affected as one might see in the case of malignant diverticulitis. It helps avoid false-negative results and defines the severity of disease in the lower sigmoid colon better than TAUS alone. TRUS may prove to be a useful adjunct in selected cases of rectosigmoid diverticulitis and perirectal involvement by diverticular disease in centers where CT scanning is not readily available.<sup>60</sup>

### Magnetic Resonance Imaging

Preliminary studies using magnetic resonance imaging colonography have shown a high correlation with CT findings in patients with diverticular disease without exposure to ionizing radiation. Three-dimensional rendered models and virtual colonoscopy can be performed only in the nonacute setting. These comprehensive three-dimensional models, rather than BE, may have a role in presurgical planning with concurrent assessment of the residual colon.<sup>61</sup>

### Differential Diagnosis

The differential diagnosis for diverticular disease includes IBS, carcinoma, IBD, appendicitis, bowel obstruction, ischemic colitis, gynecologic disease, and urologic disease. Of these, IBS is perhaps the most difficult to differentiate in many patients.

### Irritable Bowel Syndrome

In many ways, the distinction between chronic diverticulitis and noninflammatory diverticular disease relies on the pathologist whereas the distinction between noninflammatory diverticular disease and IBS relies on the diagnostic acumen of the clinician and the long-term outcomes of resection. Because of the prevalence of diverticular disease, many patients with IBS will have concomitant diverticular disease. However, because diverticular disease is usually asymptomatic, the presence of diverticulosis in these patients will often not be the source of their symptoms but rather just a source of confusion in the differential. It is helpful to be familiar with the Rome II criteria (Table 18-2) for the diagnosis of IBS in order to sort through this differential.

TABLE 18-2. The Rome II criteria for IBS

IBS can be diagnosed based on at least 12 weeks (which need not be consecutive) in the preceding 12 months, of *abdominal discomfort or pain that has two of three of these features*:

1. Relieved with defecation; and/or
2. Onset associated with a change in frequency of stool; and/or
3. Onset associated with a change in form (appearance) of stool.

Symptoms that cumulatively support the diagnosis of IBS:

1. Abnormal stool frequency (>3 stools per day or <3 stools per week)
2. Abnormal stool form (lumpy/hard or loose/watery stool)
3. Abnormal stool passage (straining, urgency, or feeling of incomplete evacuation);
4. Passage of mucus
5. Bloating or feeling of abdominal distension

Red Flag symptoms that are *not* typical of IBS:

1. Pain that often awakens/interferes with sleep
2. Diarrhea that often awakens/interferes with sleep
3. Blood in stool (visible or occult)
4. Weight loss
5. Fever
6. Abnormal physical examination

## Colon Neoplasia

Distinguishing diverticular disease from cancer can be difficult. Imaging techniques can provide significant diagnostic assistance, but occasionally a resection is necessary to be certain. Several features of BE studies support a diagnosis of diverticular disease including preservation of the mucosa, long strictures, and the presence of diverticula. A BE is preferred by some clinicians to assess the extent of the diverticulosis and evaluate the length of the colon before resection. Although colonoscopy can frequently resolve this issue, it is not always successful because of acute angulations or narrowing of the lumen. CT evaluates the entire abdomen, can identify concurrent disease, and may give clues as to the underlying colonic pathology.

The increasing incidence of colonic neoplasia with increasing age parallels that of diverticular disease. Polyps and cancer must be considered whenever a diagnostic workup for diverticular disease is begun. Although unusual, cases of adenocarcinoma arising within a diverticulum have been reported.<sup>62</sup> Because colonic diverticula are thin walled, containing only mucosa and serosa, early penetration by cancer is likely, leading to advanced stages with small primary lesions.

Although historically diverticular disease is not believed to have an etiologic link to colon cancer, a causal association has been identified between left-sided colon cancer and diverticulitis. In a review of 7159 patients from the Swedish Cancer Registry, patients with diverticulitis had a long-term increased risk of left-sided colon cancer compared with patients with asymptomatic diverticulosis (odds ratio = 4.2).<sup>63–65</sup>

## Inflammatory Bowel Disease

Crohn's disease can be a particularly difficult differential to make. Both Crohn's and diverticular disease may present with

similar complications including fistulas, phlegmons, and abscesses. Rectal involvement, anal disease, extracolonic signs, and bleeding suggest Crohn's. Recurrent "diverticulitis" requiring a repeat resection should always raise the question of possible Crohn's disease.<sup>66</sup> Ulcerative colitis is rarely a significant differential problem because bleeding is not a prominent symptom of diverticulitis and a simple endoscopic examination showing inflammation within the rectum should suffice to rule out diverticular disease. In the unusual circumstance in which diverticulitis and ulcerative colitis both exist, treatment should be targeted to both entities simultaneously.

## Other Colitides, Appendicitis, Gynecologic and Urologic Disease

Endoscopy can be an important adjunct in differentiating IBD, ischemic colitis, and other forms of colitis although caution must be used in the acute setting. A major advantage of the CT scan is the ability to evaluate for many of the other potential differentials including appendicitis, gynecologic and urologic disease.

## Associated Conditions

There is such a high incidence of diverticulosis among patients with autosomal dominant polycystic kidney disease that some consider it an extrarenal manifestation.<sup>67</sup> These patients undergoing renal transplantation are at particularly high risk for devastating infectious complications because of their immunocompromised state. Many transplant centers recommend prophylactic sigmoid resection in those polycystic kidney patients scheduled for transplantation with a documented history of diverticulitis.<sup>67–70</sup>

## Uncommon Presentations

### Diverticulitis in Young Patients

Young patients with diverticular disease are usually male,<sup>45,71</sup> obese,<sup>72,73</sup> and have a higher incidence of right-sided diverticulitis.<sup>74,75</sup> Young patients undergoing operation are frequently misdiagnosed preoperatively<sup>72,73,76</sup> with appendicitis being the most common misdiagnosis.<sup>76</sup> Historically, diverticular disease in patients younger than 50 years of age has been described as more virulent and with more serious complications.<sup>45,72,77–79</sup> Many recommend that patients younger than age 50 have an elective resection after a single episode of acute disease. Recent evidence is mixed.

In some series, young people present with more severe disease at first presentation<sup>74,77–79</sup> but less frequently have a resection at that time. Reasons for this include missed diagnoses and rapid response to therapy. With fewer resections for more complex disease, a higher percentage of young patients return with delayed complications and the appearance of

more aggressive disease. Elective resection after the first episode of diverticulitis is thus advised.<sup>77-79</sup>

Others have recommended elective resections at a younger age to avoid the increased morbidity and mortality associated with urgent or emergent surgery in the elderly (0% versus 34.9%).<sup>80</sup> Some recommendations for elective resection in the young patient are based on cost savings related to definitive surgical management versus the higher costs of ongoing medical treatment for recurring disease.<sup>81</sup> These types of recommendations assume a high risk of recurrent disease.

There is evidence that diverticular disease in young patients is changing. It is not as rare as it used to be<sup>72,82,83</sup> and continues to become more common.<sup>83</sup> Recent evidence suggests there is not increased risk of complications from diverticular disease in the young.<sup>73,75,76,82-86</sup> Based on these findings, resection after a single episode of diverticulitis is not recommended.

Data are difficult to interpret because the presentations of diverticular disease are so varied and most studies are small and retrospective with risks of unrecognized selection bias. However, it does seem that diverticular disease is more common in young patients than generally recognized. Obesity may be a risk factor, probably related to diet. Diets high in fiber are less likely to result in obesity as well as diverticular disease.

The issue of male predominance could be a result of missed diagnoses in females. Young females frequently have a gynecologic focus of attention placed on causes of abdominal pain other than diverticular disease and accentuated by the general poor recognition of the prevalence of diverticular disease in younger patients.

Current recommendations for resection are based on the predicted risk of developing a serious complication that would lead to emergency surgery with increased morbidity and mortality and frequent use of colostomy in this setting. To improve management, we must become better at predicting who is at risk for recurrent disease. Age alone does not seem to be a reliable factor. The use of CT to identify "severe" or "complex" diverticular disease seems most promising.

The risk of complications within 5 years of a first attack of diverticulitis exceeds 50% if CT shows severe diverticulitis at the initial episode.<sup>86</sup> Mild findings on CT can be defined as localized thickening of colonic wall and inflammation of pericolic fat. Severe findings are defined as abscess and/or extraluminal air and/or extraluminal contrast. In a recent study, the incidence of remote complications was the highest (54% at 5 years) for young patients with severe diverticulitis on CT and the lowest (19% at 5 years) for older patients with mild disease. Young age and severe diverticulitis taken separately were both statistically significant factors of poor outcome ( $P = .007$  and  $.003$ , respectively), although age was no longer significant after stratification for disease severity on CT ( $P = .07$ ).<sup>86</sup> Other studies have shown similar risks associated with complex disease on CT.<sup>85,87</sup>

## Rectal Diverticula

Rectal diverticula are rare. They are typically true diverticula because they include the muscular layer of the rectum in their wall, and are frequently solitary. Inflammation can generally be managed with antibiotics.

## Cecal and Right-sided Diverticulitis

Right-sided diverticular disease is much more common in the Far East than in the West, representing 35%–84% of diverticula in that region. Patients present an average of 20 years younger than with sigmoid diverticulitis. Classically, cecal diverticula are described as true diverticula containing all layers of the bowel wall. However, most cecal diverticula actually are false and frequently not solitary.

It is estimated that 13% of patients with cecal diverticulosis develop diverticular inflammation. Cecal diverticulitis can be graded according to the extent of the inflammation. Grade I disease refers to an easily recognizable projecting inflamed cecal diverticulum. Grade II is an inflamed cecal mass. Grade III encompasses a localized abscess or fistula. Grade IV is a free perforation or ruptured abscess with diffuse peritonitis. Cecal diverticulitis is correctly diagnosed preoperatively only 5% of the time. Appendicitis is the preoperative diagnosis in more than two-thirds of cases.<sup>88</sup> Intraoperative diagnosis is relatively easy with Grade I and to a lesser extent with Grade II disease. Most episodes of cecal diverticulitis presenting with Grade III or Grade IV disease are misdiagnosed intraoperatively as perforated carcinoma.

If a correct diagnosis of uncomplicated cecal diverticulitis can be made preoperatively, then antibiotics and treatment similar to left-sided disease is appropriate. This is rare, however. When discovered intraoperatively, the options for treatment include: 1) appendectomy, nonresection of the diverticulum and postoperative antibiotic therapy; or 2) appendectomy with diverticulectomy for Grade I and identifiable Grade II disease. For not readily identifiable Grade II, Grade III, and Grade IV disease, failed treatment, or when cancer is a consideration, right hemicolectomy is the procedure of choice. Appendectomy should always accompany nonresection or diverticulectomy whenever the base of the appendix is not inflamed. This is to avoid confusion at a later date.<sup>89,90</sup>

## Giant Colonic Diverticulum

Giant diverticula of the colon are rare entities associated with sigmoid diverticular disease. They are generally pseudo-diverticula with inflammatory rather than colonic mucosal walls. They usually arise off of the antimesenteric border of the sigmoid colon. The mechanism of formation is unknown but they have been reported as large as 30–40 cm.<sup>91,92</sup> Twelve percent occur in patients younger than age 50.

Diagnosis is by plain film of the abdomen which shows a large, solitary, gas-filled cavity. Communication with the

colon can be demonstrated with contrast enema. The differential includes congenital duplication of the colon, cholecystenteric fistula, colonic volvulus, emphysematous cholecystitis, infected pancreatic pseudocyst, pneumatosis cystoides intestinalis, Meckel's diverticulum, intraabdominal abscess, giant duodenal diverticulum, dilated intestinal loop, gastric dilatation, tuboovarian abscess, and mesenteric cyst.<sup>93</sup>

Most patients will present with vague symptoms of abdominal discomfort or pain and a soft, mobile abdominal mass. A few patients will present with one of the known complications which include perforation, sepsis, intestinal obstruction, or volvulus. The natural history is slow enlargement over time. The treatment of choice is resection of the diverticulum and adjacent colon at time of diagnosis if the patient is symptomatic.

### Diverticular Disease of the Transverse Colon

This is an exceedingly rare condition. Clinical presentation most often mimics appendicitis, cholecystitis, or, less frequently, ischemic or Crohn's colitis. It is reported to occur in a younger age group than sigmoid disease and is more common in females. Treatment parallels that of sigmoid diverticulitis; however, resection is usually performed because a preoperative diagnosis is more difficult and a carcinoma frequently cannot be ruled out.

## Treatment

### Medical and Dietary Management

The primary management of asymptomatic diverticular disease is diet. The goal of dietary manipulation is to increase the bulkiness of stool thus increasing lumen size, decreasing transit time, and decreasing intraluminal pressures. This decreases segmentation which has been described as a significant factor in the development of diverticular disease. The ideal amount of fiber is not known; however, the recommended daily amount is 20–30 g. In general, fiber can be obtained by consuming foods high in fiber or through supplementation with one or more of a large variety of bulk laxatives. Epidemiologic evidence strongly suggests a diet high in fiber can reduce the risk of developing diverticulosis. What is less clear is whether a high fiber diet can prevent diverticulitis and its complications in patients who already have diverticulosis. Recent evidence is building in support of this concept.<sup>94–97</sup>

### Acute Diverticulitis

In the absence of systemic signs and symptoms (high fever, marked leukocytosis, tachycardia, and hypotension), most patients experiencing symptoms of diverticulitis will respond to a regimen of bowel rest and antibiotics as outpatients. Diet

is usually restricted to low residue or clear liquids during the acute illness but with resolution of the acute symptoms, a high fiber diet should be instituted. There is no need to restrict the ingestion of seeds or hulls because there are no data to substantiate this practice.

Appropriate antibiotics should be instituted to include coverage of Gram-negative and anaerobic bacteria. The most predominant organisms cultured from acute diverticular abscess and peritonitis include the aerobic and facultative bacteria *Escherichia coli* and *Streptococcus* spp. The most frequently isolated anaerobes include *Bacteroides* spp. (*B. fragilis* group), *Peptostreptococcus*, *Clostridium*, and *Fusobacterium* spp.<sup>98</sup>

The use of anticholinergics as adjunctive therapy is based on theoretically reducing pain related to spasm and hypermotility in the sigmoid colon. Efficacy has not been proven.

Signs of more advanced disease including marked leukocytosis, high fever, tachycardia, or hypotension as well as a physical examination demonstrating more advanced intraabdominal pathology, dictate a need for inpatient management. Patients admitted for inpatient care will usually undergo a baseline CT scan which can confirm the diagnosis, rule out potential alternative diagnoses, and evaluate for complicated disease that would require a change in initial management.<sup>59</sup>

Antibiotics should be administered via an intravenous route. Generally the patient will be placed NPO (nothing by mouth) until there is evidence that clinical progress is being made and surgery will not be necessary. The diet is then gradually advanced from clear liquids and then to low residue for a variable period of time before reinstating a high fiber diet. Symptoms should improve within 24–72 hours. Failure to improve should prompt further diagnostic workup including repeat CT scan and reevaluation of the need for alternative interventions such as operation or abscess drainage. Worsening of the patient's clinical condition, particularly progression to generalized peritonitis, should prompt urgent operative management.

### Surgical Management

The surgical management of diverticular disease is replete with varied options that allow for customizing an operation to meet the needs of the individual patient. A thorough knowledge of these options and the indications for each are necessary for the surgeon managing these cases. The goal should always be to manage a complex patient in a way that will maximize the opportunity to avoid emergency surgery in favor of an elective resection.

Surgical options include primary resection with anastomosis with or without proximal diversion, resection with proximal colostomy, and oversewing of the rectal remnant (Hartmann's procedure) or mucous fistula (Mikulicz operation), simple diversion with drainage of the affected segment, diversion with oversewing of the perforation site, and, rarely, subtotal colectomy. Adjunctive measures include on-table lavage and the option of a laparoscopic approach.

The historical discussion of these options would include the use of a three-stage approach with diversion and drainage followed by a second operation for resection and a third operation for reestablishment of intestinal continuity. A modification of this approach includes oversewing of a visible site of perforation with an omental patch as a part of the initial operation.<sup>99</sup> Alternatives include a two-stage approach consisting of a Hartmann's or Mikulicz procedure followed by a second operation for reestablishment of intestinal continuity and resection with primary anastomosis, with or without proximal diversion, as a single operation. For the most part, today's discussions revolve around the relative merits of a one-stage versus a two-stage approach in acute cases requiring urgent or emergent surgery.<sup>100-102</sup> The three-stage approach is unlikely to be used except in the most extreme cases of medical instability.<sup>103,104</sup>

The following sections will discuss the applications of these approaches to the various presentations of diverticular disease including both chronic and acute forms. Special consideration will be given to the management of intraabdominal abscess.

### *Intraabdominal Abscess*

For a patient found to have an abscess, there is much clinical evidence supporting the advantages of percutaneous drainage and the conversion of an emergent operation with its attendant increased morbidity and mortality to the relative safety of elective operation.<sup>59,105</sup> An abscess not responding to medical management should be drained percutaneously or transrectally as appropriate to its location (Figure 18-2).

If drainage cannot be accomplished nonoperatively or if drainage is performed but fails to resolve systemic signs and symptoms, operation is indicated. Generally, the clinical scenario in this situation would be that of an advanced Hinchey class II. Although it is possible that intraoperative findings would support a resection with primary anastomosis with or without proximal diversion, it is more likely that a Hartmann's resection will be required.

### *Indications for Surgery for Acute Disease*

The indications for surgery of acute disease include: 1) failure to respond to nonoperative management including a persistent phlegmon, failure of percutaneous or transrectal drainage of an abscess or increasing fever, leukocytosis, tachycardia, hypotension, signs of sepsis, or a worsening physical examination; 2) free perforation with peritonitis; and 3) obstruction that does not resolve with conservative therapy. Perforation without peritonitis may not require operation (Figure 18-3).

### *Surgical Procedures*

For acute disease, the choice of operation is highly dependent on the degree of inflammatory response encountered at the time of operation. Because most acute disease can be managed nonoperatively (including the percutaneous drainage of most abscesses), the fact that an operation has

A

become necessary suggests rather advanced pathology and the need to be conservative. *In general*, most Hinchey class I and some class II disease can be managed with a one-stage procedure (resection and anastomosis) if the patient is stable, the extent of contamination is limited, and adequate bowel

FIGURE 18-3. This CT scan shows a small pneumoperitoneum anteriorly. There was not physical evidence of peritonitis. This patient was managed nonoperatively with intravenous antibiotics.

preparation is possible,<sup>100,106</sup> recognizing, however, that the necessity of mechanical bowel preparation in elective colon resections has been recently questioned.<sup>107</sup> Proximal diversion may be appropriate. Most cases of Hinchey class III and IV disease will require a two-stage approach. Some recent evidence suggests a possible role for resection with primary anastomosis and proximal diversion in highly selected cases without gross fecal contamination.<sup>100,103</sup>

A major disadvantage of a two-stage procedure is that 35%–45% of patients never have their colostomy closed. Women are more likely than men to not have closure.<sup>108,109</sup> However, in patients with preexisting incontinence, a Hartman's pouch should be the procedure of choice. For patients who do not undergo closure of their stoma, it is critical that their rectal stump undergo scheduled surveillance for neoplasia as the remaining rectum has the same risk for neoplasia as the remainder of the colon.<sup>110</sup>

### Complications

Predictors of complications from resection for diverticular disease include advanced age (older than 70–75 years), two or more comorbid conditions, obstipation at initial examination, the use of steroids, sepsis, obesity,<sup>103,111,112</sup> and emergent rather than elective resection. Complications of resection

include anastomotic leak and hemorrhage. The prevalence of leak from a low intraperitoneal anastomosis is generally considered to be between 2% and 5%.<sup>113</sup> Such leaks can lead to localized or systemic sepsis without an abscess, an abscess with or without sepsis, peritonitis, and stricture. The diagnosis is dependent on a high index of suspicion on the part of the surgeon and quick response to any unusual signs of sepsis. Fever, vague abdominal pain, diarrhea, obstructive symptoms, oliguria, prolonged postoperative ileus, and sepsis all should raise the concern of a leak. The diagnosis is usually confirmed by water-soluble contrast enema and/or CT scan with intravenous, oral, and rectal contrast.

A contained leak without an abscess can usually be managed with intravenous antibiotics and response assessed. Free extravasation of contrast failure to respond to treatment within 24–48 hours or initial severe sepsis or peritonitis requires exploration with resection of the anastomosis and proximal diversion. Repair of the anastomosis with proximal diversion is usually unsatisfactory because of the high risk for recurrent leak in this inflammatory setting. An exception would be a “pin-hole” leak with limited inflammatory response which may be managed with repair, colonic lavage, and proximal diversion.

A leak that results in an abscess can generally be managed with percutaneous or transrectal drainage. Again, failure to respond will require laparotomy, take down of the anastomosis, and proximal diversion.

A colocolic fistula related to a diverticular resection will usually respond to nonoperative measures. Provided that there is no distal obstruction or foreign body and that Crohn's was not the cause of the original symptoms, spontaneous closure should be anticipated. Important steps to take to facilitate this closure include drainage of any undrained abscess, attention to nutritional needs, and appropriate wound care.

Stricture is an unusual complication related to diverticular resections unless the underlying process is Crohn's disease. In the rare instance when stricture does occur, the likely etiologies include ischemia or localized sepsis caused by confined leak. Such strictures can usually be managed by dilatation with a hydrostatic balloon or rigid proctoscopy but occasionally will require a formal restapling or resection.

Ureteral injuries are reported to occur in 1%–10% of abdominal surgeries.<sup>114</sup> Early identification of any injury is the key to preventing significant morbidity. Although ureteral stents have not been shown to decrease the rate of injury, they do improve intraoperative identification of the ureters and the early identification of any ureteral injury.<sup>115</sup> The decision to place ureteral stents before operation should be a function of clinical suspicion and the extent of retroperitoneal inflammation on CT scan.

General postoperative complications related to colon and rectal surgery and specifics related to the recognition and management of the specific complications mentioned above are discussed more thoroughly in Chapter 10, Postoperative Complications.

### *Indications for Surgery for Recurring and Chronic Disease*

Patients with multiple, recurrent episodes of acute diverticulitis documented by CT scan should be considered for resection. The practice parameters of the American Society of Colon and Rectal Surgeons states that elective resection should be considered after one or two well-documented attacks of diverticulitis depending on the severity of the attack and age and medical fitness of the patient. Patients with complicated diverticulitis should be considered for resection after one attack.<sup>116</sup> The ultimate goal is to perform an operation electively rather than as an emergency. This requires correctly predicting those patients that are most likely to end up with a serious complication as a result of their disease. One suggestion has been to resect after one episode of diverticulitis in young patients (generally younger than 40–50 years).

It is now doubtful that age itself should be a primary consideration in the decision to operate. The literature is mixed with proponents of a more aggressive approach to the disease in young patients<sup>45,72,74,77–79,81</sup> and those that believe age alone does not significantly increase risk.<sup>71,73,75,76,80,82–84</sup> Other factors apply, most of which are not age related.

CT evidence of complicated or “severe” disease has been one of those criteria that have shown some promise in predicting risk. Abscess, extraluminal air, and extraluminal contrast have been associated with an increased risk of poor outcome from medical management regardless of age.<sup>85,87</sup>

Another approach is to identify specific groups of patients (other than age) who are at increased risk. Immunocompromised patients are one group that is at particular risk for poor outcome.<sup>33</sup> The risk is attributable to a higher incidence of free perforation and more severe inflammatory complications when perforation does occur. Patients with autosomal dominant polycystic kidney disease undergoing renal transplant are a very high risk group.<sup>67–70</sup> Prophylactic resection in such patients with a history of any diverticulitis is recommended.

Recent data have suggested that the recommendation for resection after two episodes of diverticulitis treated as an inpatient may result in too many patients undergoing resection thereby increasing the total cost of health care. Performing resection after the third episode of diverticulitis results in significant cost savings.<sup>117</sup> Performing resection after four documented episodes rather than after two results in fewer deaths, fewer colostomies, and additional cost savings of more than \$5000 per patient in those younger than 50.<sup>118</sup> Others question the role of elective resection at all because of the high success rate of nonoperative management and the large percentage of patients presenting with urgent surgical disease that have no previous history of diverticulitis.<sup>119,120</sup> This mirrors the experience of one of the authors (S.M.G.) in which it has *not* been found necessary to resect *all* patients with complicated disease, even after percutaneous drainage of diverticular abscesses.

### *Surgical Procedures*

Patients undergoing resection for chronic disease will almost always be candidates for single-stage resection with primary anastomosis. Additionally, patients returning for closure of a colostomy after initial diversion and drainage, diversion with oversew of perforation, or diversion with resection via either Hartmann’s or a Mikulicz procedure, can all typically be managed with one additional operation only.

### *Complications*

The complications related to operation for chronic disease in many ways parallel those already discussed for acute disease. In addition, a noted complication of operating on chronic disease is failure to achieve symptomatic relief. This usually results from a missed diagnosis of Crohn’s disease or IBS. Any “recurrence” of symptoms after resection for chronic diverticulitis should raise the suspicion of this possibility. The presence of functional bowel symptoms preoperatively in this group of patients has been associated with poorer functional results postoperatively.<sup>121</sup>

### *Management of Fistula*

The general principle of management is resection of the colon, usually with primary anastomosis. Treatment of the other involved organ/site varies. For the bladder, simple drainage of the bladder with an indwelling urethral catheter for 5–7 days is advised. No treatment of the vagina is required in most circumstances. Cutaneous fistulas will usually close by delay or secondary intention. Enteric fistulas require repair or resection of the involved small bowel or colon. Ureteral drainage for fistulas to the ureter, observation or hysterectomy for uterine fistulas, salpingo-oophorectomy for fistulas to the tubes, and appendectomy would be the most common treatments for uncomplicated fistulas of the other less common varieties. If there is any question of cancer, an en bloc resection of a portion of the involved organ must accompany the resection.

Occasionally nonoperative management is appropriate when symptoms are minor or when the patient is at otherwise too great a risk for other health reasons. The use of long-term suppressive antibiotic therapy in selected patients with colovesical fistula has been shown to eliminate symptoms and prevent complications related to the fistula until death from other causes.<sup>122</sup>

### *Techniques for Appropriate Resection*

The practice parameters of the American Society of Colon and Rectal Surgeons set out several general recommendations regarding resection of diverticular disease. For elective resections, all thickened, diseased colon, but not necessarily the entire proximal diverticula-bearing colon, should be removed. It may be acceptable to retain proximal diverticular colon as long as the remaining bowel is not hypertrophied. All of the

sigmoid colon should be removed. When anastomosis is elected, it should be made to normal rectum and must be free of tension and well vascularized.<sup>123</sup> The single most important predictor of recurrence after sigmoid resection for uncomplicated diverticulitis is an anastomosis to the distal sigmoid colon rather than the rectum.<sup>124</sup>

### Laparoscopic Surgery

The role of laparoscopy in the management of diverticular disease is evolving. Recent data suggest decreased overall costs associated with laparoscopic resections when compared with open resections.<sup>125,126</sup> Patients who are converted from laparoscopic to open procedures are a concern with regard to added costs but conversion rates are less than 20% in experienced centers, and are somewhat<sup>125-131</sup> predictable<sup>128,131</sup> and thus probably avoidable in many instances.<sup>128</sup> Higher conversion rates are associated with more complex disease.<sup>132</sup> Recurrence rates match those for open procedures,<sup>129,131,132</sup> and length of stay is shorter<sup>125,126</sup> and complications fewer.<sup>126</sup> As data continue to accumulate, it seems that laparoscopic surgery will have a significant role in the management of diverticular disease.

## Appendix: Practice Parameters for the Treatment of Sigmoid Diverticulitis

Prepared by The Standards Task Force, The American Society of Colon and Rectal Surgeons.

The initial evaluation of a new patient with suspected acute diverticulitis should include a problem-specific history and physical examination; a complete blood count, urinalysis, and plain abdominal radiographs may be useful in selected clinical scenarios. Computerized tomography scan of the abdomen and pelvis is usually the most appropriate imaging modality in the assessment of suspected diverticulitis. Contrast enema x-ray, cystography, ultrasound, and endoscopy are sometimes useful in the initial evaluation of a patient with suspected acute diverticulitis.

Nonoperative treatment typically includes dietary modification and oral or intravenous antibiotics. Radiologically guided percutaneous drainage is usually the most appropriate treatment for patients with a large diverticular abscess.

After resolution of an initial episode of acute diverticulitis, the colon should be adequately evaluated to confirm the diagnosis. Colonoscopy or contrast enema x-ray (probably with flexible sigmoidoscopy) is appropriate to exclude other diagnoses, primarily cancer, ischemia, and inflammatory bowel disease.

Urgent sigmoid colectomy is required for patients with diffuse peritonitis or for those who fail nonoperative management of acute diverticulitis. The decision to recommend elective sigmoid colectomy after recovery from acute diverti-

culitis should be made on a case-by-case basis. Elective colon resection should typically be advised if an episode of complicated diverticulitis is treated nonoperatively. The resection should be carried proximally to compliant bowel and extend distally to the upper rectum. When a colectomy for diverticular disease is performed, a laparoscopic approach is appropriate in selected patients.

## Colonic Volvulus

Michael D. Hellinger and Randolph M. Steinhagen

### Introduction/Historical Perspective

Volvulus of the bowel refers to a twisting or torsion of the intestine about its mesentery. The term volvulus, which may involve any segment of the intestinal tract from stomach to rectum, is a Latin word for twisted used by the Romans to signify this condition.<sup>1</sup> Volvulus of the colon usually occurs in the sigmoid or cecum, but may involve any segment of colon. In addition, synchronous volvulus of the sigmoid and cecum,<sup>2</sup> or sigmoid and ileum may occur.<sup>3</sup> In the United States, volvulus represents a rare cause of intestinal obstruction, encompassing less than 5% of large bowel obstructions. However, worldwide it is a much more common form of large bowel obstruction, representing more than 50% of the cases in some countries.<sup>4-6</sup>

The first record of colonic volvulus is found in the Ebers Papyrus from ancient Egypt. This record stated that either volvulus would spontaneously reduce or the segment of bowel would “rot in his belly.” The writings further document that if this condition did not resolve, the patient should be prepared for remedies to induce detorsion. As early as 1500 BC, therefore, it was recognized that detorsion was crucial for resolution of this condition. Even in ancient times, a high fiber diet was believed to be contributory to the development of volvulus. At that time, treatment was directed at symptoms and relief of the obstruction. External manipulation combined with purgatives was the treatment of the times. Hippocrates advocated use of a 10-digit long suppository and air blown into the anus with a metal worker’s bellows. This is perhaps the earliest predecessor to today’s sigmoidoscopic decompression.<sup>1,7</sup>

During subsequent years, reports concerning colonic volvulus were infrequent. It was not until the 19th century, when investigators began attempting to determine causes of disease, that this entity was discussed further. Perhaps the fact that volvulus was not recognized as a cause of colonic obstruction was accounted for by the rarity of the diagnosis before the 1800s. In 1872, Crise reported 12 cases, and in 1884 Treves reported 34 cases of colonic volvulus. In 1894, Obalinski recognized regional variations in frequency of volvulus.<sup>1,7,8</sup>

Throughout most of the 19th century, management was nonoperative. Operative intervention was reserved for life-threatening situations. High mortality rates for intestinal operations in the face of obstruction were the reasons cited in avoiding surgery. With advances in anesthesia and antisepsis, surgical procedures were developed. In 1883, Atherton performed the first successful operative detorsion of a sigmoid volvulus in the United States. The next year, Treves recommended colectomy for volvulus complicated by gangrene. By 1889, in fact, all of the surgical options for volvulus, including detorsion, -pexy, and resection with or without stoma, had been described.<sup>1,7</sup>

Early in the 20th century, with improvements in early diagnosis and rapid therapy, mortality rates began to decrease and surgical therapy became the mainstay. Mortality rates decreased from 30%–60% to under 20%. Mortality for gangrenous bowel remained high (30%–40%), reflecting a delay in diagnosis and treatment. Moynihan’s statement in 1905 that a mortality of greater than 10% is the mortality of delay had been confirmed in many series.<sup>1,7</sup> Until the mid-20th century, immediate surgical intervention was the standard of care.

In 1947, Bruusgaard, from Norway, challenged the routine surgical approach, and reported a success rate of 86% for nonoperative reduction of sigmoid volvulus with proctoscopic decompression and placement of a rectal tube.<sup>9</sup> This paved the way for today’s therapeutic algorithms in the management of colonic and specifically sigmoid volvulus.<sup>1,7</sup> Finally, with widespread use of flexible endoscopy, many authors have reported successful detorsion and decompression of all forms of colonic volvulus using the colonoscope or flexible sigmoidoscope.<sup>10-15</sup> Because of high recurrence rates, these endoscopic methods are currently recommended as definitive treatment only for very high-risk individuals who are too ill to undergo surgery, and as a temporizing measure until eventual surgery under more controlled conditions for all other patients.<sup>1,7,9,14-16</sup>

The differential diagnosis of colonic volvulus encompasses any cause of colonic distention. This includes all of the mechanical as well as the nonobstructive causes. Mechanical causes include colonic and extracolonic neoplasms, as well as

benign entities such as diverticulitis and inflammatory bowel disease. Nonobstructive causes include colonic pseudo-obstruction (Ogilvie's syndrome), and various intraabdominal processes that may result in an intestinal paralysis. In addition, Hirschsprung's disease must also be considered.<sup>5,6,17</sup>

## Cecal Volvulus

### Incidence and Epidemiology

Worldwide, cecal volvulus accounts for 40%–60% of all colonic volvuli. Originally described in 1837 by Rokitansky, it remains, however, an uncommon cause of intestinal obstruction. The worldwide incidence is estimated at 2.8–7.1 per million people per year. Most reported cases occur in younger individuals with a predilection for females.<sup>18–20</sup> In a review of the published literature between 1959 and 1989, Rabinovici et al.<sup>19</sup> found a mean age of 53 years and a female to male ratio of 1.4:1.

### Pathogenesis/Etiology

True cecal volvulus is actually an axial torsion of the cecum, terminal ileum, and ascending colon about its mesentery (Figure 19-1A). A variant, cecal bascule (Figure 19-1B), occurs when the cecum folds anteriorly over the ascending colon without an axial twist. This represents approximately 10% of cases of cecal volvulus. Review of patient characteristics indicates that there is a high rate of prior abdominal operations in patients who subsequently develop cecal volvulus, and previous surgery has been considered to be a potential causative factor. A clear prerequisite is a mobile cecum and ascending colon. A congenital component involves lack of fixation of the right colon, which then assumes an intraabdominal position.<sup>4,18–20</sup> In fact, a cadaver study revealed an 11% incidence of freely mobile right colons, and a 26% incidence of cecal mobility sufficient to allow folding. The authors concluded that 37% had cecums mobile enough to allow for volvulus.<sup>4</sup>

However, because cecal volvulus is so rare, factors other than cecal mobility must be involved. Prior abdominal surgery with colonic mobilization, recent surgical manipulation, adhesion formation, congenital bands, distal colonic obstruction, pregnancy, pelvic masses, extremes of exertion, and hyperperistalsis have all been implicated.<sup>4,18–20</sup> During abdominal surgery, excessive mobilization or manipulation of the cecum and ascending colon or placement/withdrawal of packs may precipitate postoperative volvulus.<sup>4</sup> Previous reports of cecal volvulus reveal that 30%–70% of patients had undergone prior surgery.<sup>19,20</sup> In the long term, an adhesive band may act as a fulcrum for a previously mobilized ileum and right colon to rotate axially. Displacement of the cecum by an enlarged uterus or pelvic mass may also promote volvulus. In fact, several series report that 10% of patients with cecal volvulus are pregnant at the time of presentation.<sup>4,20</sup>

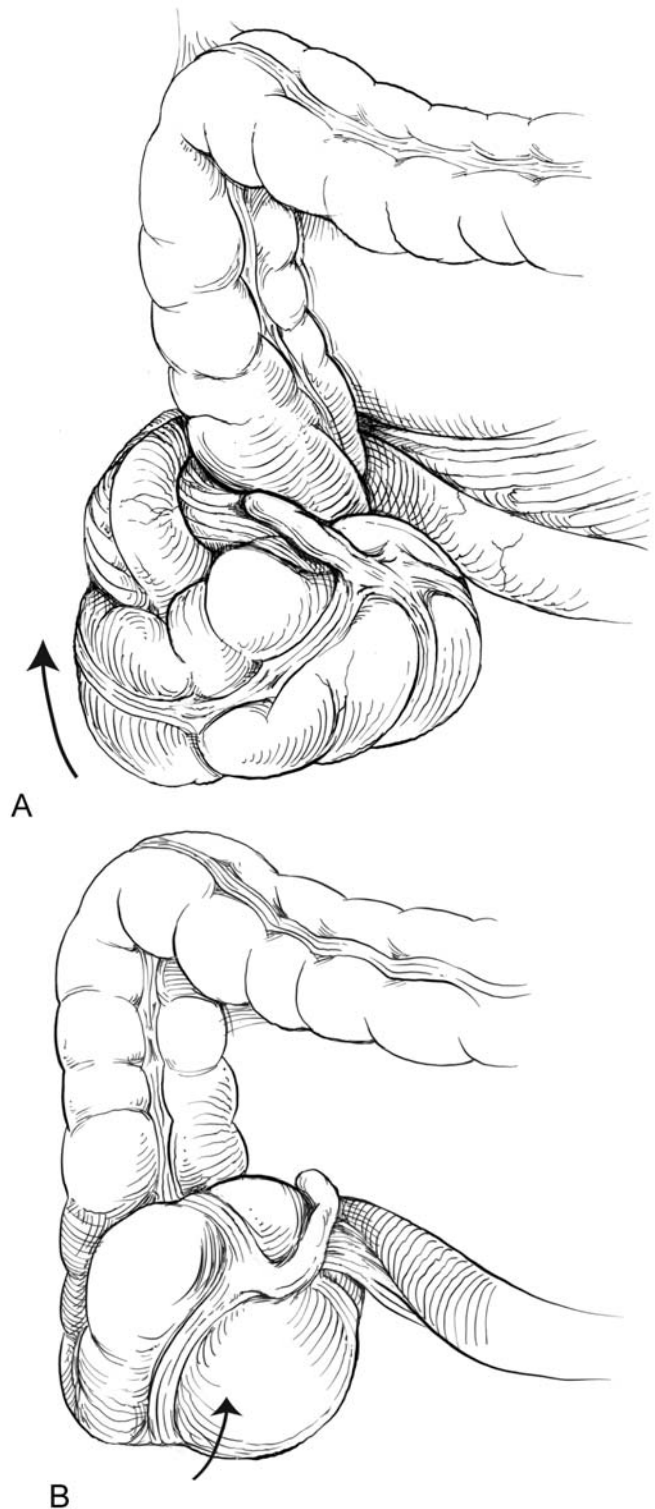

FIGURE 19-1. **A** Schematic illustration of a cecal volvulus. **B** Schematic illustration of a cecal bascule.

### Clinical Presentation

Symptoms and signs of cecal volvulus are that of small bowel obstruction. The majority of patients present with abdominal

pain, distention, constipation, nausea, and vomiting. Abdominal distention is less marked than with more distal forms of colonic volvulus. The presentation may be that of an acute obstruction or one of an intermittent or recurrent pattern. In the intermittent pattern, because duration of symptoms is brief, diagnosis may be quite difficult. Acute volvulus results in a closed loop cecal obstruction and distal small bowel obstruction. This may progress to a more fulminant presentation when ischemia and gangrene develop. At that point, the patient will present with peritoneal signs and systemic manifestations of an acute abdominal process. Before onset of gangrene, fever and leukocytosis are unreliable factors.<sup>17-19,21</sup>

### Diagnosis

The diagnosis is most often made on the basis of the combination of clinical presentation and plain abdominal films or barium enema. Plain films may identify the classic coffee bean deformity directed toward the left upper quadrant (Figure 19-2A). If not, barium enema may reveal a “bird’s beak” or column cut-off sign in the right colon (Figure 19-2B).<sup>4,17-19</sup> In the review by Rabinovici et al., 53% of cases were diagnosed preoperatively with clinical evaluation combined with radiologic investigation. The diagnosis was suspected in 46% of plain films, and barium enema was diagnostic in 88% of cases when obtained. However, 47% were not diagnosed until laparotomy.<sup>18</sup> Although barium enema is of clear value when the diagnosis is in question, in obvious cases, performance of this study may needlessly delay surgical therapy. It therefore should not be routinely used.<sup>4</sup>

### Treatment/Outcome

Laparotomy remains the primary treatment modality for cecal volvulus. Many patients are not diagnosed until exploration, and nonoperative modalities have generally been unsuccessful. However, both radiographic and endoscopic reduction have been reported. Whereas radiographic attempts at reduction are generally believed to carry a high risk of perforation, other modalities have been used as temporizing measures.<sup>4,5,16,18</sup> Percutaneous decompression via computed tomographic scan guidance has been reported to be effective in decompressing a massively dilated colon in otherwise inoperable candidates.<sup>22,23</sup>

Although significantly less efficacious than in the treatment of distal volvulus, colonoscopic reduction of cecal volvulus (Figure 19-3) has been reported with some success. Reasons cited for limited use of this approach include difficulty traversing the extent of unprepared bowel to reach the right colon, difficulty performing the detorsion, the relative infrequency in which the diagnosis is made before laparotomy, and the higher rate of ischemic changes in cecal volvulus than in sigmoid volvulus. In fact, several authors have condemned this approach as only unnecessarily delaying definitive surgical intervention and potentially placing the patient at risk for perforation. However, if successfully used, there may be a

A

B

FIGURE 19-2. **A** Plain abdominal X-ray of a cecal volvulus with a “coffee bean” deformity evident in the left upper quadrant. **B** Barium enema study of a cecal volvulus revealing a bird’s beak deformity.

FIGURE 19-3. Colonoscopic reduction of a cecal bascule.

relatively low rate of recurrence and the requirement for subsequent surgery is debated.<sup>4,5,10,11,16,18,24,25</sup>

In general, the majority of individuals undergo surgical intervention with a clear diagnosis of cecal volvulus, for complete bowel obstruction, or for an acute surgical abdomen. Obviously, in the face of gangrenous or ischemic bowel, resection is mandatory. When viable bowel is encountered, although resection is the preferred option, other alternatives exist. These include detorsion alone or combined with some fixation procedure. Fixation options include cecopexy and/or cecostomy. Appendicostomy has also been reported.<sup>4,5,18,19,25,26</sup>

Generally, fixation is accomplished by cecopexy and/or cecostomy. Cecopexy is performed by elevating a lateral peritoneal flap along the entire length of the ascending colon, and suturing the flap to the serosa of the anterior colonic wall, thereby placing the ascending colon in a partially retroperitoneal location, and eliminating the excess mobility (Figure 19-4). An advantage of tube cecostomy is that it not only anchors the cecum, but also provides a vent for the distended colon. Cecostomy is relatively simple to perform, and after removal of the tube, spontaneous closure is common.<sup>4,5,18,25</sup> In a review of the literature, Rabinovici et al.<sup>19</sup> found that detorsion, cecopexy, and cecostomy all carry similar recurrence rates of 12%–14%. Interestingly, they also noted a mortality for cecostomy triple that of either cecopexy or detorsion (32%

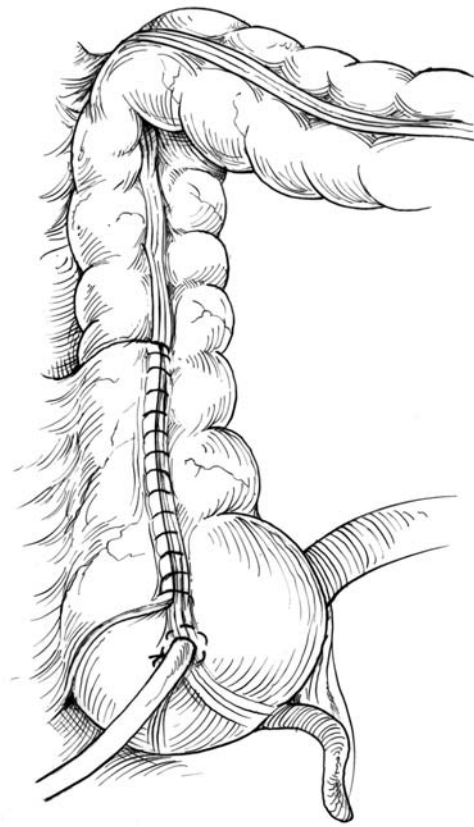

FIGURE 19-4. Colopexy and cecostomy for cecal volvulus.

versus 10% and 13%, respectively). Other authors have reported recurrence rates ranging from 0% to 30%.<sup>4,5,18,25</sup>

Resection, however, carries virtually no risk of recurrence and is not associated with a higher rate of postoperative complications when compared with cecopexy alone.<sup>18,25</sup> After resection, primary anastomosis can usually be safely performed. However, in the face of gangrenous bowel, end ileostomy may be a safer procedure. The ultimate decision regarding intestinal anastomosis is one made at the time of surgery, taking into account degree of contamination, and the patient's overall status.<sup>4,5,18,19,25,26</sup> Overall mortality is independent of the procedure chosen, rather it is related to whether or not the surgery is elective or emergent and the presence or absence of gangrene. Literature documents no mortality in the elective situation. If viable bowel is found at the time of an emergency operation, mortality ranges from 7% to 15%. This increases to 33%–41% in the face of gangrenous bowel.<sup>4,18,25</sup>

## Transverse Colon Volvulus

### Incidence and Epidemiology

Volvulus of the transverse colon is an exceptionally rare finding. It is estimated to represent from 1% to 4% of all forms of colonic volvulus. However, in Eastern and Scandinavian

countries, it may comprise 30%–40% of cases. This form of volvulus tends to occur more often in the young, with most series showing a peak incidence in the second through fourth decades of life. There is a two- to threefold female predominance.<sup>4,18,20,27–29</sup>

### Pathogenesis/Etiology

Although anatomic factors are key to the development of transverse colon volvulus, physiologic, rather than congenital, factors seem to have a crucial role in the development. These patients frequently have a history of chronic constipation and/or laxative abuse, previous abdominal surgery, a diet high in fiber, recurrent distal obstruction, and institutionalization. There are also reports, however, of an association with malrotation, Hirschsprung's disease, and Chilaiditi's syndrome. Finally, adhesive bands, frequently reported in these patients, may act as a fulcrum around which the bowel can twist. Specific factors that may increase the risk of occurrence are a redundant or elongated transverse colon with narrow mesenteric attachments, narrowed distance between the flexures, and an absence or paucity of fixation of the mesentery. These factors increase the likelihood of an axial rotation of the transverse colon about its mesentery.<sup>4,18,20,27–31</sup>

### Clinical Presentation

Transverse colon volvulus presents as a large bowel obstruction. Presentation may be as a subacute recurring process or may take a more fulminant course. The subacute form is associated with repetitive episodes, each with gradual onset. Although associated with significant abdominal distension, pain is mild to moderate, and vomiting is usually absent. Up to 50% of patients admit to previous episodes. The fulminant form is associated with less distension, but marked pain and vomiting. Clinical deterioration is rapid in these cases.<sup>4,17,27–29,31</sup>

Although diagnosis may be suspected on clinical presentation, plain films are rarely diagnostic. The diagnosis is therefore usually made at the time of exploration. Plain films may reveal a distended proximal colon with decompressed distal bowel and two distinct air-fluid levels representing two limbs of the volvulized transverse colon. This has been described as a bent inner-tube appearance with the apex pointing inferiorly. Barium contrast studies, if performed, will demonstrate a bird's beak deformity at the distal transverse colon. However, awaiting these studies only leads to a delay in definitive management.<sup>4,17,27–30</sup>

### Treatment/Outcome

Although successful endoscopic decompression has been reported, surgical intervention is the recommended treatment modality. Based on literature from surgical detorsion, it is assumed that endoscopic treatment will lead to a high rate of

recurrence, and may therefore be best reserved for those high-risk individuals who show no signs of compromised bowel.<sup>12,14,18</sup> However, colonoscopy may serve to confirm intestinal viability and allow for a less emergent definitive procedure to be performed.<sup>30</sup>

Operative procedures include detorsion with or without colopexy, and resection. Most authors recommend either segmental transverse colectomy or extended right colectomy as definitive treatment. Clearly, in the presence of nonviable bowel, resection is mandatory.<sup>12,14,18,30–32</sup> As in cecal volvulus, the decision regarding primary anastomosis versus diversion is made during surgery, taking into account the severity of the disease process and the patient's overall condition. When viable bowel is encountered, several different colopexy procedures have been reported. These include suture of the greater omentum, transverse mesocolon, or transverse colon itself to the anterior abdominal wall and/or pelvis,<sup>18,30,32</sup> and the U colopexy reported by Mortensen.<sup>31</sup> In this procedure, after reduction and needle decompression of the volvulus, the redundant U-shaped loop of transverse colon is sutured to the adjacent limbs of ascending and descending colon (Figure 19-5).

Recurrence from either detorsion or colopexy has been reported to range from 30% to 75%, whereas resection eliminates virtually all risk of recurrence.<sup>25,32</sup> Mortality, however,

FIGURE 19-5. Parallel coloplasty as described by Mortensen.<sup>31</sup>

from resection has been reported to be as high as 33%. This is primarily in the setting of gangrene or perforation.<sup>18,27</sup> In these cases, mortality may be decreased by construction of an end stoma or extended resection with ileocolic anastomosis.<sup>30</sup>

## Splenic Flexure Volvulus

### Incidence and Epidemiology

Having been described in fewer than 50 patients in the English literature, volvulus of the splenic flexure of the colon is the rarest form of colonic volvulus. It is estimated to represent 1%–2% of all cases of colonic volvulus. It seems to be more common in women and occurs at a younger age than cecal or sigmoid volvulus.<sup>4,13,25,33,34</sup>

### Pathogenesis/Etiology

The infrequency of this form of volvulus is believed to be the result of multiple attachments of the splenic flexure, and the retroperitoneal position of the descending colon. Three ligaments, the gastrocolic, splenocolic, and phrenocolic, are responsible for fixation of the splenic flexure. Congenital absence, laxity, or iatrogenic disruption of these ligaments may lead to excessive mobility of the splenic flexure. In addition, an intraperitoneal descending colon and adhesive bands from previous surgery may further predispose to the development of this form of volvulus. In fact, up to two-thirds of patients have had prior abdominal surgery. Finally, it has been speculated that chronic constipation may lead to redundancy of the colon and elongation of the mesentery. This may possibly create laxity of the ligamentous attachments.<sup>4,13,25,33,34</sup>

### Clinical Presentation

As in transverse colon volvulus, the presentation may be acute and fulminant, or a more chronic or subacute event. Many patients have a history of severe chronic constipation, with longstanding laxative abuse. At presentation, the majority of patients have significant abdominal distention and pain. Although nausea and vomiting are common, obstipation is rare. Very few patients present with strangulation, gangrene, or findings of an acute surgical abdomen.<sup>4,33,34</sup>

Four features have been described radiographically that may suggest splenic flexure volvulus. They are: 1) a markedly dilated air-filled colon with an abrupt termination at the splenic flexure; 2) two widely spaced air-fluid levels, one in the cecum and the other in the transverse colon; 3) an empty descending and sigmoid colon; and 4) a bird's beak obstruction at the splenic flexure on contrast enema examination (Figure 19-6). An additional sign is a crescentic gas shadow in the left upper quadrant of the abdomen.<sup>13,33</sup>

FIGURE 19-6. Barium enema study of a chronic splenic flexure volvulus. Arrows indicate the point of rotation and bird's beak deformity.

### Treatment/Outcome

Although colonoscopic and fluoroscopic decompression have been reported, most reports have identified surgery as the primary mode of management. Surgical options include resection with or without stoma formation, or detorsion with or without colectomy. Segmental resection may be considered; however, the majority of these patients will have an associated redundant, dilated colon and a history of chronic constipation. Therefore, these patients may be better served by undergoing an extended resection with an ileosigmoid or ileorectal anastomosis. Stomas should be reserved for cases involving gangrenous bowel with perforation and peritoneal contamination, or for other high-risk cases.<sup>4,13,25,34</sup>

No mortality has been reported with either form of surgical management. The complication rate, excluding recurrence, is in the range of 10%. Resection carries a 0% recurrence rate. However, the recurrence rate after detorsion alone, whether performed surgically, endoscopically, or fluoroscopically, is approximately 20%–25%. As a result of these high recurrence rates, nonoperative decompression/detorsion should be reserved for extremely high-risk patients who are not candidates for surgical intervention, or as a temporizing measure before a semi-elective definitive resection.<sup>4,13,34</sup>

## Sigmoid Volvulus

### Incidence and Epidemiology

Although it is the most common form of volvulus seen, volvulus of the sigmoid colon is not very common in the United States and Western Europe, accounting for less than 10% of all cases of large bowel obstruction.<sup>5,6,19,35</sup> In some regions of Asia, Africa, and other less-developed portions of the world, however, the situation is significantly different. In these areas, sigmoid volvulus accounts for 20%–50% of the

cases of intestinal obstruction. Overall, there is a substantial male predominance, especially in developing nations. However, sigmoid volvulus is the most common cause of intestinal obstruction in pregnancy, accounting for nearly 45% of all intestinal obstructions in this group of women.<sup>3,4,5,19</sup> The reasons for geographic differences in incidence are thought to be primarily related to diet. In the West, relatively lower amounts of fiber are consumed, resulting in a much higher incidence of colorectal cancer and diverticular disease, which are the more common etiologies for colonic obstruction in these areas. In less-developed regions of Asia and Africa, extremely high fiber diets result in significantly elongated colons, and lead to development of sigmoid volvulus, in relatively young patients.

### Pathogenesis/Etiology

Any condition that results in an elongated colon predisposes to the development of volvulus. In order for volvulus of any part of the intestinal tract to occur, there must be a long redundant, mobile segment, with a relatively narrow mesenteric attachment, such that the sites of fixation at each end are relatively close together. The sigmoid colon is the ideal location for this configuration: the sigmoid can be extremely redundant and mobile and the sites of fixation at the descending-sigmoid junction and the rectosigmoid junction are often in close proximity to each other.<sup>3,19</sup>

Although a single etiology has not been identified, several theories do exist. In 1849, in his *Manual of Pathological Anatomy*, Von Rokitsky proposed that the primary causative factor was a “congenital or acquired long, loose, and floppy mesentery.” Thirty-five years later, in his text of intestinal obstruction, Treves indicated that the loop in sigmoid volvulus “must be of considerable length, the mesocolon must be long and very narrow at its parietal attachment, so that two ends of the loop may be brought as close together as possible.”<sup>3</sup>

In the West, the typical patient with sigmoid volvulus is an elderly institutionalized male, often receiving psychotropic medications, who is usually extremely constipated. Other factors that have been implicated are laxative abuse, previous abdominal surgery, and diabetes.<sup>3,5,18</sup> In other parts of the world, the patients are significantly younger.<sup>24,36,37</sup> Megacolon from any etiology, but especially Hirschsprung’s disease or Chagas’ disease, predisposes to volvulus.<sup>3,8,19</sup>

Gross features of the sigmoid colon include progressive widening and eventual loss of taenia coli, absence of appendices epiploicae, and a thickened narrowed fibrous mesentery. The scarring forms patches and bands coined “shrinking mesosigmoiditis” by Brusgaard, and is believed to be the result of previous episodes of volvulus.<sup>9,19,38</sup> The rotation may be either clockwise or counterclockwise. Once the rotation has reached 360 degrees, a closed loop obstruction occurs. Hyperperistalsis and fluid secretion into the closed loop add to increased pressure and tension. Eventually, as blood flow is

compromised, ischemia and necrosis develop. Additionally, the diminished blood flow may lead to arterial and venous thrombosis. Three patterns of necrosis have been described: 1) at the neck of the volvulus, 2) any location within the closed loop, and 3) in the proximal descending colon or distal rectum because of retrograde mesenteric thrombosis. Because the sigmoid loop is usually chronically thickened, it is unlikely for a perforation to occur in this location. In the face of a competent ileocecal valve, perforation is more common in the cecum.<sup>39</sup>

### Clinical Presentation

As previously described, the patient is typically a male nursing home resident, on psychotropic medications, with a history of chronic constipation. These patients may not complain of pain, but rather a caregiver notices an extremely long interval between bowel movements, associated with significant abdominal distension. In younger patients, constipation, distension, and abdominal pain are the predominant symptoms.<sup>38</sup> Before arrival at the hospital, the patient may have been given enemas or laxatives, without relief. This therapy may have, in fact, made the distension worse. There is often significant delay between onset and evaluation.<sup>40,41</sup> It has been reported that 40%–60% of patients will give a history of having had similar episodes.<sup>4,38</sup>

On presentation, the distension is often dramatic. Unlike the patient with fecal impaction, the rectal ampulla is empty. Plain abdominal films typically show massive colonic distension, with or without small bowel dilatation (depending on the competence of the ileocecal valve). The very large sigmoid loop will be orientated toward the right upper quadrant. The adjacent walls of the sigmoid will appear to be thickened, arising out of the left lower quadrant, giving the classical “bent inner tube” sign (Figure 19-7A).<sup>38</sup> In the majority of cases, plain radiographs are sufficient to establish the diagnosis.<sup>40</sup> In fact, plain abdominal X-rays alone are diagnostic in 60%–75% of cases.<sup>39,42</sup> However, the massive distension may, occasionally, make the diagnosis difficult to establish with certainty. In those cases, a contrast enema should be obtained. This study will show the obstruction at the rectosigmoid junction, with the classical bird’s beak configuration (Figure 19-7B).<sup>5,39</sup> The addition of barium enema to the plain abdominal X-rays may increase the diagnostic yield to near 100%.<sup>42</sup>

The major diagnosis from which sigmoid volvulus must be distinguished is colonic obstruction caused by neoplasm. Usually the abdominal X-rays can distinguish one from the other; however, in the presence of truly massive distension, differentiation may be difficult. At the time of attempted sigmoidoscopic detorsion, the obstructing neoplasm will hopefully be visualized and the true diagnosis will be apparent. The other condition that may cause clinical confusion is colonic megacolon associated with abnormal colonic motility. This condition also presents in elderly, constipated nursing home patients. The X-rays can look remarkably similar.

FIGURE 19-7. **A** Plain abdominal X-ray of a sigmoid volvulus indicating the “bent inner tube” sign. **B** Barium enema study of a sigmoid volvulus indicating the bird’s beak deformity and complete obstruction to retrograde flow of contrast.

Because rectal tube decompression will generally rapidly and successfully relieve the distension associated with this form of megacolon, distinction from volvulus can be difficult. It is important to make the distinction, however, because this condition is also associated with a high incidence of recurrence, but will not be successfully treated by sigmoid resection. In one series, a 37% incidence of recurrent “volvulus” was seen after sigmoid resection and anastomosis. However, virtually all of these patients had megacolon-associated abnormal colonic motility.<sup>43</sup>

### Treatment/Outcome

The patient with sigmoid colon volvulus should be hydrated and resuscitated. Since 1947, when Bruusgaard<sup>9</sup> reported a 90% success rate with sigmoidoscopic detorsion, the mainstay of emergency therapy has generally been detorsion and decompression. Detorsion of sigmoid volvulus has been described using several techniques, including rigid proctoscopy, flexible sigmoidoscopy or colonoscopy, blind

passage of a rectal tube, and use of a column of barium during barium enema examination.<sup>7,9,10,14,15,24</sup> Successful decompression using one of these techniques is generally reported in the range of 70%–80%.<sup>18,39–41,44</sup>

A significant concern is that the sigmoid may already be gangrenous. Several authors in Asia and Africa have noted an incidence of gangrene approaching 50%, as well as a significant incidence of double volvulus (ileosigmoid knotting) rarely seen in the West, and have therefore recommended emergency laparotomy without attempts at detorsion.<sup>36,37,45–47</sup> If ischemic mucosa is visualized, attempts at detorsion should be immediately abandoned and operative intervention should be undertaken emergently. For this reason, we strongly recommend using only those detorsion techniques that visualize the mucosa before detorsion. Attempts at detorsion via blind passage of a rectal tube should be avoided. Attempted detorsion of nonviable bowel will lead to a high incidence of perforation and peritonitis. The presence of nonviability should be suspected by the presence of signs and symptoms of compromised bowel and/or systemic sepsis, such as fever,

leukocytosis, and especially localized tenderness over the sigmoid loop. If these are present, decompression should not even be attempted. The patient should be taken for emergent surgery. In approximately 25% of cases, the site of the twist will be more proximal than can be reached with a rigid proctoscope.<sup>14</sup> Use of flexible scopes can obviate this problem. The major complication associated with attempted detorsion is inadvertent perforation. This is more likely in the presence of gangrene, but can occur with viable bowel as well.

Once decompression has been accomplished, there is usually forceful evacuation of flatus and stool (frequently all over the clothes and shoes of an unsuspecting novice) and visible deflation of the patient's abdominal distension. A rectal tube should then be gently inserted into the colon to a point proximal to the site of the twist (which is usually within 20 cm of the anus). The tube should then be fixed in place, to allow continued decompression and prevention of recurrence. A plain abdominal film should be obtained to document decompression and the patient should be admitted to the hospital. Successful detorsion provides the advantage of converting a surgical emergency to an elective situation.

Over the next several days, bowel function is likely to return to normal. Medical conditions (cardiac, pulmonary, renal, etc.) should be addressed, electrolyte abnormalities should be corrected, and the patient's condition optimized. Colonoscopy, to rule out a proximal lesion, should be performed, and then a decision must be made. The rectal tube can be safely removed and the patient could be discharged from the hospital; however, it is well established that the rate of recurrent sigmoid volvulus is in excess of 25%.<sup>48,49</sup> In fact, most authors document a recurrence rate of greater than 50%, and some report recurrences as high as 80%–90%.<sup>18,21</sup> However, one report notes that 15 of 29 patients (52%) with sigmoid volvulus never required surgery. Twenty-three of 26 successfully decompressed patients were observed. Twelve recurred, six of whom were again decompressed and observed. Four of these patients had no further recurrence. Whereas none of the conservatively treated patients developed a complication, 43% of the surgical patients died.<sup>35</sup> The overall condition of the patient, the ease with which the volvulus was untwisted, and whether or not there were previous episodes of volvulus, are all factors that must be considered in the decision to perform definitive surgery.

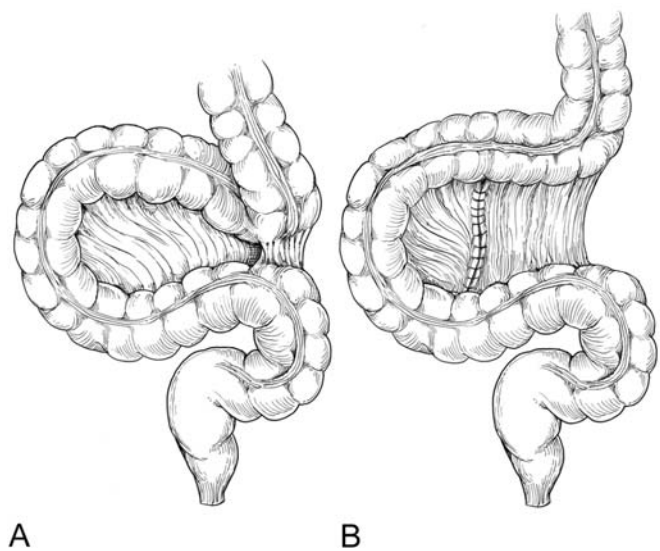

The standard elective surgical procedure is sigmoid resection with primary anastomosis; however, a number of nonresective techniques have been described, including nonsurgical endoscopic sigmoidopexy with or without tube fixation,<sup>17,50,51</sup> extraperitoneal sigmoidopexy,<sup>52</sup> sigmoidopexy to the transverse colon and/or the parietes,<sup>17</sup> mesosigmoidoplasty,<sup>53,54</sup> colopexy with banding,<sup>55</sup> mesenteric fixation,<sup>7</sup> and laparoscopic fixation.<sup>56</sup> Although several authors have reported excellent results using pexy without resection,<sup>52–54</sup> others have reported recurrence rates in excess of 25%.<sup>38</sup> Whereas recurrence after resection approaches zero, resection with anastomosis was historically accompanied by relatively

substantial morbidity and mortality,<sup>42</sup> prompting a number of investigators to seek less risky alternatives.

Bhatnagar and Sharma<sup>52</sup> reported a series of 84 patients treated by sigmoidopexy with extraperitonealization. They reported a mortality of 9%. Patients were followed for a mean of 6.7 years with no evidence of recurrence (48 patients were followed for more than 5 years). Salim,<sup>55</sup> however, reported on a technique of percutaneous deflation, followed by tube detorsion and decompression, and finally intraperitoneal sigmoidopexy. He conducted a prospective, randomized trial of this nonresectional technique compared with resection and primary anastomosis. Of the initial 21 patients randomized to the decompression followed by surgical arm, six required emergency surgery. The remaining 15 were able to undergo an elective resection. Of note, he reported no recurrences and a mortality of 0% in the colopexy group as opposed to 13% in the group undergoing resection.<sup>55</sup>

Finally, the technique of mesosigmoidoplasty deserves discussion. This procedure is performed by incising the elongated sigmoid mesentery vertically along its axis. Peritoneal flaps are then created which are then approximated transversely (Figure 19-8). This procedure thereby creates a shortened, broad mesentery precluding future bowel rotation. Although one author has reported a recurrence of 28%, most report recurrences of less than 2%. Mortality ranges from 0% to 7%.<sup>53,54</sup>

Modern surgical and anesthetic techniques, including the use of surgical staplers, have reduced operative complications substantially. Resection with anastomosis, therefore, should currently be considered the standard of care for elective cases. However, in circumstances in which continence is an issue, an end stoma may be a better alternative. Colostomy via a

**FIGURE 19-8.** Mesosigmoidoplasty. **A** A longitudinal peritoneal incision is made in the elongated, narrow mesentery. **B** The incision is then closed transversely, broadening the mesenteric base and shortening the height of the sigmoid loop.

minimal left lower quadrant incision has been suggested for debilitated patients, too sick to undergo formal laparotomy.<sup>57</sup>

Laparoscopic techniques have also been applied,<sup>58–60</sup> but in general, because the redundant distended colon obscures the working space and the incision required to deliver the specimen is also large enough to exteriorize the redundant sigmoid colon and perform an adequate resection and anastomosis, there is little to be gained by the use of laparoscopy.<sup>60</sup> In fact, the entire resection and anastomosis can often be performed via a limited left lower quadrant muscle splitting incision, a very small midline incision, or via a Pfannenstiel incision.

If decompression is not possible, if the patient has signs and symptoms of peritonitis or colonic ischemia, or if gangrenous mucosa is visualized during attempted decompression, the situation becomes a surgical emergency. The patient should be rehydrated, electrolyte abnormalities and anemia should be corrected, the patient should be given intravenous antibiotics, and emergency surgery should be undertaken. The patient should be explored via a midline laparotomy, the volvulus should be manually reduced if the bowel is viable, and the redundant, twisted sigmoid should be resected. However, when gangrenous bowel is encountered during laparotomy, detorsion should not be performed. Accumulated toxins and bacteria may be released into the circulation, resulting in sepsis and cardiovascular collapse. Maintenance of the volvulus is therefore paramount as one obtains early vascular control. Inspection of the proximal colon must be performed, because in the face of a competent ileocecal valve, the closed loop obstruction produces rapid cecal ischemia and perforation.<sup>21,38</sup> Obviously, avoidance of fecal contamination is paramount. With the use of 90-mm linear staplers, even though the bowel proximal to the volvulus may be enormously dilated, resection without spillage is usually possible. Generally, an anastomosis should be avoided if the proximal colon is massively dilated and loaded with feces. Some authors have applied the technique of intraoperative colonic lavage to facilitate primary anastomosis.<sup>61</sup> In most cases, the proximal sigmoid should be exteriorized as an end-sigmoid colostomy; the distal end can be treated with a Hartmann-type closure, or a mucus fistula. A single prospective, randomized trial comparing primary anastomosis to the Hartmann's procedure in 14 patients with gangrenous bowel, revealed a 50% anastomotic leak rate. In addition, mortality was more than double in those patients in whom an anastomosis was performed (33% versus 13%).<sup>36</sup> Although the colostomy can generally easily be reversed in an elective manner, it must be recognized that because of the age and infirmity of many of these patients, in actual practice, the colostomy is often permanent.

Overall mortality rates for the treatment of sigmoid volvulus range from 14% to 45%. Emergency surgery without preoperative detorsion is associated with mortality rates of 20%–45%. If nonviable bowel is encountered, these rates may exceed 50%. In fact, several studies report mortality of 60%–80% in these cases.<sup>9,17,21,35,36,38–41,62</sup> Elective surgery,

after detorsion, is currently associated with mortality rates below 10%, despite the fact that these are generally patients with multiple comorbidities. However, older data reveal this mortality was as high as 25%.<sup>7,9,17,21,35,36,38–41,62</sup>

Paradoxically, outcomes in developed nations tend to be far worse than those in developing countries. This is presumed to be attributable to the older age and presence of significant comorbidities of the patients in the Western nations.<sup>4,38</sup> Ballantyne,<sup>42</sup> in a review of 67 series of sigmoid volvulus worldwide before 1981, compared mortality of nongangrenous and gangrenous bowel in the United States as compared with the rest of the world. He noted that the overall mortality in the United States was 25% and internationally 18%. When gangrenous bowel was present, the United States mortality further exceeded the international rate (80% versus 48%). However, for the nongangrenous, elective procedures, the United States mortality was somewhat less than the worldwide rate (10.6% versus 12.6%).

It has been suggested that a nonresectional approach may be safer in these ill patients. However, nonoperative decompression alone carries 0%–12% mortality. This may be related to attempted detorsion in the presence of ischemic bowel. Finally, operative detorsion with or without pexy carries a similar mortality to elective resection and anastomosis (8%–14%). Therefore, one must consider the overall risk of recurrence as well as the risk of mortality. As expected, any nonresectional procedure carries a substantial risk of recurrence. For decompression alone it ranges from 25% to 70%, whereas detorsion, with or without pexy, has been associated with recurrence rates of 23%–40%. Most authors indicate that the risk of recurrence after resection approaches zero; it has been reported to be as high as 5% in some series.<sup>17,9,21,35,36,38–41,62</sup> This is usually attributed to concomitant megacolon and/or megarectum.<sup>48</sup> The only prospective randomized trial comparing elective resection and primary anastomosis with mesosigmoidoplasty confirms these findings. None of the resected patients and 29% of the plastied patients experienced recurrence. However, there was no mortality in the plasty group as compared with 10% in the resection group.<sup>36</sup>

## Ileosigmoid Knotting

### Incidence and Epidemiology

Ileosigmoid knotting, also called compound volvulus, is a rare form of volvulus uncommon in the West. It is, however, comparatively more common in certain areas of Africa, Asia, and the Middle East. In particular, large series are reported from Turkey, Russia, Scandinavia, Uganda, and India. It is more common in males than females, and presents at a younger age than sigmoid volvulus. In fact, it has rarely been reported in individuals older than 50 years of age.<sup>3,63–67</sup>

The geographic distribution corresponds with regions of the world where diets high in bulk and carbohydrates are

consumed with large volumes of liquid. The incidence is highest in groups in which one single large meal is consumed daily. It has been reported to peak in the followers of Islam during Ramzan when a single large meal is consumed at sunset after a full day's fast.<sup>3,63-67</sup>

### Pathogenesis/Etiology

Theories of the pathogenesis of ileosigmoid knotting focus on a large volume diet high in bulk and carbohydrates, associated with large volumes of concomitant liquid ingestion. This may lead to an elongated abnormally mobile small intestinal mesentery, in addition to a long narrow pedicled sigmoid mesentery. The simultaneous consumption of a large meal combined with a large volume of fluid may then initiate an acute knot formation. As the bolus empties into the jejunum, the bowel becomes hyperperistaltic, and the weight acts to pull it into the left paracolic gutter. The empty distal loops of small bowel are then displaced around a narrow-based sigmoid. Continued peristalsis leads to further rotation of the loop, internal herniation, and knot formation (Figure 19-9). The fact that this entity usually occurs in the early morning hours lends further credence to the theory that dietary and dining habits of certain populations are causative.<sup>3,63-67</sup>

Alver et al.,<sup>64</sup> in a review of 68 cases, described four different patterns of ileosigmoid knot formation which differentiate between an active or passive segment of bowel and the direction of rotation. Usually, the ileum is the active component and wraps around the sigmoid in either a clockwise or counterclockwise manner. Alternatively, the sigmoid may wrap around a passive segment of ileum, either clockwise or counterclockwise.

### Clinical Presentation

The presentation of ileosigmoid knotting is one of acute onset, often with a fulminant course. There is a dramatic absence of prior similar attacks that are frequently seen in other forms of volvulus. Patients usually present in shock with signs of an intraabdominal catastrophe. The patient may complain of severe colicky abdominal pain, which begins in the periumbilical region. Nausea and vomiting, as well as distension, are early findings. At surgery, gangrenous intestine is found in 70%–100% of cases. As the result of the severity of the condition at presentation, acidosis, hypovolemia, oliguria, hypotension, and tachycardia are common findings.<sup>3,63-67</sup>

Preoperative diagnosis is extremely difficult because of the confusing nature of the presentation and unfamiliarity with

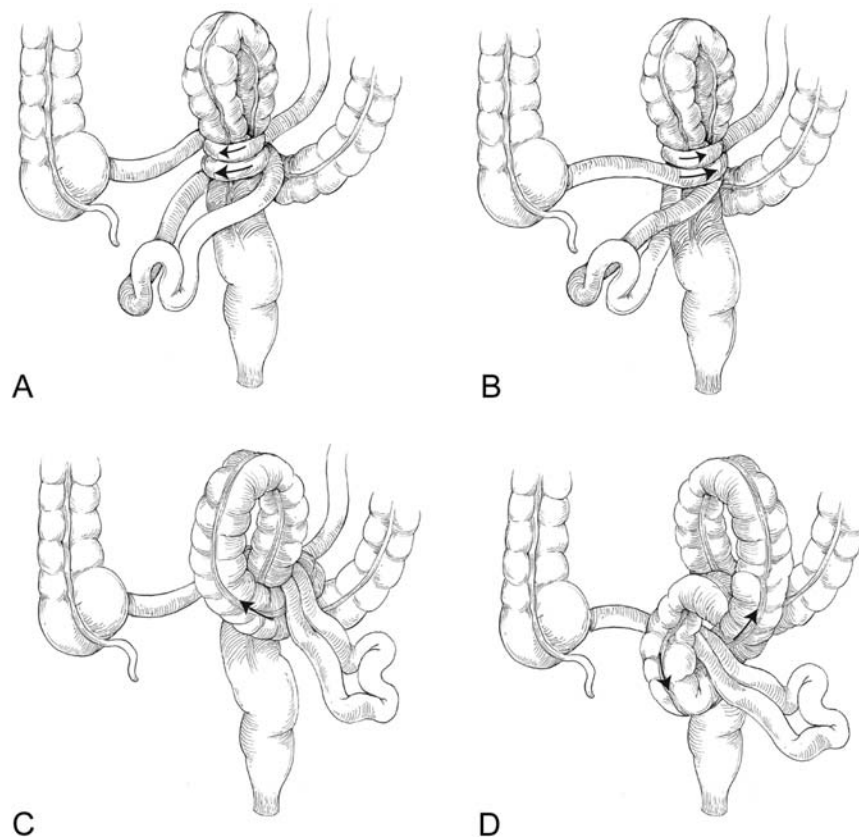

FIGURE 19-9. Ileosigmoid knotting: these schematic illustrations indicate the four forms of knotting. The active ileum may rotate around the sigmoid colon in either a clockwise **A** or counterclockwise **B** direction. Much more infrequently, the sigmoid colon may act as the active loop and rotate in either a clockwise **C** or counterclockwise **D** direction around the ileum.

this entity. Clinically, the patient's condition presents as a small bowel obstruction, but radiographic evaluation is more consistent with a large intestinal obstruction. In fact, X-rays are often atypical, and the diagnosis is correctly made in fewer than 20% of patients preoperatively. However, several characteristic radiographic features of ileosigmoid knotting have been identified. These include a double obstruction, with an obstructed distended sigmoid loop pulled to the right and a proximal small bowel obstruction on the left. A diagnostic triad has been proposed consisting of a clinical small bowel obstruction, a radiographic large bowel obstruction, and the inability to pass a sigmoidoscope to decompress a suspected sigmoid volvulus.<sup>3,64-67</sup>

### Treatment/Outcome

Because of the high incidence of ischemia and gangrene at the time of presentation, after an initial period of rapid resuscitation and antibiotic administration, patients should be taken for emergent abdominal exploration. Controversy clearly exists regarding the preferred surgical approach. Treatment recommendations have ranged from simple detorsion to double resection. Because of the high likelihood of gangrenous bowel, most authors advocate en bloc resection of both segments of intestine without attempts to untwist the bowel. They state that untying the knot may be time consuming, difficult, hazardous, and may lead to systemic release of endotoxin and propagation of shock. Finally, perforation may ensue, leading to peritoneal contamination.<sup>3,63-66</sup> However, others have recommended detorsion if one or both segments of bowel are thought to be viable. Deflation of the torsed segments had been shown to assist in untying the knot and diminishing the risk of rupture. There are conflicting data on recurrence after detorsion alone.<sup>3,63-66</sup> Some authors advise resection of the sigmoid in all cases because of the possibility of recurrent knotting or eventual sigmoid volvulus.<sup>62,64-66</sup>

Although most perform a primary ileoileal or ileocolic anastomosis in patients with gangrenous small bowel, a Hartmann's procedure is usually performed when the sigmoid is found to be nonviable. When the sigmoid is viable, despite the lack of bowel preparation, some authors have reported safe colorectal anastomoses. Because of the risk of inferior mesenteric artery or superior rectal artery thrombosis, most authors also advocate resection of the sigmoid well past the areas of twisting and/or gangrene to ensure adequate blood supply.<sup>3,63-67</sup>

Overall surgical mortality generally ranges from 30% to 50%. One review of seven patients reported no mortality, despite finding gangrenous colon in all seven patients, and gangrenous ileum in three.<sup>63-67</sup> Mortality for nongangrenous bowel is generally less than that for gangrenous bowel. Reports range from 10% to 30% for nongangrenous intestine, and 40% to 50% for gangrenous bowel.<sup>3,64-66</sup> Alver et al.,<sup>64</sup> however, noted a paradoxical relationship between duration of symptoms and mortality. Those patients who presented within

24 hours had a mortality of 42%, whereas those that presented later had a much lower mortality rate of 20%. Additionally, he noted that the rate of gangrene was 91% in the early presenters but only 57% in the late presenters. This reflects the more rapid fulminant course of the patients that present earlier.<sup>64</sup> In addition, when extensive gangrene of the small bowel is found, leaving the patient with less than 60 cm of residual bowel, mortality has been shown to be 100%.<sup>64</sup>

## Lower Gastrointestinal Hemorrhage

Frank G. Opelka, J. Byron Gathright, Jr., and David E. Beck

Lower gastrointestinal hemorrhage refers to a spectrum of intestinal bleeding that arises distal to the ligament of Treitz. It may range from occult bleeding or occasional spotting of blood to massive lower intestinal hemorrhage. Massive lower intestinal hemorrhage is difficult to define. Patients often describe massive bleeding into their commode even when a small amount of blood discolors the water. True massive intestinal hemorrhage typically involves hemodynamic compromise or symptomatic anemia. Multiple sources define massive bleeding to include patients with a hematocrit less than 30%, patients with transfusion requirements (up to 3–5 units of blood/blood products), or orthostasis requiring resuscitation.

Primarily, lower intestinal hemorrhage arises from within the colon. Billingham<sup>1</sup> described lower gastrointestinal hemorrhage as a conundrum with five key concerns. First, the condition may arise from bleeding throughout the gastrointestinal tract. Second, intermittent bleeding precludes a prompt identification of the site of hemorrhage. Third, patients requiring surgery may undergo a procedure without a specific pre-planned site of resection and with considerable morbidity and mortality. Fourth, despite aggressive surgical management, persistent bleeding may occur. And finally, there is no consensus about the precise diagnostic and therapeutic pathways for patients.

From the perspective of the emergency room care, massive lower gastrointestinal hemorrhage is a relatively uncommon emergency. Longstreth<sup>2</sup> studied a large health maintenance organization (HMO)-based population in San Diego, California, noting an annual incidence rate of 20.5/100,000 patients with a male predominance. His study reflected a retrospective survey and chart review defining incidence. The incidence of significant bleeding increases with age. The association with aging may suggest senescent changes associated with the small intestine and colon. Certainly aging reflects the surging prevalence of colonic diverticulosis and intestinal angiodysplasia in the elderly. It is of interest to note that the California HMO group had a high incidence of diverticulosis (41.6%) and infrequent angiodysplasia (2.7%).

However, Longstreth admits the limitations of the study design may not precisely determine the true etiologies of lower gastrointestinal hemorrhage.

Lower gastrointestinal bleeding presents with varying degrees of hemorrhage. Patients may experience minor bleeding when they describe the passage of 100–250 mL of blood, possibly a few clots, and often mixed with mucous. Other patients experience brisk, copious bleeding with major, self-limited hemorrhage. Finally, certain patients present with massive and continuous hemorrhage associated with hypovolemia. The hemorrhage may present as melena or hematochezia. Melena typically suggests bleeding from a more proximal source in the colon or small intestine. Hematochezia suggests left colonic, rectal, or anal sources. It is wise to note that upper gastrointestinal hemorrhage may present with the rectal bleeding given blood's cathartic effect and rapid intestinal transit. Jensen and Machicado<sup>3</sup> outlined the safety of emergency panendoscopy in patients with hematochezia and negative nasogastric lavage. His 1988 study provided additional insights in demonstrating an upper source for bleeding in 11% of patients.<sup>4</sup> Overall, it is believed that upper sources may present with lower gastrointestinal bleeding symptoms in 10%–15% of cases.

Most often the intestinal bleeding resolves spontaneously with supportive hospital care. Once it resolves, investigations should begin to identify the potential sources. Actual bleeding sources are not so frequently identified by the current limitations of our diagnostic tools. In clinical scenarios in which the bleeding resolved spontaneously, the diagnostic evaluation may only unmask potential sources. Without associated attached clot or active bleeding, the true site of hemorrhage may never be elucidated. On occasion, the intestinal hemorrhage does not resolve. It continues, creating hemodynamic compromise. Ongoing hemorrhage demands aggressive medical and surgical management. Oftentimes, patients with massive hemorrhage are plagued with significant comorbidities that complicate their individual resuscitation. Their comorbidities must be considered in the diagnostic and therapeutic phases of the care plan.

History and physical examination fall short of an adequate classification system to ultimately predict patient needs or clinical outcome. A patient may portray a worrisome history of massive hemorrhage and still resolve spontaneously with simple, supportive measures. Other patients may sequester blood in large volume and seem to have stopped bleeding. While under observation their scenario promptly changes with ongoing, massive hemorrhage. They require prompt therapy. Still other patients may bleed aggressively, stop for a few days, and then repeat their massive exsanguinations. In addition, diagnostic studies often are invasive procedures with limited sensitivities and specificities.

More and more, physicians witness special patient groups with massive lower gastrointestinal hemorrhage. Current disease managements call for concurrent care with anticoagulants or antiplatelet agents for underlying cardiovascular conditions. Current treatment regimens incorporate long-term anticoagulants and antiplatelet agents. Hemorrhage in these patients proves more life-threatening. Landefeld and Goldman<sup>5</sup> noted a 22% long-term risk of bleeding on anticoagulant therapy with warfarin. Gastrointestinal hemorrhage is one of five independent risk factors. Current increased patient exposure to antiplatelet therapy associated with treatment of cardiovascular conditions may increase the comorbid challenges in patients with lower gastrointestinal massive hemorrhage.

## Etiologies

Common causes for lower gastrointestinal hemorrhage include colonic diverticula, angiodysplasia, ischemic colitis, and inflammatory bowel disease. Hemorrhage also stems from intestinal tumors or malignancies. Unusual causes include nonsteroidal antiinflammatory drug (NSAID)-related nonspecific colitis, Meckel's diverticulum, and anorectal diseases. The reported mortality with varying etiologies is summarized in Table 20-1.

## Diverticular Disease

Diverticulosis is a common malady in Western civilization. Approximately 50% of the population by age 60 years has evidence of diverticulosis.<sup>10</sup> Most diverticula represent pulsion diverticula or pseudodiverticula that are actually out-pouchings of the mucosa and submucosa through defects in the muscular layer of the bowel at sites of penetration of the

vasa recta. It is theorized that slow intestinal transit and increased intraluminal pressure within the segmentation process promote the development of the diverticula.

The precise mechanism of diverticular hemorrhage is unknown. In the late 1800s, Kebs outlined the vascular anatomy of the vasa recta and the mucosal blood supply. Further, Drummond,<sup>11</sup> in 1916, displayed the relationship between the vasa recta and the neck of the diverticulum. In 1976, Meyers et al.<sup>12</sup> defined the bleeding sites as the ruptured vasa recta in the diverticulum. He noted structural changes located eccentrically in the vasa recta at the site of rupture, intimal thickening with thinning of the media, the absence of any acute or chronic inflammation, and stated that these vascular changes were typically the result of focal injury. It is generally accepted that thinning of the media in the vasa recta predisposes to intraluminal rupture: focal injury may occur from trauma related to a fecalith.

It is unclear how frequently diverticula are the true cause of hemorrhage. The incidence spans a range of 15% to 48%. Oftentimes, authors attribute the condition to diverticula after the hemorrhage has ceased despite a lack of proof of actual cause, a presumptive diagnosis. Diagnostic evaluations, such as colonoscopy, do not identify a precise source for the hemorrhage without the presence of witnessed bleeding or an adherent clot. Oftentimes, for lack of a more precise etiology, diverticula are present and, therefore, become the primary culprit. Despite being considered a major source for colonic hemorrhage, bleeding from diverticula is a relatively rare event affecting only 4%–17% of patients with diverticulosis.<sup>13</sup>

In most cases, bleeding ceases spontaneously, but in 10%–20% of cases, the bleeding continues unabated in the absence of intervention.<sup>14</sup> Once bleeding has occurred, the natural history and risk of rebleeding are poorly understood. Finne<sup>15</sup> comments that the risk of rebleeding after an episode of bleeding is approximately 25% but increases to 50% among patients who have had two or more prior episodes of diverticular bleeding. Right sided colonic diverticula occur less frequently than left sided or sigmoid diverticula but are thought to be responsible for a disproportionate incidence of diverticular bleeding. This finding is not well established, however, and there is often difficulty distinguishing between bleeding from an arteriovenous malformation or angiodysplasias and bleeding from diverticulosis. The overall high prevalence of diverticulosis in the population at risk for lower gastrointestinal hemorrhage makes the exact diagnosis of many bleeding episodes equivocal.

TABLE 20-1. Mortality of lower gastrointestinal bleeding by etiology

Investigator	Diverticulosis (%)	Angiodysplasia (%)	Cancer/polyp (%)	Colitis/ulcer (%)	Anorectal (%)	Other (%)	Mortality (%)
Jensen and Machicado, <sup>3</sup> 1997	23	40	15	12	5	4	NA
Longstreth, <sup>2</sup> 1997	41	3	9	16	5	14	3.6
Bramley et al., <sup>6</sup> 1996	24	7	10	21	9	4	5.1
Richter et al., <sup>7</sup> 1995	48	12	11	6	3	6	2
Rossini et al., <sup>8</sup> 1989	15	4	30	22	0	11	NA
Jensen and Machicado, <sup>9</sup> 1988	20	37	14	11	5	5	NA

Operative management of diverticular bleeding is indicated when bleeding continues unabated and is not amenable to angiographic or endoscopic therapy. It also should be considered in patients with recurrent bleeding localized to the same colonic segment. In a stable healthy patient, the operation consists of a segmental bowel resection (usually a right colectomy or sigmoid colectomy) followed by a primary anastomosis. One additional note about diverticular hemorrhage focuses on recurrence for patients who stopped bleeding and required no operative intervention. In Longstreth's San Diego study,<sup>2</sup> the author noted that 9% of patients returned within 1 year with another episode. At 2 years, there was little change, 10%; 19% at 3 years; and 25% at 4 years.

## Angiodysplasia

Angiodysplasia was described by Margolis et al.<sup>16</sup> in 1960 when they noted the radiographic features during an intraoperative angiogram performed for colonic bleeding. Angiodysplasias are thin-walled arteriovenous communications located within the submucosa and mucosa of the intestine. Angiodysplasias may be congenital or, more typically, acquired. They could be isolated or multiple. In the acquired form, distortions of the postcapillary venules may arise as a degenerative lesion associated with increases in intraluminal pressure. The intraluminal pressure occurs from loss of the precapillary sphincter and a resultant increased pressure transmitted through the capillary bed into the venules. As these vessels respond to the arterial flow, it results in thickening and ectasia. The vessels eventually entangle as tufts within the submucosa and erode into the mucosa proper.

No one is quite certain precisely why angiodysplasias occur. Current hypotheses suggest a loss of vascular integrity related to loss of transforming growth factor (TGF)  $\beta$  signaling cascade or from a deficiency in mucosal type IV collagen. McAllister et al.<sup>17</sup> suggest that a genetic error in endoglin production alters TGF  $\beta$  and, thus, the integrity of the vascular endothelial cells. Roskell et al.<sup>18</sup> noted the loss of mucosal type IV collagen in pathologic specimens of angiodysplasia.

Angiodysplasias are uncommon before age 60, increase with age, and are associated with aortic stenosis (Heyde's syndrome), chronic renal failure, and von Willebrand's disease. Osler-Weber-Rendu (hereditary hemorrhagic telangiectasias) is a hereditary condition with telangiectasias of the lung, nervous system, skin, and intestine. These patients present with multiple lesions. In 1995, Christopher Gostout<sup>19</sup> editorialized in questioning the association of angiodysplasias with aortic stenosis.

When angiodysplasias are noted during angiography or colonoscopy, unless a hemorrhagic blush is seen during the angiogram or colonoscopy, it is difficult to accurately accuse this malady as the source of hemorrhage.<sup>20</sup> In the past, angiodysplasia was the diagnosis chosen when no bleeding source could be identified and the abnormal vessels were present. In addition, many drew an association between the

angiodysplasias and aortic stenosis. The association between the ecstatic vascular tufts and aortic stenosis was dispelled by Imperiale and Ransohoff<sup>21</sup> in the late 1980s. However, the association persisted in anecdotes until Bhutani and colleagues<sup>20</sup> reviewed 37 patients and found no greater incidence of aortic valvular disease than the control group.

Angiography remains the gold standard for the diagnosis of angiodysplasia. After injection of contrast, a series of images are collected in three phases. In the arterial phase, the radiographic findings of angiodysplasia demonstrate early venous filling which normally occurs in later phases. During the next phase, capillary phase, small, tortuous tufts are seen entangled and filled with contrast. Finally, the late phase study demonstrates a persistent of this arteriovenous tuft and a persistent of a slow, emptying vein.<sup>22</sup> When angiography identifies a bleeding angiodysplasia, treatment with embolization therapy or directed infusion of vasopressin will decrease or stop the bleeding.

Colonoscopy has increased as a screening agent for colorectal cancers as well as during the investigation for colorectal bleeding. Expectantly, more angiodysplasias are seen during endoscopy than in the past. In contrast to the angiographic findings described by Boley et al., Bhutani et al.<sup>20</sup> highlighted the colonoscopic criteria in describing these lesions. The mucosal surface contains a cherry red lesion that is typically flat. The lesions are greater than 2 mm in size and have a "fern-like" appearance. A central feeding vessel is not always visible. It is important to identify these lesions during scope insertion. Occasionally, the inexperienced endoscopists may attribute colonoscopic suction trauma to an angiodysplastic area. By searching for the vascular muscular lesions during scope insertion, the endoscopist will avoid misnaming scope mucosal trauma as angiodysplasia. Initial experience in identifying these lesions related to a few angiographic studies. The early evidence suggested the lesions were predominantly right sides. Since colonoscopy has become more available, both left and right sided lesions are thought to occur.

## Other Causes of Lower Gastrointestinal Hemorrhage

Multiple other etiologies cause lower gastrointestinal bleeding and most are not associated with a massive hemorrhage or acute symptomatic anemia. Colonic ischemia, inflammatory bowel disease, and colonic malignancies occur frequently. Each presents in a different manner. Typically, ischemic colitis presents with the abrupt onset of abdominal pain, followed by colic and a mucoid, bloody diarrhea. Inflammatory bowel disease, Crohn's, and ulcerative colitis present with a change in stool patterns. Patients develop diarrhea followed by hematochezia or melena. Localized transmural involvement or colic could add pain-related symptoms. Colorectal carcinomas are associated with exophytic, ulcerative lesions that may bleed insidiously. Only rarely does the malignant process proceed to acute, symptomatic hemorrhage.

More unusual causes of hemorrhage involve small intestinal tumors, known also as gastrointestinal stromal tumors (GIST). These lesions enlarge and surpass their blood supply. In that event, the ischemia in the tumor will ulcerate and may cause a localized hemorrhage. Meckel's diverticulum represent another atypical cause of bleeding. These lesions occur in the distal ileum. Ectopic gastric mucosa leads to localized acidic contents and resultant ulcerations of the contralateral intestinal wall. Finally, NSAID-associated intestinal hemorrhage occurs most frequently in the terminal ileum and cecum. Long-acting NSAIDs cause a localized mucosal injury. These remnants from the agents have been noted at the site of perforating ulcers. It seems that the terminal ileum and cecum may serve as a reservoir and harbor these agents long enough to establish the mucosal defects. Diaphragm-like strictures are pathognomonic for NSAID injuries and may result from a healing ridge related to repeated injuries from the agents.

### Occult Hemorrhage

Obscure or occult gastrointestinal bleeding is a condition that frustrates the patient and the physicians. The hemorrhage is often massive and intermittent. The traditional tests of nuclear scintigraphy, colonoscopy, and angiography provide no solution. It occurs infrequently. One study noted occult bleeding in no more than 5% of all patients admitted with lower gastrointestinal massive hemorrhage. Frequent recurrences create chronic anemic states in patients and require occasional admissions for transfusions. These patients may harbor angiodysplasias in the small intestine or right colon. Patients in this situation may benefit from small bowel contrast radiography or capsule endoscopy.<sup>23-26</sup> Additionally, elective angiography with cecal magnification may reveal small angiodysplasias.

If the occult hemorrhage recurs and investigations fail to reveal the source, a variety of provocative diagnostic angiographic studies have been described. Most studies prefer to incite bleeding using either heparin or thrombolytics. Once the site of bleeding is identified, it may be difficult to control without an operation. In these instances, the surgeon should prepare and hold an operating room. Once the location is identified, a superselective catheter is left in the distal artery. During the conduct of surgery, the surgeon can palpate the catheter within the vessel and direct the surgical resection.

### Initial Assessment, Resuscitation, and Stabilization

Massive lower gastrointestinal hemorrhage requires prompt clinical attention. Patients who present with symptoms secondary to the bleeding have urgent resuscitation needs. These symptoms further define the significance of the hemorrhage. Patients may demonstrate pallor, fatigue, angina, tachypnea, cardiac palpitations, postural hypotension, and syncope.

Prompt attention requires placement of vascular access with large bore intravenous fluids. Further hemodynamic monitoring requires cardiac rhythm monitoring and placement of a urinary catheter. A nasogastric tube placed will screen for the presence of upper gastric sources for bleeding. Kovacs and Jensen<sup>27</sup> noted 17.9% of lower gastrointestinal hemorrhage presentations involved an upper gastrointestinal source. The nasogastric tube is effective in detecting prepyloric hemorrhage. The nasogastric decompression need not be continued after an appropriate period of observation to exclude upper intestinal sources.

The treatment goals for resuscitation are to restore volume and, replete red blood cell deficiencies and their impact on oxygen delivery. In addition, all coagulopathies require reversal. Patients require laboratory profiles that include a complete blood count, serum electrolytes, a coagulation profile, and a type and crossmatch for packed red blood cells.

The initial specific diagnostic evaluation begins with a digital anorectal examination and anoscopy. A rigid proctosigmoidoscopy will allow the examiner to evacuate the rectum of blood and clots. A complete mucosal assessment serves to exclude internal hemorrhoids, anorectal solitary ulcers, neoplasms, and colitis. If nothing is found and subsequent surgery becomes necessary, the evaluation of the rectum and anorectal function greatly aids in surgical decisions. A normal anorectal examination allows the surgeon to consider a primary rectal anastomosis as a treatment possibility. In the event that the physician discovers a source for bleeding during the examination, oftentimes therapy can immediately control the hemorrhage.

Once the resuscitation demonstrates a stable patient, the next phase of the diagnostic evaluation ensues. What is the first test to evaluate the cause of bleeding? Currently, three tests are considered for the initial evaluation. These tests include colonoscopy, nuclear scintigraphy, and angiography. Colonoscopy and angiography offer therapeutic intervention whereas nuclear scanning is purely diagnostic. Decisions as to which test to use depend on the clinical judgment, local expertise, severity of the event, and the current activity of the hemorrhage.

It may be helpful to subdivide patients into three general clinical categories based on the history, physical, and the initial laboratory data. Is the hemorrhagic event 1) minor and self-limited, 2) major and self-limited, or 3) major and ongoing? Major ongoing hemorrhage requires prompt intervention with angiography or surgery. Minor, self-limited may undergo a colonic lavage and colonoscopy within 24 hours. Major, self-limited may be more difficult to define. Within the spectrum of these three clinical groups, the major, self-limited hemorrhage patients create the current controversy. These patients need a diagnostic test to determine if they require prompt therapy or observation. Should these patients undergo nuclear imaging or colonoscopy?

Radionuclide imaging (Figure 20-1) detects the slowest bleeding rates. It is able to detect rates of 0.1–0.5 mL/min.

A

B

FIGURE 20-1. Selected images from a  $^{99m}\text{Tc}$ -labeled RBC gastrointestinal bleeding study in a patient with known diureticulosis. Images acquired at 1 minute (A) and 14 minutes (B). Abnormal increased isotopic activity developed in the proximal transverse colon, which progressed antegrade to the descending colon.

Thus, it is a technique that is more sensitive than angiography. Unfortunately, the nuclear scanning cannot reliably localize the site of hemorrhage. The specificity (precise origin) using radionuclide scans of small bowel versus large intestine bleeding does not reliably compare with angiography.<sup>28</sup> Two general techniques are used for nuclear imaging, technetium sulfur colloid scans and  $^{99m}\text{Tc}$  pertechnetate-tagged red blood cells (RBCs). Sulfur colloid scans have a short half-life and detect very low rates of hemorrhage (0.1 mL/min). It is effective to detect brisk hemorrhage but cannot detect sporadic bleeding. The more frequently preferred agent for lower gastrointestinal hemorrhage radionuclide scanning is the pertechnetate-tagged RBC scans. The tagged RBC scans may cover a period of hours

and allow for reimaging within 24 hours. Nuclear scintigraphy has variable results, suggesting that scan timing, technical skills, and experience may increase accuracy. Current reports suggest accuracies ranging from 24% to 91%.<sup>29</sup>

Ng et al.<sup>30</sup> recommend nuclear imaging for the patients with a major, self-limited hemorrhage. Their data suggest that the timing of the blush predicts the success of angiography. In other words, if the nuclear scan demonstrates an immediately positive blush (within the first 2 minutes of scanning), it is highly predictive of a positive angiogram (60%). The data of Ng et al. seemed predictive for surgery in 24% of patients if the first blush was positive. Just as important, if the initial images in the Ng et al. study did not demonstrate a blush, the study is highly predictive of a negative angiogram (93%) and the need for surgery decreased to 7%. Thus, if the nuclear scan is negative, it provides objective evidence that the patient is not actively bleeding and may be evaluated by colonoscopy.

### Colonoscopy

Many authors believe that colonoscopy has clearly demonstrated the highest efficacy and should be the first study in patients with major bleeding that appears self-limited.<sup>31</sup> In general, this may be true if efficacy of the study includes a broad array of the common etiologies for properly defined massive hemorrhage. Controversy abounds with colonoscopy as the preferred first study if the etiologies for hemorrhage are unlikely sources for major hemorrhage. Whether colonoscopy should be undertaken emergently depends on the general ability to maintain a stable patient. If the hemodynamic profile continues to drift toward hypotension and the massive hemorrhage continues unabated during the resuscitation process, the rate of hemorrhage may require more prompt attention. Patients with extremely brisk hemorrhage require a prompt angiogram. Colonoscopy in such patients proves difficult to prep with lavage and the acute exsanguinations may limit intraluminal visualization to deploy all the therapeutic options except for only the most experienced endoscopists.

If the patient appears stable with self-limited hemorrhage, colonoscopy is the preferred diagnostic study. Jensen et al.<sup>3,4,9</sup> have long been proponents of "emergency colonoscopy." This group and others have demonstrated high cecal intubation rates (95%) and a diagnostic accuracy of 72% and 86%. On a cautious note, the Jensen diagnostic studies demonstrated atypical etiologies for massive hemorrhage including ischemic colitis, inflammatory bowel disease, and cancer. The rate of bleeding in these conditions may be more amenable to urgent colonoscopy (within 24 hours) rather than emergent colonoscopy in patients diverticular or angiodysplastic, hemorrhagic rates.

Should the patient undergo a colonic lavage before colonoscopy? Longstreth<sup>2</sup> reported that 80.8% of patients had colonoscopy after electrolyte-polyethylene glycol solution purge, usually within 24 hours of admission. His report reflects the more typical approach to patients. Once the

patient undergoes observation and stabilization, the need for acute intervention seems avoided. Then the endoscopist may plan for a more controlled, stable, urgent colonoscopy with a lavage which occurs within the first 24 hours. The Longstreth Kaiser Permanente study demonstrated a broad scope of etiologies (see Table 20-2).

The major benefit of colonoscopy depends on the ability to provide a definitive localization of ongoing active bleeding and the potential for therapy. Many landmarks for colonoscopy may be obscured during hemorrhage. Because of the inability to appreciate all intraluminal landmarks and locate the segment that is bleeding, once the endoscopist highlights a bleeding source, the region of the intestine requires a tattoo to mark the site with India ink. In such patients, if the hemorrhage continues and fails medical management, the tattoo greatly assists the surgeon in localizing the hemorrhage.

The endoscopist has many therapeutic options to control the bleeding. Kovacs and Jensen<sup>27</sup> have described several therapeutic tools to control bleeding in upper and lower gastrointestinal hemorrhage. Therapeutic armamentarium for the colon includes thermal agents such as heater probes, bipolar coagulation, and laser therapy. Injection therapy primarily uses topical and intramucosal epinephrine. Mechanical therapy includes endoscopically applied clips (Figure 20-2).<sup>27</sup>

## Angiography

Angiography is diagnostic and therapeutic in the treatment of intestinal hemorrhage. The clinical judgment for choosing angiography involves three different types of hemorrhage. First, acute, major hemorrhage with ongoing bleeding requires emergency angiography. Second, patients with an early blush during nuclear scintigraphy may benefit from therapeutic angiography. Finally, angiograms may define a potential source for hemorrhage in occult and recurrent gastrointestinal hemorrhage. To appreciate an angiographic blush of contrast, the study requires a hemorrhage rate of at least 1 mL/min.<sup>32</sup> Positive yields with angiography vary greatly. Patient selection will increase yields and avoid overuse of angiograms. Generally, reports demonstrate yields that range from 40% to 78%.<sup>33-36</sup>

TABLE 20-2. Final diagnosis in patients hospitalized for acute lower gastrointestinal hemorrhage<sup>31</sup>

	n (%)
Colonic diverticulosis	91 (41.6)
Colorectal malignancy	20 (9.1)
Ischemic colitis	19 (8.7)

Hemorrhoids	10 (4.6)
Postpolypectomy hemorrhage	9 (4.1)
Colonic angiodysplasia	6 (2.7)
Crohn's disease	5 (2.3)
Other	22 (10.1)
Unknown	26 (11.9)
Total	219 (100)

FIGURE 20-2. Clip applied to bleeding diverticular vessel.

Angiography provides highly accurate localization of the site of bleeding (Figure 20-3) and the angiographic blush may suggest a specific etiology, but it lacks the accuracy of colonoscopy. Highly accurate localization provides for focused therapy. Hemorrhagic site may receive highly selective, intraarterial vasopressin infusion. The potent arterial contraction may reduce or halt the hemorrhage. Infusion rates of vasopressin are at concentrations of 0.2 U/min and may progress to 0.4 U/min. The systemic effects and cardiac impact of vasopressin may limit maximizing the dosage. Vasopressin controls bleeding in as many as 91% of patients. Bleeding may recur in as many as 50% of patients once the vasopressin is tapered.

Angiographic technology also allows for arterial embolization to control hemorrhage. Superselective mesenteric angiography with current microcatheters allows for embolization of the vasa recta of the intestine, vessels as small as 1 mm. In the past, arterial embolization of larger vessels risked intestinal ischemia or infarction. The risk of intestinal infarctions of larger selective vessels may exceed 20%. Arteriography also has complication rates related to angiography, separate from the therapy delivered at the site of bleeding. These include arterial thrombosis, distant arterial emboli, and renal toxicity from the angiographic dye.

Embolization therapy provides immediate arrest of the bleeding. Embolization uses a combination of agents to control bleeding including Gelfoam pledgets, coils, and polyvinyl alcohol particles. In 2001, Funaki et al.<sup>37</sup> reported experience with microcoil embolization in 27 patients. They succeeded in 93% and had reasonable long-term

FIGURE 20-3. Angiogram demonstrating extravasation (hemorrhage) in cecum.

results—81%. Most of his patients had diverticular hemorrhages. His recurrent bleed patients had angiodysplasias. In a similar experience, Peck et al.<sup>38</sup> reported rebleeding in three of four patients with cecal angiodysplasias. The data suggest that angiodysplasias have multiple feeding vessels and may contribute to the recurrence.

### Operative Therapy

Surgical therapy for massive lower intestinal bleeding is rare, often definitive, and associated with significant mortality. Most sources of bleeding spontaneously resolve or are controlled with the current therapeutic interventions. Few patients currently require surgical treatment. If the patient is hemodynamically unresponsive to the initial resuscitation, then radiographic, radionuclide, and endoscopic evaluations are usurped by the need for urgent surgery. Other patients may have the site of hemorrhage localized, yet the available therapeutic interventions fail to control the bleeding. Patient mortality increases with their transfusion requirements, suggesting the severity of the hemorrhage. Bender noted a reduced mortality (7%) for patients requiring less than 10 units of blood. The mortality increased to 27% for patients in excess of 10 units.<sup>39</sup> Therefore, once a patient reaches 6–7

units during the resuscitation and the hemorrhage remains ongoing, surgical intervention becomes eminent.

The surgeon tailors the approach to the patient and depends on the diagnostic information gathered before the operation. All patients require an open laparotomy with a thorough examination of the entire intestine. The first objective in surgery focuses on the location of the intraluminal blood with the hope of segmentally isolating the possible sources of bleeding. If the colon visually appears filled with blood and the small intestine remains spared, the surgeon must still examine the entire abdomen and then focus on colonic sources of bleeding. If the small bowel contains blood, then the operative team has a larger area of concern and close inspection.

Once the surgeon completes the initial visual inspection, a complete exploration ensues. The exploration begins in the stomach, duodenum, and considers possible missed upper gastrointestinal sources. Next, the small intestine must undergo examination from the ligament of Treitz to the ileocecal valve. Palpation of the intestine may demonstrate such etiologies as a Meckel's diverticulum, ileitis, colitis, or a GIST.

Upon completion of the exploration phase, if no source appears obvious, the surgeon may consider intestinal enteroscopy. The enteroscope or colonoscope will expose the luminal surface and transilluminate the intestinal wall for occult lesions. Transillumination may identify vascular anomalies, small ulcers or tumors. Endoscopic access to the intestine may require upper enteroscopy, a transgastric approach, a transcolonic approach, or insertion through the anus. Once a hemorrhage site is identified, the surgeon can perform an appropriate segmental resection. Intraoperative endoscopy is a technically difficult endeavor. A team approach with two surgeons or the availability of an experienced endoscopist is important to identify the elusive lesions causing the hemorrhage.

If the source of bleeding cannot be found, and it appears to arise from the colon, the surgeon should perform a subtotal or total colectomy. Stable patients will tolerate a primary ileosigmoid or ileorectal anastomosis in this circumstance. Unstable patients require an end ileostomy with closure of the rectal stump or a mucous fistula. Once stable, the patient may return for ileostomy closure. The rectum and sigmoid colon require reexamination endoscopically to assure no bleeding persists. Before the endoscopy, a simple saline “washout” with a transanal catheter or via the rigid proctosigmoidoscope may provide for safe passage and careful examination of the remaining mucosa.

The key concerns with operative management are, first, a delay in the decision to operate until the hemorrhage reaches a critical point beyond 10 units of blood. This seems to contribute to the high mortality rate. Second, mortality rates for patients requiring urgent surgery consistently reach a range hovering between 10% and 35%.<sup>40</sup> Few authors note mortalities less than 10% or greater than 40%. Third, notable recurrence rates of 10% are attributable to the limits of isolating the

precise cause of the bleeding. The rates of recurrence increase if a surgeon elects to perform a limited right or left colectomy without precise localization of the hemorrhage. Limited segmental colectomies continue to have high mortality rates and excessive persistent bleed rates of 20%.<sup>41</sup> A total colectomy offers the same mortality with a lower chance of recurrent or persistent hemorrhage.

## New Frontiers

Horton and Fishman<sup>42</sup> commented about the advanced imaging within computerized tomography. Current thinly sliced, fast image acquisition combined with three-dimensional software packages has revolutionized the imaging of the vascular tree. Abdominal, and specifically intestinal vascular imaging now details smaller than “named” vessels. Current use focuses on chronic conditions such as mesenteric ischemia and inflammatory bowel disease. Case reports and animal modeling note it is a feasible study for gastrointestinal hemorrhage. New scanners promise even more with 16 0.5-mm slices acquired in 0.4 seconds. Image acquisition synchronized with intravascular contrast may outline a site of contrast extravasation or blush. The detail available may define intestinal hemangiomas, arteriovenous malformations, and angiodysplasias. The sensitivity and specificity of computed tomographic angiography in patients with gastrointestinal hemorrhage are unknown and require further comparison studies to current diagnostic studies.

Anderson<sup>43</sup> noted magnetic resonance angiogram creates images using the bright signal from blood. The three-dimensional images are reconstructed using computerized imaging to project a two-dimensional image that mimics a conventional angiogram. Further improvement develops from contrast-enhanced magnetic resonance angiography (CEMRA). With current techniques, the resultant images are not as specific or as refined as an angiogram. The technique may detect the extravasation of blood pooling in various segments of the intestine. In addition to localizing the side, the study may distinguish small intestine versus large intestine. These studies may prove an enhancement when compared with nuclear scintigraphy.

Wireless capsular endoscopy is an ideal diagnostic adjunct for patients with occult hemorrhage.<sup>24,25</sup> The first generation of capsules are 11 × 30 mm. The capsules are easily swallowed and tolerated. The current system captures two images per second and transmits the images to a recording apparatus secured to a belt the patient wears. Transmitted images are later reviewed by the endoscopist.

Lewis and Swain<sup>44</sup> reported the results from the first clinical trial. They noted a source of occult hemorrhage in 7 of 11 patients. The sites noted included angiodysplasia, ileal ulcers, and a tumor. Rossini et al.<sup>45</sup> corroborated their work in noting success in 7 of 10 patients.

The evaluation and management of lower gastrointestinal hemorrhage remains a challenge for surgeons. An algorithm summarizing the management is provided in Figure 20-4.

## Endometriosis

Michael J. Snyder and Steven J. Stryker

Endometriosis is a disease characterized by the presence of endometrial glands and stroma outside the uterine cavity. It is one of the most common conditions requiring surgery for women during their reproductive years. Endometriosis, although not fatal, may be associated with disabling pain and intractable infertility. The degree of symptoms varies widely and does not always correspond to the extent of pathology encountered at surgery. Small lesions may cause severe pain and infertility whereas larger lesions may be asymptomatic and found only incidentally during surgery for other diagnoses. Diagnosis is typically made or confirmed at laparoscopy or during laparotomy. Colon and rectal surgeons often become involved in the management of patients with intestinal endometriosis. This involvement may occur as a result of a combined procedure with a gynecologist or in management of an endometrioma masquerading as a neoplastic or inflammatory lesion. Treatment for endometriosis is usually multimodal and may include an operation in those patients with infertility, pelvic pain, obstruction, or a poor response to hormonal suppression. Although advances in diagnostic tests and therapy have been made, endometriosis remains a frustrating and incompletely understood disease for both patients and physicians.

### Epidemiology

The true prevalence of endometriosis is unknown. There is no noninvasive screening test for endometriosis, and its diagnosis depends on the visual or pathologic identification of implants during laparoscopy or laparotomy. Various authors have estimated that up to 15% of all women of reproductive age and one-third of infertile women have endometriosis.<sup>1,2</sup> A study by Houston et al.<sup>3</sup> is the only population-based study of endometriosis. After reviewing the medical records for Caucasian women in Rochester, Minnesota, during the 1970s, they estimated that 6.2% of premenopausal women have endometriosis.

Although endometriosis is primarily a disease of the reproductive years, the widespread use of exogenous estrogens and

increasing obesity in our society have made it more prevalent in postmenopausal women. Conversely, there is a decrease in the incidence of the disease when women use oral contraceptives or experience multiple pregnancies.<sup>4</sup> These observations, coupled with the fact that the incidence of endometriosis increases over time after a woman's last childbirth, suggest that uninterrupted menstrual cycles predispose susceptible individuals to the development of endometrial implants.<sup>5</sup> There is no racial predilection for endometriosis other than in Japanese women, who have double the incidence of the disease compared with Caucasian women.<sup>6</sup>

### Etiology

The precise etiology that completely explains the cause and pathogenesis of endometriosis is unknown. The two most popular theories as to etiology are coelomic metaplasia and the implantation of viable endometrial cells from retrograde menstruation through the fallopian tubes. Coelomic metaplasia, postulated by Meyers, suggests that under the correct hormonal milieu, the coelomic epithelium will undergo metaplastic changes and transform into endometrial tissue.<sup>7</sup> He bases his theory on studies demonstrating that the peritoneum and uterine endometrium both originate from embryonic coelomic epithelium. Although this theory offers a good explanation for endometriosis in men and nonmenstruating women, it does not adequately address the anatomic distribution and clinical pattern of endometriosis. The vast majority of endometriosis occurs in the pelvis, but the peritoneum at risk with this theory is evenly distributed throughout the abdominal cavity. In addition, metaplasia should worsen with age and endometriosis clearly does not.

Retrograde menstruation, first proposed by Sampson<sup>8</sup> in 1921, remains the most plausible explanation for the distribution of endometrial implants. This theory postulates that endometriosis arises from retrograde menstruation through the fallopian tubes and into the peritoneal cavity. Viable endometrial tissue has been demonstrated in menstrual effluent, and

endometriosis has been induced both in primates, with artificially produced retrograde menstruation,<sup>9</sup> and in women volunteers who permitted injection of menstrual tissue into their peritoneum.<sup>10</sup> This theory, however, is probably only part of the answer.

Whereas retrograde menstruation is very common, occurring in virtually all women, endometriosis affects only a small minority. Clearly, other factors must be involved to permit the implantation and growth of endometrial tissue. Several studies indicate a possible genetic aspect to endometriosis. Simpson et al.<sup>11</sup> demonstrated that the disease seems to occur more frequently within families. He found a 7% relative risk for blood relatives of affected individuals as opposed to a 1% relative risk for nonblood controls. Additionally, the clinical manifestations of the disease were more severe among the related group. It seems that the inheritance pattern is polygenic or a combination of genetic and environmental factors. This conclusion is consistent with the clinical associations with delayed childbearing and uninterrupted cyclic menstruation.

Dmowski et al.<sup>12</sup> have theorized that the genetic factor may involve the immune system. They demonstrated depressed cellular immunity in monkeys with spontaneous endometriosis. Other investigators have confirmed alterations in both cellular and humoral immunity in women with endometriosis.<sup>13,14</sup> The most striking change observed in cellular immunity is the high concentration of activated macrophages and decreased functional capacity of natural killer cells. The most significant abnormality in humoral immunity is the presence of autoantibodies against different cellular components. These changes have been observed in both the peritoneal cavity and the systemic circulation, suggesting that endometriosis may be a systemic disease. It is still unclear whether these changes represent manifestations of the disease or a subsequent reaction to it. This research, however, suggests that mild subclinical immunosuppression may subsequently lead to endometriosis many years later.

## Clinical Manifestations

The most common sites where endometriosis occurs are summarized in Table 21-1. The most frequent of these are in the pelvis. Potential sites of implantation in the abdomen include the appendix, small bowel, and diaphragm. Rarely, implantation may occur in the inguinal canal (in patients with hernias), surgical incisions, the vulva, vagina, cervix, or systemically in the lungs, bronchi, or kidneys.

TABLE 21-1. Sites and incidence of endometriosis

Common	Less common	Rare
Ovaries 60%–75%	Appendix 2%	Diaphragm
Uterosacral ligaments 30%–65%	Ureter 1%–2%	Inguinal canal
Cul-de-sac 20%–30%	Terminal ileum 1%	Liver
Uterus 4%–20%	Bladder <1%	Spleen
Rectosigmoid colon 3%–10%	Abdominal scars < 1%	Kidney

Because the majority of women have disease confined to the pelvis, the most common presenting complaints relate to menstrual irregularities, pelvic pain, and infertility. Many women with endometriosis may be completely asymptomatic and the natural history of the disease in these patients has never been well defined. In studies with placebo arms, a few interesting observations have been made. A trial involving infertile women with otherwise asymptomatic endometriosis revealed that laparoscopic scoring of the severity of the disease increased over the length of the study in almost 50% of the placebo group.<sup>15</sup> Another study compared pain scores in women receiving placebo versus gonadotropin-releasing hormone (GnRH) analogs.<sup>16</sup> The cumulative dysmenorrhea rate and severity of pain were significantly lower in the treatment group suggesting a progressive course of the disease when untreated. Other studies on infertile women revealed that mild endometriosis can spontaneously resolve and that medical therapy may only suppress the disease until hormonal stimulation resumes.<sup>17</sup>

Ovarian hormones to varying degrees influence all endometrial tissue, and many of the clinical manifestations of endometriosis reflect the changing concentration of these hormones during a typical menstrual cycle. Under the influence of pituitary-stimulating hormones, the ovary begins to secrete estrogen at the beginning of the menstrual cycle. This stimulates endometrial mitosis with cellular proliferation in concert with neovascularization. At the midpoint of the cycle, progesterone production by the corpus luteum begins and promotes secretory changes in the endometrium in anticipation of implantation. The loss of progesterone at the end of the menstrual cycle from involution of the corpus luteum destabilizes the endometrium and induces menstruation.

## Pelvic Pain and Dysmenorrhea

Pain is the most common symptom of endometriosis, affecting up to 80% of patients subsequently diagnosed with the disease. Endometriosis has been discovered in 30%–50% of women undergoing laparoscopy for pelvic pain.<sup>18</sup> Pelvic pain associated with endometriosis presents as dysmenorrhea, dyspareunia, or chronic noncyclic pelvic pain. There are women, however, with extensive endometriosis and little or no pain. Total lesion volume does seem to correlate directly to the degree of pain.<sup>19</sup> Symptoms are related to the depth of penetration of the lesion, the type of lesion, and its location. Implants involving the uterosacral ligaments and rectovaginal septum are most frequently implicated. The pain is typically most intense just before menstruation and lasts for the duration of menstruation. The pain is often associated with back pain, dyschezia, and levator muscle spasm, and is more severe with advanced stages of endometriosis.

Dysmenorrhea occurs in most women with endometriosis. The association is not well understood, and some have hypothesized that high uterine pressures cause dysmenorrhea with retrograde menstruation, a consequence of these increased pressures.<sup>20</sup> Other investigators, however, have

failed to show an increase in the prevalence of dysmenorrhea with early-stage endometriosis.<sup>21</sup>

Dyspareunia, deep pelvic pain with vaginal penetration, is usually a symptom of advanced endometriosis. Dyspareunia is most pronounced just before menstruation and is associated with specific coital positions. The presence of dyspareunia is often indicative of the degree of fixation of the pelvic organs, especially in the cul-de-sac of Douglas and the rectovaginal septum.

Chronic noncyclic pelvic pain is pain present for longer than 6 months, and may be intermittent or continuous. The pain is often associated with both perineural inflammation and uterosacral ligament involvement with endometriosis.<sup>22</sup> Gastrointestinal and urinary complaints may accompany the pain.

Pain in the shoulder during or just preceding menstruation may be attributable to endometrial implants involving the diaphragm. The diaphragm should always be viewed during laparoscopy, so these diaphragmatic deposits can possibly be treated with laser vaporization. Differentiation from adhesions associated with pelvic inflammatory disease (Fitz-Hugh and Curtis syndrome) is usually not difficult unless the two pathologies coexist.

The pathophysiology of pain arising from endometriosis is not completely clear. Pain may occur from the cyclic growth and subsequent increase in pressure within the capsule surrounding the implant. Alternatively, extravasation of menstrual debris into the surrounding tissue may occur with subsequent edema and release of inflammatory mediators. As the implant matures with surrounding unyielding scar tissue, the stretching of this scar by the products of the endometrial glands may produce pain. This scenario is probably particularly true for deeper implants. A study by Cornillie et al.<sup>22</sup> discovered that all women with implants deeper than 1 cm experienced severe pelvic pain.

Adhesions, very common in endometriosis, may also be associated with pain. Adherence of the colon and small bowel along with retroflexion of the uterus from extensive posterior adhesions may occur. Such retroflexion and fixation of the rectosigmoid can result in pressure on the sacrum with consequent back and rectal pain.

Since the 1960s, multiple investigators have attempted to define the role of prostaglandins in the pathogenesis of pelvic pain.<sup>23,24</sup> Macrophages are responsible for the removal of foreign material such as the endometrial implants. They are present around the endometrial implants and are potent producers of inflammatory mediators such as the prostaglandins. Both prostacyclin (PGI-2) and prostaglandin E-2 are able to sensitize pain receptors to chemical mediators. Leukotriene B-4, another macrophage product, is a potent chemotactic agent and leukocyte activator. These factors are thought to explain some of the pelvic pain, but not all studies agree.<sup>24</sup> The relative transient nature of prostaglandin action and the inherent difficulty in measuring pain complicates attempts to quantify the impact of chemical mediators.

## Infertility

The relationship between endometriosis and infertility is also unclear. Some studies have demonstrated a high percentage of infertile patients with endometriosis.<sup>25</sup> Certainly, those reports comparing rates of endometriosis for women undergoing elective laparoscopic sterilization versus laparoscopy for infertility have demonstrated a fourfold or greater increase in the infertile group. In women with known endometriosis, the infertility rate is 30%–50%. Whether endometriosis causes infertility or is the product of uninterrupted menstruation is still hotly debated.

There is little disagreement that moderate to severe disease with mechanical distortion of the fallopian tubes, ovaries, and peritoneum can potentiate infertility. Pelvic endometriosis and the resulting inflammatory response can produce dense, fibrotic adhesions that may significantly interfere with both the oocyte release from the ovary and the ability of the fallopian tube to pick up and transmit the oocyte to the uterus. Blockage of the tube may produce a hydrosalpinx, and in one recent study, endometriosis was the etiology in 14% of patients undergoing tubal reconstruction for occlusion.<sup>26</sup> In moderate or severe endometriosis, the pregnancy rates after surgery are 50% and 40%, respectively, compared with only 7% when expectant management is practiced.<sup>27,28</sup> Surgical treatment of these patients is clearly beneficial.

Treatment of infertile patients with mild endometriosis is more problematic. A study by Inoue et al.<sup>29</sup> on 2000 infertile women with mild endometriosis did not reveal any improvement in fertility with either medical or surgical therapy when compared with expectant management. Other studies have demonstrated a lower pregnancy per cycle rate in patients with endometriosis compared with those free of the disease.<sup>30</sup>

## Intestinal Symptoms

Although some women with intestinal endometriosis may be asymptomatic, some degree of intestinal complaints is typically found in those women with moderate to severe disease. Bowel involvement occurs in 12%–37% of cases of endometriosis, and depending on the site of involvement, the symptoms of endometriosis may vary somewhat. In patients with intestinal endometriosis, the rectosigmoid is involved in more than 70%, followed by the small bowel and appendix. Rectosigmoid disease often results in alterations in bowel habits such as constipation, diarrhea, a decreased caliber of the stool, tenesmus, or, rarely, rectal bleeding. Such symptoms appear more often around the time of menses. Colonic endometriosis can present with obstruction and may be difficult to differentiate from other causes of large bowel obstruction, such as Crohn's disease or neoplasm. This difficulty is of particular concern in the postmenopausal woman on hormone replacement therapy.

Intestinal perforation may occur with endometriosis. Colonic perforation has been reported during pregnancy from

endometriosis.<sup>31</sup> Perforation also occurs with transmural appendiceal endometriosis.

For those patients with asymptomatic intestinal endometriosis, the natural history seems to be benign. Prystowsky et al.,<sup>32</sup> who followed 44 patients with known intestinal endometriosis for a period of 1–12 years, found that only one patient developed clinically significant gastrointestinal symptoms. Consequently, intestinal resection in these asymptomatic patients is probably unwarranted.

Confusion between small bowel endometriosis and Crohn's disease is common, because both can produce similar endoscopic and even histologic findings (Figure 21-1). Small bowel implants involving the terminal ileum are often noted incidentally at the time of laparoscopy and may often be asymptomatic. When symptoms occur, they are usually non-specific such as recurrent abdominal pain and bloating. Occasionally, acute or chronic small bowel obstruction develops from extensive fibrotic adhesions which are caused by endometriosis.

The next most frequent site of intestinal endometriosis is the appendix. Endometrial implants are not infrequently found when the appendix is removed incidentally. The clinical significance of appendiceal endometriosis is less than that involving the small bowel and colon. Although endometrial implants may produce acute appendicitis with right lower quadrant abdominal pain, nausea, fever, and leukocytosis, historically most abdominal explorations for presumed acute appendicitis with a subsequent diagnosis of endometriosis have been attributable to ruptured endometrial cystic implants involving the ovary. Endometriosis of the appendix may also produce a chronic obstruction of the intestinal lumen with formation of a mucocele or periappendiceal inflammatory mass that is difficult to distinguish from a neoplasm. Finally, endometrial implants of the appendix and cecum may serve as lead points for an intussusception.

FIGURE 21.1. Endometriosis involving the small intestine.

## Malignant Transformation

Malignant transformation of endometriosis is an uncommon complication of the disease. Almost 80% of the tumors are ovarian and two-thirds are endometrioid carcinomas. Patients with ovarian neoplasms arising from endometriosis are younger than the typical ovarian cancer patient, with most tumors occurring in the fourth decade of life.<sup>33</sup> Symptoms of pelvic pain and an enlarging pelvic mass are the most common symptoms. In women with known endometriosis, a cyst larger than 10 cm, cyst rupture, or a change in the nature of the chronic pelvic pain are potential signs of malignancy.

The rectosigmoid colon is the most common site for extragonadal tumors arising from endometriosis. Prolonged unopposed estrogen exposure is a significant risk factor, and rectal bleeding is the most common symptom. Recurrent symptoms of pelvic endometriosis after hysterectomy and bilateral salpingo-oophorectomy can be possible signs of malignant degeneration. Endometrial carcinoma is the most common tumor type. Histologically, the tumor must be shown to arise from the colon rather than invading it from another source. The diagnosis also requires that endometriosis or premalignant changes in endometrial glands be found contiguous with the invasive neoplasm.<sup>34</sup>

Treatment of both ovarian and extragonadal tumors is based on the particular stage of the tumor. The prognosis is generally good with tumors confined to the ovary or an extragonadal site having 5-year survivals greater than 60%. Even if a locally extensive tumor is encountered, there may be a benefit from aggressive local resection.

## Diagnosis

### Physical Examination

Patients with mild cases of endometriosis may have a normal physical examination and the diagnosis may not even be suspected unless the patient undergoes laparoscopy. For patients with pelvic pain, careful bimanual and rectal examination may reveal nodularity or induration especially in the uterosacral ligaments or cul-de-sac of Douglas. Fixed tender retroversion of the uterus in a patient without previous pelvic surgery may raise suspicion for endometriosis. Palpation of the ovaries may reveal an ovarian mass. Because these ovarian masses are generally soft and cystic, those less than 5 cm in diameter may be difficult to palpate. Cyclical pain or bleeding from any location, especially coinciding with menses, should be adequately investigated for endometriosis. The inguinal canal, previous incisions, umbilicus, and lungs can all be potentially involved with endometrial implants.

### Laboratory Evaluation

CA-125, an antigen expressed on tissues derived from human coelomic epithelium, is increased in women with moderate to

severe endometriosis. However, the sensitivity and specificity of this test is poor because the antigen may be mildly increased in other diseases and within the normal range in women with mild endometriosis. The concentration of CA-125 does correlate with the severity of the disease and is probably most useful in gauging response to medical therapy. It may also be of value in following women after resection who had increased levels preoperatively and are again exhibiting symptoms of endometriosis. No other serum markers are commercially available, but assays of antiendometrial antibodies and endometrial secretory protein PP14 are currently being evaluated for clinical relevance.<sup>35</sup>

## Endoscopy

Because the lesions begin on the outside of the intestine, endoscopic evaluation of the large bowel is often normal except in severe disease or infiltrating nodular endometrial implants. Occasionally, serosal involvement with adhesions can lead to obstruction. Endoscopically, the mucosa is generally intact, occasionally associated with significant luminal narrowing. Infiltration of the submucosa, although uncommon, may produce nodularity and distortion of the overlying mucosa (Figure 21-2). These findings may be difficult to visually differentiate from Crohn's disease, ischemia, or malignancy. Pressure against these areas of distorted bowel may produce pain that suggests the diagnosis of endometriosis. In addition, biopsies of the mucosa, taken in areas of endometriosis, can resemble solitary rectal ulcer or prolapse syndromes. Rarely is the diagnosis of endometriosis definitively confirmed by endoscopy or from endoscopic biopsies. Colonoscopy is, however, useful in excluding colon cancer from the differential diagnosis, especially in older patients presenting with a rectosigmoid mass while on hormone replacement.

Rigid proctoscopy is very helpful in predicting the depth of rectosigmoid involvement in patients with severe endometriosis of the cul-de-sac of Douglas. After two enemas are given

FIGURE 21.2. Polypoid endometrial implant of the colon.

to remove any fecal debris, the rigid proctoscope is deployed above the rectosigmoid and slowly withdrawn with care to maintain adequate insufflation. The mucosa is often fixed over area of submucosal or deep muscular involvement with tethering or puckering and loss of the normal mucosal mobility. In our experience, these mucosal findings have correlated with significant intestinal wall invasion by the endometrial implant and often a need for intestinal resection.

## Imaging Techniques

Imaging techniques used to facilitate the diagnosis of endometriosis include ultrasonography, barium enema, computed tomography (CT), magnetic resonance imaging (MRI), and immunoscintigraphy. Many of these tests are obtained for the evaluation of chronic pelvic pain and/or bleeding from the reproductive tract or colon. They are primarily used to rule out more common conditions, but there are some findings that may strongly suggest the diagnosis of endometriosis before visual or pathologic confirmation by laparoscopy or laparotomy.

Transvaginal ultrasound has been used for several years to evaluate ovarian endometriomas. It is a sensitive test and in experienced hands provides specificity greater than 90% for ovarian endometriosis. Ultrasound of the pelvis, however, is not very sensitive in detecting focal nonovarian endometrial implants. Endometriosis has been termed "the great mimicker" because the appearance on ultrasound is highly variable with some lesions being nearly sonolucent and others quite echogenic.

Endorectal ultrasound is a potentially valuable tool to determine rectal wall invasion by endometrial implants in the cul-de-sac. Chapron and colleagues<sup>36</sup> studied the reliability of endorectal ultrasound in assessing the depth of bowel invasion with rectovaginal endometriosis. In 17 patients with proven deep pelvic endometriosis, the ultrasound revealed infiltration of the bowel wall and suggested the need for intestinal resection. The ultrasound findings were subsequently confirmed at laparoscopy and evaluation of the pathologic specimen in 16 patients. Twenty-one other patients with endometriosis of the cul-de-sac of Douglas whose ultrasounds did not show infiltration of the rectal wall did not require intestinal resection and were able to have complete removal of the endometriosis with laparoscopic techniques without complications. The accuracy of ultrasound was recently confirmed by Doniec and colleagues<sup>37</sup> who determined both the sensitivity and specificity of preoperative staging of rectal wall involvement by endometriosis to be 97%. The only real concern in evaluating patients having cul-de-sac endometriosis by endorectal ultrasound is the significant discomfort experienced by the patient when rectal distention from the balloon probe compresses the implant.

Barium enema examination is another imaging technique often obtained by gynecologists for the intestinal complaints associated with deep pelvic endometriosis. The lateral and

prone cross-table views of the rectum offer excellent evaluation of the cul-de-sac of Douglas as long as care is taken in ensuring that the balloon is kept in the distal rectum (Figure 21-3). Studies in patients without bowel wall involvement are either normal or reveal smooth extrinsic compression with normal mucosa. Deep invasion of the bowel wall by endometriosis produces a variety of appearances on barium enema. Irregularities of the rectal wall such as tethering or even polypoid lesions may be difficult to distinguish from inflammatory bowel disease or neoplasm. Strictures of the rectosigmoid may also be identified on barium enema.

CT is the imaging technique probably used most frequently for the evaluation of abdominal and pelvic pain. Unfortunately, there is no standard CT appearance for a mass caused by endometriosis to clearly differentiate it from pelvic masses attributable to other causes. Cystic lesions are more often seen on the ovaries, whereas deeper pelvic disease usually consists of either solid lesions or mixed cystic/solid lesions. CT evaluation of the pelvic sidewall for endometrial implants is better than ultrasound, but there is still significant overlap between endometriosis and infectious or malignant pathology. CT scanning is probably most useful for patients with pelvic pain and a negative ultrasound to assess the musculoskeletal boundaries of the pelvis and the rectosigmoid colon.

When pelvic endometriosis is strongly suspected, MRI is more useful than CT scanning because of the benefit of imaging in multiple planes and the lack of ionizing radiation. MRI

FIGURE 21.3. Barium enema demonstrating a rectosigmoid stricture.

is rarely used, however, as an initial study in women with pelvic pain because of the higher cost, patient discomfort (claustrophobia), the length of the scanning, and, until recently, the relative inaccessibility of scanners outside major medical centers. Sagittal images are particularly valuable in imaging the cul-de-sac of Douglas. MRI is superior to CT scanning for extraperitoneal lesions and the evaluation of pelvic masses.<sup>38</sup> Identification of endometrial implants is dependent on the hemorrhage that occurs in these lesions. The time between imaging and the most recent hemorrhage may determine in which weighted images the masses are most intensely seen.

Immunoscintigraphy with radioactive iodine-labeled CA-125 monoclonal antibodies has been studied to clarify the extent of pelvic endometriosis, particularly in the face of severe pelvic adhesive disease.<sup>39</sup> In such a study of 28 women, 22 had a positive test with 16 confirmed to have endometriosis. Two of five women had a negative test despite having histologically confirmed endometriosis. As such, immunoscintigraphy is not currently recommended for screening and remains primarily a research tool.

### Laparoscopy

The diagnosis of endometriosis usually requires direct visual and/or tactile assessment of the abdomen and pelvis. Laparoscopy is currently the initial approach to many patients suspected of having endometriosis, and has revolutionized both its diagnosis and treatment. Most patients with severe pelvic pain and many patients with refractory infertility undergo laparoscopy. The timing of laparoscopy in relation to the menstrual cycle is unimportant except in patients being evaluated for infertility. In these patients, the procedure is performed in the luteal phase to provide additional valuable information concerning ovarian function.

The technique of diagnostic laparoscopy has become widespread in both the surgical and gynecologic literature. A camera, often attached to a video monitoring system with photographic and recording capabilities, is introduced at the level of the umbilicus or upper abdomen, and a second instrument is placed in a suprapubic location to allow manipulation of the pelvic and abdominal viscera. A thorough examination of the entire abdomen and especially the pelvis is critical to enable complete assessment of the disease. Both ovaries should be mobilized to evaluate the pelvic peritoneum, and the uterus should be manipulated to allow complete visualization of the cul-de-sac of Douglas, uterosacral ligaments, sigmoid colon, and ureters. It is important to view the base of the appendix as well as the distal small bowel and surface of the diaphragm.

Obtaining a complete assessment of the abdominal and pelvic viscera can be technically demanding. The accuracy of laparoscopy is completely dependent on the surgeon's visual evaluation of the abdomen and pelvis. The findings of endometriosis can be very subtle, and several studies have

demonstrated that visually normal peritoneum may have microscopic evidence of endometriosis.<sup>40</sup> The extent of endometriosis should be carefully documented and staged. The current staging system has been formulated primarily for infertility and was revised by the American Society for

Reproductive Medicine in 1998 (Figure 21-4).<sup>41</sup> This revision is certainly an improvement over previous staging systems that were more concerned with adhesions than with implants. Virtually all patients with intestinal lesions requiring resection are Stage IV, especially if they have cul-de-sac involvement.

FIGURE 21.4. Revised American Society for Reproductive Medicine 1996 classification of endometriosis.<sup>41</sup>

The current classification system, however, is often not useful for the gastrointestinal surgeon. The more critical information for the surgeon is the identification and location of intestinal lesions. There is no uniform type of endometrial lesion. The classic implant is nodular with a variable degree of fibrosis and pigmentation. The color may be black, white, brown, blue, or even red. The appearance of the lesion may be vesicular, papular, or hemorrhagic (Figure 21-5). Glandular tissue is found in the great majority of these lesions. Lesions may change color or consistency over time, with red lesions noted early in the course of the disease and blue/black ones typical of older implants. Healed implants appear as fibrotic nodules. There are also a wide variety of atypical lesions occasionally associated with positive biopsies. The inability to definitively identify endometriosis through purely visual means necessitates pathologic confirmation of the disease before a definitive diagnosis can be made, especially in mild disease.

Implants in the cul-de-sac of Douglas, which occur in nearly 20% of women with endometriosis, were initially described by Cullen in 1920. Ninety percent of these represent an important variant that is especially relevant for the intestinal surgeon. Unlike endometriomas found at other sites, these lesions are histologically characterized by desmoplastic tissue composed of fibrous and smooth muscle cells with strands of endometrial glands and stroma. The major component of the lesion is the fibromuscular tissue and not the endometrial tissue typical of other locations. These implants are both proliferative and infiltrating and more than 25% extend at least 5 mm in depth.<sup>42</sup> The depth of invasion may be difficult to assess laparoscopically, and the full extent of the implant may not be appreciated until laparotomy. The progressive fibrosis leads to narrowing of the intestinal lumen and occasionally to bowel obstruction.

These rectovaginal implants also behave differently during the menstrual cycle. There are poor to absent secretory changes during the luteal phase. Vasodilatation and not necro-

FIGURE 21.5. Endometrial implants with hemorrhagic centers and fibrosis.

sis and bleeding occur at menstruation. Resistance to medical therapy is common with several studies demonstrating no significant decrease in mitotic activity in rectovaginal endometriosis after GnRH agonist (GnRH-a) treatment.<sup>43</sup> This resistance is thought to be attributable to estrogen receptor inactivity, inadequate drug access, or genetic programming that is only secondarily affected by estrogen.

## Treatment

Treatment options for women with endometriosis are currently based on the severity and type of symptoms. Currently, prevention of endometriosis is not yet possible, and therefore treatment is primarily begun to ameliorate symptoms. Some women with endometriosis are completely asymptomatic and the implants are found incidentally at the time of surgery for other reasons. A study by Martin et al.<sup>44</sup> in 1989 revealed that 25% of women undergoing elective tubal ligation had asymptomatic endometrial implants. This finding strongly suggests that not all women with endometriosis require treatment. Other authors have analyzed the prevalence of endometriosis in these asymptomatic women with regard to the time from their last pregnancy. They discovered that the odds of having endometrial implants increased significantly at 10 years after the last pregnancy.<sup>5,45</sup> Consequently, as the natural history seems unclear, long-term follow-up of these patient cohorts may demonstrate late development of symptoms and the need for more aggressive medical or surgical management. Even menopause, either surgical or natural, is not completely protective. The widespread use of hormone replacement therapy has revealed that up to 20% of these patients will have recurrent endometriosis. Not surprisingly, the majority of these patients had deep pelvic or intestinal disease.<sup>46</sup>

Before the introduction of diagnostic laparoscopy in the 1960s, exploratory laparotomy was the only modality available for the diagnosis and treatment of endometriosis. Laparoscopy revolutionized the diagnostic evaluation of these women and allowed patients with limited disease to undergo medical therapy. With improvements in laparoscopic techniques and equipment in the past decade, notably the development of laparoscopic laser techniques, many if not most early endometrial lesions can now be ablated at the time of diagnosis. Even complex excisional surgery involving the bowel and ureter can be occasionally performed safely via a laparoscopic approach in many patients. As advanced laparoscopic techniques have become more widespread, the indications and use of medical therapy is also evolving.

## Medical Management

Medical therapy is designed to treat the symptoms of endometriosis, notably pelvic pain. Because pelvic pain may have causes other than the endometriosis seen during laparoscopy, a trial of ovarian suppression with a 3-month

course of either danazol or a GnRH-a is often used to help determine the contribution of the pain from the endometrial implants. Most patients will have cessation of pain from endometriosis in the first month of amenorrhea. In those patients with infertility, with or without pelvic pain, the primary goal is an intrauterine pregnancy. After other causes of infertility have been excluded, ovarian suppression may allow for laparoscopic removal of downsized, smaller endometrial lesions with optimal preservation of ovarian tissue.

Despite the many advances in the surgical treatment of endometriosis, there are still some significant advantages to medical therapy. Surgery can remove only lesions that are both visible and accessible. Microscopic disease or disease on vital structures is often left behind. Subsequent recurrence is not surprising. Additionally, there are complications associated with ablative surgery in the pelvis, especially if the woman requires multiple attempts at control of her disease. For infertile women, the adhesions that can form after any pelvic surgery may further impair the ability to conceive. In addition, laser destruction of ovarian implants may destroy germinal tissue and conceivably limit the reproductive potential from the involved ovary. In limited disease, medical therapy is comparable with surgery in terms of relief of symptoms, recurrence of disease, and subsequent pregnancy rates. Finally, medical therapy does not require specialized training or equipment, and is much less costly than surgery.

Medical therapy alone also has significant potential disadvantages. All the hormonal therapies subsequently discussed have side effects and often require prolonged treatment. Medical therapies manipulate the hormonal environment to suppress the cyclic secretion of ovarian estrogen and progesterone, and this suppression induces atrophy of the ectopic endometrium so that over several months the implants regress. Advanced lesions, especially those with a nodular, proliferative histology will often only partially regress. No current hormonal regimen can completely eradicate these lesions, and upon cessation of therapy, the lesions may again become symptomatic.

### Oral Contraceptives

The first effective medical therapy for endometriosis was introduced by Kistner. He proposed the administration of high-dose, continuous estrogen/progestins in 1958. These agents result in the induction of pseudo-pregnancy with hyperhormonal amenorrhea. Pituitary and ovarian function is thereby suppressed, and in the later stages of the treatment regimen, endometrial implants resorb and resolve. The usual treatment regimen consists of daily administration of a tablet for 6–9 months. When Vercellini and colleagues<sup>47</sup> compared oral contraceptives with GnRH-a, they found that deep dyspareunia and pelvic pain were reduced in both groups, with fewer side effects experienced by the oral contraceptive women. Pain relief appeared similar in the two groups at 1 year. Side effects rarely cause cessation of treatment, but

exacerbation of endometriotic symptoms may occur early in the course of treatment.

Another drug regimen used for the treatment of endometriosis involves administration of synthetic progestins alone. This may induce a pseudo-pregnancy by acting in concert with endogenous estrogens. Ovarian suppression is often inconsistent. Both oral and depot preparations are available. In patients who do not desire pregnancy and in whom surgery is contraindicated, depot progestins have been effective in ameliorating pelvic pain with equivalent efficacy to danazol.<sup>48</sup> Side effects include breakthrough vaginal bleeding, weight gain, and fluid retention.

### Danazol

Danazol was first used extensively for endometriosis in the mid-1970s, and until the introduction of GnRH-a, was the most widely used drug for suppression of the ectopic endometrium. Danazol lowers peripheral estrogen and progesterone levels by a direct effect on ovarian steroidogenesis and pituitary production of follicle-stimulating hormone (FSH) and luteinizing hormone (LH). Danazol also binds directly to endometrial cellular receptors leading to atrophy and suppression of proliferation. In addition, danazol is a potent immunomodulator with beneficial effects on both humoral and cellular immunity.<sup>49</sup>

The side effects of danazol necessitate discontinuation in less than 5% of patients for short courses,<sup>50</sup> but is poorly tolerated for long-term suppression. Predictable manifestations of menopause are most common. Danazol also raises free testosterone levels and produces a hyperandrogenic state, especially at lower doses. Hirsutism, acne, weight gain, and deepening voice changes may occur. In addition, because danazol alters lipid metabolism and liver function, it should not be used in women with increased liver enzymes, liver disease, or complications of atherosclerosis.

### Gonadotropin-releasing Hormone Agonists

The introduction of GnRH-a as a new treatment modality for endometriosis has improved results, primarily by a reduction in side effects. GnRH-a are synthetic molecules derived from the 10 peptide long GnRH. Continuous administration of GnRH-a completely suppresses pituitary release of FSH and LH. Administered either by injection or intranasally beginning in the mid-luteal phase of the menstrual cycle, the current recommended length of therapy is 6 months. Pain relief is complete in more than 50% of women and significantly decreased in more than 90%. Laparoscopic evaluation after 6 months of treatment indicates resolution or a significant decrease in size of the lesions in the majority of patients. Studies comparing danazol and GnRH-a indicate similar clinical efficacy.<sup>51</sup>

Side effects of GnRH-a are predictably attributable to the sometimes profound hypoestrogenic state many of these

women experience. Up to 90% of patients will experience hot flashes, night sweats, vasomotor instability, atrophic vaginitis, migraines, or depression. Cessation of therapy for side effects is uncommon. The degree of bone loss that can occur with the typical 6-month treatment regimen is unclear, but GnRH-a is not recommended for women with osteoporosis. Interestingly, a potentially serious complication can result when GnRH-a is inadvertently administered at the wrong point in the menstrual cycle, and a brief period of hypersecretion of FSH and LH occurs. Rarely, this upsurge in gonadotropin activity may precipitate an acute exacerbation in endometriotic symptoms, occasionally necessitating emergency surgical intervention.<sup>52</sup>

## Surgical Management

Surgical treatment of endometriosis has evolved significantly over time. Before the advent of laparoscopy and suppressive medical therapy, most operations were performed for advanced disease and consisted of radical removal of the uterus and ovaries. Although the most effective treatment of pelvic pain still consists of surgical castration along with resection of the endometrial implants, many of these young patients strongly desire to maintain their options for pregnancy. Currently, surgery is considered conservative only when reproductive potential is preserved. Therefore, the major goal of surgical therapy for endometriosis is to completely excise or ablate the endometrial implants. Secondary goals include preservation of ovarian function and minimizing postoperative adhesion formation. Currently, we approach these patients in concert with gynecologists experienced with treating ovarian endometriosis to completely remove all gross disease, restore normal anatomy, and optimize fertility.

## General Principles

Endometriosis is an invasive disease that can extend deeply into the retroperitoneum, and is often surrounded by a rim of fibrosis that may make it difficult to completely assess the true extent of the implant. Removal of the lesions requires sharp excision or vaporization with electrocautery and/or the CO<sub>2</sub> laser. Both techniques have the potential for iatrogenic injury to the intestinal or urinary tracts. Recognizing when a lesion is completely ablated is highly dependent on surgical technique and the expertise of the surgeon. Utilizing techniques that minimize injury to the surrounding tissue, such as a cutting current to outline lesions to be removed by electrocautery and high-power density settings with the CO<sub>2</sub> laser are desirable. Laparoscopic hydrodissection is also very useful in identifying normal surrounding tissue.

Meticulous hemostasis and frequent irrigation is critical to maintaining good visualization of the operative field in both open and laparoscopic surgery. Tissue planes are often distorted, especially in the cul-de-sac of Douglas, and intraoperative instrumentation of the vagina or proctoscopic evaluation of the rectum may help avoid iatrogenic injury to these

structures. Finally, minimizing tissue trauma with gentle handling will decrease adhesions and maximize potential fertility.

All patients undergoing surgery for advanced endometriosis, either by an open or laparoscopic approach, should have a full mechanical and antibiotic bowel preparation. Prophylactic antibiotics and other appropriate practices for patients undergoing major abdominal or pelvic surgery are standard. Patients are positioned in the low lithotomy position with access to both the vagina and rectum for instrumentation. Ureteral stents are liberally used and are especially useful in women with severe obliterative disease in the cul-de-sac and in reoperative pelvic surgical procedures.

Provided that complete removal of the endometriosis is performed, no specific technique or approach has been proven to be superior. With endometriosis, the surgeon's experience and skill are paramount. In experienced hands, laparoscopic removal of extensive endometriosis can be accomplished. However, removal of deep lesions in the rectovaginal septum necessitating bowel resection still often requires open laparotomy to safely and completely excise the endometrial implant with restoration of intestinal continuity.

The management and techniques concerning the surgical treatment of ovarian and ureteral endometriosis are extensively discussed in the appropriate gynecologic and urologic literature. This discussion on surgical therapy will concentrate on management of intestinal lesions.

## Rectovaginal Endometriosis

Endometriosis of the cul-de-sac of Douglas that extends into the rectovaginal septum is the most common site of intestinal involvement and may require intestinal resection. These lesions are often deep fibrotic nodules that extend from the posterior vagina and anterior rectum to the uterosacral ligaments (Figure 21-6). Small superficial lesions involving the intraperitoneal rectum may be vaporized with the CO<sub>2</sub> laser or

FIGURE 21.6. Deep infiltrating endometrial implant of the rectosigmoid.

electrocautery. When using either technique, it is critical to initially outline the lesion to be removed to ensure complete extirpation because distortion of the planes and tissue can otherwise make it difficult to assess the completeness of excision. Cutting current as opposed to coagulating current is preferred. The former technique minimizes carbonization that can make it challenging to recognize when an adequate depth has been achieved by the appearance of normal tissue. After the lesion is removed, the bowel wall is carefully assessed. Because most of these superficial lesions can be removed without entering the mucosa, the defects can be closed with interrupted transversely placed Lembert stitches.

Surgical treatment of the deeper lesions is more controversial. Removal of the rectosigmoid with reanastomosis is technically demanding and should be performed by skilled intestinal surgeons to minimize complications in these young patients. As experience has grown, there has been a shift to more aggressive therapy, usually in conjunction with gynecologists who remove endometrial deposits on the ovaries and fallopian tubes. Medical treatment has not proven adequate for these infiltrating lesions, so it is no surprise that castration alone has also proven ineffective.<sup>53</sup> Many of these women have chronic pain or partial colonic obstructive symptoms after bilateral salpingo-oophorectomy when the endometrial implant is not resected. As a result, excision of the implant either with a disc of rectal wall or a formal anterior resection is recommended for women with symptoms related to the endometriosis. Both procedures can occasionally be performed laparoscopically if the endometriosis is completely removed. Unfortunately, laparoscopy often misses lesions that are not visually apparent and discernible only by palpation. It should be noted, however, that for severe disease, laparoscopic ablation, when possible, had similar crude pregnancy rates in comparison to laparotomy, and both techniques were clearly superior to medical management alone.<sup>54</sup>

The infiltrating nodular endometrial implants involving the rectovaginal portion of the cul-de-sac often invade both the vagina and rectum. Because removal of the implant will require resection of a portion of the rectal wall, dissection of the lesion from the vagina allows for en bloc removal of the lesion with the rectal wall. There is often no discernible plane between these lesions and the walls of the rectum or vagina. Care must be taken to avoid penetration of the vaginal wall with possible injury to the cervix, especially in women desiring eventual pregnancy. Often it is advantageous to mobilize the rectum in the posterior and lateral tissue planes to adequately define the lesion before attempting the anterior dissection. Blunt dissection of the rectovaginal plane below the area of involvement may help clarify the distorted anatomy and avoid inadvertent entry into the bowel lumen. After careful dissection of the lesion from the vagina, the normal rectovaginal plane is reached, and the fixed, hard mass may suddenly become mobile and amenable to resection.

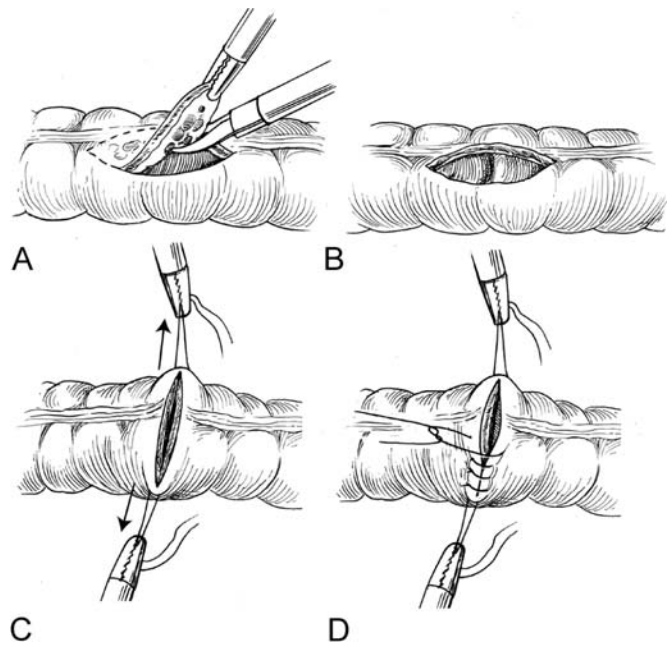

FIGURE 21.7. Disc excision of an endometrial implant.

Disc excision of the anterior rectal wall, by either laparoscopic or open technique, is performed for single lesions usually less than 3 cm in diameter (Figure 21-7). After marking the lesions circumferentially with electrocautery, stay sutures are placed on either side of the endometrial implant. Full-thickness bowel wall excision is then performed with the cutting current electrocautery. Interrupted transverse absorbable sutures are subsequently placed to close the resulting defect.

Segmental resection of the rectosigmoid is performed for larger lesions or when neoplasia is a concern. Margins are to grossly normal bowel, and unless there are multiple lesions, an extensive colonic resection is not required. High ligation of the sigmoid vessels is also unnecessary, and the anastomosis may be either hand-sewn or stapled. When resection is performed laparoscopically, the involved segment may be removed by extending one of the port sites. Nezhat et al.<sup>55</sup> have described a technique of prolapsing the lesion outside the anus for resection. Redwine et al.<sup>56</sup> have described a transvaginal approach for specimen removal. Open or laparoscopic excision of these deeply infiltrating rectovaginal lesions is very technically demanding. The lack of discernible tissue planes, the intimate association of the rectum and vagina, and the frequent occurrence of distal infiltration of endometriosis down to the mid to lower rectum makes laparoscopic resection possible in only a small minority of these patients and only by surgeons very experienced in complex intestinal laparoscopy. Even in the hands of experienced laparoscopists, rectovaginal fistula requiring ileostomy has been reported to occur after these resections.<sup>54</sup> Proctoscopic insufflation to assess for leak is practiced routinely by the authors with all rectal anastomoses, whether performed open or laparoscopically.

## Small Bowel and Appendiceal Endometriosis

Although endometriosis involving the small bowel or appendix is much less common than rectosigmoid disease, careful inspection of these organs is critical in patients with advanced endometriosis to ensure complete removal of all gross disease and to minimize recurrence. Superficial small bowel implants may be treated with sharp excision, electrocautery, or the laser, as described above. Deeper implants may require small bowel resection, and, if within 5 cm of the ileocecal valve, may need an ileocecectomy. Appendiceal endometriosis is treated with appendectomy. Occasionally, a surgeon will encounter a patient with an endometrial implant while operating for another condition. Although the lesion may exhibit a classic visual appearance consistent with endometriosis, a biopsy to confirm the diagnosis and exclude malignancy is important. Several studies have suggested that few patients with small asymptomatic endometrial implants of the appendix will become symptomatic, but no study has yet defined the natural history of these lesions. As a result, for those patients with asymptomatic endometriosis, observation is probably sufficient, but hormone replacement therapy should be avoided to avoid stimulation of the implants.

## Results After Surgical Therapy

Recurrence of endometriosis after surgical excision is difficult to assess because of a wide variability in the operative approach to endometriosis by various authors and the obvious need for postoperative laparoscopy to document asymptomatic recurrence. Although there are no long-term prospective studies to date, the larger studies suggest a histologically confirmed rate of recurrent endometriosis of approximately 19%.<sup>57</sup> Gauging the response to surgery by the resolution of preoperative pelvic pain or infertility is easier to measure. The largest series of intestinal resections for advanced intestinal endometriosis by Bailey et al.<sup>58</sup> found that 86% of patients had complete or near complete relief of their preoperative pelvic pain. In addition, a 50% crude pregnancy rate was achieved which was comparable with rates found when treating much lower stages of disease. These results in more than 130 cases with a median follow-up of 5 years were achieved with minimal morbidity, no anastomotic leaks, and no documented instance of recurrent colorectal endometriosis. Laparoscopic series of intestinal resections performed for extensive endometriosis have reported similar pregnancy rates albeit with smaller number of cases, higher complication rates, and shorter long-term follow-up.<sup>59</sup>

## Combined Medical and Surgical Therapy

Both medical and surgical therapies for endometriosis have potential reasons why each treatment alone may not be successful in eradicating the disease and minimizing recurrence.

Medical therapy affects endometrial implants variably, and there is a high instance of recurrence after cessation of therapy. Surgery may not remove microscopic disease, and post-surgical adhesions may contribute to postoperative pelvic pain and infertility. For these reasons, combination therapy either pre- or postoperatively has been used for several years, although with a paucity of prospective, randomized data to conclusively prove long-term improvement in recurrence and symptoms.

The rationale for preoperative medical therapy conducted over a period of 3–6 months is principally to decrease the inflammation and possibly the size of the endometrial implants. Presumably, this therapy will allow easier excision with diminished adhesion formation. Medical therapy may also reduce the vascularity of endometrial implants. A prospective study by Buttram<sup>60</sup> in 1985 revealed an improvement in pregnancy rates with 6 months of danazol given preoperatively with all stages of endometriosis. The optimal length of therapy and long-term (and not just delayed) recurrence rates must still be elucidated. Postoperative treatment with danazol and oral contraceptive pills has not been shown to have durability, and the initial excitement over improved recurrence rates at 12 months has not been duplicated after longer follow-ups.<sup>60</sup> Our current use of combined therapy, after laparoscopic confirmation of advanced pelvic endometriosis, is a 3- to 6-month course of a GnRH-a before definitive surgery for virtually all patients able to tolerate the medical therapy.

## Conclusion

The diagnosis and management of intestinal endometriosis has evolved tremendously over the last 20 years with the widespread availability of laparoscopy and a clear understanding of the necessity to remove all endometrial implants in symptomatic patients. With the advent of stapling devices that facilitate low pelvic anastomoses, the intestinal surgeon should be able to resect the endometrial implants and restore bowel continuity in virtually all patients with minimal morbidity and preserved fertility, when desired. Further improvements in outcomes will probably not occur until a better understanding of the precise etiology and growth of the endometrial implant is discovered.

## Colon and Rectal Trauma and Rectal Foreign Bodies

Demetrios Demetriades and Ali Salim

### Colon Injuries

The management of colon injuries has been one of the most controversial issues in trauma and has undergone many radical changes in the last few decades. Despite the dramatic reduction of colon-related mortality from about 60% during World War I to about 40% during World War II to about 10% during the Vietnam War and to lower than 3% in the last decade, the colon-related morbidity remains unacceptably high. The abdominal sepsis rate has remained at about 20% in most prospective studies in the last decade (Table 22-1).<sup>1-6</sup> No other organ injury is associated with a higher septic complication rate than colon. In some subgroups of patients with colon injuries in the presence of Penetrating Abdominal Trauma Index (PATI) >25 or with multiple blood transfusions, the incidence of intraabdominal sepsis has been reported to be as high as 27%.<sup>7</sup> In patients with destructive colon injuries requiring resection, the reported incidence of abdominal complications is about 24%.<sup>6</sup> Many studies have attempted to identify risk factors for complications and optimize the treatment.

### Epidemiology

The vast majority of colon injuries are caused by penetrating trauma. In American urban centers, firearms are by far the most common cause of injury. In anterior or posterior abdominal gunshot wounds, the colon is the second most frequently injured organ after the small bowel and it is involved in about 27% of cases undergoing laparotomy.<sup>8,9</sup> In anterior abdominal stab wounds, the colon is the third most frequently injured organ after the liver and small bowel and an injury is found in about 18% of patients undergoing laparotomy. In posterior stab wounds, the colon is the most frequently injured organ and is injured in about 20% of patients undergoing laparotomy.<sup>10</sup> In gunshot wounds, the transverse colon is the most frequently affected segment. In stab wounds, the left colon is the most frequently injured segment, probably because of the predominance of right-handed assailants.

Blunt trauma to the colon is uncommon and is diagnosed in about 0.5% of all major blunt trauma or in 10.6% of patients undergoing laparotomy.<sup>11,12</sup> Most of these injuries are partial thickness and only 3% of patients undergoing laparotomy have full-thickness colon perforations.<sup>11,13</sup> Traffic trauma is the most common cause of blunt colon injury. Deceleration injuries may cause avulsion of the colon from the mesentery resulting in ischemia but blowout perforations caused by transient closed loop formation may occur as well. Seatbelts increase the risk of hollow viscous perforations and the presence of a seatbelt mark sign is a predictor of hollow viscous injury. In rare cases, colonic wall hematoma or contusion may result in delayed perforation several days after the injury. The left colon is the most frequently injured segment followed by the right colon and the transverse colon.<sup>11</sup>

### Diagnosis

The diagnosis of colon injury is almost always made intraoperatively. However, with the introduction of selective nonoperative management of penetrating abdominal trauma, there has been a concern of missing colon injuries. This is particularly important in penetrating injuries of the back because small retroperitoneal colon injuries may not give early clinical signs. A rectal examination may show blood in the stool, especially in cases with distal colon or rectal injuries. A preoperative erect chest film may show the nonspecific presence of free air under the diaphragm. The colon can reliably be evaluated by soluble enema studies or abdominal computed tomography (CT) scan with soluble rectal contrast. Retroperitoneal gas or contrast extravasation are diagnostic and an exploratory laparotomy should be performed. Other investigations, such as ultrasound or diagnostic peritoneal lavage have no role in the evaluation of suspected colon injuries.

The preoperative diagnosis of colon injury after blunt trauma can be a major challenge, especially if the patient is unevaluable because of severe associated head injuries. The diagnosis may be suspected by the presence of free gas or thickened colonic wall on the routine abdominal CT scan. In

TABLE 22-1. Incidence of abdominal septic complications in colon injuries (prospective studies)

Gonzalez et al., <sup>5</sup> 1996	114	24
Demetriades et al., <sup>6</sup> 2001	297	24
Overall	921	22

some cases, the diagnosis may be delayed by many days with catastrophic consequences.

Intraoperatively, every paracolic hematoma caused by penetrating trauma should be explored and the underlying colon should be evaluated carefully. Failure to adhere to this important surgical principle is a serious error with medical and legal implications. Paracolic hematomas caused by blunt trauma should not undergo routine exploration unless there is evidence of colon perforation.

## Colon Injury Scale

The American Association for the Surgery of Trauma (AAST) developed a grading system for organ injuries in order to have objective criteria for the classification of the severity of the injury and enable reliable comparisons of results. On the basis of the injury grade, an Abbreviated Injury Score is assigned and may be used for the calculation of the Injury Severity Score (ISS). The AAST Colon Injury Scale is shown in Table 22-2.

## Operative Management

### Historical Perspective

The first guidelines regarding the management of colon injuries were published by the United States Surgeon General and mandated proximal diversion or exteriorization of all colon wounds.<sup>14</sup> This unusual directive was initiated because of the very high mortality of colorectal injuries during the early years of World War II. The mortality in both civilian and military reports exceeded 50%.<sup>15,16</sup> Although these guidelines were not based on any scientific evidence, they were credited

TABLE 22-2. AAST Colon Injury Scale

Grade	Injury description
I	a) Contusion or hematoma without devascularization b) Partial thickness laceration
II	Laceration $\leq$ 50% of circumference
III	Laceration $>$ 50% of circumference
IV	Transection of the colon
V	Transection of the colon with segmental tissue loss

for the significant reduction of mortality in the last years of the war. However, during this period, many other major changes in trauma care took place. Faster evacuation from the battlefield and early definitive care, improved resuscitation protocols, and introduction of penicillin and sulfadiazine could all have contributed to the reduction of mortality. The policy of mandatory colostomy for all colon injuries remained the unchallenged standard of care until the late 1970s. Stone and Fabian<sup>17</sup> reported the first major scientific challenge of this policy in 1979. In a prospective, randomized study, which excluded patients with hypotension, multiple associated injuries, destructive colon injuries, and delayed operations, the authors concluded that primary repair was associated with fewer complications than colostomy. The exclusion criteria were perceived as risk factors for anastomotic leak and were absolute indications for diversion.

With mortality rates attributable to colon-related complications improving over the next few years, surgeons challenged the validity of the “standard” contraindications for primary repair or resection and anastomosis. A few prospective randomized studies with no exclusion criteria (class I evidence) confirmed the safety of primary repair, at least in nondestructive colon injuries. Another alternative to primary repair or colostomy was exteriorized repair, which was introduced in the 1970s. With this technique, the sutured colon was exteriorized and observed for 4–5 days. If the repair remained intact during this period of observation, the colon was returned to the abdominal cavity. If the repair leaked, it was converted to a loop colostomy.<sup>18,19</sup> The enthusiasm for this approach waned in the 1980s because of the overwhelming evidence of the superiority of primary repair.

In the 1990s and 2000s, primary repair became the standard of care in most cases although there is still some skepticism by many surgeons, especially in the presence of certain risk factors such as destructive colon injuries, severe contamination, multiple injuries, and delays in treatment.

### Nondestructive Colon Injuries

There is now enough class I evidence (prospective, randomized studies) supporting primary repair in all nondestructive colon injuries (injuries involving  $<$ 50% of the bowel wall and without devascularization) irrespective of risk factors. Chappuis et al.<sup>2</sup> in a randomized study of 56 patients with no exclusionary criteria concluded that primary repair should be considered in all colon injuries irrespective of risk factors. In another landmark study, Sasaki et al.<sup>20</sup> randomized 71 patients with colon injuries to either primary repair or diversion, without any exclusionary criteria. The overall complication rate was 19% in the primary repair group and 36% in the diversion group. In addition, the complication rate for colostomy closure was 7%. The authors concluded that primary repair is the method of choice of treatment of all penetrating colon injuries in the civilian population despite any associated risk factors for adverse outcome.

Gonzalez et al.<sup>5</sup> published another important prospective, randomized study in 1996. The authors randomized 109 patients to primary repair on diversion, independent of any risk factors. The sepsis-related complication rate was 20% in the primary repair group and 25% in the diversion group. In the presence of certain risk factors, such as severe fecal contamination, shock on admission, blood loss 1000 mL, or more than two associated organ injuries, the diversion group had a higher complication rate, although this difference did not reach statistical significance. Gonzalez et al.<sup>21</sup> continued their study and the series increased to 176 patients with penetrating colon injury. The study concluded again that in civilian trauma, all penetrating colon injuries should be primarily repaired.

Overall, collective review of all available prospective, randomized studies (class I evidence) identified 160 patients with primary repair and an incidence of 13.1% of abdominal sepsis complications. In the group of 143 patients treated with diversion, the abdominal sepsis complication rate was 21.7% (Table 22-3). In addition to the available class I evidence, numerous prospective observational studies (class II evidence) demonstrated the superiority of primary repair over diversion in nondestructive injuries.<sup>1,3,4,22</sup> In conclusion, there is sufficient class I and II data to support routine primary repair of all nondestructive colon injuries, irrespective of risk factors for abdominal complications. No study has ever shown that colostomy is associated with better results than primary repair.

Despite the available scientific evidence, there is still some skepticism about liberal primary repair and many surgeons still consider colostomy as the procedure of choice in many colon injuries. In a survey of 317 Canadian surgeons in 1996, 75% of them chose colostomy in low-velocity gunshot wounds to the colon.<sup>23</sup> In another survey of 342 American Trauma Surgeons, members of the AAST, a colostomy was the procedure of choice in 3% of colon perforations with minimal spillage, in 43% of perforations with gross spillage, in 18% of colon injuries involving >50% of the wall, and in 33% of cases with colon transection.<sup>24</sup> It is obvious that old traditions still have a significant role in modern trauma surgery.

## Destructive Colon Injuries

Until recently, there was no sufficient class I or II data regarding the management of destructive colon injuries requiring resection (loss of >50% of bowel wall or devascularization). The available prospective, randomized studies included only 36 patients with colon resection and anastomosis. The overall

incidence of anastomotic leak was 2.5% and no deaths occurred. All these studies recommended primary anastomosis irrespective of the presence of any risk factors for abdominal complications.<sup>2,20,21</sup> In a recent prospective but not randomized study on colon injuries by Cornwell et al.,<sup>7</sup> there were 25 patients with destructive colon injuries treated by resection and anastomosis and two patients treated by resection and colostomy. All patients had a PATI >25 or were transfused with >6 units of blood or the operation was delayed by >6 hours from the time of injury. There were two anastomotic leaks (8%) and both were fatal. The study concluded that some high-risk patients with destructive colon injuries might benefit from diversion. Unfortunately, the study did not include enough patients with diversion for comparison with the primary anastomosis group. There are two retrospective studies, which included only destructive colon injuries requiring resection: Stewart et al.<sup>25</sup> analyzed 60 patients, 43 of whom were managed by resection and anastomosis and 17 by diversion. The overall anastomotic leak rate was 14% and in the subgroup of patients with blood transfusion >6 units, the leak rate was 33%. The authors suggested that primary anastomosis should not be performed in patients receiving massive blood transfusions or in the presence of underlying medical illness. Another retrospective study from Los Angeles analyzed the complications in a series of 140 patients with destructive colon injuries requiring resection.<sup>26</sup> The incidence of intraabdominal sepsis was similar in the groups with primary anastomosis or diversion. Univariate analysis identified Abdominal Trauma Index >25 or hypotension in the emergency room to be associated with increased risk of anastomotic leak. The study suggested that a diversion procedure might be appropriate in these high-risk subgroups of patients.

In summary, the available prospective, randomized studies, which include only a small number of cases, recommend resection with anastomosis irrespective of risk factors. Two large retrospective studies advocate diversion in the subgroups of patients with certain risk factors such as PATI >25, multiple blood transfusions, or associated medical illness.<sup>25,26</sup> The guidelines of the Eastern Association for the Surgery of Trauma published in 1998<sup>27</sup> supported resection and primary anastomosis in the subgroups of patients with destructive colon injuries if they are a) hemodynamically stable intraoperatively, b) have minimal associated injuries (PATI <25, ISS <25), c) have no peritonitis, and d) have no underlying medical illness. The guidelines suggest that patients with shock, significant associated injuries, peritonitis, or underlying disease should be managed with resection and colostomy.<sup>27</sup> However, these

TABLE 22-3. Primary repair versus diversion: prospective, randomized studies with no exclusion criteria

Study	Primary Repair		Diversion	
	No. of patients	Abdominal septic complications (%)	No. of patients	Abdominal complications (%)
Chappuis et al. <sup>2</sup>	28	4(14.3)	28	5(17.9)
Sasaki et al. <sup>20</sup>	43	1(2.3)	28	8(28.6)
Gonzalez et al. <sup>21</sup>	89	16(18)	87	18(21)
Total	160	21(13.1)	143	31(21.7)

guidelines were based on class III evidence. In their review of the literature, there were only 40 patients in class I studies with resection and anastomosis and the anastomotic leak rate was 2.5% and without mortality. In class II studies, there were only 12 patients who underwent resection and anastomosis and the leak rate was 8.3% without mortality. In class III retrospective studies, there were 303 patients with a leak rate of 5.2% and three deaths (1%) as a result of the leak.

In view of the lack of large prospective studies in the literature, the AAST sponsored a prospective multicenter study to evaluate the safety of primary anastomosis or diversion and identify independent risk factors for colon-related complications in patients with destructive colon injuries requiring resection.<sup>6</sup> The study included 297 patients with penetrating injuries requiring colon resection (rectal injuries were excluded) that survived at least 72 hours. The overall colon-related mortality was 1.3% (four deaths) and all deaths occurred in the diversion groups ( $P = .01$ ). The overall incidence of abdominal complications was 24% and the most common complication was an intraabdominal abscess (19% of patients) followed by fascia dehiscence (9%). The incidence of anastomotic leaks was 6.6%. Multivariate analysis identified three independent risk factors for abdominal complications: severe fecal contamination, >4 units of blood transfusions within the first 24 hours, and single-agent antibiotic prophylaxis. If all three risk factors were present, the incidence of abdominal complications was about 60%, if any two factors were present the complications rate was 34%, if only one factor was present this figure was about 20%, and with no risk factors it was 13%. The method of colon management, delay of operation >6 hours, shock at admission, site of colon injury, PATI >25, ISS >20, or associated intraabdominal injuries were not found to be independent risk factors. In a second analysis, the group of patients with primary anastomosis was compared with the group with diversion, using multivariate analysis which controlled for PATI >25, transfusion >6 units of blood, >6 hours' delay of operation, shock at admission, and severe fecal contamination. These factors have been described in previous studies as significant risks for abdominal complications. With colon diversion serving as reference (RR 1.00) for comparison, the adjusted relative risk of primary anastomosis was exactly the same (1.00).

In a similar analysis according to subgroups with ileocolostomy, colocolostomy, ileostomy, and colostomy, the adjusted relative risk of abdominal complications was similar. In another analysis, all patients were classified into either a

high-risk group (if any of the following factors was present: hypotension at admission, blood transfusions >6 units, delay of operation >6 hours, severe peritoneal contamination, or PATI >25) or a low-risk group if the above factors were not present. These risk factors are considered by many surgeons as strong indications for diversion. The colon-related mortality in the high-risk patients was 4.5% (4 of 88 patients) in the diversion group and no deaths in the 121 patients who underwent primary anastomosis ( $P = .03$ ). Multivariate analysis showed that the adjusted relative risk of abdominal complication in patients with primary anastomosis or diversion was similar, in both the low-risk and high-risk patients (Table 22-4). There was a trend toward shorter intensive care unit and hospital stay in the primary anastomosis group. The study concluded that "In view of these findings and the fact that colon diversion is associated with worse quality of life and requires an additional operation for closure, colon injuries requiring resection should be managed by primary repair, irrespective of risk factors."<sup>6</sup> Damage control procedures with abdominal packing and temporary closure of the abdominal wall with a prosthetic material pose a special dilemma regarding the management of destructive colon injuries. No studies have ever addressed this issue and the existing practices are based on personal beliefs and experience. The authors advocate primary anastomosis because of the theoretical disadvantages of having a colostomy, which is an open source of fecal material, near an open abdomen. The only conditions for which there is agreement for colostomy are the presence of severe colon edema or a questionable blood supply of the colon. In these situations, at least theoretically, a diversion procedure might be a safe option.

### Risk Factors for Abdominal Complications

The abdominal complication rate in colon injuries is very high, with a sepsis rate of about 20% (Table 22-1). In destructive colon injuries requiring resection, the prospective AAST colon resection study of 298 patients recorded an overall incidence of 24% of abdominal complications. Many studies attempted to identify risk factors for complications and on the basis of these risks to modify the treatment.

### Left Versus Right Colon Injuries

For many years and until recently, there was an anecdotal perception that left colon injuries are associated with a higher risk of anastomotic leaks and septic complications than right

TABLE 22-4. AAST colon resection study: comparison of abdominal complications between primary anastomosis and diversion in high- and low-risk patients<sup>6</sup>

Patient population	Primary anastomosis: abdominal complications (%)	Diversion: abdominal complications (%)	Adjusted relative risk (95% CI)	<i>P</i> value
All patients	22	27	0.81 (0.55–1.41)	.69
Low-risk patients*	13	8	1.26 (0.21–8.39)	.82
High-risk patients*	28	30	0.90 (0.53–1.40)	.67

\*High-risk patients were those with PATI >25 or severe fecal contamination or 6 hours from injury to operation or transfusion of >6 units of blood pre/intraoperatively systolic blood pressure ≤90 mm Hg. Low-risk patients were those without any of the above risk factors.

colon injuries. This perception was based on theoretical reasons (different anatomy and blood supply, higher concentration of bacteria, and poorer healing properties in the left colon) rather than clinical evidence. This perception led surgeons to advocate liberal primary repair of right colon wounds and colostomy in left colon wounds. However, no clinical or experimental study has ever demonstrated any healing differences between the two sides of the colon or any evidence that the two anatomic sides should be treated differently. Experimental work in baboons, which have very similar anatomy and bacteriology with humans, showed no difference of the healing properties between the right and left colon.<sup>28</sup> The study involved resection of a 10-cm segment of right colon and a 10-cm segment of left colon and primary anastomosis, without any mechanical or chemical preparation of the colon. The healing of the anastomosis was assessed at autopsy 7 days postoperatively (leak, local abscess), mechanically by measuring the breaking strength of the anastomosis, and biochemically by measuring the hydroxyproline concentrations at the anastomotic site. The study showed identical healing properties of the two sides of the colon.<sup>28</sup>

In another study using the same model, one of the authors evaluated the effect of hypovolemia (blood loss of 20 mL/kg) on healing of the left and right sides of the colon and again no differences were found<sup>29</sup> (Figures 22-1 and 22-2).

### Associated Abdominal Injuries

Earlier studies suggested that multiple or severe associated intraabdominal injuries (PATI >25) are associated with a high incidence of septic complications and they were considered as contraindications for primary repair of the colon.<sup>4,7</sup> This factor was considered even more critical in destructive colon injuries and was suggested as indication for diversion.<sup>26,27</sup> However, class I and II studies have shown that although multiple associated intraabdominal injuries are significant risk factors for intraabdominal sepsis, the method of colon management does

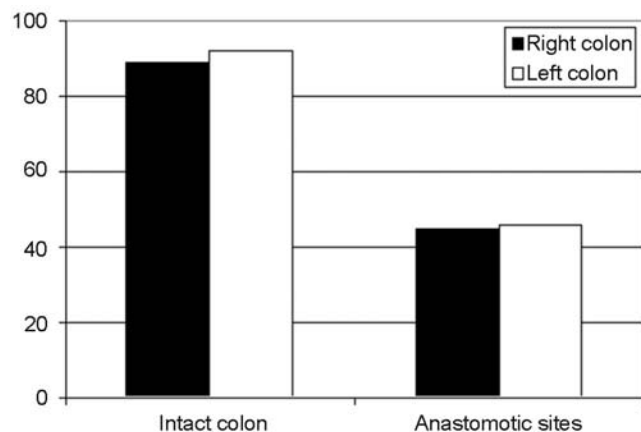

FIGURE 22-1. Hydroxyproline concentrations (biochemical marker of wound healing) are similar in both sides of the colon (values in µg/mg).

FIGURE 22-2. Breaking strengths of the right and left colon are similar (values in N/mm<sup>2</sup>).

not affect the incidence of abdominal sepsis.<sup>3,5-7,30</sup> Some studies have suggested that the creation of an ostomy in these high-risk patients may independently contribute to abdominal sepsis.<sup>30</sup> The current class I and II literature supports primary repair or resection and anastomosis in patients with severe or multiple associated abdominal injuries.

### Shock

There is now sufficient class I and II evidence that preoperative or intraoperative shock is neither an independent risk factor for abdominal sepsis nor a contradiction for primary colon repair or anastomosis.<sup>3,5,6</sup>

### Blood Transfusions

Multiple blood transfusion (>4 units of blood within the first 24 hours) has been shown to be a major independent risk factor for abdominal septic complications.<sup>6,30</sup> In a large prospective AAST study of 297 patients with penetrating destructive colon injuries requiring resection, blood transfusion was the most critical independent factor for abdominal sepsis [adjusted relative risk (RR), 2.0; 95% confidence interval (CI), 1.31-2.83;  $P = .001$ ].<sup>6</sup> However, the method of colon management did not influence the complication rate in this group of patients and primary anastomosis was recommended.<sup>6</sup>

### Injury Severity Score

The ISS is not an independent risk factor for abdominal sepsis and high ISS (>15) is not a contraindication for primary repair or anastomosis.<sup>3,6</sup>

### Fecal Contamination

Severe fecal contamination of the peritoneal cavity is a major independent risk factor for abdominal sepsis.<sup>1,6,11,26,30,31</sup> This finding led some studies to suggest that the presence of severe contamination should be a contraindication for primary repair

or anastomosis.<sup>1,11,31,32</sup> However, all prospective, randomized studies and recent large prospective observational studies have shown that the method of colon management in this group of patients does not influence the septic complication rate and recommended primary repair or anastomosis.<sup>2,5,6</sup>

### *Specific Associated Abdominal Injuries*

There is class III evidence that the combination of colon injuries with pancreatic or ureteric injuries is associated with an increased incidence of septic complications.<sup>33,34</sup> However, there is no evidence that the presence of any of these injuries is a contraindication for primary repair or anastomosis.<sup>6</sup>

### *Time from Injury to Operation*

The length of delay of surgical repair over which the septic complication rate increases is not well defined. Some studies suggest >6 hours whereas others >12 hours as the critical delays associated with an increased risk of infections.<sup>7,22,26,35</sup> It seems that the degree of contamination is much more important than the delay in surgical management and the time delay in itself should not be used as a criterion for primary repair or diversion. In a prospective study of 297 destructive colon injuries, the incidence of abdominal complication was 11.4% (4/35) in the group of patients with preoperative time >6 hours and 26.1% in patients with times <6 hours. Multivariate analysis failed to identify time delay as an independent risk factor.<sup>6</sup>

### *Retained Missiles*

Missiles, which passed through the colon and remained lodged in the tissues, are not associated with increased risk of local sepsis and they should be removed only if it is technically easy and does not prolong the operation. In a study of 84 patients with gunshot wounds of the colon, the bullet remained in the body in 40 and was removed in 44. The incidence of local septic complications was 5% in patients with retained bullets and 7% in those without.<sup>36</sup>

### *Anatomic Location of Colon Injury*

There is a plethora of classes I, II, and III evidence that the incidence of complications is similar in right and left colon injuries.

### *Temporary Abdominal Wall Closure*

Damage control laparotomy and temporary abdominal wall closure with prosthetic material seem to be associated with increased incidence of abdominal septic complications. The crude relative risk of abdominal sepsis in patients with temporary abdominal wall closure has been reported to be 2.12 (1.32–3.40) ( $P = .005$ ) in a study of 297 of destructive colon injuries requiring resection. However, multivariate analysis failed to identify this method as independent risk factor.<sup>6</sup> There is no literature addressing the optimal management of

colon injuries in this group of patients. The authors prefer primary repair or resection and anastomosis, to avoid a colostomy near an open abdomen.

### *Anastomotic Leaks*

Colon leaks remain the most serious complication in repaired or anastomosed colons. The overall incidence of suture line failures is fairly low. In a collective review of 35 prospective or retrospective studies with 2964 primary repairs, Curran reported 66 (2.2%) leaks.<sup>6,37</sup> In prospective studies including 534 patients with colon repair or resection and anastomosis, there were 17 (3.2%) leaks.<sup>6,37</sup> The leak rate after resection and anastomosis is significantly higher than in simple repairs. In a collective review of 362 patients with resection and anastomosis, the overall incidence of anastomotic leak was 5.5%.<sup>37</sup> In another large retrospective study of 112 patients with penetrating or blunt colonic injuries treated by resection and primary anastomosis, Murray et al.<sup>26</sup> reported a leak rate of 9%. In a more recent multicenter prospective study of 197 patients with penetrating colon injuries who underwent resection and primary anastomosis, the leak rate was 6.6%.<sup>6</sup>

The risk factors for anastomotic leak are not well defined. It seems that colocolostomies are associated with a higher incidence of anastomotic leaks than ileocolostomies. Murray et al.<sup>26</sup> reported a leak rate of 4% in 56 patients with ileocolostomies and 13% in 56 colocolostomies. Univariate analysis identified PATI >25, >6 units of blood transfusion, and hypotension in the emergency room as risk factors for anastomotic leak. A multicenter prospective AAST study reported a leak rate of 4.2% for ileocolostomies and 8.9% in colocolostomies.<sup>6</sup> The leaks occurred in patients with or without multiple blood transfusions, severe contamination, and multiple associated injuries. No significant independent risk factors could be identified.

The prognosis of anastomotic leaks is usually good and most of the patients can safely be managed nonoperatively with low-residue diet. In most cases, the leak results in a fecal fistula, which heals spontaneously within a few days. In other cases, the leak results in a local abscess, which can be drained percutaneously. However, in some patients, the colonic leak causes severe intraabdominal sepsis and a proximal diversion procedure may be required. Curran and Borzotta<sup>37</sup> reported no deaths in a collective series of 66 patients with repair leaks. However, Murray et al. reported two colon-related deaths in a group of 10 patients with anastomotic leak. The AAST multicenter study reported no deaths in the 13 patients with anastomotic leaks. The overall mortality attributable to colon leak-related complications in a collective review of 3161 trauma patients treated with primary repair or resection and anastomosis was only 0.1%.<sup>6,37</sup>

In summary, colonic leaks occur more often in patients with colocolostomies than patients with ileocolostomies. External fecal fistulas can safely be managed nonoperatively with low-residue diet. Localized abscesses are best drained

percutaneously by interventional radiology and the ensuing fecal fistula almost always closes spontaneously. Reexploration of the abdomen and creation of fecal diversion with or without resection of the leaking colon should be reserved only for patients with generalized peritonitis or failed percutaneous drainage.

## Technique of Colon Repair

In nondestructive injuries, repair of the injured colon should be performed after debridement of the perforation. This step is critical in gunshot wounds and failure to debride may result in breakdown of the suture line. In destructive injuries, resection to normal and well-perfused edges should be performed and the anastomosis should be tension free. The method of anastomosis, hand-sewn or stapled, does not influence the incidence of abdominal complications or leak rate and it should be surgeon's preference. In a prospective AAST study of 207 patients with penetrating destructive injuries who underwent resection and anastomosis, 128 cases were managed by hand-sewn and 79 cases by stapled anastomosis. The incidence of anastomotic leak was 7.8% and 6.3%, respectively. Multivariate analysis adjusting for blood transfusions, degree of fecal contamination, and antibiotic coverage showed identical complication rates (stapled anastomosis adjusted RR = 0.99).<sup>38</sup> Application of fibrin glue around the anastomosis may be beneficial although no study has ever evaluated its role in colonic anastomosis in trauma. Further protection of the anastomosis with adjacent omentum is recommended whenever possible. It is the practice of the authors to apply fibrin glue and cover the anastomosis with omentum in all cases with resection and anastomosis.

## Rectal Injuries

The management of rectal trauma has undergone many changes in the same manner as colon injuries, with many of the principles of management evolving from wartime experiences. The mortality related to rectal trauma has decreased dramatically from 67% during World War I down to today's civilian reports of 0%–10%.<sup>39–44</sup> Likewise, the morbidity, which was as high as 72% during the Vietnam War, is now as low as 10%.<sup>44,45</sup> The mainstay of management, developed from lessons learned from combat experiences, has remained controversial and includes: 1) diversion of fecal stream, 2) distal rectal washout, 3) presacral drainage, and 4) debridement and closure of wounds when possible. Because of the paucity of class I and class II data, no consensus has been achieved with respect to the optimal management of rectal trauma.

## Anatomy

The anatomy of the rectum makes it difficult to apply the principles of colon trauma management. The majority of the rectum is completely surrounded by the bony pelvis, making

injuries infrequent, and exposure difficult. The rectum varies in length from 12 to 15 cm, with only the upper two-thirds anteriorly and the upper one-third laterally covered by peritoneum (intraperitoneal rectum). The lower third of the rectum completely lacks peritoneal covering (extraperitoneal rectum) which makes exposure and repair of injuries difficult. Finally, the rectum is easily accessible from the anus, with the anterior peritoneal reflection only approximately 6 cm from the anal verge. This results in a not uncommon finding of intraperitoneal injury from rectal foreign bodies.

## Epidemiology

For the various anatomic reasons, injuries to the rectum occur infrequently, and are usually the result of penetrating trauma. In most series, gunshot and shotgun wounds account for 80%–85% of injuries, and stab wounds for 3%–5%.<sup>39,46,47</sup> The incidence of rectal trauma is low, with most series describing relatively few injuries. In a series of 59 patients with gunshot wounds to the buttocks, only 3.4% had rectal injuries.<sup>48</sup> In another series of 192 patients with gunshot wounds to the back, 2.6% had a rectal injury.<sup>9</sup> Interestingly, in a series of 309 anterior abdominal gunshot wounds, and a series of 37 transpelvic gunshot wounds, no rectal injuries were identified, reiterating the infrequency of this injury.<sup>8,49</sup>

Other causes include iatrogenic injuries from urologic and endoscopic procedures, sexual misadventure, and anorectal foreign bodies. Blunt trauma accounts for 5%–10% of cases, and is usually the result of pelvic fractures or impalement.<sup>39,42,46,47,50</sup> Rectal injuries have been reported in nearly 2% of all pelvic fractures.<sup>51</sup>

## Diagnosis

The diagnosis of intraperitoneal rectal injury, similar to colonic injuries, is almost always made intraoperatively. Extraperitoneal rectal injuries may not always be as obvious. A high index of suspicion is necessary with both blunt and penetrating mechanisms to avoid missing an injury. The cornerstone for diagnosing an extraperitoneal injury is the combination of a digital rectal examination and rigid proctoscopy. In most series, the diagnostic accuracy of the digital rectal examination and rigid proctoscopy ranges from 80% to 95%.<sup>39,44,47,52–54</sup> However, the false-negative rate of the two has been reported to be as high as 31%.<sup>40</sup> For this reason, any suggestion of a rectal injury, even with a normal rectal and proctoscopic examination, should prompt further evaluation. In hemodynamically stable patients with a mechanism suspicious for a rectal injury (gluteal, perineal, and transpelvic gunshot wounds, pelvic fractures, and foreign body insertion), a digital rectal examination and a rigid proctoscopy must be performed and in the appropriate cases further evaluation by means of a contrast study should be considered.

## Rectal Organ Injury Scale

The grading system developed by the AAST for rectal injuries (Table 22-5) is similar to that of colonic injuries (Table 22-2).

TABLE 22-5. AAST Rectal Organ Injury Scale

Grade	Injury description
I	a) Contusion or hematoma without devascularization b) Partial-thickness laceration
II	Laceration $\leq 50\%$ of circumference
III	Laceration $> 50\%$ of circumference
IV	Full-thickness laceration with extension into the perineum
V	Devascularized segment

## Operative Management

### Historical Perspective

The history of rectal trauma parallels that of colon trauma with much of the early management principles evolving from lessons learned from wartime experiences. Mortality from rectal gunshot wounds was as high as 67% in World War I and the early part of World War II, until the Army Surgeon General mandated colostomy for fecal diversion for all colon and rectal injuries.<sup>14,39,55</sup> Subsequently, the mortality decreased to 35%.<sup>55</sup> Retrorectal drainage was added in 1943, which appeared to bring the mortality down further to approximately 5%.<sup>39,56</sup> Shortly after World War II, several civilian series demonstrated satisfactory results with colostomy and presacral drainage.<sup>57,58</sup> During the Vietnam War, in which more destructive injuries were encountered, colostomy and presacral drainage alone was found to be inadequate. Rectal repair and distal rectal washout were added to the management and was associated with improved results.<sup>45</sup> Early post-war civilian studies demonstrated acceptable results when colostomy, rectal repair, presacral drainage, and distal irrigation were all used.<sup>40,59</sup> Interestingly, there were other studies that also demonstrated acceptable results when only colostomy and presacral drainage were used.<sup>42,56,60</sup> Presently there is no acceptable gold standard for the treatment of rectal injuries, because most studies have been unable to demonstrate any advantage of the various treatment options.

### Intraperitoneal Injuries

With no class I or class II data present regarding the management of intraperitoneal rectal injuries and limited class III data that combines both extraperitoneal and intraperitoneal injuries, it is difficult to make a conclusion regarding management. However, several studies do indicate that injuries to the intraperitoneal rectum can be managed similar to left colon injuries with primary repair without the need for colostomy.<sup>43,47,52,54,61</sup> No increase in abdominal complications was found in these series when primary repair without colostomy was performed. The authors' program advocates primary repair in this group of patients.

### Extraperitoneal Injuries

As previously mentioned, there is no agreement in terms of the optimal management of extraperitoneal rectal injuries,

but the mainstay of treatment has included four main components: 1) fecal diversion with colostomy, 2) presacral drainage, 3) distal rectal washout, and 4) repair of the injury when possible. Each will be addressed separately below.

### *Fecal Diversion with Colostomy*

Since World War II, the mainstay of management of extraperitoneal injuries has been proximal colostomy.<sup>39,42,43,50,52-54</sup> The only controversial aspect has been whether to perform a loop colostomy versus an end colostomy. Some argue that a loop colostomy does not offer complete fecal diversion, whereas proponents of loop colostomy argue that a properly constructed loop colostomy will function as a true diverting colostomy with the benefit of simple construction and rapid closure.<sup>39,52</sup> In fact, Rombeau et al.<sup>62</sup> demonstrated that a properly constructed loop colostomy, supported by a solid rod above the level of the skin, achieves complete fecal diversion. The authors believe that the type of colostomy should be dictated by the operative findings. Extensive destruction of the rectum that requires a resection may best be served with a Hartmann's procedure, whereas injuries that are not repaired or require limited dissection may be addressed by a loop colostomy.

Recently, there have been reports of primary repair without fecal diversion in selected extraperitoneal rectal injuries.<sup>46,47,52,54,63</sup> In a series of 30 patients with extraperitoneal rectal injuries, five were transanally repaired without fecal diversion and no subsequent morbidity.<sup>47</sup> Similarly, injuries right at the peritoneal reflection, or injuries encountered with minimal dissection, may also be primarily repaired without the need for colostomy.<sup>54</sup>

### *Presacral Drainage*

Presacral drainage was added to the armamentarium in World War II, because it was thought to decrease the pelvic sepsis rate.<sup>52,64</sup> It has remained controversial, with many studies showing a benefit with its use,<sup>39,40,42,52,65</sup> whereas other studies failing to show any benefit.<sup>43,46,53,54,66</sup> In a series of 30 consecutive patients with extraperitoneal injuries from the authors' institution, no benefit with the use of presacral drains was found.<sup>53</sup> Despite the conflicting data, many authors still recommended its use for most injuries.<sup>54</sup> This was challenged recently by a randomized, prospective trial evaluating the importance of presacral drainage.<sup>67</sup> In a series of 48 patients, 23 randomized to presacral drainage and 25 randomized to no drainage, no difference in pelvic sepsis was encountered. This represents the first and only class I study involving rectal injuries. Although it was a study with relatively few patients, it convincingly demonstrated that the addition of presacral drainage is unnecessary. The authors have completely abandoned the use of presacral drainage several years ago. It involves an additional procedure and dissection into an uninvolved space. The drains that are placed often become malpositioned or malfunction. Most importantly, there is no proof that it improves outcome.

### Distal Rectal Washout

Distal rectal irrigation was added to the management of rectal injuries during the Vietnam War, when Lavenson and Cohen<sup>45</sup> reported a decrease in morbidity from 72% to 10% with its use. Since then, there have been supporters of rectal washout<sup>46,41,43,59</sup> as well as nonsupporters.<sup>39,42,46,52,66</sup> The overall value of distal washout is questionable. It has been suggested that there may be a benefit in patients with high velocity wounds,<sup>39,44</sup> and in patients with rectal injuries from pelvic fractures.<sup>68,69</sup> However, this remains controversial. The authors do not recommend distal bowel irrigation. There is no proven benefit, and it may be associated with a high risk of infection because of spillage of intraluminal contents out of unrepaired rectal injuries.<sup>56</sup>

### Rectal Repair

The addition of rectal repair to colostomy was also introduced during the Vietnam War.<sup>45</sup> However, rectal repair with or without a diverting colostomy is infrequently performed for extraperitoneal injuries.<sup>53</sup> In the majority of cases, repair is not technically feasible, with some series reporting successful repair in only 20%–37% of cases.<sup>39,43,52</sup> Even when repair is performed, no outcome advantage has been proven.<sup>39,42,43</sup> Attempts at repair are associated with extensive dissection and unnecessary contamination of the peritoneal cavity. Attempts at repair should only be made when the rectal injury is encountered during the exposure of an associated injury such as bladder or iliac vessel, or if the injury is easily accessible at the peritoneal reflection. As previously mentioned, injuries that are easily accessible from the transanal route may also be repaired with excellent results.<sup>47</sup>

### Miscellaneous Options

Although extremely rare, abdominoperineal resection has been described for patients with severe bleeding, massive tissue loss, or devascularizing injuries.<sup>40,63,70</sup> Recent reports have introduced laparoscopy in the management of rectal injuries.<sup>71,72</sup> In a prospective study of 20 patients with extraperitoneal rectal injuries, laparoscopy (to rule out an intraperitoneal injury), followed by a diverting loop sigmoid colostomy without laparotomy yielded excellent results.<sup>72</sup>

### Associated Injuries

Associated injuries are often seen with rectal injuries and have been reported to occur in as many as 77% of cases.<sup>39,53</sup> Genitourinary, and in particular bladder injuries, are usually the most frequently seen associated injuries, occurring in 30%–64% of cases.<sup>39,42,46</sup> Every effort should be made to close both injuries and separate both sites with well-vascularized tissue such as omentum. This should reduce the high incidence of rectovesical fistula, which can occur in up to 24% of patients with combined bladder and rectal injuries<sup>52,73</sup> (Figure 22-3).

FIGURE 22-3. Rectovesical fistula after repair of a gunshot wound involving the rectum and the bladder. Every effort should be made to separate the two organs with vascularized tissue such as omentum, to reduce the risk of this complication.

## Wound Management

The incidence of wound sepsis in patients with colon or rectal injury is high. In a prospective study of 100 patients with gunshot wounds and routine skin closure, the wound infection rate was 11%.<sup>3</sup> Primary wound closure in the presence of severe fecal spillage is a significant risk factor for wound sepsis and fascia dehiscence. This high-risk group of patients is best managed by delayed primary closure of the skin 3–5 days postoperatively.

## Antibiotic Prophylaxis

In view of the high incidence of septic complications in patients with colon injuries, appropriate antibiotic prophylaxis is critical. It is a standard practice to cover against both aerobes and anaerobes. In early studies, the combination of penicillin/aminoglycoside/metronidazole was a popular antibiotic choice. Subsequent studies showed that in penetrating abdominal trauma, single agents were as good as combination antibiotics.<sup>74,75</sup> However, practically all available studies included a large number of fairly minor or moderately severe abdominal injuries and only a small number of severe colon injuries with extensive fecal spillage. The reported overall incidence of intraabdominal abscess in

abdominal trauma series is about 3%<sup>75</sup> whereas in severe colon injuries is about 19%.<sup>6</sup> The AAST destructive colon injury study identified single-antibiotic-agent prophylaxis as an independent risk factor for abdominal sepsis. The overall incidence of abdominal septic complications was 31% in patients who received single-agent prophylaxis and 16% in patients who received combination antibiotics (adjusted RR, 1.78; 95% CI, 1.12–2.67;  $P = .02$ ). Further comparison of the two agents used for single antibiotic prophylaxis (cephalosporin versus ampicillin/sulbactam) showed an abdominal infection rate of 37% in the cephalosporin group and 22% in the ampicillin/sulbactam group (crude RR, 1.67; 95% CI, 0.93–2.99;  $P = .07$ ). It is possible that although single agents may be effective in minor or moderate trauma, they might be suboptimal in severe colon injuries. It is also possible that it might be necessary to cover against *Enterococcus*. Weigelt et al.<sup>76</sup> in a prospective, randomized study of 595 abdominal trauma patients compared ampicillin/sulbactam with cefoxitin. The wound infection rate was significantly lower with ampicillin/sulbactam. The study suggested that the lower infection rate with ampicillin/sulbactam was attributable to better *Enterococcus* coverage. The issue of antibiotic coverage in colon injuries merits further investigation. The authors' current choice is ampicillin/sulbactam prophylaxis in all suspected abdominal hollow viscus injury.

The duration of antibiotic prophylaxis has been a controversial issue. There is now class I evidence that 24-hour prophylaxis is at least as effective as prolonged prophylaxis for 3–5 days, even in the presence of major risk factors for abdominal sepsis, such as colon injury, multiple blood transfusions, and high Abdominal Trauma Index. In a prospective, randomized study of 63 patients with penetrating colon injuries and associate Abdominal Trauma Index >25 or >6 units of blood transfusions or delay of operation >6 hours, Cornwell et al.<sup>7</sup> reported an abdominal infection complication rate of 19% in patients who received 24 hours' antibiotic prophylaxis and 38% in patients who received 5 days' prophylaxis.

With respect to rectal injuries, no study has addressed the type or length of antibiotic therapy. In the available studies that have even mentioned antibiotics, length of therapy has been at least 2 days using single or double agents covering both aerobes and anaerobes.<sup>39,67,72</sup> It is the authors' preference to use ampicillin/sulbactam for prophylaxis in all patients with rectal injuries.

## Trauma Ostomy Complications

When deciding about the method of management of a colon or rectal injury, the surgeon should take into account the problems related to the creation of a stoma and later on the complications associated with the subsequent operation for colostomy closure. The presence of an ostomy is in itself a significant emotional trauma, especially in an image-conscious

young person. In addition, the incidence of complications directly related to the ostomy construction is a significant one. The most common serious complications include necrosis, retraction, prolapse, parastomal abscess, and parastomal hernia. Less serious complications include troublesome skin irritation and poor location with difficulties in the application of the collection bag. Park et al.<sup>77</sup> in a series of 528 stomas created for trauma reported an incidence 22% of severe or minor early complications and 3% of late complications directly related to the stoma.

The morbidity of colostomy closure is significant (Figure 22-4). In a collective review of 809 colostomy closures in trauma patients during the period 1970–1990, the overall incidence of colon-related complications was 13.1% (major complications 5.3%; minor complications 7.8%).<sup>37</sup> Another study of 110 colostomy closures reported an overall local complication rate of 14.5%, including 2.7% colon leaks.<sup>78</sup> In a more recent collective review of 1085 colostomy closures, the overall complication rate was 14.8%.<sup>79</sup>

The timing of colostomy closure does not seem to have an important role in the incidence of complications. Early studies had suggested colostomy closure should be performed after 3 months from the original operation to allow time for the colostomy to “mature.”<sup>80,81</sup> Subsequent studies showed that closure of the stoma earlier than 3 months is safe and not associated with increased complication rates.<sup>78,82</sup> More recent studies even recommended closure during the same admission of the injury, which is usually within 2 weeks of the colostomy construction.<sup>83</sup> The optimal time for colostomy closure should be individualized and time should be allowed for wound healing and nutritional recovery. This might

FIGURE 22-4. End colostomy in the presence of a complicated abdominal wound with protruding mesh. Closure of this colostomy is a high-risk procedure.

require only a few weeks for some patients or many months in severely injured patients.

## Rectal Foreign Bodies

Rectal foreign bodies represent an uncommon cause of rectal injury, accounting for <5% of cases<sup>39,42,52</sup> (see Figure 22-5). More often, patients present to the hospital with a retained foreign body. These patients present an unusual, yet surprisingly common management dilemma.<sup>84</sup> Most objects can be safely removed in the emergency department; however, a small percentage of patients will require general anesthesia and operative management with or without laparotomy. In a review of 87

patients presenting with a retained foreign body at the authors' institution, 75% were successfully retrieved at the bedside whereas 8% required laparotomy with colotomy for foreign body extraction.<sup>85</sup> The only independent risk factor for operative intervention was if the foreign body was located in the sigmoid colon (odds ratio, 2.25; 95% CI, 1.1–4.4;  $P = .04$ ).

Patients with a history of retained foreign body who present with peritonitis should be taken directly to the operating room. Without peritonitis, patients should have an attempt at retrieval at the bedside. If unsuccessful, patients should be taken to the operating room with an attempt at transanal extraction under intravenous sedation. As mentioned previously, patients most likely to require operative intervention are those with the foreign body located in the sigmoid colon.<sup>85</sup> The use of grasping

FIGURE 22-5. A–C Rectal foreign bodies of various shapes and sizes.

forceps should be avoided because it may lead to rectal mucosal injury. If transanal extraction is unsuccessful, then a laparotomy should be performed to maneuver the foreign body into the rectum for transanal removal.<sup>86</sup> If this is unsuccessful, then a colotomy may be necessary for foreign body retrieval.

## Colorectal Cancer: Epidemiology, Etiology, and Molecular Basis

Nancy N. Baxter and Jose G. Guillem

### Epidemiology

Colorectal cancer (CRC) is a disease with a major worldwide burden. It is the fourth most frequently diagnosed malignancy in both sexes with almost 1 million people developing CRC annually.<sup>1</sup> CRC is the third most common cause of cancer death in the world, responsible for 630,000 deaths annually.<sup>2</sup> In the United States, CRC is the third most common cancer in men and women and the second most common cause of cancer death overall. CRC accounts for 11% of cancers diagnosed.<sup>3</sup> It is estimated that 147,000 cases will be diagnosed in the United States in 2004 and that there will be 57,000 deaths from the disease.<sup>3</sup>

The worldwide incidence of CRC is increasing; in 1975, the worldwide incidence of CRC was only 500,000.<sup>4</sup> In Western countries, some of the increase is attributable to the aging of the population; however, in countries with a low baseline rate of CRC, an increase in incidence after adjustment for age has been found. Before 1985, the age-adjusted incidence of CRC in the United States had been increasing; however, since this time, the rates have declined an average of  $-1.6\%$  per year<sup>5</sup> (Figure 23-1). This reduction has been mainly confined to the Caucasian race and is largely limited to a decrease in the incidence of distal cancers. Therefore, the recent decrease in incidence in the United States may be attributable to screening, specifically screening with flexible sigmoidoscopy,<sup>6</sup> although other factors are likely to have influenced this trend. The incidence of proximal cancers has remained relatively stable over the same time period.<sup>5,6</sup> Currently, the overall probability of an individual developing CRC in United States over a lifetime is almost 6%.<sup>3</sup>

From a population perspective, age is the most important risk factor for CRC. CRC is predominantly a disease of older individuals; 90% of cases are diagnosed over the age of 50.<sup>3</sup> The risk of CRC continues to increase with age (Figure 23-2). The incidence per 100,000 people aged 80–84 is more than 7 times the incidence in people aged 50–54. However, CRC can

occur at any age and the incidence of CRC occurring in patients younger than age 40 may be increasing.<sup>7</sup>

In the United States the risk of CRC differs by gender. The incidence of CRC is more than 40% higher in men than women.<sup>5</sup> Overall, the incidence of CRC in men is 64 per 100,000 males as compared with 46 per 100,000 females.<sup>3</sup> In addition, the ratio of colon to rectal cancer differs in the United States by gender; the ratio of colon to rectal cases for women is 3:1 as compared with 2:1 for males.<sup>3</sup>

Race and ethnicity influence CRC risk; Ashkenazi Jewish individuals seem to be at a slightly increased risk of CRC.<sup>8</sup> At least part of this increased incidence may be attributable to a higher prevalence of the *I1307K* mutation of the adenomatous polyposis gene, a mutation that confers an increased risk of CRC development. The *I1307K* mutation is found in 6.1% of unselected Ashkenazi Jewish individuals and 28% of Jewish individuals with CRC<sup>9</sup> whereas the mutation is rare in other populations.<sup>10</sup> In the United States, the incidence of CRC is higher in African-Americans of either gender as compared with Caucasians. Asian American/Pacific Islanders, Native Americans, and Hispanic Americans experience a lower incidence of CRC than Caucasians<sup>3,11</sup> (Table 23-1). African-Americans have not experienced the substantial reduction in incidence of CRC found to have occurred in Caucasians; before 1980, incidence in African-Americans was actually lower than in Caucasians. In African-Americans, the increased rate of cancer is predominantly attributable to a higher rate of proximal cancers.<sup>12–14</sup>

The Surveillance Epidemiology and End Results registry (a National Cancer Institute population-based cancer registry representing 14% of the population in the United States) reports cancer incidence and stage over time (Table 23-2). Between 1992 and 1999 for all patients diagnosed with CRC, 38% of patients were diagnosed with localized disease, 38% with regional disease, and 19% with metastatic disease. Five percent of patients were unstaged. As a proportion of total cases, African-Americans were more likely to present with advanced disease; 24% of African-Americans have metastatic

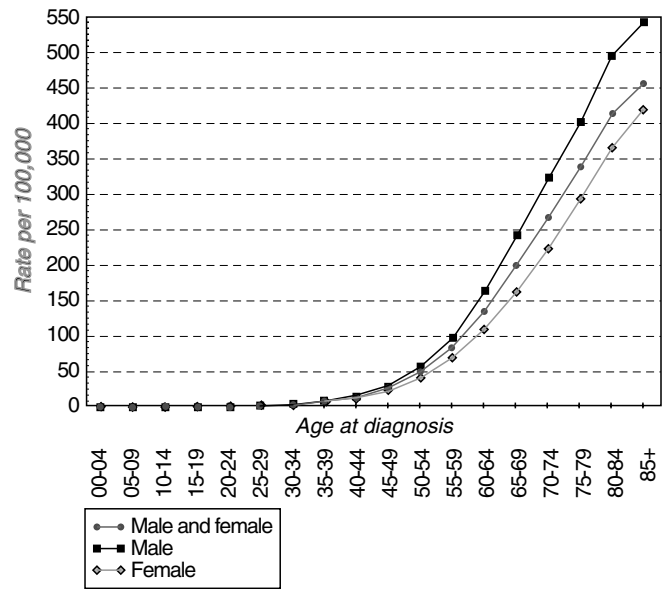

FIGURE 23-2. Age-specific incidence rates in the United States. Age-specific incidence both genders—circles. Age-specific incidence in males—squares. Age-specific incidence in females—diamonds. [Generated from the Surveillance, Epidemiology, and End Results (SEER) Program (www.seer.cancer.gov) SEER\*Stat Database: Incidence—SEER 9 Regs Public-Use, Nov 2002 Sub (1973–2000), National Cancer Institute, DCCPS, Surveillance Research Program, Cancer Statistics Branch, released April 2003, based on the November 2002 submission.]

disease at presentation.<sup>11</sup> Rates of metastatic disease have fallen over time, most notably for CRC of the distal colon and rectum in Caucasians.<sup>14</sup>

There is substantial geographic variation in the incidence of CRC, with relatively high rates in North America, Western Europe, and Australia and relatively low rates in Africa and Asia<sup>15</sup> (Figure 23-3). Such observations led to Burkitt's<sup>16</sup> hypothesis—that dietary differences, specifically fiber and fat intake, between populations were responsible for the marked variation in rates of CRC found around the world. Burkitt observed that populations in low-risk areas of the third world had greater stool bulk, a faster colonic transit time, and higher dietary fiber intake than populations in high-risk westernized regions. Although such ecologic studies are confounded by numerous factors (for example, variations in average life expectancy, cancer detection methods, etc.), environmental factors (most prominently dietary factors) are still considered

to have a major role in this disease. This argument is supported by studies of migrants from low prevalence areas to high prevalence areas. Such studies generally demonstrate that the incidence of CRC in the migrants increases rapidly to become similar and in some cases to exceed the incidence of the high-risk area.<sup>17</sup> Interestingly, there is less variation in the incidence of rectal cancer between countries as compared with the incidence of colon cancer.<sup>18,19</sup>

Mortality from CRC is declining in the United States as age-adjusted CRC death rates peaked in the 1940s at 35 per 100,000. Rates in women have steadily decreased since this time and in 1998, the CRC death rate in women was 18.6 per 100,000. In men, death rates changed little until the 1980s and 1990s then decreased significantly; in 1998, the CRC death rate was 26.1 per 100,000 for men.<sup>19</sup> Improvements in surgical and medical treatments likely explain some of the change particularly that identified before 1985. More recently, the

TABLE 23-1. Incidence and mortality rates\* for CRC by site, race, and ethnicity, United States 1996–2000

		Caucasian	African-American	Asian American and Pacific Islander	American Indian/Alaska Native	Hispanic/Latino
Incidence	Male	64.1	72.4	57.2	37.5	49.8
	Female	46.2	56.2	38.8	32.6	32.9
Mortality	Male	25.3	34.6	15.8	18.5	18.4
	Female	17.5	24.6	11.0	12.1	11.4

	Caucasians	African-Americans
Localized	38	34
Regional	38	36
Distant	19	24
Unstaged	5	7

reduced mortality rate is likely secondary to the reduced incidence of CRC. In fact, no improvement in case fatality has been identified since 1986<sup>20</sup> indicating the trends in mortality are likely complex, particularly given the gender differences. African-Americans have the highest mortality rate from CRC in the United States (Table 23-1). The reasons for the higher mortality rate are likely multifactorial including the higher incidence of CRC, and the differences in stage distribution. However, African-Americans had worse 5-year survival for all stages of disease, and the difference in 5-year survival rates between Caucasians and African-Americans has actually increased over time; from an absolute difference of 5% in the 1970s (51% versus 46%) to an absolute difference of 13%

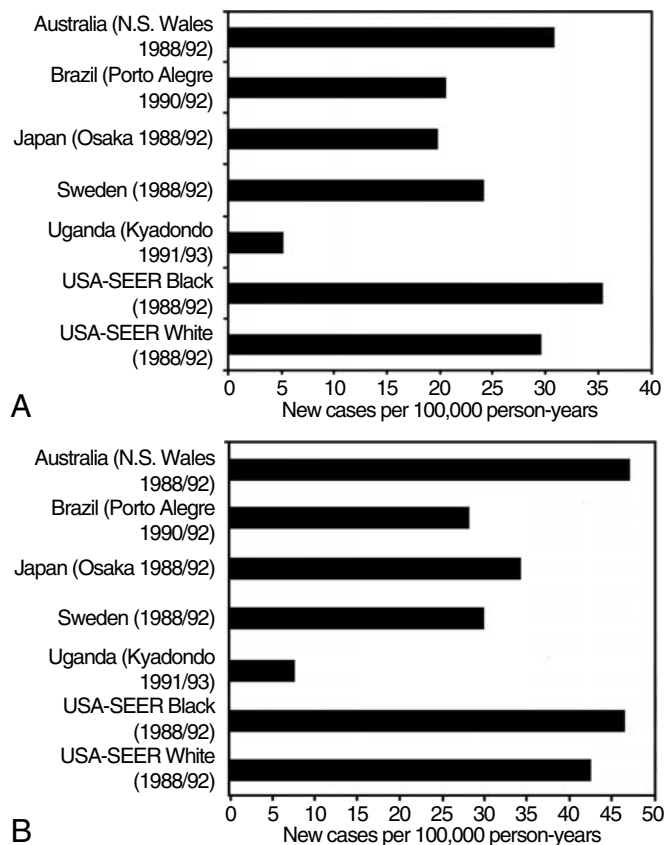

FIGURE 23-3. **A** Age-standardized (to the world population) incidence rates of cancer of the large bowel among females. **B** Age-standardized (to the world population) incidence rates of cancer of the large bowel among males. in the 1990s (63% versus 53%).<sup>11,21</sup> Differences in incidence, stage distribution, and survival of CRC between Caucasians and African-Americans are in part attributable to differences in socioeconomic status, screening rates, and treatment<sup>22</sup>; however, the differences may also be attributable to genetic and environmental factors that have yet to be elucidated.<sup>23</sup>

Because CRC is a survivable cancer, with 5-year survival rates adjusted for life expectancy of 63%,<sup>3</sup> the prevalence of people living with a diagnosis of CRC in the population is substantial. In 1996, more than 380,000 Americans older than 65 years of age received some type of CRC care (treatment or follow-up).<sup>24</sup> In total in 2004, more than 1 million living Americans have had a diagnosis of CRC.<sup>25</sup>

## Etiology

### Dietary Constituents and Supplements

The colon is constantly exposed to the substances we ingest and the byproducts of ingestion. Thus, the role of diet in the pathogenesis of CRC has long been speculated. However, the relationship between diet and CRC risk is at best unclear. Studies in this area are difficult to conduct, because exposures tend to be multifactorial and change over time with our diet. In addition, because colorectal carcinogenesis is a multistep process, a number or combination of exposures may be necessary, and genetic susceptibility is likely to have a role. In addition, in most cases, randomized trials are not feasible, and therefore studies must be observational in nature. When intervention studies are possible, follow-up is relatively short term (compared with the long-term exposure that may be necessary for cancer development), and single dietary components are generally selected for evaluation although the influence of diet may depend on complex interactions between dietary constituents. In addition, to reduce sample size, some studies are conducted on patients with a history of adenomatous polyps. Some interventions in these patients may not be effective, because such patients may have already acquired numerous genetic alterations in normal-appearing colonic mucosa. Some interventions may need to be instituted before development of polyps. Although it can be stated that an individual with no other risk factors for CRC who ingests a diet that is high in fiber, fruits, and vegetables and low in animal fat and red meat will be on average at lower risk of CRC than an individual who eats a diet low in fiber, fruits, and vegetables and high in animal fat and red meat, it is difficult to determine with certainty which dietary components or combinations are responsible for the decreased risk.

### Dietary Fat

Dietary fat, particularly saturated animal fat has been implicated in carcinogenesis in the colon and rectum. Early research using animal models demonstrated a carcinogenic effect of dietary fat on colonic mucosa,<sup>26-28</sup> and ecologic

studies found parallels between CRC rates and dietary fat consumption. Countries with populations eating a high fat diet had higher CRC rates than countries with populations eating a lower fat diet.<sup>29</sup> However, dietary fat consumption is related to a number of other factors that may influence cancer risk, including other dietary factors such as dietary fiber and micronutrient consumption, as well as life-style factors such as exercise and alcohol consumption. Therefore, ecologic comparisons between countries are subject to a substantial risk of confounding.<sup>30</sup>

More than 13 case-control studies have been conducted to evaluate the relationship between dietary fat intake and the risk of CRC. These have been quantitatively summarized by Howe et al.<sup>31</sup> and include 5287 cases with CRC and 10,470 controls. Although positive associations were identified for total energy intake and CRC in almost all of the studies, there was no energy-independent relationship between dietary fat intake and CRC risk. After controlling for total energy intake, the odds of development of CRC in subjects with the highest dietary fat intake as compared with those with the lowest intake was 0.90 [95% confidence interval (CI), 0.72–1.13]. Overall, there was no evidence for any association of total dietary fat intake and development of CRC. A small but consistent relationship between cholesterol intake and CRC was identified.

At least six cohort studies have been conducted to evaluate the relationship between dietary fat and CRC.<sup>32–37</sup> Only one study<sup>36</sup> identified an association between dietary animal fat and development of CRC, with a twofold increase in CRC in the highest consumers of animal fat as compared with the lowest consumers. A separate analysis of this same cohort indicated that regular intake of red meat was associated with a 2.5-fold increase in CRC risk as compared with infrequent consumption.<sup>38</sup> In fact, the evidence that red meat consumption is associated with CRC is in general more compelling than the evidence of an association with dietary fat. Given the lack of evidence for an independent association of dietary fat with CRC, it is unlikely that the animal fat in red meat is responsible for the association between red meat and CRC.

### *Red Meat*

There are a number of potential carcinogenic mechanisms unrelated to fat content that may result in a causal relationship between red meat ingestion and CRC. Red meat is high in iron, a prooxidant. Dietary iron may increase free-radical production in the colon, and these free radicals may cause chronic mucosal damage or promote other carcinogens. In humans, red meat ingestion stimulates production of N-nitroso compounds in a dose-response manner.<sup>39</sup> Because many N-nitroso compounds are known carcinogens, this is a potential mechanism for an association between red meat and CRC. Formation of heterocyclic amines and polycyclic aromatic hydrocarbons in meat by cooking over an open flame or cooking until well done may be an important factor because these compounds are carcinogenic in animal models.<sup>40</sup>

Many epidemiologic studies have been conducted to determine the effect of ingestion of red meat on CRC risk. Two metaanalyses have been published,<sup>41,42</sup> one combining the results of 13 cohort studies,<sup>41</sup> the other combining 21 case-control studies and six cohort studies.<sup>42</sup> In the two studies, the pooled estimate for the increase in the risk of CRC caused by meat consumption was similar; the pooled estimate for the odds of development of CRC in the highest meat-consuming groups as compared with the lowest was 1.14. A daily increase of 100 g of red meat (3.5 ounces) was associated with a 12%–17% increased risk of CRC. The risk was substantially higher with the ingestion of processed meat. Of note, individuals that consume diets high in red meat generally consume diets low in other dietary factors,<sup>43</sup> such as antioxidants that may themselves be important in colorectal carcinogenesis. It is therefore difficult to rule out the possibility that the apparent effect of red meat on development of CRC may be confounded or modified by other dietary or lifestyle factors.

### *Fruit and Vegetable Intake*

The effect of dietary intake of fruit and vegetables on CRC risk has been extensively evaluated. Fruits and vegetables are a source of antioxidants, including carotenoids and ascorbate. Other bioactive constituents in fruits and vegetables that may protect against carcinogenesis include the indoles and isothiocyanates. Previous research, including results from 22 case-control studies and four prospective cohort studies, has provided substantial support for the hypothesis that vegetable intake reduces the risk of CRC, whereas intake of fruit did not seem to have an effect.<sup>44</sup> More recent data, however, have not demonstrated a convincing link between vegetable or fruit intake and a reduced risk of CRC. In four large prospective cohort studies (the Nurse's Health Study of 121,700 women, the Health Professionals Follow-up Study of 51,529 men, the Netherlands Cohort Study on Diet and Cancer including 120,852 men and women, and the Cancer Prevention Study II Nutrition Cohort, including 133,163 men and women),<sup>45–47</sup> fruit and vegetable intake was not statistically significantly associated with a reduced risk of CRC. Of note, participants in the Nurse's Health Study and the Health Professionals Follow-up Study had a higher consumption of fruits and vegetables and a higher prevalence of multivitamin use than the general United States population.<sup>48</sup> The Netherlands study did show a trend toward a reduced risk of colon cancer in women eating large amounts of fruit and vegetables, particularly the brassica vegetables (cabbages, kale, broccoli, Brussels sprouts, and cauliflower) and cooked leafy vegetables. The Cancer Prevention Study II<sup>47</sup> also demonstrated a non-statistically significant trend for a higher colon cancer risk in men with the lowest vegetable consumption and women with the lowest fruit consumption.

Two additional studies have recently evaluated the effect of fruit and vegetable consumption in cohorts of women enrolled

in breast cancer screening studies.<sup>48,49</sup> In the first study<sup>48</sup> of 61,463 women enrolled in the Swedish Two Counties randomized trial of screening mammography, fruit and vegetable consumption was associated with a decreased risk of CRC. Individuals consuming greater than 5.0 servings per day had a relative risk (RR) of CRC of 0.73 compared with individuals consuming less than 2.5 servings. The second study<sup>49</sup> included 45,490 women who participated in the Breast Cancer Detection Demonstration Project, a National Cancer Institute–sponsored breast cancer screening program. These women completed a food frequency questionnaire and were followed for 386,142 person-years. No association between fruit and vegetable intake and CRC risk was identified, even after adjustment for other potential confounders. In addition, a dietary intervention trial has been conducted; the Polyp Prevention Trial, randomized 2079 people with colorectal adenomas to either intensive dietary counseling with assignment to a diet low in fat and high in fruits, vegetables, and fiber or control.<sup>50</sup> No difference in adenoma recurrence rate was found in the intervention group as compared with the control group.

Overall, the evidence for an association between fruit and vegetable intake and the risk of CRC is inconsistent. Given this lack of concordant data, it is unlikely that a large number of cases of CRC can be attributed directly to a lack of fruit or vegetables, or that major additional interventions to increase consumption would lead to a substantial reduction in the incidence of CRC.

### *Fiber*

Dietary fiber was one of the first dietary components thought to have a protective role in carcinogenesis. An association of a high fiber diet with a decreased risk of CRC was first theorized in 1969 by Burkitt<sup>16</sup>; however, the data regarding the association between fiber and CRC risk are conflicting. Several mechanisms have been proposed for the protective effects of fiber: fiber may increase intestinal transit and therefore reduce the length of exposure of the colon to carcinogens, and fiber may dilute or absorb various potential carcinogens, particularly bile salts. In addition, products of fiber degradation and fermentation in the colon (such as butyrate) may also have a role.<sup>51</sup> Overall, there has been little consistent evidence that a high fiber intake is associated with a decreased risk of CRC.<sup>51</sup> Two large American cohort studies, the Nurses Health study<sup>52</sup> and the Health Professionals' Follow-up Study,<sup>35</sup> found no evidence of benefit of fiber on CRC risk.

However, two recent studies have reopened the debate. In the Prostate, Lung, Colorectal and Ovarian Screening Trial,<sup>53</sup> a nested case-control study of more than 37,508 people undergoing flexible sigmoidoscopy was performed using food frequency questionnaires. People who reported the highest amounts of fiber in their diets had the lowest risk of colorectal adenomas, 27% less than people who ate the least amount of fiber. The strongest association was found for fiber from

grains, cereals, and fruits but not for fiber from legumes and vegetables. When colonic and rectal adenomas were evaluated separately, the effect of fiber was seen only in colonic adenoma. In a second study, a prospective cohort study comparing the diet of more than 500,000 people in 10 European countries, investigators in the European Prospective Investigation into Cancer and Nutrition<sup>54</sup> found that people who ate the most fiber had a 25% lower incidence of CRC than those who ate the least fiber. Again, the protective effect was highest for colon and least for rectum.

Dietary interventions to increase fiber intake have proven unsuccessful in reducing the risk of colorectal neoplasia. A metaanalysis has evaluated the effect of five intervention trials.<sup>55</sup> These studies randomized a total of 4349 individuals to some form of fiber supplementation or high fiber dietary intervention.<sup>50,56–59</sup> When the data were combined, there was no difference between the intervention and control groups for the number of subjects developing at least one adenoma [RR = 1.04 (95% CI, 0.95–1.13)]. The authors concluded that there is currently no evidence from randomized studies to suggest that increased dietary fiber intake will reduce the incidence or recurrence of adenomatous polyps within a 2- to 4-year period.

Currently there is no single accepted definition of fiber. Many different types of fiber exist (soluble/nonsoluble, polysaccharides/nonpolysaccharides) and these differences may influence CRC risk. In addition, fiber intake itself may not be protective but may be correlated with other healthy lifestyle choices as well as other components of a healthy diet (for example, high vegetable, low fat, and low meat). The lack of effect found in randomized trials as compared with observational studies indicates this may be the case. However, the intervention trials may have been too short in duration to be able to demonstrate an effect.

### *Calcium*

Substantial epidemiologic and experimental evidence exists to support the beneficial effect of calcium on the prevention of colorectal neoplasia. Calcium has the capacity to bind and precipitate bile acids and may directly influence mucosal cell proliferation. Most, although not all, of the observational studies evaluating the influence of dietary calcium have demonstrated a protective effect of calcium on risk of CRC. Particularly compelling, two randomized double-blind placebo-controlled intervention trials of calcium for the prevention of adenoma recurrence that included a total of 1346 subjects<sup>57,60</sup> have demonstrated that the use of calcium supplementation (1200 mg daily for a mean duration of 4 years or 2000 mg daily for a mean duration of 3 years) was associated with a reduction in the recurrence of colorectal adenoma, although only one study<sup>60</sup> achieved statistical significance. In a metaanalysis of the two studies, the overall odds of developing recurrent adenomas was 0.74 for patients randomized to receive calcium as compared with placebo.<sup>61</sup>

The effect of calcium on a non-high-risk cohort is less clear. A metaanalysis of available studies conducted in 1996<sup>62</sup> concluded that the evidence to support the benefit of calcium intake on reduction of colorectal neoplasia was not consistent with a substantial effect. More recently, large observational studies have supported a modest effect of calcium in the prevention of CRC, particularly calcium supplementation. In a study of 87,998 women from the Nurses' Health Study and 47,344 men from the Health Professionals Follow-up Study, an RR of distal CRC of 0.73 was found for those ingesting more than 700 mg of calcium per day. No association was found for proximal cancers.<sup>63</sup> In the Cancer Prevention Study II, Nutrition Cohort Study, 60,866 men and 66,883 women completed a detailed dietary questionnaire and were followed for 5 years. Total calcium intake (from diet and supplements) was associated with marginally lower CRC risk in men and women (RR = 0.87; 95% CI, 0.67–1.12, highest versus lowest quintiles, *P* trend = .02).<sup>64</sup> A pooled analysis of 10 cohort studies including 534,536 individuals<sup>65</sup> evaluating the influence of dairy foods and calcium on CRC confirms a consistently decreased risk of CRC for those with the highest intake of dietary calcium as compared with those with the lowest intake. Although the effect of calcium may be modest, given that CRC is a common disease, the overall impact of optimizing calcium intake from a population standpoint could be substantial.

### *Folate*

Folate, a B vitamin, is important for normal DNA methylation. Methylation is important in the regulation of cellular gene expression. Folate deficiency may lead to cancer through disruption of DNA synthesis and repair, or loss of control of proto-oncogene activity.<sup>66</sup> In 15 retrospective epidemiologic<sup>67</sup> studies evaluating the association between folate and CRC risk, most demonstrate a statistically significant or trend toward a significant relationship between higher intake of folate and a reduced risk of CRC or adenoma formation. There are 11 prospective studies that have evaluated the influence of folate on CRC risk in North American and European populations.<sup>67</sup> In an unpublished metaanalysis of these data, a 20% reduction in the risk of CRC was found in those with the highest folate ingestion as compared with those with the lowest level of ingestion.<sup>68</sup> Although the relationship between folate and CRC in epidemiologic studies is generally consistent, it is not uniform, and there are no large-scale randomized trials evaluating the effect of folate supplementation on CRC or adenoma risk in the general population. Of note, since 1998, the United States Food and Drug Administration has required folate fortification of all flour and cereal grain products in the United States,<sup>69</sup> and thus folate consumption in the population is likely increasing.

### *Alcohol*

Alcohol ingestion has a possible role in colorectal carcinogenesis. Alcohol may alter folate absorption, increasing CRC

through reduction of folate bioavailability. Acetaldehyde, a product of alcohol metabolism may have a role, and alcohol may also contribute to abnormal DNA methylation directly. A metaanalysis of five follow-up studies and 22 case-control studies published in 1990<sup>70</sup> demonstrated only a weak association between alcohol and CRC, although the effect was stronger when only rectal cancer was considered. A more recent pooled analysis<sup>71</sup> of eight cohort studies examining the relationship between alcohol intake and CRC including a total of 489,979 people in five countries has been conducted. An increased risk of CRC was identified in persons with an alcohol intake of two or more drinks per day (an amount consumed by only 4% of women and 13% of men in these studies). For those individuals who drank two to three drinks per day, the RR of CRC as compared with nondrinkers was 1.16. For those people who drank three or more drinks per day, the RR (1.41) was greater. The association was found for all sites in the colon and rectum and for both women and men. No clear difference was seen in the risk attributable to specific types of alcohol (beer versus wine versus spirits). Of note, these cohort studies were limited to a single measure of alcohol consumption at baseline and thus could not assess duration of alcohol use or lifetime alcohol exposure. However, the findings of an association with alcohol intake are consistent, and there are no studies that demonstrate a protective effect of higher alcohol consumption.<sup>72</sup> Thus, the totality of the evidence indicates that a high level of alcohol intake (two or more drinks per day) is associated with an increased risk of CRC.

### *Aspirin and Nonsteroidal Antiinflammatory Drugs*

There is considerable observational evidence that the use of aspirin or other nonsteroidal antiinflammatory drugs (NSAIDs) has protective effects at all stages of colorectal carcinogenesis (aberrant crypt foci, adenoma, carcinoma, and death from CRC).<sup>73</sup> The mechanism of antineoplastic action of NSAIDs is incompletely understood but it is believed that both cyclooxygenase (COX)-dependent and COX-independent pathways may be important.

At least 30 observational studies have been conducted to evaluate the influence of NSAID (primarily aspirin) use on development of CRC and colorectal adenoma. A consistent reduction in the risk of colorectal neoplasia in NSAID users is identified in these studies of various design, that use various methods of controlling for potential confounders.<sup>73</sup> In a pooled analysis of studies evaluating the effect on colorectal adenoma, the summary RR for colorectal adenoma in aspirin users was 0.7 and in NSAID users was 0.6, indicating a statistically significant reduction in risk in aspirin and NSAID users.<sup>74</sup> In the pooled analysis of the effect of aspirin and NSAIDs on CRC risk, the results were virtually the same.<sup>75</sup> Overall, the data evaluating the effect of nonaspirin NSAIDs is more limited than that for aspirin.<sup>76</sup>

Several intervention studies have been conducted, and a Cochrane review of the results of the randomized controlled

intervention trials has been published.<sup>77,78</sup> The authors of this metaanalysis reviewed one population-based prevention trial (including 22,071 people),<sup>79</sup> three secondary prevention trials in people with sporadic polyps (including 2028 patients),<sup>80–82</sup> and four trials in 150 patients with familial adenomatous polyposis (FAP).<sup>83–86</sup> The authors conclude based on data from these high-quality trials that there is some evidence for the effectiveness of intervention strategies using NSAIDs for the prevention of colorectal adenoma. However, the single primary prevention trial reviewed<sup>79</sup> did not demonstrate a decreased incidence of CRC in the intervention group. Therefore, the results of ongoing trials evaluating the effects of NSAIDs on CRC development are necessary before the widespread usage of NSAIDs as a chemopreventive agent for this disease. Serious gastrointestinal complications occur in regular users of aspirin and NSAIDs. Although events are rare, hospitalizations for gastrointestinal complications occur in 7 to 13 per 1000 chronic users of NSAIDs per year.<sup>87,88</sup> Because chemopreventive agents must be used in the general population to substantially reduce the burden of disease, the risks of chemoprophylaxis with aspirin or NSAIDs may outweigh the benefits. Some recent studies have evaluated the role of COX-2 inhibitors in the prevention of CRC.<sup>89,90</sup> However, in comparison to aspirin, the research evaluating COX-2 inhibitors is limited. In addition, because there are potential cardiotoxic effects of COX-2 inhibitors, their use in chemoprevention cannot be supported.<sup>91</sup> A number of authors have evaluated the cost-effectiveness of chemoprevention of CRC with NSAIDs<sup>92,93</sup> or COX-2 inhibitors<sup>94,95</sup> and found that chemoprophylaxis with these compounds is not cost effective.

### Hormone Replacement Therapy

Observational studies have demonstrated an association between hormone replacement therapy (HRT) in women and a reduction in both incidence and mortality from CRC. Possible mechanisms for the effect of HRT include a reduction in bile acid secretion (a potential promoter or initiator of CRC), as well as estrogen effects on colonic epithelium, both directly and through alterations in insulin-like growth factor with the use of estrogens. A metaanalysis of 18 observational studies of postmenopausal HRT demonstrated a 20% reduction in incidence of CRC in women who had taken HRT as compared with those that had never taken HRT.<sup>96</sup> The Women's Health Initiative was a randomized trial of estrogen plus progestin in postmenopausal women including 16,608 women. The study was discontinued early, because after a mean of 5.2 years of follow-up, it was determined that the relative risk of breast cancer in the treatment group exceeded the predefined stopping boundary and the overall risk of adverse outcomes exceeded the benefits.<sup>97</sup> At that time, there seemed to be a protective effect of HRT on incidence of CRC. With further follow-up, a total of 122 cases of CRC developed in this cohort<sup>98</sup>: 43 cases in the group receiving HRT and 72

cases in the group receiving placebo, indicating that relatively short-term HRT was associated with a significantly decreased risk of CRC. Interestingly, the women who developed CRC while on HRT were more likely to present at an advanced stage than women who developed CRC when on placebo. The frequency of screening for CRC was similar between the two groups.

Overall, there seems to be a consistent reduction in the risk of CRC with the use of HRT. However, given the potential adverse effect of HRT, this should not be used as a primary preventive strategy for CRC.<sup>99</sup> Interestingly, some authors have found that the influence of estrogen on CRC risk is related to microsatellite instability (MSI)—the presence of estrogen seems to protect against MSI whereas lack of estrogen in older women increases the risk of development of an MSI-positive tumor.<sup>100</sup>

### Obesity

Obesity seems to increase the risk of colon cancer in men and premenopausal women. Case-control studies<sup>101,102</sup> and cohort studies<sup>103–105</sup> have demonstrated a strong association between a high body mass index and incidence of CRC, with a twofold increased risk of CRC found in the obese. One of the proposed mechanisms for the association is the relative insulin resistance found in many obese patients. Insulin resistance results in hyperinsulinemia and increased activity of IGF (insulinlike growth factor) peptides. High IGF-1 levels are associated with cell proliferation<sup>103</sup> and may increase the risk of colonic neoplasia. In the past, most studies have demonstrated a stronger association between obesity and CRC risk in men than in women. More recent evidence has demonstrated that in women, the association between obesity and CRC risk may be modified by estrogen. Several observational studies have demonstrated an increased risk of CRC in obese women; however, the association was limited to premenopausal women.<sup>104,106,107</sup> In postmenopausal women, the increased estrogen production associated with obesity was thought to mitigate the risk. Of note, not all observational studies have confirmed this relationship.<sup>103</sup>

### Physical Activity

More than 50 studies have been conducted to evaluate the influence of physical activity on CRC risk. Overall, the literature is relatively consistent with respect to the effect: greater physical activity (occupational, leisure, or total activity) is associated with a reduced risk of CRC. The effect is relatively small; the estimated increased risk of colon cancer in the sedentary ranges from 1.6 to 2.0. (Of note, this figure compares to the increased risk of heart disease attributable to a sedentary lifestyle of 1.3 to 1.4.) The effect of physical activity on colon cancer is consistent in both case-control studies and cohort studies.<sup>108</sup> Although physical activity may be associated with a number of other healthy lifestyle factors, studies

controlling for such factors (diet, smoking, nonsteroidal use, body mass) show an independent protective effect of physical activity. The effect of physical activity on the risk of rectal cancer is somewhat less consistent; some studies demonstrate no effect, and in studies that do demonstrate an effect, it is weaker. The amount of physical activity required to have an effect is substantial—risk reduction is estimated to occur with 3.5–4 hours of vigorous activity (running) per week but requires 7–35 hours of moderate activity (walking at a brisk pace) per week.<sup>108</sup>

The biologic mechanisms that explain the relationship between physical activity and CRC risk are unclear. Increased physical activity leads to changes in insulin sensitivity and IGF levels, and both insulin and IGF have been demonstrated to potentially be involved with colorectal carcinogenesis.<sup>109–111</sup> Additional proposed mechanisms include effects of physical activity on prostaglandin synthesis, effects on antitumor immune defenses, and the reduction in percent body fat associated with exercise.<sup>112</sup> The mechanism is almost certainly multifactorial. Nonetheless, for a host of health-related reasons, frequent moderate to vigorous physical activity can be recommended to most patients without hesitation.

## Smoking

Consistent with a 35- to 40-year time lag between exposure and induction of cancer, early studies did not demonstrate an association between cigarette smoking and colorectal neoplasia. More recent studies are more consistently positive. In a review of the literature conducted in 2001,<sup>113</sup> 21 of 22 studies evaluating the relationship between cigarette smoking and colorectal adenoma were positive, smokers demonstrating a two- to threefold increase of adenoma risk as compared with nonsmokers. Twenty-seven epidemiologic studies have been conducted that demonstrate an association between tobacco and risk of CRC.<sup>113</sup> Of studies conducted in the United States, conducted after 1970 in men, and 1990 in women (studies with adequate induction time—35 to 40 years after smoking became prevalent), most demonstrated an association between heavy smoking and increased CRC risk. Most studies demonstrated an effect at relatively high levels of smoking (20 or more cigarettes per day). In the studies reviewed, the CRC risk was 1.4- to 2-fold higher in smokers than in nonsmokers.

Smoking may modify the effect of micronutrients on CRC risk. In a randomized, controlled trial of antioxidants including  $\beta$ -carotene, or vitamin C and E supplementation in the prevention of recurrence of colorectal adenomas, among subjects who neither smoked nor drank alcohol,  $\beta$ -carotene was associated with a substantial reduction in the risk of recurrent adenoma (RR = 0.56). This effect was significantly attenuated in participants who were either smokers or drinkers. For participants who were both smokers and drank alcohol,  $\beta$ -carotene supplementation actually resulted in a doubling of the risk of recurrent adenoma formation.<sup>114</sup> A large study<sup>115</sup> found that patients with MSI-positive tumors were more

likely to smoke more than 20 cigarettes a day, and had smoked for longer period of times than controls or patients with MSI-negative tumors. In this study, other factors such as physical activity, NSAID use, and body mass index were less consistently associated with MSI-positive tumors. The authors postulate that cigarette smoke may generate replication errors, overwhelming the DNA mismatch repair (MMR) mechanism, or may affect MMR directly.

## Cholecystectomy

Abnormal bile acid metabolism may predispose both to CRC and cholelithiasis. After cholecystectomy, increased quantities of secondary bile acids have been detected in the feces and may have a role in colonic carcinogenesis. Studies in this area are difficult, because dietary and lifestyle factors related to cholelithiasis may confound the relationship between gallbladder disease and CRC risk. A metaanalysis of studies evaluating the effect of cholecystectomy on CRC risk published in 1993<sup>116</sup> demonstrated conflicting results. Analysis of the 33 case-control studies generated a pooled RR for CRC after cholecystectomy of 1.34 (95% CI, 1.14–1.57), limited to the proximal colon. However, no significant effect was found when the results of six cohort studies were evaluated.

Two recent large prospective cohort studies have been conducted to evaluate this relationship. In a long-term follow-up study of 278,460 patients after cholecystectomy followed for up to 33 years,<sup>117</sup> a significantly increased risk of small bowel malignancies and proximal colonic malignancies was found as compared with the general population. No association was found with more distal bowel cancer. In a study using data from the Nurses' Health Study,<sup>118</sup> a significant positive association between cholecystectomy and the risk of CRC was found (RR 1.21, 95% CI 1.01–1.46, after adjusting for important CRC risk factors including diet, family history, calcium intake, body mass index, and use of hormone replacement therapy). In this study, the risk of CRC after cholecystectomy was increased both for proximal bowel and rectal cancers. A history of gallstones was associated with similar risks. No increase in the risk of colorectal adenoma was identified in those patients having had a cholecystectomy.

## Inflammatory Bowel Disease

Patients with long-standing inflammatory bowel disease (IBD) are known to be at an increased risk of CRC, although it is difficult to precisely estimate the risk. The magnitude of the risk has been studied extensively in ulcerative colitis (UC); however, rates vary among studies, particularly those performed in referral centers versus population-based studies. In addition, treatment and surveillance may influence the risk and thus more recent studies may have a lower risk than in studies before surveillance was common. A metaanalysis<sup>119</sup> of 116 studies evaluating the risk of CRC in UC patients

found the overall prevalence of CRC in UC patients was 3.7% (95% CI, 3.2%–4.2%). In 19 of the studies reviewed, the duration of colitis was reported by decade. In the first 10 years after onset of colitis, the incidence rate of CRC was 2/1000 per year of disease, for the second decade the incidence rate of CRC was estimated to be 7/1000 per year of disease, and in the third decade the incidence rate of CRC was 12/1000 per year of disease. This corresponds to a cumulative probability of CRC of 2% after 10 years of disease, 8% after 20 years, and 18% after 30 years. The risk of CRC geographically varied and was higher in studies conducted in the United States. The metaanalysis did not evaluate extent of disease (pancolitis versus left-sided disease versus proctitis).

Extent of disease does seem to have a significant influence on CRC risk in UC. In a Swedish population-based cohort of 3117 patients with UC,<sup>120</sup> less extensive disease was associated with a lesser risk of CRC. As a ratio of the observed incidence and expected incidence, the increased risk of CRC in this cohort was 1.7 for those with ulcerative proctitis (95% CI, 0.8–3.2); 2.8 for those with left-sided colitis (95% CI, 1.6–4.4); and 14.8 for those with pancolitis (95% CI, 11.4–18.9). Other studies have supported these findings.<sup>121</sup>

Other factors that may modify the risk of CRC in patients with UC but are currently not proven include age at onset of UC, family history of CRC, and the related diagnosis of primary sclerosing cholangitis.<sup>121</sup> For patients with long-standing extensive UC, colectomy is an effective (albeit aggressive) strategy for prevention of CRC. Other strategies include endoscopic surveillance for dysplasia and/or the use of chemopreventive agents. Overall, the evidence for the effectiveness of surveillance colonoscopy is weak<sup>122</sup>; there are no randomized, controlled trials or cohort studies that have been conducted to evaluate surveillance colonoscopy in the prevention of CRC in UC.<sup>123</sup> In addition, neither of the two published case-control studies<sup>124,125</sup> has demonstrated a clear statistically significant benefit for endoscopic surveillance (although there was a trend toward benefit). Nevertheless, endoscopic surveillance is usually performed in patients with pancolitis for more than 10 years' duration who wish to avoid colectomy. There is also some evidence that chemoprevention of CRC in patients with UC may be possible. There is some evidence that 5-ASA products may decrease the rate of dysplasia in patients with UC.<sup>126</sup> Other promising agents include folate, calcium, and in patients with primary sclerosing cholangitis, ursodiol.<sup>126</sup>

The relationship between Crohn's disease and the development of CRC has been less consistently demonstrated. In studies using data from referral-based practices, the risk of development of CRC seems to be significantly increased in patients with extensive Crohn's colitis.<sup>121</sup> The magnitude of increased risk seems similar to that of UC<sup>127</sup>; however, in population-based studies, particularly those more recently published, a less dramatic effect is seen. The two largest studies have conflicting results. In a Canadian population-based cohort study, the risk of CRC in 2857 patients with

Crohn's disease was compared with a randomly selected group of controls matched 10:1 for age, gender, and geographic location. Patients with Crohn's disease were found to have an increased risk of colon cancer [incidence rate ratio (IRR) = 2.6; 95% CI, 1.69–4.12] but not rectal cancer (IRR = 1.08; 95% CI, 0.43–2.70). Patients with Crohn's disease also had an increased risk of cancer of the small intestine (IRR = 17.4; 95% CI, 4.16–72.9), and lymphoma (IRR = 2.40; 95% CI, 1.17–4.97). Some of these results are similar to those data from a population-based study in Denmark of 2645 patients hospitalized for Crohn's disease<sup>128</sup> and followed for up to 17 years. The rate of CRC in this group was not substantially increased as compared with the expected rate of CRC in the Danish population, the standardized incidence ratio for CRC was 1.1 (95% CI, 0.6–1.9). However, similar to the Canadian study, the risk of small intestinal cancer was increased 18-fold in the Crohn's disease group. Of note, in both studies, relatively few cases of CRC developed in Crohn's patients. Still, it is difficult to explain the dramatically different findings of the studies. It is possible that the pattern of disease or treatment differs between these two populations in a way that influenced CRC risk. Regardless, the effect of Crohn's disease on development of CRC requires further investigation.

### Family History

Individuals with a family history of CRC are at an increased risk of themselves developing CRC. In a metaanalysis<sup>129</sup> of 27 observational studies that have evaluated the risk of family history on development of CRC, individuals with a first-degree relative with CRC had a 2.25 RR (95% CI, 2.00–2.53) of developing CRC as compared with those without a family history. The risk was slightly higher with a first-degree relative with colon cancer (RR = 2.42) than with rectal cancer (RR = 1.89). The risk increased if more than one first-degree relative had CRC (RR = 4.25) or if a relative was diagnosed before the age of 45 (RR = 3.87). The RR of CRC was also increased if a first-degree relative had a history of a colorectal adenoma (RR = 1.99). The clustering of risk in families may be attributed to an inherited susceptibility, common environmental exposures, or a combination of both factors. The influence of a more distant family history of CRC on individual risk has not been determined with certainty.

Some of the increased risk attributed to family history is due to inheritance of known susceptibility genes, such as mutations in the adenomatous polyposis coli gene, *p53* gene, or in MMR genes, particularly *MSH2*, *MLH1*, and *MSH6*<sup>130</sup> and these are discussed in detail elsewhere in this text. Importantly, the majority of cases of CRC cannot be attributed to known genetic defects even when associated with a family history of CRC. Recognized genetic syndromes account for only a small proportion of all cases of CRC. Additional autosomal dominant genetic defects conferring a high risk of CRC will almost certainly be found; however, at

least some of the increased risk of CRC associated with a family history is likely attributable to other genetic factors, such as recessive susceptibility genes, autosomal dominant genes with low penetrance, or complex interactions between an individual's genetic makeup and environmental factors.

Despite the importance of family history on risk of CRC, up to 25% of individuals with a first-degree relative with confirmed CRC do not report having such a family history,<sup>131</sup> and even those that do report a history may not be aware of the increased risk associated with this.<sup>132</sup> This fact has important implications for assessment of family history as well as patient and family counseling.

## Other Risk Factors

### *Radiation*

Cases of rectal carcinoma have been reported in individuals who have undergone radiation for pelvic malignancies, primarily cervical cancer<sup>133</sup> and prostate cancer.<sup>134</sup> Because rectal cancer is relatively common, these cases may represent sporadic rectal cancers developing after long-term survival from other pelvic malignancies. However, the cancers occur in the radiated field, tend to be associated with radiation changes to the adjacent rectal mucosa, and are more likely to be of mucinous histology<sup>135,136</sup> than typical sporadic cancers, thereby strengthening the likelihood of a causal association. Nevertheless, the vast majority of individuals undergoing radiation for pelvic malignancies will not develop rectal cancer.

### *Ureterosigmoidostomy*

Formation of a ureterosigmoidostomy has been associated with an increased risk of carcinoma in the area of the ureterosigmoid anastomoses. It is difficult to estimate the increase in risk of colon cancer attributable to ureterosigmoidostomy—many were fashioned for malignant diseases that may themselves be associated with an increased risk of colon cancer, nevertheless the risk seems to be high. The estimated increase ranges from 100 to 7000 times the risk in the normal population<sup>137</sup> and up to 24% of patients with a ureterosigmoidostomy will develop neoplasia at the anastomosis. The average latency period from formation of the ureterosigmoidostomy to development of malignancy is 26 years.<sup>138</sup> Patients who have undergone conversion to another form of urinary diversion remain at risk of neoplasia if the ureterosigmoid anastomoses were not resected in their entirety. Although the cause of this dramatic increased risk is not known, it seems to require the exposure of colonic mucosa to the mixture of urine and feces.<sup>137</sup>

Fortunately, with several options for urinary diversion, this procedure is now rarely performed. Those individuals living with a functional ureterosigmoidostomy should be counseled regarding their heightened risk and undergo regular sigmoidoscopic surveillance.<sup>137</sup>

### *Acromegaly*

Acromegaly, a rare endocrine syndrome resulting from secretion of excess growth hormone from a pituitary neoplasm has been found to be associated with an increased risk of CRC in several studies.<sup>139–141</sup> The magnitude of the risk is unclear, with reports ranging from nonsignificant increases in risk to an RR of 18.3.<sup>141</sup> In a population-based cohort study performed in Sweden and Denmark, the standardized incidence ratio of colon cancer in patients with acromegaly as compared with the general population was 2.6 (95% CI, 1.6–2.7).<sup>139</sup> Patients with acromegaly have increased levels of circulating IGF-1, and this may be responsible for the increased risk of colorectal neoplasia identified in these patients.<sup>142</sup>

## Molecular Basis

All cancer, at its root, has a genetic basis. Carcinogenesis is a multistep process, requiring an accumulation of acquired and inherited genetic alterations. With this succession of genetic alterations, cells acquire a growth advantage over surrounding cells, and in a Darwinian-type process normal cells evolve into cancer cells.<sup>143</sup> In normal cells, growth and replication is a highly regulated process, and disruption of this regulation at multiple levels is required for clinically relevant cancer to develop. Defects in genes that code for important proteins in the regulation of the cell cycle seem to be critical for carcinogenesis. Hanahan and Weinberg<sup>143</sup> have described six alterations in regulatory mechanisms that seem constant in most cancers from the several hundred genetic mutations that have been identified in cancer cells (Figure 23-4):

1. Self-sufficiency in growth signals. Ordinarily, cells must receive growth signals to actively proliferate, assuring that cellular proliferation occurs only when necessary to maintain homeostasis. To proliferate autonomously, cancer cells must lose this need for exogenous growth signal.
2. Insensitivity to antigrowth signals. Normally, there are numerous growth-inhibitory signals that function within a cell to maintain the cell in a quiescent and/or differentiated state. Cells with neoplastic potential must develop mechanisms to evade these antigrowth signals, enabling proliferation and dedifferentiation.
3. Evading apoptosis. Development of cancer requires not only a loss of control over cellular proliferation, but also a loss of control over programmed cell death (apoptosis). Apoptosis normally occurs in response to the cellular environment and is likely a major mechanism whereby cells that have acquired significant genetic mutations are destroyed. Tumor cells must circumvent apoptosis (either at a regulatory level or at an effector level) to continue to develop and proliferate.
4. Limitless replicative potential. Many cells are able to replicate only a finite number of times preventing clonal expansion of any given cell. Even after acquiring independence

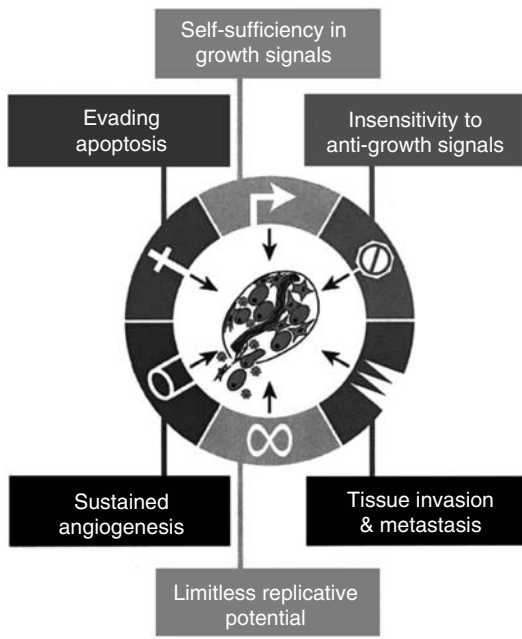

FIGURE 23-4. Alterations in regulatory mechanisms important for carcinogenesis. (Reprinted from Hanahan and Weinberg,<sup>143</sup> copyright © 2000, with permission from Elsevier.)

from normal signals for cellular growth and death to develop into clinically significant cancer, cancer cells must gain unlimited capacity for replication. Intrinsic limits to proliferation must be evaded.

5. Sustained angiogenesis. Virtually all cells must reside within 100  $\mu\text{m}$  of a capillary to supply the cell with oxygen and nutrients required for functioning. Angiogenesis in normal tissue is closely regulated, and balancing of inducers and inhibitors of angiogenesis is an essential component of homeostasis. For neoplastic cells to develop into clinically significant cancer, they must develop the ability to induce and sustain angiogenesis, circumventing these homeostatic mechanisms to provide an adequate blood supply to support their ongoing growth.
6. Development of ability to invade and metastasize. For cancer cells to develop the ability to invade other tissue and metastasize, a number of changes must occur. Normally, cells in tissue adhere to each other. A loss of this normal cell to cell adhesion must occur in the cancer microenvironment to permit metastasis to occur. In addition, the cancer cells must develop methods of modifying new environments to support continued growth.

Although all six alterations in cell regulation are required for the development of clinically significant cancer, the sequence of events and mechanisms are variable. The sequence of genetic mutations (or alterations) is less important than the accumulation of mutations, although some mutations tend to occur early in the neoplastic process and are termed initiators, whereas others tend to occur later and are termed

promoters. In addition, certain genetic mutations (somatic or inherited) may be particularly critical and affect cell regulation in several important ways. Many such critical genes belong to two broad categories of genes involved in carcinogenesis: oncogenes and tumor suppressor genes. Additionally, caretaker genes that function to prevent the accumulation of somatic mutations are also critical to colorectal carcinogenesis. Abnormalities in caretaker genes greatly increase the risk of cancer development, independent of environmental influence. Of note, although the role of genes in carcinogenesis is described, in reality it is the protein products of the genes that are directly involved in changes in cell regulation.

Mutations in oncogenes result in an abnormal gain or excess of a particular protein function. An oncogene product when expressed in a given cell (or when the product is expressed at the wrong time in the cell cycle, expressed with an enhanced function, or expressed in larger quantities than normally present) contributes to development of critical alterations in the mechanisms of cell regulation. Mutations causing such expression behave in a dominant manner, i.e., mutation of only one of the two alleles present is required to produce activation and phenotypic expression and promote carcinogenesis. The *ras* oncogene is the most frequently mutated oncogene identified in CRCs. The *K-ras* proto-oncogene, located on the short arm of chromosome 12 (12p) is mutated in approximately half of all CRCs.<sup>144</sup> The *K-ras* gene product seems to be involved in the transduction of exogenous growth signals. Point mutations in the *K-ras* gene lead to a function gain, conferring a growth advantage to the cells, although the role of *K-ras* in carcinogenesis is incompletely understood. Other oncogenes that are frequently identified in sporadic colon cancer include *c-myc* and *c-erbB2*.<sup>145</sup>

Tumor suppressor genes normally inhibit cellular proliferation or promote apoptosis. When gene expression is lost, there is a loss of this normal inhibitory control of the cell cycle. In general, gene expression is lost only when both alleles of the gene are inactivated [Knudson's two-hit theory of carcinogenesis<sup>146</sup> (Figure 23-5)], either through inherited mutation, somatic mutations, or both.

There are a number of tumor suppressor genes that have been found to have an important role in CRC carcinogenesis, including the *APC*, *DCC*, *p53*, and *MCC* genes.

The adenomatous polyposis coli (*APC*) gene located on the long arm of chromosome 5 (5q), is considered a gatekeeper gene of colorectal carcinogenesis as mutations in the *APC* gene seem to be initiators of this disease. Mutations in the *APC* gene have been found in 50% of sporadic adenomas and in 75% of sporadic cases of CRC.<sup>144</sup> FAP, discussed in detail elsewhere in this text, results from inheritance of a germline mutation in the *APC* gene. Mutations involve base-pair mutations, insertions or deletions that result in the formation of a stop codon, halting protein synthesis leading to formation of a truncated or shortened protein product that affects the function of the protein. The location of the germline mutation in the *APC* gene varies between families with FAP, and results

FIGURE 23-5. Loss of suppressor-gene function. (Reprinted from Calvert and Frucht<sup>145</sup> with permission from *Annals of Internal Medicine*.)

in the varying phenotypic expression of FAP found between families. Although only a single abnormal allele is inherited in FAP, sporadic mutations are always acquired resulting in the formation of hundreds to thousands of colonic adenomas and ultimately carcinoma. A specific germline mutation of the *APC* gene, the *I1307K* mutation, although not resulting in FAP, is found primarily in persons of Ashkenazi Jewish origin,<sup>147</sup> and results in an increased predisposition to CRC,<sup>148</sup> although the risk is much lower than for individuals with FAP. An additional mutation, *E1317Q*, may also result in an increased predisposition to CRC.<sup>149</sup>

The *APC* protein normally regulates the *Wnt* (wingless signaling pathway), an important pathway in cell regulation and development, through modulation of beta-catenin—a critical protein in the *Wnt* pathway. Normally, the protein product of the *APC* gene binds beta-catenin intracellularly forming a multiprotein complex that inhibits beta-catenin function. The increased functional levels of beta-catenin that result from alterations in *APC* protein product function leads to cell proliferation, and enhances cell to cell adhesion, limiting cell migration. Thus, hyperproliferating cells accumulate and aberrant crypt foci, the earliest phase of colorectal neoplasia.<sup>150</sup>

The *p53* gene, located on the short arm of chromosome 17 (17p) is an important gatekeeper gene for carcinogenesis—it is the most frequently mutated gene in human cancers.<sup>151</sup> Normally, by slowing the cell cycle, *p53* facilitates DNA repair during replication. When repair is not feasible, *p53* induces apoptosis. Inactivation of *p53* is found in up to 75% of sporadic colorectal tumors<sup>145</sup>; however, the mutation seems to occur late in the tumorigenic sequence. Thus *p53* gene mutations do not seem to be initiators of carcinogenesis but act as key limiting factors for malignant transformation. This

thought is supported by the finding that patients with Li Fraumeni syndrome (an inherited defect in *p53*) do not have an increased risk of CRC.<sup>152</sup> In addition, *p53* expression may be an independent prognostic marker in patients with CRC.<sup>153,154</sup> Most studies demonstrate a lower survival rate in patients with advanced cancers that are *p53* negative as compared with those whose tumors express *p53* gene product particularly in those who receive chemotherapy.<sup>155</sup>

The “deleted in colorectal cancer” (*DCC*) gene was identified on the long arm of chromosome 18 (18q) in 1989.<sup>156</sup> Mutations in this gene have been found in the majority of CRCs. The gene product of *DCC* is a transmembrane protein that is important in cell–cell adhesion, and therefore inactivation of *DCC* may enhance the metastatic potential of CRC through changes in adhesion. Similar to *p53*, patients who have *DCC*-positive tumors may have a better prognosis than those with *DCC*-negative (mutated) tumors.<sup>157</sup>

Located in close proximity to the *DCC* gene, mutations in a group of genes termed *SMADs* (*SMAD2* and *SMAD4*) have been reported in CRCs. The protein products of these genes are components of the transforming growth factor (TGF)- $\beta$  signaling pathway, which mediates growth inhibitory signals from cell surface to nucleus.

Because millions of base-pairs must be replicated during mitosis, errors in DNA replication occur and must be corrected by caretaker genes. The MMR system has a critical function in the detection and correction of errors in DNA replication, maintaining DNA integrity. MMR genes function as spell checkers—base-pair mismatches are identified, excised, and the correct sequence is synthesized and replaced.<sup>72</sup> Lack of MMR function results in an accumulation in errors in DNA replication, increasing the probability that a mutation in an important gene in cell regulation will occur, will be preserved, and carcinogenesis will thus be initiated or promoted. Defects in the MMR system are identified by the detection of microsatellite instability. Microsatellites are small regions of DNA located throughout the genome that do not code for individual genes. They consist of small base sequences that are repeated in a highly polymorphic manner—the number of repeats may range from dozens to hundreds and the number of repeats varies from allele to allele, and from individual to individual. Microsatellites are particularly susceptible to MMR gene defects, thus in cases of CRC attributable to MMR gene mutations, microsatellite replication errors accumulate, leading to detectable differences in the pattern of microsatellites in the tumor and in normal tissue; this is termed microsatellite instability (MSI). When testing CRC for MSI, laboratories evaluate a number of microsatellite loci. The National Cancer Institute recommends the testing of five microsatellite sequences<sup>158</sup> to determine the MSI status of a tumor. If two or more of the five sequences demonstrate MSI, the tumor is designated MSI-high (MSI-H). If only one of the five sequences demonstrates changes in tumor microsatellite markers, the tumor is designated MSI-low (MSI-L). If no markers are changed, the tumor is microsatellite stable.

Approximately 15% of CRC is MSI.<sup>158</sup> MSI-H tumors are more likely to be high-grade, right-sided,<sup>159</sup> mucinous, and have tumor-infiltrating lymphocytes.<sup>160,161</sup> In addition, MSI tumors may have a better prognosis than microsatellite stable tumors,<sup>162</sup> but may be less responsive to chemotherapy.<sup>163</sup>

A number of MMR genes (*MLH1*, *MSH2*, *MSH3*, *MSH6*, and *PMS1*) have been identified. Germline mutations in the *MLH1* and *MSH2* genes are responsible for the majority (>90%)<sup>164,165</sup> of cases of the hereditary nonpolyposis colorectal cancer (HNPCC) syndrome (discussed fully elsewhere in the text), whereas approximately 5%–10% of HNPCC cases are attributable to mutations in the *MSH6* gene. Germline mutations in other MMR genes are rare.<sup>166</sup> Similar to tumor suppressor genes, both alleles of an MMR gene must be mutated or inactivated for MMR function to be lost. Sporadic tumors that demonstrate an MSI-H phenotype generally have a loss of *MLH1* function, attributable not to mutation but to aberrant methylation of the promoter region of the *MLH1* gene.<sup>167</sup> Methylation of cytosines in cytosine–guanosinedinucleotide repeats (termed CpG islands) results in the silencing of transcription, without an actual change in the nucleotide sequence of the gene.<sup>168</sup> The cause of the methylation is unknown, although it is associated with increasing age<sup>169</sup> and is not limited to MMR genes.

*MYH* is an additional DNA repair gene specifically active for adenine–guanine mismatches.<sup>170</sup> This gene has been found to be responsible for some cases of *APC* mutation–negative FAP. This defect is inherited in an autosomal recessive manner, i.e., defects must be inherited from both parents to result in phenotypic expression of the disease.<sup>171</sup>

In their landmark article, Vogelstein et al.<sup>172</sup> (Figure 23-6) described the pathogenesis of colon cancer as one that follows a predictable sequence of events, from adenoma to carcinoma, with histologic changes developing as genetic mutations are acquired over time. Initially, a mutation in a gatekeeper gene such as the *APC* gene occurs resulting in proliferation of the colorectal mucosa and leads to the first histologically detectable event, the aberrant crypt focus. In aberrant crypt foci, the crypts have larger diameters than normal and stain more darkly with methylene blue<sup>150</sup> and can be detected in rats as soon as 2 weeks after carcinogen exposure.<sup>173</sup> With additional genetic changes, cells within the aberrant crypt become dysplastic and an adenoma forms. Further genetic alterations are acquired, resulting in an increase in the size of the adenoma. However, the majority of adenomas do not develop into carcinoma. Therefore, additional genetic alterations are required before the severity of dysplasia increases, and eventually, particularly with mutations in tumor promoters such as *p53*, carcinoma develops. This pathway to carcinogenesis is termed the chromosomal instability pathway. Tumors forming through this pathway demonstrate extensive cytogenetic abnormalities, such as aneuploidy, and visible chromosomal losses and gains.<sup>174</sup>

CRC most frequently demonstrates chromosomal instability, indicating this is the most common genetic cause of colorectal carcinogenesis.<sup>175</sup> However, tumors that are MSI-H appear to develop through a separate pathway, termed the microsatellite mutator or microsatellite unstable pathway. These tumors are diploid and tend not to demonstrate gross chromosomal abnormalities. MMR defects in these tumors

FIGURE 23-6. The adenoma to carcinoma sequence of colorectal carcinogenesis. (Reprinted from Hardy RG, Meltzer SJ, Jankowski JA. ABC of CRC. Molecular basis for risk factors. Br Med J 2000;321:886–889, with permission of the BMJ Publishing Group.)

lead to genetic mutations in key cell regulator genes, particularly the TGF- $\beta$  pathway. Although MSI-H tumors may arise from adenomas, there is increasing evidence that sporadic MSI-H tumors also arise from hyperplastic polyps and serrated adenomas.<sup>176</sup> Serrated adenomas are polyps that in the past would have been classified as hyperplastic polyps but have architectural features both of hyperplastic polyps and cytologic features of classic adenomas. Because only 70% of all colorectal carcinomas are believed to arise from classic adenomas, serrated adenomas may be the precursor lesion for a substantial number of cancers.<sup>177</sup> However, the risk associated with serrated adenomas, in terms of progression to cancer, is unknown and currently under investigation.

Development of CRC in UC represents a third pathway to the carcinogenesis in the colon. Most cancers develop in UC without a precursor polyp and therefore a direct dysplasia to carcinoma sequence is postulated.<sup>72</sup> Genetically, cancers associated with UC seem to be heterogeneous; aneuploidy and disruption of *p53* may occur as early events, however MMR genes may also be affected.

# Screening for Colorectal Neoplasms

Thomas E. Read and Philip F. Caushaj

Cancer of the colon and rectum is the second leading cause of cancer-related death in the United States. In 1997, it was estimated that 131,000 Americans were diagnosed with colorectal cancer, and 55,000 died from this disease.<sup>1</sup> Without undergoing screening or preventive action, approximately 1 in every 17 people in this country will develop colorectal cancer at some point in life. However, evidence is mounting that colorectal adenocarcinoma can be prevented by detecting and removing adenomatous polyps, and that detecting early-stage cancers reduces mortality from the disease.<sup>2-6</sup> Both polyps and early-stage cancers are usually asymptomatic; cancers that have grown large enough to cause symptoms have a much worse prognosis. This contrast highlights the need for screening in asymptomatic persons.

Most people will be of average risk and require screening for colorectal cancer and polyps beginning at age 50.<sup>7</sup> However, a substantial number of people are at increased risk because of an inherited predisposition to the disease and need screening or treatment as early as puberty. By virtue of their practice, colon and rectal surgeons, gastroenterologists, and medical oncologists have contact with many patients with colorectal carcinoma as well as at-risk family members. These specialists have the opportunity to guide the evaluation of at-risk persons and be advocates for appropriate screening examinations.

The explosion of genetic research in the last 15 years has enabled us to better understand inherited forms of colorectal cancer, and has helped to define high-risk populations that need endoscopic or genetic screening for these diseases early in life. The adenomatous polyposis coli gene is thought to function as a gatekeeper of colorectal neoplasia. Germline and somatic truncating mutations of the adenomatous polyposis coli gene are thought to initiate colorectal tumor formation in familial adenomatous polyposis (FAP) and sporadic colorectal carcinogenesis, respectively. Genetic testing for FAP can help guide surveillance and treatment of patients at risk for the disease. Hereditary nonpolyposis colorectal cancer

(HNPCC) is thought to be the result of DNA mismatch repair deficiency, and genetic testing for HNPCC may ultimately prove to have clinical value for patients in HNPCC families.

The effectiveness of screening for colorectal cancer has been a subject of controversy. In 1995, the United States Preventive Task Force reversed earlier position statements and endorsed screening of asymptomatic average-risk persons, using fecal occult blood testing and sigmoidoscopy.<sup>8,9</sup> In 1996, the federal Agency for Health Care Policy and Research (AHCPR) convened a collaborative group of experts representing the American College of Gastroenterology, American Gastroenterological Association, American Society of Colon and Rectal Surgeons, American Society for Gastrointestinal Endoscopy, and Society of American Gastrointestinal Endoscopic Surgeons to critically evaluate the available evidence on colorectal cancer screening and to develop appropriate clinical practice guidelines.<sup>10</sup> The panel studied 3500 peer-reviewed publications to assess the performance, effectiveness, acceptability to patients, cost-effectiveness, and outcome of different screening examinations. The AHCPR guidelines<sup>7</sup> were, in essence, endorsed by the American Cancer Society<sup>11</sup> and are virtually identical to the Practice Parameters for the Detection of Colorectal Neoplasms published by the Standards Committee of the American Society of Colon and Rectal Surgeons.<sup>12</sup> They provide the framework for this review.

## Classification of Risk and Screening Recommendations

The cornerstone in determining a patient's risk for developing colorectal cancer is the family history. Failure to properly investigate a patient's family history of colorectal neoplasia can lead to inappropriate and inadequate treatment of both the patient and at-risk family members.

TABLE 24-1. Patients with colorectal cancer

75%	Average risk (sporadic)
15%–20%	Family history of colorectal cancer
3%–8%	HNPCC
1%	FAP
1%	Ulcerative colitis

### Average Risk

As can be seen in Table 24-1, the majority of patients who develop colorectal cancer have no identifiable risk factors. Persons considered to be at average risk for colorectal cancer do not fit any of the higher risk categories. Specifically, average-risk persons have no symptoms associated with colorectal cancer, no personal history of colorectal cancer or adenomatous polyps, no family history of colorectal neoplasia, no inflammatory bowel disease, and no unexplained anemia.

Screening recommendations (Table 24-2): The AHCPR panel recommended that average-risk persons should undergo one of the following screening regimens, beginning at age 50:

1. Fecal occult blood testing annually
2. Flexible sigmoidoscopy every 5 years
3. Fecal occult blood testing annually and flexible sigmoidoscopy every 5 years
4. Air contrast barium enema every 5–10 years
5. Colonoscopy every 10 years

Although the panel stated that all of the screening strategies are acceptable options,<sup>7</sup> each strategy has unique strengths and weaknesses. The fecal occult blood test (FOBT) is a guaiac-based test for peroxidase activity that is nonspecific and will fail to detect many small cancers and precancerous lesions.<sup>13</sup> Nevertheless, several large randomized controlled trials have shown that annual or biannual testing for fecal

occult blood with complete diagnostic evaluation of the colon (primarily with colonoscopy) for patients with a positive FOBT reduces mortality from colorectal cancer.<sup>3,14,15</sup> The AHCPR panel listed FOBT alone as an option for colorectal cancer screening. However, because of the lack of sensitivity of FOBT, the American Cancer Society recommends combining annual FOBT with flexible sigmoidoscopy every 5 years rather than using FOBT alone as a screening method.<sup>11</sup>

A major drawback to using FOBT as a screening technique is poor compliance. Only 38%–60% of the patients in prospective trials completed all the planned FOBT tests,<sup>3,14,15</sup> and use of FOBT in the general population is estimated to be lower than in the research environment.<sup>16</sup> The steps necessary for adequate sample collection, combined with dietary restrictions to avoid agents that can cause false-positive and false-negative results may also hinder compliance with FOBT. Proper performance of FOBT involves the sampling of atraumatically obtained stool from three consecutive bowel movements in a patient who has not ingested red meat, aspirin, nonsteroidal inflammatory medications, turnips, melons, salmon, sardines, horseradish, or vitamin C for the 2 days preceding the test and throughout the test period.<sup>7,17</sup> The restriction of frequently ingested foods and medications, combined with the natural aversion to stool sampling, makes annual FOBT unappealing to many persons.

FOBT should not be confused with random stool guaiac testing, which is the analysis of stool found on digital rectal examination for blood. The lack of adequate diet and medication restriction before the test, potential for trauma to the anal canal during digital rectal examination, and the inability to reliably obtain stool from the distal rectum make the test unreliable.<sup>18</sup> To date, random stool guaiac examination has not been demonstrated to have benefit in screening for colorectal cancer.

TABLE 24-2. Screening for colorectal cancer and polyps

Risk category	Screening method	Age to begin screening
Average risk	Choose one of the following: FOBT annually* Flexible sigmoidoscopy every 5 yr* FOBT annually + flexible sigmoidoscopy every 5 yr Air contrast barium enema every 5–10 yr† Colonoscopy every 10 yr	50 yr
Family history	Choose one of the following: 1. Colonoscopy every 10 yr 2. Air contrast barium enema every 5 yr†	40 yr, or 10 yr before diagnosis of the youngest affected family member, whichever is earliest
HNPCC	Colonoscopy every 1–3 yr Genetic counseling Consider genetic testing	21 yr
FAP	Flexible sigmoidoscopy or colonoscopy every 1–2 yr Genetic counseling Consider genetic testing	Puberty
Ulcerative colitis	Colonoscopy with biopsies for dysplasia every 1–2 yr	7–8 yr after the diagnosis of pancolitis; 12–15 yr after the diagnosis of left-sided colitis

\*The American Cancer Society recommends the combination of yearly FOBT and flexible sigmoidoscopy as preferable to either examination alone.

†Rigid proctoscopy is recommended as an adjunctive examination to allow adequate visualization of the distal rectum. Furthermore, flexible sigmoidoscopy may be necessary to more completely evaluate a tortuous or spastic sigmoid colon.

In some settings, FOBT test slides are rehydrated, which contributes to the high incidence of false-positive tests and is not recommended by the manufacturer. Hemoccult SENSEA, which seems to be as sensitive as the original Hemoccult test, is the guaiac technique currently recommended for use.<sup>19</sup> In the future, immunochemical techniques or genetic analysis of cellular material in stool may prove to be more effective than current FOBT technology in detecting occult colorectal neoplasms via stool sampling.<sup>20,21</sup>

The effectiveness of *sigmoidoscopy* as a screening tool depends on its ability to detect cancers and adenomatous polyps in the distal colon. If adenomatous polyps are found at flexible sigmoidoscopy, colonoscopy should be strongly considered because almost one-third of such patients will have neoplastic lesions in the proximal colon.<sup>22</sup> The effectiveness of sigmoidoscopy in reducing mortality from colorectal cancer has never been proven by a randomized, controlled trial, although case-control studies have shown a benefit.<sup>2,6,23</sup> There was only a trend toward limited benefit of one-time screening sigmoidoscopy, followed by colonoscopy for patients found to have polyps, in the Telemark study from Norway.<sup>24,25</sup> The Prostate, Lung, Colon and Ovary Trial supported by the National Cancer Institute is evaluating flexible sigmoidoscopy in a randomized, controlled setting, but mortality data are not expected until 2008.<sup>7</sup> A multicenter prospective trial examining the potential benefit of one-time screening flexible sigmoidoscopy at age 60 is currently underway in the United Kingdom and Italy.<sup>26</sup>

The AHCPR panel listed flexible sigmoidoscopy alone as an option for colorectal cancer screening, although such a strategy will fail to detect neoplasms in the proximal colon unless adenomatous polyps or cancer are found in the distal colon that prompt colonoscopy. For this reason, The American Cancer Society recommends combining flexible sigmoidoscopy every 5 years with annual FOBT, rather than using flexible sigmoidoscopy alone as a screening method.<sup>11</sup> Although this combined approach may detect more proximal neoplasms than flexible sigmoidoscopy alone, 15%–25% of patients with negative flexible sigmoidoscopy and negative FOBT will have neoplastic lesions in the proximal colon at colonoscopy, calling the rationale for this approach into question.<sup>27–31</sup>

The efficacy of *barium enema* in preventing colorectal cancer mortality has never been evaluated in a controlled trial, but can be inferred from the fact that detecting polyps and early-stage cancers by other methods reduces the incidence and mortality from colorectal cancer. Air contrast barium enema will detect 50%–80% of polyps <1 cm, 70%–90% of polyps >1 cm, and 50%–80% of Stage I and II adenocarcinomas.<sup>32–35</sup> Single column barium enema is less sensitive and should be combined with flexible sigmoidoscopy if used as a screening tool.<sup>7</sup> Rigid proctoscopy should be considered as an adjunct examination because the balloon on the enema catheter often prevents adequate imaging of the distal rectum. Another major limitation of barium enema as a screening method is

that patients usually require colonoscopy if lesions are detected.

*Colonoscopy* is the only screening technique that allows the detection and removal of premalignant lesions throughout the colon and rectum, and is the final common pathway for any positive screening test. Although its effectiveness depends on the skill and experience of the endoscopist to both reach the cecum and to identify small lesions, it remains the gold standard to evaluate the colonic mucosa.<sup>7</sup> The ability of colonoscopy to reduce colorectal cancer mortality has been demonstrated indirectly through studies showing that detecting and removing polyps reduces the incidence of colorectal cancer and that detecting early cancers lowers the mortality from the disease.<sup>2–6</sup> Compliance with screening colonoscopy may be superior to that of other methods because no confirmatory examinations are required, and thus, patients are subjected to a single bowel preparation.

*CT colography (virtual colonoscopy)* was developed in an attempt to increase compliance with colorectal cancer screening, based on the impression that persons would be more inclined to have a “scan” than a “scope.” The technique involves thin-section computed tomography (CT) with three-dimensional computer reconstructions to examine the colonic mucosa (Figure 24-1A,B).<sup>36,37</sup> Although the technique has the advantages of being noninvasive and not requiring sedation, a vigorous oral laxative preparation is required, because adherent stool cannot be differentiated from neoplasia on CT. In addition, a rectal catheter and air insufflation is used to distend the colon. CT colography cannot be assumed to be more appealing to all patients who are reluctant to undergo colonoscopy, because many patients are deterred more by the laxative preparation beforehand than by the endoscopic procedure itself, and find rectal air insufflation in the absence of sedation uncomfortable.<sup>38</sup> Initial trials demonstrated that CT colography was not as sensitive as colonoscopy in the detection of small polyps,<sup>39</sup> although with improvements in technology and with greater experience with interpretation, CT colography may ultimately prove to be as reliable as colonoscopy in detecting colorectal neoplasia.<sup>40</sup> Regardless of its accuracy, CT colography suffers (as does contrast enema) from the disadvantage that biopsies cannot be obtained and positive findings require endoscopic confirmation.

The Office of Technology Assessment of the United States Congress found that FOBT, flexible sigmoidoscopy, air contrast barium enema, and colonoscopy are equally cost effective as screening strategies, with an estimated cost of less than \$20,000 per year of life saved (assuming screening begins at age 50 and is discontinued at age 85).<sup>7,41,42</sup> Although cost-benefit analyses such as these are exceedingly complex, this estimate is well within the acceptable range of cost effectiveness by United States health standards and compares favorably to screening mammography for women older than age 50. As of January 1, 1998, Medicare has reimbursed screening examinations for colorectal cancer in average-risk persons older than the age of 50.<sup>43</sup> In 2001,

A

B

FIGURE 24-1. **A** CT colography of an 87-year-old patient with a large tumor of the splenic flexure who could not undergo colonoscopy. The circumferential cancer can be seen occupying the lumen of the colon. **B** This image is of the transverse colon proximal to the cancer.

Medicare authorized reimbursement for screening colonoscopy for average-risk persons. As of January 2004, the Centers for Medicare and Medicaid Services guidelines for reimbursement for colorectal cancer screening are as

follows (excerpted from their Web site, <http://www.cms.hhs.gov/medlearn/refcolcn.asp>):

- FOBT: once every 12 months
- Flexible sigmoidoscopy: once every 48 months
- Colonoscopy: once every 24 months if the patient is at high risk for colon cancer; and once every 10 years (but not within 48 months of a screening sigmoidoscopy) if the patient is not at high risk for colon cancer
- Double contrast barium enema: physician can decide to use instead of a sigmoidoscopy or colonoscopy

At present, the choice of screening strategy for average-risk persons is made with influence from primary care physicians, patients, and third-party payers. Although the AHCPR panel's recommendation of five different screening strategies may offer flexibility, it may also cause confusion and uncertainty.<sup>44</sup> Two of the five strategies depend on compliance with yearly FOBT, which has been extremely difficult to achieve even in the setting of controlled trials. Only air contrast barium enema and colonoscopy provide total colonic evaluation, and contrast enema suffers from the necessity of performing colonoscopy if a lesion is detected. Screening colonoscopy every 10–15 years beginning at age 50 may ultimately prove to be the most cost-effective method of screening average-risk persons for colorectal cancer. Hopefully, future technologic advances will allow for total colonic evaluation with minimal patient discomfort and embarrassment, at reasonable cost. If a simple stool-labeling technique is developed that allows for reliable differentiation of stool from mucosa on CT without the need for cathartic bowel preparation, CT colography may fit these criteria.

### Personal History of Adenomatous Polyps or Adenocarcinoma

A personal history of adenomatous polyps or colorectal adenocarcinoma places a person at higher than average risk for the development of metachronous neoplasms. Surveillance colonoscopy is thus recommended by virtually all consensus groups.<sup>12,45</sup> The interval between colonoscopies has been the subject of some debate, and no blanket recommendation can be given for all patients. A rational surveillance strategy should take into account the patient's age, comorbid conditions, life expectancy, completeness of prior examinations, pattern of neoplastic growth, and histologic features of previously resected neoplasms. For instance, a 60-year-old patient in good health who undergoes colonoscopic polypectomy of a single small tubular adenoma should probably undergo surveillance colonoscopy in 3–5 years.<sup>45</sup> A patient in good health who is found to have adenomas that are multiple, large, or dysplastic on initial screening colonoscopy should be considered for colonoscopy at an earlier interval, such as 6–12 months. However, a 90-year-old patient with severe comorbidities and limited life expectancy would not

benefit as much from early surveillance, because removal of premalignant lesions will probably not alter lifespan or quality of life.

Patients who undergo curative resection of colorectal adenocarcinoma should undergo regular surveillance colonoscopy to detect new metachronous primary neoplasms. The recommendation of the Standards Task Committee of the American Society of Colon and Rectal Surgeons is for initial postresection colonoscopy at 1 year, followed by colonoscopy every 3–5 years thereafter, depending on the pathology found at the preceding colonoscopic examination. Obviously, all the considerations made for the selection of postpolypectomy surveillance intervals, as noted above, apply in this situation as well. The purpose of the colonoscopy is not specifically to look for tumor recurrence at the anastomotic suture line, because suture line recurrence in the absence of unresectable extraluminal disease is extremely uncommon,<sup>46</sup> but rather to search for new primary neoplasms.

### Family History of Colorectal Cancer or Adenomatous Polyps

A family history of colorectal cancer or adenomatous polyps increases the risk of developing colorectal cancer. In general, closer familial relationships to affected relatives, younger age of onset, and larger numbers of affected relatives increase the risk.<sup>7,47,48</sup> A careful family history should always be obtained to exclude one of the better-defined inherited colorectal cancer syndromes, such as HNPCC or FAP.

As a greater understanding of the molecular genetics of colorectal cancer is gained, many patients with familial colorectal cancer may eventually be categorized as having distinct inherited syndromes. Recently, a germline mutation of the adenomatous polyposis coli gene (I1307K variant) was identified in persons of Ashkenazi Jewish descent that predisposes to the development of colorectal adenomas and carcinoma.<sup>10,49–54</sup> The mutation causes hypermutability of the adenomatous polyposis coli gene and is thought to contribute to carcinogenesis independent of mismatch repair deficiency.<sup>51</sup> In the future, genetic testing for this mutation in at-risk persons may have clinical utility.

*Screening recommendations:* The AHCPR panel recommended that patients with first-degree relatives with colorectal cancer or adenomatous polyps begin screening for colorectal neoplasia at age 40, or 10 years before the age at diagnosis of the affected relative, whichever is earliest.<sup>7</sup> Those patients whose first-degree relatives developed colorectal cancer before age 50 may be at higher risk, and complete colonic evaluation with colonoscopy should be strongly considered.<sup>7</sup> Patients with a second-degree relative with colorectal cancer, or relative with adenomatous polyps diagnosed over age 60, may be screened as an average-risk person.<sup>7</sup> As of January 1, 1998, Medicare will reimburse for screening colonoscopy for high-risk patients when

performed at least 2 years after the last screening colonoscopy or barium enema.<sup>43</sup>

### Hereditary Nonpolyposis Colorectal Cancer

HNPCC is an inherited disorder that predisposes patients to the development of colorectal cancer, with up to 75% of patients developing the disease by age 65.<sup>55–58</sup> HNPCC is inherited in an autosomal dominant manner, and is thought to be the result of germline mutations in mismatch repair genes (genes that code for proteins responsible for correcting errors during DNA replication). Patients with HNPCC typically develop cancer between age 40 to 50 and most tumors occur proximal to the splenic flexure. “Nonpolyposis” refers to the distinction between HNPCC and FAP (in which patients have hundreds of polyps), but is somewhat misleading because patients with HNPCC develop adenomatous polyps. The progression from adenoma to carcinoma seems to be accelerated in HNPCC patients as compared with patients with sporadic cancers, and there is a tendency to develop multiple colorectal cancers in HNPCC.<sup>55,59–61</sup> Patients with HNPCC are also at high risk for cancers of other organs, especially the ovary and uterus.

The ability to conclusively identify gene carriers is not yet fully developed, thus the penetrance of colorectal cancer in gene carriers can only be estimated (about 90%). In addition, some patients in HNPCC families who do not have identifiable germline mismatch repair gene mutations will develop colorectal cancer.<sup>62</sup> For these reasons, the diagnosis of HNPCC in a family remains clinical. The Amsterdam criteria (colorectal cancer in three or more family members; two generations affected; one affected person a first-degree relative of another; and one cancer diagnosed before age 50) are the strictest criteria and have the highest concordance with known mismatch repair gene mutations.<sup>62</sup> These criteria were originally developed for research purposes, to standardize the definition of HNPCC. However, they fail to identify patients who may be affected with HNPCC but do not fit the strict criteria because of unknown or abbreviated family histories, as well as patients with a personal or family history of extracolonic malignancies associated with HNPCC. A recent National Cancer Institute working group acknowledged the shortcomings of the Amsterdam criteria as clinical guidelines and published recommendations to expand the clinical suspicion of HNPCC to a broader range of patients.<sup>58</sup> The International Collaborative Group on Hereditary Non-Polyposis Colorectal Cancer has also proposed similar criteria.<sup>62</sup>

Microsatellite instability has been reported in 85%–90% of HNPCC colorectal cancers.<sup>56</sup> Detection of this phenotype has been proposed as a screening method to trigger germline mutational analysis in kindreds with uncertain family histories.<sup>58</sup> However, microsatellite instability is also found in approximately 15% of sporadic cancers, and has not been universally found to be predictive of familial cancer.<sup>62,63</sup>

At present, the “true” definition of HNPCC remains uncertain. Neither refined clinical criteria nor germline mutational analysis has provided a model of the syndrome that is predictive of phenotype in all cases. Clinically, the absence of microsatellite instability or mismatch repair gene mutation does not negate a family history that suggests an autosomal dominant predisposition to developing colorectal cancer. At-risk family members still require aggressive screening.

*Screening recommendations:* Expert panels convened by the AHCPR<sup>7</sup> and the Cancer Genetics Studies Consortium<sup>55</sup> recommend that persons who are members of a family that fits clinical criteria for HNPCC undergo colonoscopy at age 20–25, and repeat colonoscopy every 1–3 years. The short time interval between colonoscopies results from the accelerated adenoma to carcinoma progression thought to occur in HNPCC. Patients and their family members should be referred for genetic counseling. Germline testing for mismatch repair gene mutations can be considered,<sup>64</sup> but because the predictive value of such testing is only 30%–50%,<sup>62</sup> colonoscopy should be performed regardless.

### Familial Adenomatous Polyposis

FAP is caused by a defect in the adenomatous polyposis coli gene, which is inherited in an autosomal dominant manner.<sup>65</sup> Patients with FAP develop hundreds of adenomatous polyps as early as puberty, and will ultimately develop colorectal cancer, usually by age 40.<sup>66,67</sup> Patients with FAP are also prone to develop a variety of extracolonic tumors, notably duodenal adenomas and carcinomas, and desmoid tumors.<sup>66</sup> FAP mutations do occur spontaneously, accounting for patients who are diagnosed with the disease without a family history of FAP.<sup>68</sup> Attenuated FAP is a rare variant of the disease, with polyps and cancers developing later in life.<sup>69</sup>

The most frequently used genetic test for FAP is an assay for a truncated protein product of the mutated adenomatous polyposis coli gene. Because only about 80% of families with FAP will have a mutation that produces a truncated protein, the predictive value of testing at-risk family members is greatest if the proband (affected relative) has a positive test.<sup>70</sup>

*Screening recommendations:* Patients with a family history of FAP should undergo flexible sigmoidoscopy or colonoscopy at puberty.<sup>71</sup> Lower endoscopy should be repeated every 1–2 years. Genetic testing should be considered, especially in large pedigrees where genotyping might be more cost effective than repeated endoscopy.<sup>71</sup> If the proband has a positive truncated protein assay, at-risk relatives who test negative may be screened as average-risk persons.<sup>71</sup>

Because of the socioeconomic, medicolegal, and emotional issues surrounding genetic testing, it cannot be emphasized enough that genetic testing for FAP should be done after genetic counseling and informed consent.<sup>70</sup> Trained genetic counselors can guide patients through the testing process and help interpret results. Giardiello et al.<sup>70</sup> found that 32% of physicians ordering genetic tests for FAP misinterpreted the

results of the test, and that less than 20% of patients tested had received pretest genetic counseling or written informed consent. These numbers are sobering when one considers that FAP has 100% mortality if left untreated. Patients should also undergo screening upper endoscopy for duodenal adenomas.<sup>72</sup>

### Inflammatory Bowel Disease

Patients with ulcerative colitis have an increased risk of developing colorectal cancer. This risk begins approximately 7–8 years after diagnosis in patients with pancolitis, and 12–15 years after diagnosis in patients with limited left-sided colitis.<sup>7</sup> There may be an increased risk of colorectal cancer in patients with Crohn’s colitis, although this is less well defined.<sup>73–78</sup>

*Screening recommendations:* It is common practice for patients with ulcerative colitis to undergo screening colonoscopy with multiple random biopsies looking for dysplasia every 1–2 years, beginning 7–8 years after diagnosis in patients with pancolitis and 12–15 years after diagnosis in patients with left-sided colitis.<sup>79,80</sup> However, evidence that surveillance reduces mortality, or is better than timing a colectomy according to extent and duration of disease, is weak.<sup>79,80</sup>

### Future Directions

It is troubling that so much energy and expense is devoted to the cure of advanced or recurrent colorectal cancer in the United States, while so little is devoted to screening for polyps and early-stage cancers. It is estimated that only 10%–30% of adults older than the age of 50 in this country undergo any regular screening for colorectal neoplasia.<sup>16,81,82</sup> In a report issued in 2002, the United States General Accounting Office found that colorectal cancer screening is the least utilized preventive health benefit available to Medicare beneficiaries (General Accounting Office, Medicare–Beneficiary Use of Clinical Preventive Services, Report No. GAO-22-422; April 2002). As is the case in the general population, only 25% of Medicare beneficiaries are screened each year with FOBT, compared with much higher rates for other regular cancer screening tests such as mammography (75%) or Pap smear testing (66%). Until recently, screening for colorectal cancer has not received much publicity in the United States, despite colorectal cancer being the second leading cause of cancer-related death in this country, and despite having a well-defined, identifiable, and treatable precursor lesion (the adenomatous polyp). Both health care professionals and the public need to become more aware of the potential benefits of colorectal cancer screening.

As the genetics of inherited colorectal cancer syndromes become better understood, it will be possible to conclusively identify high-risk populations. It is of paramount importance

that screening efforts be directed toward these populations. Genetic counselors are invaluable resources, both to counsel family members and to help direct genetic testing.

## Polyps

Marcus J. Burnstein and Terry C. Hicks

The word polyp refers to a macroscopically visible lesion or mass projecting from an epithelial surface. Polyp is a descriptive and nonspecific term—the specific diagnosis of a polyp is made by histopathologic examination. Polyps may be classified as neoplastic or nonneoplastic. Neoplastic polyps encompass epithelial tumors such as adenomas, polypoid adenocarcinomas, and carcinoid tumors, as well as nonepithelial lesions such as lipomas, leiomyomas, and lymphomatous polyps. Nonneoplastic polyps include hamartomas, hyperplastic polyps, and inflammatory polyps. Colorectal polyps may be further classified on the basis of clinical information as sporadic or hereditary, the latter category making up the polyposis syndromes discussed in Chapter 26.

### Adenomas

The adenoma, a benign neoplasm of the epithelium, is the most common and most important colorectal polyp. Adenomas may be single or multiple, sporadic or hereditary. Adenomas are dysplastic and premalignant. Most adenocarcinomas arise from adenomas, and the removal of adenomas has been shown to be effective in decreasing the incidence of colorectal cancer.<sup>1</sup> It is the relationship between adenomas and adenocarcinomas that confers upon adenomas their tremendous clinical significance.

### Clinical Presentation

Most adenomas are clinically silent and are found by screening or by investigation of symptoms unrelated to the adenoma. Large colonic adenomas may cause gross bleeding or may cause anemia secondary to occult blood loss. Large rectal adenomas, in addition to bleeding, may cause mucus discharge, tenesmus, and urgency. Mucus production in sufficient volume to cause electrolyte disturbances has been described. Distal rectal adenomas may rarely prolapse through the anus.

Colonoscopy is the most accurate test for polyps. The US National Polyp Study showed conclusively that colonoscopy is more accurate than double contrast barium enema for the diagnosis of colorectal polyps.<sup>2</sup> Barium enema detected a polyp in only 39% of cases in which one was subsequently found at colonoscopy. Even when a patient had a polyp  $\geq 1$  cm in diameter, the barium enema was negative in 52% of cases. The false-positive rate for barium enema was 14%. Computed tomography (CT) colonography (virtual colonoscopy) has a sensitivity for adenomas  $>1$  cm of approximately 90% and for adenomas 0.6–0.9 cm of approximately 80%. The false-positive rate is 17%. CT colonography is an evolving technology and its role in screening is being defined. Virtual colonoscopy may be particularly useful in the evaluation of patients with incomplete colonoscopy.<sup>3,4</sup>

### Pathology

Small adenomas are usually sessile (broad-based) and redder than the background mucosa. As polyps enlarge, some become pedunculated (attached to the bowel wall by a stalk of submucosa lined by normal mucosa) and some remain sessile, diffusely carpeting the bowel wall. The distribution of adenomas in the National Polyp Study was cecum 8%, ascending colon 9%, hepatic flexure 5%, transverse colon 10%, splenic flexure 4%, descending colon 14%, sigmoid 43%, and rectum 8%.<sup>5</sup> The likelihood of synchronous sporadic adenomas when one adenoma was found approached 40%.<sup>6</sup>

There are three main histologic subtypes of adenomas: tubular, villous, and tubulovillous. Tubular adenomas exhibit dysplastic tubules in  $\geq 80\%$  of the lesion. Villous adenomas have dysplastic villous fronds in  $\geq 80\%$  of the lesion. The finger-like villi are actually elongated crypts with a length that is more than twice the length of normal crypts. Tubulovillous adenomas have  $>20\%$  tubular and  $<80\%$  villous formation.<sup>7</sup> In the National Polyp Study, of 3358 sporadic colorectal adenomas, 87% were tubular, 5% villous, and 8% tubulovillous.<sup>5</sup>

In adenomas, cellular proliferation is not limited to the lower half of the tubule, as in normal colonic epithelium, and

the normal process of cellular maturation and differentiation from the basal zone of the crypt to the surface of the lesion does not occur. Adenomas can be graded by the degree to which epithelial growth is disturbed. Mild dysplasia is characterized by tubules that are lined from top to bottom by epithelium that is morphologically similar to the normal basal proliferative zone. The nuclei are enlarged, oval, hyperchromatic, and normally oriented. There is a slight excess of mitotic figures but the architecture is not disrupted. In moderate dysplasia, the nuclear features are more advanced, cellular polarity is less preserved, there is nuclear stratification, and glands are more crowded. In severe dysplasia, there are large vesicular nuclei, irregular, and conspicuous nucleoli, scalloped nuclear membranes, and increased nuclear to cytoplasmic ratio. Nuclear polarity is disrupted and marked cellular pleomorphism and aberrant mitoses are present. Structural alterations include budding and branching tubules, back-to-back arrangement of glands, and cribriform growth of epithelial cells in clusters and sheets; mitotic figures are numerous. The terms carcinoma in situ and intramucosal carcinoma are often used to describe these severely dysplastic adenomas, but these terms are potentially misleading because these lesions do not have metastatic potential. Although the lymphatics of the colon and rectum are closely associated with the muscularis mucosa, only lesions that have invaded through the muscularis mucosa have the potential to metastasize. The dominant risk factors for invasive carcinoma, that is, cancer cells invading beyond the muscularis mucosa, are polyp size and villous histology.<sup>8,9</sup>

Dysplastic epithelium may become misplaced within the submucosa of a polyp and may mimic invasive cancer. This situation, called pseudo-invasion, is usually seen in pedunculated sigmoid polyps and is believed to be the result of torsion, ischemia, and architectural distortion. Pseudo-invasion is distinguished from invasive cancer by retention of lamina propria around the displaced glands, a lack of morphologic features of malignancy in the epithelium, and the presence of hemosiderin, indicating mucosal ischemia and hemorrhage.<sup>10</sup>

## Epidemiology

Adenoma prevalence, the percentage of the population bearing one or more adenomas at a given point in time, is largely a function of age, gender, and family history.<sup>11</sup> Colonoscopy-determined prevalence rates in asymptomatic average risk individuals older than 50 years range from 24% to 47%.<sup>12-15</sup> Prevalence rates determined by colonoscopy are approximately double the rates determined by flexible sigmoidoscopy.<sup>11</sup> The prevalence rate approximately doubles from age 50 to 60, but does not clearly continue to increase with age, unlike the incidence of colorectal cancer. Higher prevalence rates have been identified in men, with a 1.5 relative risk compared with age-matched women.<sup>12,13,15</sup> A multicentered screening colonoscopy study examined the risk of colorectal adenomas in a cohort of individuals with one affected

first-degree relative with sporadic colorectal cancer and found the odds ratio to be 1.5 for adenomas, 2.5 for large adenomas, 1.2 for small adenomas, and 2.6 for high-risk adenomas (see below).<sup>16</sup> The prevalence of adenomas is higher in relatives of individuals with colorectal cancer or adenoma at a young age, and in individuals with multiple relatives with cancer or adenomas.<sup>17</sup>

The incidence of adenomas is the rate at which individuals develop colorectal adenomas over a specified time interval.<sup>11</sup> The incidence of adenomas at intervals ranging from 6 months to 4 years in postpolypectomy surveillance colonoscopy studies varies from 30% to 50%.<sup>18-21</sup> Most incident polyps are small, and a higher incidence has been associated with polyp multiplicity at the index colonoscopy, increased size of the index polyp, older age, and a family history of a parent with colorectal cancer.<sup>1,18,22-24</sup>

The incidence rate after a clearing colonoscopy is actually the sum of the true incidence rate of new adenoma formation plus the miss rate at the initial colonoscopy, plus the recurrence rate of incompletely removed polyps.<sup>11</sup> Judged by repeat endoscopy, including studies with same-day back-to-back colonoscopies, the miss rate for adenomas  $\geq 1$  cm is approximately 5%, for adenomas 6–9 mm is approximately 10%, and for adenomas  $\leq 5$  mm approaches 30%.<sup>25-28</sup> The high miss rates for small lesions suggest that most adenomas detected on surveillance colonoscopy are actually lesions that were missed during the index examination. Incident polyps are distributed more proximally, consistent with the observation that miss rates for adenomas are higher in the proximal colon.<sup>25</sup> The miss rates must be kept in perspective; in postpolypectomy surveillance studies, the cancer incidence is low and in the National Polyp Study, colonoscopic surveillance was associated with a 76%–90% reduction in the cancer incidence compared with reference populations.<sup>1</sup>

More important than the overall incidence rate is the incidence rate for advanced adenomas, defined as polyps  $\geq 1$  cm in size or containing high-grade dysplasia, or containing appreciable villous tissue.<sup>29</sup> The incidence rate for advanced adenomas ranges from 6% to 9%.<sup>29</sup> and is closely related to the findings at initial colonoscopy. Three or more polyps at the initial colonoscopy has been shown to increase the risk of subsequent advanced adenomas, and in the National Polyp Study, age  $>60$  years plus a family history of a parent with colorectal cancer was also a predictor of incident advanced adenomas.<sup>30</sup> The cumulative incidence of advanced adenomas at 3 and 6 years of follow-up in the National Polyp Study in the highest risk group (three or more adenomas at baseline, or age  $\geq 60$  years plus a parent with colorectal cancer) were 10% and 20%, respectively.<sup>30</sup> The lowest risk group (only one adenoma and age  $<60$  years at baseline) had an incidence of advanced adenomas of  $<1\%$  at both 3- and 6-year follow-up. The 5-year incidence of advanced adenomas in individuals with a previously negative colonoscopy is also  $<1\%$ .<sup>31</sup>

The appearance of incident cancers at short intervals in patients who have had a clearing colonoscopy suggests that

either a neoplasm was missed or that cancer developed rapidly. Aggressive adenomas have been recognized in hereditary non-polyposis colorectal cancer, a condition in which patients may go from a normal colonoscopy to an established cancer in 1–3 years.<sup>18,32,33</sup> These cancers show a phenotype called microsatellite instability (MSI), a feature that is also present in 15% of sporadic cancers. Sporadic cancers with high-frequency MSI (MSI-H) may have developed rapidly.<sup>11</sup>

### Adenoma-carcinoma Sequence

The prevalence of sporadic adenomas in the general population  $\geq 60$  years is approximately 30%–40% but the lifetime risk of developing colorectal cancer in Western countries is 6% by age 85; this observation suggests that only a few adenomas become adenocarcinomas. The likelihood that a diminutive tubular adenoma will progress to become an adenocarcinoma is difficult to determine. One longitudinal study showed that over a 3- to 5-year period, only 4% of 213 adenomas measuring 2–15 mm increased in size.<sup>34</sup> Slow transformation of adenomas is suggested by the fact that the mean age of adenoma patients precedes the mean age of cancer patients by 7 years. A mathematical model suggested that it takes 2–3 years for an adenoma  $\leq 5$  mm to grow to 1 cm, and another 2–5 years for the 1-cm adenoma to progress to cancer.<sup>35</sup> For a lesion  $\geq 1$  cm, the cancer probability is 3%, 8%, and 24% after 5, 10, and 20 years, respectively.<sup>36</sup> Overall, the yearly rate of conversion from adenoma to carcinoma has been estimated to be 0.25%, but the risk is higher for polyps  $> 1$  cm (3%) for villous adenomas (17%) and for adenomas with high-grade dysplasia (37%).<sup>37</sup>

In a study that analyzed 7590 adenomatous polyps to determine risk factors for high-grade dysplasia or invasion, size was the strongest predictor.<sup>9</sup> The percent of adenomas with high-grade dysplasia or invasive cancer based on the size of the polyp was:  $< 5$  mm, 3.4%; 5–10 mm, 13.5%; and  $> 10$  mm, 38.5%. Villous change, left-sided lesions, and age  $\geq 60$  years were also associated with advanced histologic features; no invasive cancer was found in polyps  $\leq 5$  mm.

On a molecular level, a simplified view of the traditional pathway from adenoma to adenocarcinoma is as follows: adenoma development is dependent on an individual epithelial cell having both copies of the *APC* gene deactivated.<sup>38</sup> This feature seems to allow for mutations in additional oncogenes, the key targets being *K-ras*, *DCC*, *P53*.<sup>39</sup> The accumulation of molecular abnormalities is associated with the development of invasive cancer. This pathway is the predominant pathway of colorectal carcinogenesis and is what is seen in familial adenomatous polyposis. Not all colorectal cancer follows the adenoma-carcinoma pathway, and alternate pathways to colorectal cancer are increasingly recognized. These pathways may involve polypoid lesions such as the hyperplastic polyp, the mixed polyp, and the serrated adenoma.

In hereditary nonpolyposis colorectal cancer (HNPCC), patients inherit a mutated copy of a DNA mismatch repair

(MMR) gene. When the second copy is inactivated, loss of MMR function results in the development of mutations throughout the gene. The accumulation of mutations is associated with the rapid evolution of adenocarcinoma, often without a recognizable precursor lesion. When there is a precursor lesion for an HNPCC cancer, it is often a typical adenoma, but hyperplastic polyps and mixed polyps with distinct components of hyperplastic and adenomatous polyps have been implicated in some HNPCC cancers.<sup>40–42</sup>

### Management

When an adenoma is found, every effort should be made to do a complete colonoscopy to the cecum because of the high rate of synchronous neoplasms in patients with adenomas and adenocarcinomas. However, the significance of a single, small ( $< 1$  cm) tubular adenoma on a screening flexible sigmoidoscopy is controversial. Most studies of screening flexible sigmoidoscopy suggest that patients with no distal polyps, distal hyperplastic polyps, or single small tubular adenomas have a similar low risk of proximal advanced adenomas, in the range of 0%–4%. Multiple studies support the recommendation that villous polyps regardless of size and adenomas  $> 1$  cm are important markers for the presence of advanced adenomas and carcinoma in the proximal colon.<sup>43</sup>

The majority of colorectal polyps are treated by endoscopic snare polypectomy; polyp removal is performed using electrocautery snare. As current is delivered to the snare, heat is generated in the encircled tissue which is cut and coagulated. The polyp is transected as the snare is tightened. The degree of thermal damage must balance the need for vessel coagulation with the need to avoid full-thickness injury to the bowel wall. The colon wall is thin, varying from 1.7 to 2.2 mm.<sup>44</sup> The mucosa, submucosa, and muscularis propria each contribute approximately one-third to the thickness of the wall. Injection of saline solution (with or without epinephrine) into the submucosa, increases the distance between the mucosa and the muscularis propria and increases the safety of endoscopic polypectomy.<sup>45</sup> Submucosal injection is most often used for sessile polyps in the right colon, especially those  $> 1.5$  cm in diameter. The addition of dye, such as methylene blue, to the injected solution may make it easier to recognize the edges of the polyp. Injection volumes range from a few milliliters to 30 mL. Sessile polyps  $> 2$  cm are often best dealt with by a piecemeal approach. Tissue is retrieved for histologic analysis which should include the histologic type of polyp, degree of dysplasia, and status of the margins. Even small polyps should be removed. For some small polyps, a specimen for histologic examination may be most efficiently obtained and the lesion most safely eradicated by cold biopsy or cold snare, that is, without current.

The technical aspects of colonoscopy, including the potential complications of this procedure, are reviewed in Chapter 5. Some technical tips in polypectomy include<sup>45</sup>:

- Aspiration of gas and decreasing wall tension may facilitate placing the snare around the polyp.
- Position the polyp at 5–6 o'clock; the snare enters the field at this orientation and makes it easier to capture the polyp.
- Perform polypectomy on withdrawal when the scope is "straight"—this method increases the effectiveness of tip deflection and scope rotation.
- Use submucosal injection of saline for large (>1.5–2 cm) sessile lesions; begin the injection on the proximal aspect of the polyp, thereby tilting the lesion toward the scope.
- In piecemeal polypectomy, start on the proximal aspect; a spike-tip snare allows the snare to be anchored so that pushing the sheath causes the snare loop to widen for more effective placement.
- Retrieval of proximal lesions is best accomplished with a device such as a Roth basket (US Endoscopy Group, Mentor, OH); smaller polyps may be suctioned into a trap; distal lesions may be suctioned onto the end of the scope.

Almost all polyps can be safely endoscopically removed, but if the polyp appears to be malignant, snare polypectomy may not be possible, and is generally inadvisable. Malignancy should be suspected in the setting of irregular surface contour, ulceration, friability, firm or hard consistency, thickening of the stalk, and nonlifting with submucosal injection (a feature of submucosal invasion or fibrosis from previous attempts at polypectomy).<sup>45,46</sup> It is particularly important that if polypectomy is performed for a suspicious polyp, the site of the polyp should be precisely localized by tattooing the bowel wall with India ink or similar dye.

Some large polyps may not be amenable to polypectomy and are treated by colon resection; in these instances, a conventional oncologic resection should be done.

## Rectal Adenomas

Sessile villous adenomas are usually encountered in the rectum and the larger lesions may not be amenable to snare polypectomy. Local excision or rectal resection may be required. For lesions in the lower half of the rectum, endoanal excision is generally performed. For more proximal lesions, transanal endoscopic microsurgery (TEM) may be appropriate. Larger lesions that extend too proximally for endoanal excision will usually be best managed by anterior resection. If the lesion extends into the anal canal, anterior resection with endoanal mucosectomy and hand-sewn coloanal anastomosis may be needed to restore intestinal continuity.

Preoperatively, the lesion should be evaluated with respect to the risk of containing invasive cancer. The best clinical clue to the presence of invasion is firmness on digital rectal examination, although previous attempts at removal can produce fibrosis.<sup>47</sup> Endoanal ultrasound and magnetic resonance imaging may be helpful, but sensitivity with respect to a small focus of submucosal invasion is low.

When invasive cancer is present, treatment will be determined primarily by the level and size of the lesion, the depth of mural penetration, and by any evidence of lymphatic metastases. More proximal rectal lesions will usually be treated by anterior resection. Selected small proximal lesions may be managed by TEM. More distal lesions will need either resection or local excision. If biopsy of a hard area reveals a poorly differentiated cancer, a resectional approach is recommended. Even small rectal cancers that are not poorly differentiated carry a risk of lymph node metastases. A study from Memorial Sloan-Kettering Cancer Center evaluated whether standard pathologic factors predicted lymph node metastases from small rectal cancers.<sup>48</sup> Of 318 patients with T1 or T2 rectal cancers who underwent rectal resection, 159 patients were considered potentially eligible for local excision. Even in the absence of poor pathologic factors (advanced T stage, poorly differentiated histology, lymphatic or vascular invasion), 15% of patients had lymph node metastases.

The technical aspects of TEM and endoanal excision are discussed in Chapter 30.

## Surveillance

After polypectomy of large or multiple adenomas (three or more) or advanced adenomas, cancer risk is increased three- to fivefold.<sup>49</sup> The risk of subsequent cancer is not measurably increased in patients with only one or two small tubular adenomas.<sup>22,50</sup> The National Polyp Study determined that colonoscopy performed 3 years after initial polypectomy protects patients as well as more frequent examinations.<sup>1</sup> Recommendations for surveillance postpolypectomy are based on the estimated risk of metachronous neoplasia<sup>51,52</sup>:

- After colon clearance, first follow-up colonoscopy in 3 years (for most patients).
- First follow-up colonoscopy in 5 years for low-risk patients [fewer than three small (<1 cm) tubular adenomas, no significant family history of colorectal cancer or adenomas].
- If first follow-up examination is negative, second follow-up colonoscopy in 5 years.
- Earlier follow-up colonoscopy for selected patients with multiple or large sessile adenomas.
- Individualize for age and comorbidity. (After removal of a small tubular adenoma, no follow-up may be indicated in elderly patients, or for those individuals with significant comorbidity, or the first follow-up can be delayed for 5 years.)

For large sessile polyps (>3 cm), there is a significant recurrence rate after endoscopic polypectomy. Even when the endoscopist believes that the entire polyp has been removed, follow-up examination reveals residual polyp in approximately 50%. There should be close follow-up, for example, every 3–6 months in the first year, every 6–12 months in the second year, and yearly to the fifth year. Treating the base and edge of the polypectomy defect with the argon plasma

coagulator has been shown to decrease the incidence of residual polyp.<sup>53</sup>

## The Malignant Polyp

Polyps with cancer cells penetrating the muscularis mucosa are malignant polyps. Invasion is invariably limited to the submucosa. In terms of TNM classification, these are T1N0M0 lesions. Malignant polyps (T1 lesions) account for 2%–12% of polyps in colonoscopic polypectomy series.<sup>54–56</sup> The risk of malignancy related to adenoma size in one large series was 0.6–1.5 cm, 2%; 1.6–2.5 cm, 19%; 2.6–3.5 cm, 43%; and >3.5 cm, 76%.<sup>54</sup>

The clinical decision to proceed with further treatment, such as resection or local excision, depends on the estimated risk of lymph node metastases and the patient's general condition.<sup>57</sup> The main determinant of the risk of lymph node metastasis is the depth or level of invasion of cancer within the polyp. Haggitt's classification<sup>58</sup> of malignant polyps (Figure 25-1) is based on the level of invasion:

Level 0: noninvasive (severe dysplasia)

Level 1: cancer invading through the muscularis mucosa but limited to the head of a pedunculated polyp

Level 2: cancer invading the neck of a pedunculated polyp

Level 3: cancer invading the stalk of a pedunculated polyp  
Level 4: cancer invading into the submucosa of the bowel wall below the stalk of a pedunculated polyp. All sessile polyps with invasive cancer are level 4.

The stalk of a pedunculated polyp is covered by normal mucosa and has a central core of submucosa. A line drawn at the junction of normal and adenomatous epithelium is the transition between the stalk and the head of the polyp. The junction zone is called the neck.

Kudo<sup>59</sup> has stratified the depth of submucosal invasion into three levels (Figure 25-2):

SM1: invasion into the upper third of the submucosa

SM2: invasion into the middle third of the submucosa

SM3: invasion into the lower third of the submucosa

Haggitt levels 1, 2, and 3 are SM1; Haggitt level 4 may be SM1, SM2, or SM3.

The risk of lymph node metastases is <1% for pedunculated polyps with Haggitt level 1, 2, or 3.<sup>58,60,61</sup> The risk of lymph node metastases for Haggitt level 4 lesions, pedunculated or sessile, ranges from 12% to 25%.<sup>62–64</sup> Factors reported to be associated with an increased risk of lymph node metastases include lymphovascular invasion,<sup>48,63</sup> poor differentiation,<sup>48,65,66</sup> gender,<sup>48</sup> extensive budding, microaci-

FIGURE 25-1. Anatomic landmarks of pedunculated and sessile malignant polyps. (Reprinted from Haggitt et al.,<sup>58</sup> copyright 1985, with permission from the American Gastroenterological Association.)

FIGURE 25-2. Depth of submucosal invasion in sessile malignant polyps. Sm<sub>1</sub>: invasion into upper third; Sm<sub>2</sub>: invasion into middle third; Sm<sub>3</sub>: invasion into lower third. (Reprinted from Nivatvongs S. Surgical management of early colorectal cancer. *Surg Clin North Am* 2000;82:1052–1055, copyright 2000, with permission from Elsevier.)

nar structure,<sup>67</sup> flat or depressed lesions,<sup>66</sup> and SM3 level of invasion.<sup>57,62,68</sup> In a series of 353 T1 sessile cancers, the risk factors for lymph node metastasis that were statistically significant on multivariate analysis were SM3 level of invasion, lymphovascular invasion, and location in the lower third of the rectum.<sup>62</sup> In another study, only SM3 invasion was an independent risk factor for lymph node metastases.<sup>68</sup>

The rate of lymph node metastases from rectal lesions is not different than from colon lesions. However, T1 lesions in the distal third of the rectum have been found to have a higher risk of lymph node metastases than more proximal rectal lesions.<sup>62</sup> This finding is consistent with the high local recurrence rates, in the range of 5% to 28%, which have been observed after full-thickness local excision of T1 lesions of the distal rectum.<sup>48,65,69,70</sup>

A positive polypectomy margin should not be considered an adverse risk factor for recurrence—in general, this should be regarded as inadequate treatment. A distance of 2 mm beyond the deepest level of invasion is needed to consider the margin clear.<sup>57</sup>

In view of the risk of lymph node metastases of <1%, pedunculated polyps with invasion to Haggitt levels 1 to 3 are safely treated by snare polypectomy. Level 4 pedunculated lesions are treated as sessile lesions. Sessile lesions that are snared in one piece and have a margin of at least 2 mm are considered adequately treated.<sup>57</sup> If a piecemeal polypectomy was performed, margins cannot be adequately assessed and further treatment is needed. High-risk sessile lesions such as lesions with SM3, lymphovascular invasion, poor differentiation, and those in the lower third of the rectum should have an oncologic resection. For lower rectal lesions, full-thickness endoanal excision with adjuvant chemoradiation is an alternative approach. Nivatvongs's summary of the indications for oncologic resection are presented in Table 25-1.

Close endoscopic follow-up is required to look for local recurrence. A reasonable schedule is to examine the polypectomy site in 2–3 months and then every 6 months for the first 2 years; complete colonoscopy is done in the third year, and then at 3-year intervals.

Chemoprevention after polypectomy to inhibit adenoma recurrence cannot yet be recommended. Prospective randomized intervention trials have not been supportive of this approach. The role of chemoprevention is reviewed in Chapter 23.

## Specific Adenomas

### *Flat and Depressed Adenomas*

Some adenomas display a flat or depressed growth pattern and are not elevated above the mucosal surface; they are not “true polyps.”<sup>71</sup> These lesions are recognized by color and textural changes, and by interruption of the capillary network pattern.<sup>71,72</sup> They are most readily identified by chromoendoscopy, a technique in which the mucosa is sprayed with indigo carmine dye.<sup>73</sup> The incidence of flat and depressed adenomas in three Western population studies was approximately 20%, and these lesions contained cancer more often

TABLE 25-1. Summary of malignant colorectal polyps that should have an oncologic bowel resection

- |   |   |
|---|---|
| A. Lesions in colon                               |   |
| a)  | Pedunculated Haggitt level 4 with invasion into distal third of submucosa, or pedunculated lesions with lymphovascular invasion |
| b)  | Lesions removed with margin <2 mm   |
| c)  | Sessile lesions removed piecemeal   |
| d)  | Sessile lesions with depth of invasion into distal third of submucosa (Sm <sub>3</sub> )  |
| e)  | Sessile lesions with lymphovascular invasion  |
| B. Lesions in middle third and upper third rectum |   |
| Same as lesions in colon                          |   |
| C. Lesions in distal third rectum                 |   |
| a)  | Pedunculated Haggitt level 4 with invasion into distal third of submucosa, or pedunculated lesions with lymphovascular invasion |
| b)  | All sessile lesions   |

An alternative may be a per anal full-thickness excision plus chemoradiation.

than polypoid adenomas.<sup>74–76</sup> In a large United Kingdom study of 1000 patients in which chromoendoscopy was used to search for small flat lesions, 36% of the 321 detected adenomas were flat or depressed.<sup>74</sup> The overall risk of a polypoid lesion containing early cancer was 8%, but was 14% for the flat lesions. Flat or depressed lesions that were >1 cm were about twice as likely as protruding lesions of a similar size to contain high-grade dysplasia or cancer. Twenty-nine percent of flat lesions >1 cm contained either high-grade dysplasia or cancer. The average size of advanced flat and depressed adenomas is smaller than that of their polypoid counterparts. Because of the risk of cancer, these small lesions should be removed, either by endoscopic polypectomy or by operative resection. It has been suggested that using special dyes and magnifying colonoscopy should be incorporated into general endoscopic practice.<sup>71</sup>

### *Serrated Adenomas*

The serrated adenoma is a more recently recognized histologic phenotype of sporadic adenoma.<sup>77</sup> Serrated adenomas are uncommon, accounting for approximately 0.5%–1.3% of colorectal polyps.<sup>78,79</sup> Initially, serrated adenomas were described as hyperplastic polyps that contained adenomatous features. The serrated adenoma has serrated crypts that are longer and broader than in hyperplastic polyps. The crypts contain cells with enlarged hyperchromatic and stratified nuclei (as in adenomas) as well as cells with normally arranged, small, basal nuclei (as in hyperplastic polyps).<sup>80,81</sup>

It is unclear whether serrated adenomas develop in association with hyperplastic polyps or develop *de novo*. Both types of polyps are primarily found in the rectosigmoid region, and they have similar mucin characteristics. Endoscopically, most serrated adenoma look like hyperplastic polyps—pale, slightly protruding lesions, and most are in the range of 0.2–7.5 mm in diameter. Some serrated adenomas are larger and may resemble villous adenomas.

A pathway to colorectal cancer called the “serrated pathway” has been postulated, in which colorectal cancer develops through precursor lesions that have serrated glandular architecture. The serrated polyps include the mixed polyp, in addition to the hyperplastic and serrated adenoma. The mixed polyp is recognized by distinct areas of hyperplastic and adenomatous morphology.

The relationship between hyperplastic polyps, serrated adenomas, and cancer is not clear. In one report, 5.8% of colorectal cancers were associated with an adjacent serrated adenoma and some serrated adenomas harbor high-grade dysplasia.<sup>79,82</sup> A review concluded that the risk of high-grade dysplasia was the same in serrated adenomas as in the more common adenomatous phenotypes.<sup>79</sup> The serrated adenoma pathway may be a separate route to colon cancer characterized by methylation of promoter regions leading to switching off MMR genes, resulting in replication errors and ultimately to cancer. Hyperplastic polyps and serrated

adenomas show MSI in the absence of *APC* mutations. Individuals with sporadic colorectal cancer with high-level MSI cancers (MSI-H) are 4 times more likely to harbor at least one serrated polyp than individuals with low MSI cancers.<sup>74</sup>

## Nonneoplastic Polyps

### Hyperplastic Polyps

Hyperplastic polyps are the result of a failure of programmed cell death.<sup>33,38,80,81</sup> The epithelial cells differentiate and mature normally but accumulate on the mucosal surface producing small sessile elevations. Cellular crowding results in the characteristic microscopic appearance of tubules with a saw-tooth or serrated pattern. Mature goblet cells are the main cellular component of hyperplastic polyps, whereas adenomatous crypts have reduced numbers of goblet cells. The cytoplasm of hyperplastic polyps is eosinophilic on hematoxylin and eosin staining and the nuclei remain at the base with minimal stratification.

Hyperplastic polyps are the most common polyps found on flexible sigmoidoscopy. The true ratio of hyperplastic polyps to adenomas approximates 1:1. In a study of 1964 diminutive ( $\leq 5$  mm) polyps, 41% were adenomas, 37% hyperplastic polyps, and 18% nonneoplastic. Combining histologic data from several studies of diminutive polyps revealed that 53% were adenomas and that approximately 0.5% had high-grade dysplasia; <0.1% contained invasive cancer.<sup>43</sup>

Most hyperplastic polyps are small (<3–5 mm in diameter), pale, usually located in the rectosigmoid region, and are almost always asymptomatic. Hyperplastic polyps are often multiple. Although hyperplastic and adenomatous polyps have characteristic appearances, biopsy is needed to make a diagnosis. Endoscopic diagnosis has a sensitivity of 80% and a specificity of 71%.<sup>82</sup> Chromoendoscopy can improve the endoscopist’s ability to distinguish hyperplastic from adenomatous polyps. Hyperplastic polyps have a characteristic star-like pit pattern when stained with indigo carmine and assessed with a magnifying colonoscopy. Adenomatous polyps have surface grooves. The sensitivity and specificity of this technique in discriminating between adenomatous and nonadenomatous polyps was found to be 93% and 95%, respectively.<sup>83</sup>

Data conflict as to whether hyperplastic polyps found on a screening examination represent an increased risk of future neoplasia. Whereas some authors have suggested that left-sided hyperplastic polyps are predictors of proximal adenomas, the National Polyp Study found no association between left-sided hyperplastic polyps and synchronous adenomas. A report using data from two large chemoprevention studies demonstrated that hyperplastic polyps were not predictive of an increased risk of developing adenomatous polyps on follow-up colonoscopy.<sup>84</sup> The American College of Gastroenterology states that hyperplastic polyps found on flexible

sigmoidoscopy are not an indication for colonoscopy.<sup>85</sup> There are no specific recommendations for treatment and follow-up of right-sided hyperplastic polyps.

Hyperplastic polyps have been implicated in some colorectal cancers, especially in HNPCC. HNPCC cancers arise through mutations in one of several MMR genes; sporadic colon cancer with defective MMR occurs as a result of deactivation of a single gene—*hMLH1*. Inactivation occurs through methylation of the *hMLH1* gene promoter. The molecular phenotype of abnormal MMR is MSI. MSI has been used to distinguish these high-level MSI cancers (MSI-H) from cancers with low or no level of MSI, as seen in *APC*-related cancers.<sup>86</sup> A strong association of MSI-H cancers with residual adenomas has not been observed.<sup>87</sup> Sporadic adenocarcinomas arising through the defective MMR pathway (MSI-H adenocarcinoma) occur in older patients (>70 years), have a female gender bias, and are predominantly located in the right colon.<sup>88</sup> The vast majority lack *APC* mutations. These MSI-H cancers can be associated with large hyperplastic polyps, and analysis of these combined lesions demonstrates that both the cancer component and the hyperplastic polyp epithelial cells lack *hMLH1* expression. This suggests that hyperplastic polyps may serve as fertile soil for gene-specific hypermethylation leading to knockout of *hMLH1* and loss of DNA MMR function.<sup>33,38</sup>

Carriers of hyperplastic polyps clearly at increased risk for colorectal cancer are those with the hereditary syndrome of hyperplastic polyposis. This syndrome is diagnosed if multiple (>30) or large (>10 mm) hyperplastic polyps are found, especially in the proximal colon, with a positive family history of hyperplastic polyposis. The syndrome is thought to be very rare. Reports of patients with hyperplastic polyposis syndrome showed an average age of 52 years, >100 polyps in half the cases, and an average polyp diameter of 16 mm (range, 5–45 mm), and half the reported patients also had a cancer (half of these in the right colon). There are no general guidelines for the management of hyperplastic polyps or the hyperplastic polyposis syndrome.<sup>80,81</sup> (see Chapter 26).

### Hamartomas

Juvenile polyps are hamartomas, localized overgrowths of normal mature cells. Most juvenile polyps are round, pink, smooth, and pedunculated, although some are small and sessile. Juvenile polyps are composed of dilated mucus-filled cystic spaces surrounded by lamina propria which has a mesenchymal appearance with inflammatory cells and eosinophils. The muscularis mucosa does not participate in the formation of a juvenile polyp, and the unique potential of these lesions to twist and “auto-amputate” has been ascribed to the absence of supporting muscle fibers. Most juvenile polyps present in childhood, but they may present in infancy or in adulthood. Usually, only one or two polyps are found. Up to three polyps may be seen in nonfamilial conditions. Symptoms include rectal bleeding, mucus discharge, diarrhea, and

abdominal pain, intussusception and prolapse of a polyp through the anus. Treatment is snare polypectomy.

Numerous hamartomatous polyps are present in juvenile polyposis syndrome, Peutz-Jeghers syndrome, Cowden disease, and Cronkhite-Canada Syndrome. Although sporadic hamartomatous polyps are not dysplastic and are not believed to be premalignant, the syndromes of hamartomatous polyposis have a significant rate of cancer development. These syndromes are discussed in Chapter 26.

### Inflammatory Polyps

Inflammatory or pseudopolyps (a misnomer) are associated with colitis, most often ulcerative colitis and Crohn’s disease, but can result from any form of severe colonic inflammation. The inflammatory polyp is a remnant or island of normal or minimally inflamed mucosa. The presence of inflammatory polyps in inflammatory bowel disease is not associated with dysplasia or cancer risk. Inflammatory polyps are almost always multiple. Treatment is directed at the underlying bowel disease.

### Lymphoid Polyps

Benign enlargements of lymphoid follicles may produce polyps that are usually seen in the rectum. The overlying mucosa is normal. The lesions are typically multiple; their cause is unknown. Histologic criteria for establishing the benign nature of lymphoid polyps have been described: lymphoid tissue is entirely within the mucosa and submucosa; there is no invasion of the muscularis propria; at least two germinal centers must be seen; if the specimen does not include the muscle coat and no germinal centers are seen, then the diagnosis of lymphoid polyp cannot be made.

Lipomas, leiomyomas, lymphoma, hemangiomas, and carcinoid tumors are discussed in Chapter 37.

## Polyposis Syndromes

Robin K.S. Phillips and Susan K. Clark

Multiple colorectal polyps occur in a number of conditions, including the inflammatory polyps of inflammatory bowel disease, intestinal lipomatosis, and neurofibromatosis. Usually these can all be identified histopathologically, and will not be discussed further in this chapter, but biopsy is always essential in polyposis syndromes or mistakes will be made.

### Familial Adenomatous Polyposis

Familial adenomatous polyposis (FAP) is an autosomal dominantly inherited condition caused by mutation of the *APC* gene, which occurs with a frequency of about 1:10,000.<sup>1</sup> Mutation of this tumor suppressor gene results in a generalized disorder of tissue growth regulation and a range of clinical manifestations, principally the formation of multiple gastrointestinal adenomas and carcinomas, but also a variety of extraintestinal abnormalities.

In the past, FAP accounted for about 1% of all colorectal cancers, but an understanding of its inheritance, surveillance of at-risk family members, and the introduction of prophylactic large bowel resection have resulted in this contribution now being in the region of 0.05% in countries where such services are available.<sup>2</sup> Patients with a firm diagnosis of FAP or in whom it is suspected, together with their family, should be referred to a polyposis registry.

### Polyposis Registries

The aim of polyposis registries is to provide counseling, support, and clinical services for families with FAP.<sup>3</sup> This includes thorough pedigree analysis and identification of at-risk family members, who are offered clinical surveillance and genetic testing so that those affected can be offered prophylactic surgery. Some registries also coordinate postoperative surveillance and provide a focal point for audit and research.

Observational studies suggest that the introduction of registries, together with the use of prophylactic surgery, has led

to increased life expectancy and a dramatic reduction in the incidence of colorectal cancer in FAP.<sup>2</sup>

### Features of FAP

#### *The Large Bowel*

The cardinal manifestation of FAP is the development of more than 100 colorectal adenomatous polyps, which inevitably progress to carcinoma if not removed (Figure 26-1). Polyps usually appear in adolescence, with colorectal cancer diagnosed at an average age of about 40 years. Although most patients have a family history of FAP, about 25% do not, their disease being attributable to a new mutation.<sup>1</sup> These individuals usually present with a symptomatic colorectal cancer or, more rarely, with anemia, rectal bleeding, or mucous discharge caused by benign polyps.

#### *Extracolonic Manifestations*

The extracolonic manifestations of FAP are shown in Table 26-1. Two of these, duodenal cancer and desmoid disease, have now emerged as the major sources of morbidity and mortality, exceeding colorectal cancer as cause of death<sup>6</sup> (Figure 26-2).

Other features may be a useful clue in diagnosis. Congenital hypertrophy of the retinal pigment epithelium (CHRPE), a patchy fundus discoloration, was considered a potential screening tool before advances in genetics. Isolated CHRPE is seen in normal people, but the presence of more than four is a specific phenotypic marker present in two-thirds of FAP families.<sup>7</sup>

### Genetics

#### *The APC Gene*

*APC* is a large gene situated on chromosome 5q21. A genetic basis underlying the adenoma-carcinoma sequence in colorectal carcinogenesis has been elucidated,<sup>8</sup> and subsequent studies have confirmed that in both FAP and the majority of

FIGURE 26-1. The large bowel in classical familial adenomatous polyposis.

sporadic colorectal cancers, mutation of the *APC* gene is one of the earliest events.

More than 500 germline mutations causing FAP have been identified, almost all resulting in truncation of the *APC* protein product.<sup>9</sup> Mutations have been found between codons 168 (exon 4) and 2839 (exon 15), but most are between codons 168 and 1640 (exon 15) in the 5' half of the coding region, with a particular concentration at two "hotspots," codons 1061 and 1309.

*The APC Protein*

*APC* is ubiquitously expressed, but the mRNA is found at particularly high levels in normal colonic mucosa<sup>10</sup> and in many epithelia is only found when cell replication has ceased and terminal differentiation is established.<sup>11</sup>

The 300-kDa *APC* protein is found in the cytoplasm and has sites of interaction with a range of other proteins including  $\beta$ -catenin and the cytoskeleton. It has a central role in the highly conserved Wnt signaling pathway, which has functions

TABLE 26-1. Extracolonic features of FAP

System	Feature	Frequency (%)
Upper gastrointestinal tract	Upper gastrointestinal adenomas	95
	Upper gastrointestinal carcinoma	5
Connective tissue	Fundic gland polyps	40
	Osteomas (especially jaw)	80
Dental	Desmoids	15
	Unruptured and supernumerary teeth	17
Cutaneous	Epidermoid cysts	50
Endocrine	Adrenocortical adenomas <sup>4</sup>	5
	Papillary thyroid carcinoma <sup>5</sup>	1
Hepatobiliary	Biliary tract carcinoma	<1
	Hepatoblastoma	<1
Central nervous system	CHRPE	75
	Tumors (especially medulloblastoma)	<1

in the normal development of three-dimensional structures and is abnormally activated in some malignancies. *APC* binds and down-regulates cytoplasmic  $\beta$ -catenin, preventing its translocation to the nucleus. Abnormal *APC* protein fails to do this, so that  $\beta$ -catenin is free to enter the nucleus and form a complex which results in specific transcription of cell cycle stimulating DNA sequences, and hence proliferation.<sup>12</sup>

*Genotype-phenotype Correlation in FAP*

There is evidence of correlation between the position of the germline *APC* mutation (genotype) and some aspects of the phenotype in patients with FAP (Figure 26-3). Mutation at codon 1309 is associated with particularly large numbers of colonic polyps,<sup>13</sup> and between codon 1250 and 1464 with earlier onset of, and death from, colorectal cancer. Mutations located 5' of codon 160 and 3' of codon 1597 have been identified in a form of FAP with attenuated colonic polyposis,<sup>14</sup> which accounts for about 10% of those affected.

Some extracolonic manifestations have also been associated with mutation at certain sites, but this is not clear for upper gastrointestinal polyposis.<sup>15</sup> CHRPE occurs only with mutation between codons 450 (exon 9) and 1444,<sup>16</sup> and desmoids occur in individuals with any mutation, but the presence of a germline mutation 3' of codon 1444 can be associated with highly penetrant desmoid disease.<sup>17</sup>

FIGURE 26-3. Schematic representation of the *APC* gene showing genotype-phenotype correlations.

However, identical *APC* mutations may be associated with diverse phenotypes, suggesting that other genetic modifiers are involved<sup>18</sup> and that environment probably also has some influence.

### *MYH Polyposis*

An autosomal recessive form of familial adenomatous polyposis, caused by mutation in the MutY homolog (*MYH*) gene, has recently been described.<sup>19</sup> Whereas many of the individuals identified with biallelic *MYH* mutations had fewer than 100 polyps, some had many hundreds, and thus a genuine clinical diagnosis of FAP. Colonic microadenomas and duodenal adenomas have also been reported in this group, but desmoids and fundic gland polyps have not been described to date, and CHRPE status remains uncertain. This discovery has major implications for genetic counseling, because, for the first time, an autosomal recessive form of FAP has been identified. This diagnosis should be considered in families in which no *APC* mutation has been identified, the mode of inheritance is not clearly autosomal dominant, or polyp numbers are low.

## Clinical Variants of FAP

### *Attenuated FAP*

A group of patients have been described who develop fewer than 100 colorectal polyps (usually between one and 50), at a greater age (34–44 years) than in “classical” FAP, but who may still exhibit extracolonic manifestations and carry a germline *APC* mutation.<sup>20</sup> Colorectal cancers also occur correspondingly later (mean 56 years) in this group, and with incomplete penetrance. The polyps have a rather different distribution, being more frequently found proximal to the splenic flexure, and their number varies significantly between family members, some of whom may have hundreds of adenomas.

This can result in diagnostic confusion because the clinical picture is very similar to HNPCC, and indeed the first kindreds described were thought to have a form of HNPCC before they were identified as carrying *APC* mutations.<sup>21</sup> A number of distinct mutations has been identified in individuals with attenuated FAP (AFAP); the mutations are clustered in exons 3 and 4, at the 5′ end of the gene, and also at the 3′ end of exon 15. Fundic gland polyps and duodenal adenomas are frequent, but CHRPEs are unusual in this group, as are desmoids in those with a 5′ mutation. In contrast, families with 3′ mutations (beyond about codon 1444) seem to have a high risk of desmoid disease together with attenuated large bowel disease. The missense *APC* mutation I1307K has been identified in Ashkenazi Jews with multiple adenomas and E1317Q<sup>22</sup> has also been found in association with an AFAP whereas *MYH* mutations have been found in up to 30% of cases of multiple (15–100) colorectal adenomas.<sup>19</sup>

The main consequence of the attenuated phenotype is that it causes diagnostic difficulty. Because the polyps are predominantly right sided, the disease may be missed by

flexible sigmoidoscopy. A careful search (including upper gastrointestinal endoscopy) for extracolonic features of FAP, dye-spray colonoscopy to confirm polyp number, and testing of tumor or polyp tissue for microsatellite instability and mismatch repair immunohistochemistry may be helpful.

Once diagnosis is confirmed, management is essentially the same as for FAP with a more classic phenotype,<sup>23</sup> although ileorectal anastomosis (IRA) is probably reasonable in most patients. The only exceptions to this situation might be in the small group with a strongly inherited tendency to develop severe desmoid disease, potentially triggered by surgery, and a very mild colonic phenotype, where meticulous surveillance with endoscopic polypectomy might be justified.

### *Gardner’s Syndrome*

Gardner described the association between FAP and epidermoid cysts, osteomas and “fibromas,” later found to be desmoid tumors in 1953. The term “Gardner’s syndrome” was only later used to describe colorectal polyposis occurring with these extracolonic manifestations. Gardner’s syndrome is now considered to be genetically indistinct from FAP, and systematic examination<sup>24</sup> has revealed that most patients with FAP have at least one extraintestinal feature. Although it is of historical interest, the term Gardner’s syndrome is no longer considered a genetic or clinically entity and should be regarded as obsolete.<sup>25</sup>

### *Turcot’s Syndrome*

This syndrome is the association between colorectal adenomatous polyposis and central nervous system tumors. Recent molecular genetic investigation<sup>26</sup> has shown that about two-thirds of families have mutations in the *APC* gene, with cerebellar medulloblastoma as the predominant brain tumor. Most of the other third, including Turcot’s original family, seem to be variants of HNPCC with glioblastoma as the predominant brain tumor, and multiple (but fewer than 100) colorectal adenomas. This illustrates how one syndrome can be caused by mutations in more than one gene, the phenomenon of genetic heterogeneity.

## Diagnosis

### *Genetic Testing*

Genetic testing should be preceded by thorough counseling, with the provision of written information about the process and consequences, and should only be done once informed consent has been obtained. The implications with respect to confidentiality, employment, insurance, and other financial issues vary from country to country, but must be discussed before testing.

The first step in the process is mutation detection. DNA from an individual with FAP is analyzed to identify a mutation in *APC*, which is successful in about 80% of cases. Failure to detect an *APC* mutation does not exclude a diagnosis of FAP, and may occur for a variety of reasons including gene deletion

and some missense mutations. Such results have been misinterpreted as ruling out the diagnosis of FAP,<sup>27</sup> with potentially serious consequences.

If mutation detection has been successful, at-risk family members can be offered predictive testing with a high degree of accuracy. This testing is generally done between the ages of 12 and 15 years, when the individual is old enough to take part in genetic counseling. There is no need for testing to be done earlier, because the disease does not usually become clinically manifest and treatment is rarely indicated before the mid-teens.

From time to time colorectal surgeons will encounter very young children with a positive genetic test that has been organized, not because of symptoms but as simple screening, often by a pediatrician; finding this can cause great management difficulty. There is understandable parental concern, yet the phenotype is not developed to guide surgical choice, cyclooxygenase (COX)-2 inhibitors have not been tested in a pediatric age group, and the chance of cancer is vanishingly slight. Yet abdominal pain, frequent in small children, creates a parental and even pediatrician pressure for colonoscopy and sometimes surgery earlier than is usually desirable.

In the event of negative predictive testing (i.e., an individual does not possess the family mutation), that person can be discharged from further surveillance and be reassured that they do not have FAP. This approach reduces the costs and risks associated with endoscopic surveillance, as well as removing the anxiety of living with a potential diagnosis of FAP. A positive test result allows optimal surveillance and prophylaxis to be targeted to those individuals who need it, and knowledge of the site of mutation can aid decision making with regard to prophylactic surgery.

### *Clinical Surveillance*

In kindreds in whom mutation detection has not been performed or has not been informative, at-risk individuals should be offered regular clinical surveillance. This surveillance starts at the age of 12–14 years, when adenomas would be expected to develop. Although there have been reports of polyps and even cancers occurring earlier than this, they are very rare. Clearly, anyone at risk of FAP should undergo colonoscopy if they become symptomatic.

Surveillance is initially by flexible sigmoidoscopy, because it is well tolerated and most polyps are in the left colon and rectum. If this continues, colonoscopy should then be performed from around the age of 20, alternating with flexible sigmoidoscopy so that one or other is done each year. The vast majority of individuals with FAP will develop polyps by the age of 30, but there is no consensus regarding the age at which surveillance can cease. It should certainly continue until the age of 40 years, and longer in families in which the disease tends to manifest late.

There are various pitfalls in endoscopy in these patients. In the young, lymphoid follicles may have a dramatic appearance, mimicking adenomatous polyposis. Biopsy is therefore

mandatory. Conversely, small polyps are easy to miss. The use of a dye-spray technique, together with multiple biopsies to identify microadenomas, can be very helpful in identifying FAP and avoiding an underestimate of the polyp burden.<sup>28</sup>

## Management of the Large Bowel

### *Timing of Prophylactic Surgery*

Once FAP has been diagnosed, the aim is to perform prophylactic surgery. Invasive cancer is very rare in patients younger than the age of 18 years, and usually causes symptoms.<sup>29</sup> Patients with severe polyposis (more than 1000 colonic or more than 20 rectal polyps), or those people who are symptomatic, should have surgery as soon as possible. In those individuals with milder disease, it can usually be delayed until an educationally and socially convenient time (e.g., a long school vacation). In these circumstances, annual colonoscopy is recommended to monitor disease, but the aim should be to avoid delay, so that most will have surgery between the ages of 16 and 20, which is well before invasive disease usually develops.

### *Choice of Operation*

The surgical options for the management of this condition are proctocolectomy with end ileostomy (with or without Koch pouch), colectomy with IRA or proctocolectomy with ileoanal pouch (IPAA). Because few patients desire a permanent ileostomy, proctocolectomy is rarely done, although it remains an option that should be considered in some circumstances, and may be necessary if a low rectal cancer encroaches on the anal canal, if ileoanal pouch formation is impossible (e.g., because of mesenteric desmoid) or ill advised (e.g., in the presence of poor sphincter function). In most cases, however, the choice is between the latter two options, and is a matter of considerable ongoing debate, the essence of which is the balance between functional results and morbidity of surgery on the one hand and prevention of cancer on the other. Both procedures can be performed with laparoscopic mobilization, so that a midline laparotomy is not essential, a merely cosmetic improvement but with potentially great appeal to essentially healthy young people undergoing this surgery. Both the IRA and the IPAA can be performed by laparotomy, laparoscopy, laparoscopic or hand-assisted procedures. The only proven benefit of the minimally invasive approaches is superior cosmesis as compared with laparotomy.

IRA is more straightforward to perform, and requires only one procedure, with a shorter hospital stay and fewer complications.<sup>30</sup> The risks of erectile and ejaculatory dysfunction caused by nerve damage during pelvic dissection are avoided, as is the significant reduction in fecundity observed in women after IPAA.<sup>31</sup> In addition, bowel frequency and soiling are less.<sup>32</sup> In a teenager facing prophylactic surgery, these functional factors are of great significance, particularly when

most cancer risk is a few decades away and later conversion to a pouch is usually possible.

The main disadvantage of IRA is that follow-up studies have shown a 12%–29% risk of developing a cancer in the retained rectum within 20–25 years,<sup>33</sup> the risk being dependent on age, rather than time since surgery. High-density (more than 1000) colonic polyposis is associated with a cancer risk double that in milder disease,<sup>34</sup> and also with severe polyposis in the rectum after IRA, leading to frequent need for completion proctectomy. FAP attributable to mutation in exon 15G, which includes the frequently mutated codon 1309, consistently results in this severe colorectal phenotype.<sup>35</sup> In this group, there is a high rate of subsequent proctectomy if IRA is done as the first-line procedure.<sup>36</sup>

IPAA has the attraction of removing the colon and rectum entirely, and complication rates and functional results have improved with experience. There has been controversy over the need for mucosectomy to remove the anorectal transition zone, which theoretically prevents cuff neoplasia, but results in more complications and perhaps poorer function. Dysplasia in the transition zone occurs after both double-stapled and mucosectomy techniques, and the latter technique is probably only rarely indicated in individuals with extensive severe low rectal polyposis.

Surveillance of ileoanal pouches from various centers has shown adenomas in up to 53%,<sup>37,38</sup> and even some cancers.<sup>39</sup> Because IPAA has only been available for approximately 20 years, and has only been performed frequently for FAP in the last 15 years, the full significance of this will not be clear for some time. However, the cases reported to date confirm that neoplasia can occur in these pouches, which is of considerable concern; thus, careful follow-up is essential.

Much of the data on outcome after IRA follow surgery done before IPAA was introduced, when IRA was the only way to avoid a permanent stoma. It was almost certainly done in circumstances when IPAA would now be considered preferable (i.e., more advanced age, high-density polyposis, codon 1309 mutation). There is some evidence to suggest that rectal cancer rates and the need for completion proctectomy in patients having IRA since IPAA has been practiced are much lower than previously thought.<sup>40</sup> Other factors contributing to high rectal cancer rates in historical studies include inadequate postoperative surveillance, and the fact that in many cases the operation performed was a subtotal colectomy with ileosigmoid anastomosis, leaving a long rectosigmoid segment, inherently more difficult to visualize.

IRA is a reasonable and safe option today in young patients, particularly children and teenagers without 1309 mutation or severe polyposis,<sup>23,36</sup> and is strongly indicated if there are fewer than five rectal polyps. Most individuals presenting over the age of 25 years and those with severe polyposis or known to carry a mutation in codon 1309 should be advised to undergo IPAA. But there are other issues: pouch surgery in young men has an approximately 1% risk of damage to erection, ejaculation, and bladder function; in

women fertility is compromised. In addition, some families prefer a certain operation, regardless of the medical advice they have received.

### *Postoperative Surveillance*

After IRA, the retained rectum should be examined, ideally using a flexible sigmoidoscope, every 6–12 months, the interval depending on the severity of disease. In about two-thirds of patients, rectal adenoma regression is seen in the first few years after IRA.<sup>41</sup> Polyps larger than 5 mm should be removed; repeated fulguration can result in scarring, making future surveillance difficult and unreliable. If severe dysplasia or uncontrolled polyposis develops, completion proctectomy with or without ileoanal pouch formation is indicated.

In patients who have had IPAA, the pouch should be examined by flexible endoscopy annually, and a careful digital examination of the anorectal transition zone should be performed.

### *Chemoprevention*

A range of chemopreventive agents have been studied in FAP, in part because of the problems of managing the retained rectum after IRA, but also because this disease provides a useful experimental model of colorectal carcinogenesis. In placebo controlled trials, both the nonsteroidal antiinflammatory drug (NSAID) sulindac<sup>42</sup> and the COX-2 inhibitor celecoxib<sup>43</sup> have reduced the number and size of colorectal adenomas. It would be inappropriate, however, to regard such treatment as an alternative to prophylactic surgery, because no benefit in terms of cancer reduction has been demonstrated, and there have been reports of rectal carcinoma occurring in patients on sulindac despite a good response in terms of reduction in polyp number and size. But there are circumstances, for example, when completion proctectomy is impossible because of desmoid disease, or while awaiting surgery that must otherwise unavoidably be delayed, or in patients with a very high family risk of desmoid disease, when the use of such agents has a definite place.

### *Upper Gastrointestinal Polyposis*

Fundic gland polyps, which are areas of cystic hyperplasia,<sup>44</sup> are found in about 50% of individuals with FAP. These have a very low malignant potential, but gastric adenomas, dysplasia, and invasive carcinoma have been described.<sup>45</sup> There is an increase in gastric cancers in patients with FAP in Japan<sup>46</sup> and Korea, but this finding is not seen in the West. An excess of gallbladder and bile duct adenomas and carcinoma has also been reported.<sup>47,48</sup>

Prospective studies have demonstrated that more than 95% of individuals with FAP have duodenal adenomas,<sup>49</sup> which tend to occur about 15 years later than large bowel polyps.<sup>50</sup> Adenomas are found throughout the small intestine, but most are at or just distal to the ampulla of Vater. Duodenal or

periampullary cancer occurs in approximately 5% overall, at an average age of 50 years.

### Surveillance of the Duodenum

Duodenal adenomas may be clearly defined polyps or more confluent areas, and biopsies of macroscopically normal mucosa may reveal microadenomas. In contrast to the situation in the large bowel, only a minority of these will progress to invasive carcinoma, but when they do the prognosis is very poor. To stratify the severity of duodenal polyposis, the Spigelman staging was developed<sup>51</sup> and has been widely adopted (Tables 26-2 and 26-3). A prospective 10-year follow-up of Spigelman's original cohort has identified a 36% risk of developing invasive carcinoma in those with stage IV disease at the start of the study, and a 2% risk in those with stage II or III disease. Several carcinomas were missed on endoscopy, and all of those who developed cancer died as a result, despite surgery.<sup>15</sup>

Regular endoscopic surveillance is recommended, so that individuals at high risk of developing carcinoma can be identified and offered intervention, although there is currently no evidence that this approach decreases the rate of invasive disease.<sup>52,53</sup> Examination of the duodenum using both forward- and side-viewing scopes, together with multiple biopsies,<sup>15</sup> starting at the age of 25 years, is recommended.

### Management

Management of severe duodenal polyposis is difficult, but the outcome once invasive carcinoma has developed is poor. Duodenotomy and open polypectomy are associated with 100% recurrence just a year after surgery.<sup>54</sup> Endoscopic mucosal resection seems a more attractive option, but is made difficult by the frequently plaque-like morphology of the polyps and involvement of the ampulla. Even simple biopsy of the ampulla can result in acute pancreatitis,<sup>55</sup> and repeated diathermy in this region can lead to scarring and stricturing. Argon plasma coagulation is of some use. Photodynamic therapy has been tried, but photosensitization and the need for multiple treatments<sup>56</sup> means that it is not currently a practical option.

The use of chemoprevention to prevent progression of earlier stage disease has attracted great interest. Calcium, starch, vitamin C, and ranitidine have been tried, with no effect. Sulindac can result in regression of small polyps,<sup>57</sup> but has little effect on larger ones. A randomized trial of the COX-2

TABLE 26-2. Scoring of polyp features in Spigelman staging for duodenal adenomas

Points allocated	No. of polyps	Size of polyps (mm)	Histology	Dysplasia
1	1-4	1-4	Tubular	Mild
2	5-20	5-10	Tubulovillous	Moderate
3	>20	>10	Villous	Severe

TABLE 26-3. Derivation of Spigelman stage from scores

Total points	Spigelman stage	Suggested interval to next duodenoscopy (yr)
0	0	5
1-4	I	3-5
5-6	II	3
7-8	III	1
9-12	IV	1

inhibitor celecoxib showed significant improvement in the Spigelman stage for those with mild to moderate disease.<sup>58</sup>

Duodenectomy, whether by a classical Whipple's procedure or using pylorus or pancreas preserving techniques, has been considered a last resort because of its significant morbidity and mortality. However, given the very poor prognosis once neoplasia becomes frankly invasive, the high rate of diagnosis of invasive disease which was preoperatively thought to be benign,<sup>59</sup> and the limitations of other options, it should be seriously considered for advanced premalignant disease.<sup>15,59</sup>

### Desmoid Disease

Desmoids are locally invasive, nonmetastasizing clonal proliferations of myofibroblasts.<sup>60</sup> Their etiology, pathogenesis, and natural history are not clearly understood. The importance of desmoid disease lies in its significant contribution to disease-related mortality in FAP.<sup>6</sup> Overall mortality ranges from 10% to 50%,<sup>61</sup> and desmoids can also contribute to death from other causes by making surgery for rectal or upper gastrointestinal malignancy difficult or even impossible.<sup>62,63</sup>

Ten to fifteen percent of patients with FAP develop desmoid,<sup>64</sup> with a peak incidence at around 30 years, 2-3 years after surgery. Whereas sporadic desmoids are considerably more common in females than males, this difference is less marked in the setting of FAP.

### Clinical Features

Desmoids occurring in association with FAP typically arise within the abdomen (70%), especially in the small bowel mesentery, and in the abdominal wall (15%), although many other sites have been described. Mesenteric desmoids (Figure 26-4) can be either well-defined mass lesions, or a more diffuse fibromatous infiltration. Encasement or compression of the mesenteric blood vessels can result in ischemia and perforation of the bowel, and makes resection hazardous. A desmoid tumor can also cause direct compression of bowel and ureters. The presence of a desmoid may preclude adequate mesenteric length to fashion an IPAA.

Trauma (particularly in the form of surgery) and estrogens have both been implicated in the etiology of these lesions, although they can occur spontaneously. There is evidence for some degree of genotype-phenotype correlation. Desmoids have been reported to occur more frequently in patients with germline mutations located toward the 3' end of the gene.<sup>16,65</sup>

FIGURE 26-4. Desmoid tumor arising in the small bowel mesentery.

Some mutations in this region are associated with severe desmoid disease inherited with high penetrance, but individuals with such mutations do not always develop this manifestation. However, many patients with desmoid have mutations in the 5' half of the gene so modifier genes may well also delay a part.

There is disputed evidence whether desmoid formation starts with the development of a desmoid precursor lesion, a plaque-like area of thickened peritoneum, which may progress to a more diffuse mesenteric fibromatosis and then to a desmoid mass.<sup>66,67</sup> Desmoid natural history is very variable, about 10% resolving spontaneously, 10% growing rapidly and relentlessly, and the remainder either showing cycles of growth and resolution or remaining stable.<sup>68</sup>

### Investigation

Computed tomographic scanning is the mainstay of investigation, allowing imaging and measurement of the desmoid itself, as well as demonstrating the relationship to other structures such as the ureters and bowel.<sup>69</sup> Early mesenteric fibrosis appears as ill-defined soft tissue infiltration of the mesenteric fat, with a characteristic, whorled appearance.<sup>67</sup> Magnetic resonance imaging (Figure 26-5) may have a place, and there is some evidence that T2-weighted signal intensity correlates with subsequent growth.<sup>70</sup> Because only a small proportion of desmoids grow and cause significant clinical problems, the ability to predict such progression might be very useful. Because desmoid disease frequently causes ureteric compression, regular ultrasound monitoring of the kidneys permits timely intervention.

FIGURE 26-5. MRI scan showing intraabdominal desmoid tumor.

### Management

The treatment of desmoids is controversial, empirical, and often difficult. Surgery is widely accepted as the first-line treatment for troublesome extraabdominal and abdominal wall desmoids. Recurrence is common (20%–50%), but complications are few. Within the abdomen the situation is very different, because the majority lie in the small bowel mesentery, encasing the mesenteric vasculature. The result is a high perioperative mortality rate (usually from hemorrhage)<sup>71</sup> and substantial morbidity, particularly because of extensive loss of small bowel. Ureteric obstruction is best managed with stents, and proximal defunctioning may be required in some patients with bowel obstruction or perforation.

Various medical treatments have been reported, the most widely used being NSAIDs (particularly Sulindac) and anti-estrogens (tamoxifen or toremifene). There have been no prospective controlled trials, and particularly in view of the unpredictable and variable behavior of desmoids, the small retrospective series reported are difficult to interpret. Cytotoxic chemotherapy has been used in irresectable or aggressive desmoid disease, and objective remissions have been noted with a variety of different agents. There have been several encouraging reports of an anti-sarcoma regimen consisting of doxorubicin and dacarbazine in the treatment of life-threatening intraabdominal desmoid disease<sup>72,73</sup> and more recently a less toxic combination of vinblastine and methotrexate has produced some responses.<sup>74,75</sup>

One proposed treatment protocol<sup>23</sup> for intraabdominal desmoid suggests initial treatment with sulindac 150–200 mg twice daily. If growth continues, tamoxifen (80–120 mg per day) is added. If progression is rapid or relentless,

chemotherapy is considered. Treatment of desmoids preferably should take place in the setting of an international study.

## Peutz-Jeghers Syndrome

This syndrome, which has an incidence in the region of 1 in 200,000, consists of perioral, buccal, and occasionally genital melanin pigmentation together with gastrointestinal hamartomatous polyposis. Pigmentation can also be seen on the lips and sometimes on the eyelids, hands and feet, or be absent altogether. It usually appears in early childhood and tends to fade in the late twenties. The polyps occur predominantly in the small intestine (78%), but are also found in the stomach (38%), colon (42%), and rectum (28%).<sup>76</sup> They are hamartomas with a characteristic branching morphology, containing smooth muscle. Adenomatous change with dysplasia and progression to invasive adenocarcinoma has been observed.<sup>77</sup>

### Inheritance

Peutz-Jeghers is autosomal dominantly inherited with high penetrance, and is caused by mutation of *LKB1* (also known as *STK11*) on chromosome 19p13.3,<sup>78</sup> which encodes a serine-threonine kinase of unknown function. Mutation of *LKB1* is only found in about 50% of cases, and has been formally excluded in some,<sup>79</sup> suggesting that other genes are responsible in a proportion of cases. Although a family history is frequently evident, new mutations are responsible for a significant number of cases.

### Clinical Issues

#### *Polyp-related Complications*

The most common clinical problems in Peutz-Jeghers syndrome are anemia caused by chronic blood loss from large polyps and small bowel obstruction, caused by intussusception with a polyp at the apex. Repeated emergency bowel resections can lead to increasing operative difficulty and even short-bowel syndrome.

#### *Risk of Malignancy*

Follow-up studies have shown that individuals with this syndrome are at increased risk of developing a range of malignancies at a particularly young age.<sup>80</sup> Indeed, by the age of 57 years, approximately half of all patients in one series had died of cancer, of which about half were gastrointestinal.<sup>81</sup> It is estimated that there is a 50-fold excess of gastrointestinal cancer in Peutz-Jeghers syndrome, resulting in a lifetime risk of approximately 20% of colorectal cancer and about 5% of gastric cancer, as well as breast, pancreatic (30% lifetime risk), ovarian sex-cord tumors (10% of females), feminizing Sertoli

cell testicular tumors in prepubertal boys, and cervical malignancies.

## Management

### *Gastrointestinal Surveillance*

Two or three yearly gastroduodenoscopy and colonoscopy with polypectomy are recommended, with barium study (and increasingly capsule endoscopy) of the small intestine at the same interval. Hemoglobin should be checked annually. Small bowel polyps causing symptoms or anemia, or measuring more than 1.5 cm, should be removed at laparotomy with intraoperative enteroscopy.

### *Laparotomy in Peutz-Jeghers Syndrome*

The technique of laparotomy with intraoperative enteroscopy was introduced to reduce the repeated emergency laparotomies and small bowel resections undertaken on these patients. At laparotomy an enterotomy is made, usually at the site of the largest polyp, and a flexible endoscope is passed through a sterile laparoscope sheath to the proximal and distal ends of the small bowel. During scope withdrawal, polyps are excised using a snare or electrocautery biopsy forceps, and then retrieved via the enterotomy. This approach identifies many more polyps than conventional palpation and transillumination of the bowel, permitting removal without multiple enterotomies and increasing obstruction-free interval.<sup>82</sup> This procedure may be amenable to performance in a laparoscopically assisted method.

### *Extraintestinal Surveillance*

Mammography in premenopausal woman lacks sensitivity, but there is little evidence to support ultrasound or MRI as alternatives. Testicular tumors tend to occur in prepubertal boys, and it would seem sensible to encourage regular examination. Women should undergo standard cervical and breast screening according to nationally agreed protocols. Although in some centers regular ultrasound scanning of the pancreas and ovaries is performed, there is no evidence that such measures have any impact on prognosis. Indeed, even in rare cases of familial pancreatic cancer, an appropriate screening method remains controversial. It is important that clinicians caring for these patients are aware of the high cancer risk, and maintain a high index of suspicion.

## Juvenile Polyposis

Juvenile polyps are hamartomas that lack smooth muscle histologically, having poor anchorage to the bowel wall, and not infrequently becoming detached and being passed anally. Solitary juvenile polyps may affect up to 2% of children and adolescents, but have little or no malignant potential.<sup>83</sup>

Juvenile polyposis is characterized by the finding of multiple juvenile polyps in the large bowel, although the stomach (and perhaps small intestine) is affected as well in about 50%.<sup>84</sup> The precise number of juvenile polyps needed to make the diagnosis varies among authors, with numbers between three and five being suggested. Most affected individuals develop 50–200 polyps, but some have very few. One juvenile polyp in a patient with a family history of juvenile polyposis is sufficient to diagnose juvenile polyposis.

It is a rare condition, with a frequency of about 1 per 100,000, and presents with rectal bleeding, anemia, or polyp prolapse, at an average age of approximately 9 years. The polyps are hamartomas, with a characteristic hyperplastic stroma, abundant lamina propria, cystic glands, and inflammation. Adenomatous dysplasia occurs in up to half of these, which may then progress to invasive adenocarcinoma.

Other morphologic abnormalities including macrocephaly, mental retardation, cleft lip or palate, congenital heart disease, genitourinary malformations, and malrotations are found in 10%–20%.<sup>85</sup>

### Genetics

This syndrome is genetically heterogeneous, with three separate genes currently implicated. Mutations have been identified in affected individuals in *SMAD4* which lies on chromosome 18q21 and is a known tumor suppressor gene, implicated in sporadic colorectal carcinogenesis. It codes for a protein involved in the transforming growth factor- $\beta$  signaling pathway, and germline mutations have been found in 35%–60% of juvenile polyposis patients in the United States, but rather fewer (3%–28%) in Europe.<sup>86</sup> Recently, germline mutations of *BMPRIA* on 10q22, which encodes a protein involved in the same signaling pathway, have been found in a further 15%.<sup>87</sup> *PTEN* mutations have also been reported in so-called “juvenile polyposis,”<sup>85</sup> but it is as yet unclear whether these are genuine cases, or in fact Cowden syndrome, or even whether this syndrome is simply a clinical variant of juvenile polyposis.<sup>88</sup>

### Cancer Risk and Management

The cumulative risk of colorectal cancer has been estimated at 30%–50%, and 10%–20% in the upper gastrointestinal tract.<sup>86</sup>

First-degree relatives of affected individuals should be screened by colonoscopy from around the age of 12 years if asymptomatic<sup>89</sup> and five yearly thereafter. In most cases, the polyps can be controlled by regular endoscopic polypectomy, with both upper gastrointestinal endoscopy and colonoscopy recommended at least every 2 years. In cases in which polyps are either too numerous or too large to be managed in this way, colectomy and IRA or restorative proctocolectomy is advised.<sup>90</sup> It is not clear whether endoscopic surveillance and polypectomy are adequate to prevent malignancy, but there are insufficient data to justify purely prophylactic colectomy.

Affected individuals should also undergo upper gastrointestinal surveillance from the age of 25 years.

### Other Juvenile Polyposes

Several very rare dominantly inherited conditions have been described in which juvenile-type hamartomatous colorectal polyps occur together with other features. In these syndromes, the juvenile polyps seem to be of low malignant potential.<sup>91</sup>

#### *Cowden Syndrome*

This is autosomal dominantly inherited and attributable to mutation of the *PTEN* gene,<sup>92</sup> which encodes a protein tyrosine phosphatase involved in inhibiting cell growth. It is characterized by macrocephaly (30%), trichilemmomas (which are considered pathognomonic), and both benign and malignant neoplasms of the thyroid, breast, uterus, and skin. The hamartomas occur in the mouth as well as other parts of the gastrointestinal tract, resulting in a nodular appearance of the buccal mucosa.

#### *Bannayan-Riley-Ruvalcaba Syndrome*

Here the juvenile polyps (50%) are associated with characteristic pigmented penile macules, macrocephaly, mental retardation (50%), lipomatosis, and hemangiomas. *PTEN* mutations have also been identified in this syndrome.<sup>93</sup> It seems likely as Cowden and Bannayan-Riley-Ruvalcaba syndromes are caused by mutation of the same gene that they are slightly different forms of the same disorder,<sup>87</sup> and families have been identified in which both phenotypes are evident.<sup>94</sup> The risk of colorectal cancer is not clear.

### Metaplastic Polyposis

Metaplastic (hyperplastic) polyps are the most common lesions observed in the large bowel, being found in 40% at the age of 50 years. Their significance is unclear and there is much controversy surrounding their potential as precursors of adenomas and carcinoma. There is increasing evidence of correlation between numbers of metaplastic polyps and adenomas and cancer risk.<sup>95</sup> In addition, metaplastic polyposis, a loosely defined entity in which multiple hyperplastic polyps are seen, does appear to be associated with an increased risk of colorectal cancer, often with microsatellite instability.<sup>96</sup> There are at present, however, insufficient data to allow clear guidance on clinical management.

### Cronkhite-Canada Syndrome

This is a very rare condition with onset in adulthood and no evidence of an inherited predisposition. The disease is characterized by gastrointestinal hamartomatous polyposis

together with ectodermal abnormalities including alopecia, onychodystrophy, and hyperpigmentation of the skin of the face and eyelids. The gastric mucosa resembles Ménétrier's disease, and malabsorption and protein loss can lead to anemia, diarrhea, weight loss, edema, and tetany. Hypokalemia can also be a feature.

Multiple juvenile-type polyps, with marked inflammatory features, are found in the duodenum in 75% of cases, the small intestine in 50%, and occasionally in the stomach and large bowel. Adenomatous change is seen and gastrointestinal cancer has been reported in about 10%.

The pathogenesis of this condition is unknown, and there is no established treatment. Management is essentially supportive, with aggressive fluid resuscitation and nutrition. Tetracycline can help, and corticosteroids have also been used.<sup>97</sup>

# Colon Cancer Evaluation and Staging

Eric G. Weiss and Ian Lavery

Colorectal cancer is the third most common cancer affecting persons in the United States. In 2004, there were an estimated 146,940 new cases of colon and rectal cancer with colon cancer making up the majority of new cases at 106,370.<sup>1</sup> Overall, approximately 38% of newly diagnosed patients with colorectal cancer in the United States will die of their disease.

## Clinical Presentation

Most importantly, colon cancers are diagnosed in patients who are asymptomatic, who undergo surveillance, or who are investigated for other problems such as amenia. In symptomatic patients, the most common presenting symptoms are abdominal pain, change in bowel habits, rectal bleeding, and occult blood in the stool.<sup>2</sup> These symptoms frequently mean that the tumor is more advanced than in asymptomatic patients.

Abdominal pain is the most common presenting symptom of colon cancer. The pain can vary in type, location, and intensity. In the early phases or stages of colon cancer without evidence of obstructive symptoms, the pain can be vague, dull, and poorly localized. With progression of the disease with a larger growing mass or a mass causing obstruction, symptoms of intestinal obstruction will eventually occur. This type of pain is characterized by crampy, colicky pain, often associated with meals, and occurring after meals. The location of the pain is often periumbilical or midabdominal but can be located at the site of obstruction.

A change in bowel habits is the second most common symptom of colon cancer. The changes seen can be very subtle or very significant. In early lesions the change may be minor, with only a change in stool frequency. There can be changes in size, shape, and/or consistency of bowel movements. Characteristic changes include narrowing of the stool, irregular shape, and typically looser or diarrheal stool. The symptoms will depend on the location of the tumor. Right-sided tumors occur where the bowel lumen is larger and the

stool is liquid. Symptoms occur later, but on the left side where the stool is more solid and the lumen narrower, symptoms occur at an earlier stage.

Rectal bleeding may be present in as many as 25% of patients with colon cancer.<sup>3,4</sup> The bleeding may be of varying intensity and color. Bright red rectal bleeding is more consistent with a more distal location of a cancer. The mistake of attributing rectal bleeding to hemorrhoids even in a young population can lead to serious and at times fatal delays in the diagnosis of a colon cancer. Almost all patients regardless of age who present with rectal bleeding should undergo colonoscopic evaluation. In a series of 570 patients, 50 years of age or younger with rectal bleeding who underwent endoscopic evaluation, there was a 17.5% incidence of colorectal neoplasm.<sup>5</sup>

Patients undergoing stool guaiac tests for occult blood in the stool for routine screening with a positive result have a 5.1% chance of having an invasive cancer and a 24% chance of having a benign polyp.<sup>6</sup>

As mentioned previously, some of the symptoms that occur may be early or late based on the distribution of cancer within the colon. There has been a more proximal shift overall of colon cancers with more tumors being in the proximal colon. The Lahey Clinic reported a 10-year representative anatomic site distribution in which the cancer was located in the right colon in 18%, the transverse colon in 9%, the descending colon in 5%, the sigmoid colon in 25%, and the rectum in 43%.<sup>7</sup>

## Staging and Prognostic Factors

### Evolution of Staging Systems

The original staging system for colorectal cancer was reported by Cuthbert Dukes in 1930 and then revised by him in 1932.<sup>8</sup> This classification had three stages: A, B, and C. Stage A had the cancer limited to the bowel wall, Stage B had cancer that spread by direct extension to extrarectal tissues,

and Stage C had cancer with regional lymph node metastasis. Dukes further revised the classification in 1944 to subdivide the Stage C group into those with positive regional lymph nodes below a ligature (C1) and at a ligature (C2). In addition a more advanced stage, Stage D was added for distant metastases.

Others have subsequently modified the Dukes' staging system in an attempt to further stratify, prognosticate, and treat patients with a more useful system. The most common modification is known as the Astler Collier Modification.<sup>9</sup> In this modification, the Dukes' B and Dukes' C tumors are subdivided into two groups, each with Dukes' B having depth of tumor invasion into but not through the colonic wall with (B2) or without (B1) lymph node involvement. Similarly, Dukes' C tumors with full-thickness tumor invasion involving lymph nodes, Stage C2, and when they are not C1. Although both the Dukes' and modified Dukes' staging systems are still used, the TMN staging system is the preferred method of colorectal cancer staging.

## Current Staging Systems

The TNM classification is the system developed by the American Joint Committee on Cancer (AJCC) and the International Union Against Cancer (UICC). It utilizes three descriptors based on each letter in the name, T for tumor depth, N for nodal involvement, and M for metastases. Based on a combination of T, N, and M for any given tumor, an overall stage from Stage I to IV can be determined. The most recent AJCC/UICC definitions were published in 2002.<sup>10</sup>

The T stage can be divided into seven possible categories based on the depth of invasion. Tis, carcinoma in situ, represents a nonmalignant tumor, T1 has invasion into the submucosa, T2 has invasion into the muscularis propria, T3 has invasion into the subserosa or nonperitonealized pericolic or rectal tissue (through the bowel wall). T4 has invasion of other organs or structures. The T3 category can be further subdivided by the depth of penetration into the muscularis propria. The N stage can be divided into three categories. N0, with no lymph node involvement, N1 with 1–3 lymph nodes involved, and N2 with 4 or more lymph nodes involved. The M stage is only divided into two categories, either no metastases (M0) or distant metastases (M1).

Typically, the combination of T, N, and M will lead to one of four stages based on the combination of findings. Stage 0 is Tis, N0, and M0. Stage 1 is T1 or T2, N0, M0. Stage 2 is T3 or T4, N0, M0. Stage 3 is Any T, N1 or N2, and M0. Stage 4 is Any T, Any N, and M1. In the most recent AJCC/UICC Definitions, Stage II and III are subdivided into two Stage II categories: Stage IIA (T3, N0, M0) and Stage IIB (T4, N0, M0); and three Stage III categories: Stage IIIA (T1 or T2, N1, M0), Stage IIIB (T3 or T4, N1, M0), and Stage IIIC (Any T, N2, M0).

The importance of staging is for treatment planning and prognosis.

## Clinical Prognostic Factors

### Age

As with many cancers, colon cancer incidence increases with increasing age. Most series report a mean age in the sixth decade for nonhereditary colon cancer. Patients with familial adenomatous polyposis (FAP) will present with colon cancer in their mid to late 30s if colectomy is not performed before this age. Patients with hereditary nonpolyposis colorectal cancer (HNPCC) can present at any age but tend to have colon cancer between the ages of 40 and 60, significantly younger than individuals with nonhereditary colon cancers.

It has been reported that younger patients present with worse tumors being of more advanced stage and grade. However, recent studies refute this claim. O'Connell et al.<sup>11</sup> recently reported using SEER data a comparison of two groups of patients with colon cancer. The SEER database is a prospectively entered database of the National Cancer Institute in the United States and stands for Surveillance, Epidemiology, and End Results. They compared outcome in patients 20–40 years of age to those 40–60 years of age. Although there was an increased incidence of higher stage tumors, stage for stage they had an equivalent or improved 5-year survival.

### Symptoms

Obstruction and perforation are poor prognostic signs often associated with advanced disease. In addition, because patients are operated on in an urgent manner, their operative morbidity and mortality is increased. Chen and Sheen-Chen<sup>12</sup> reported on outcome in patients with obstructing and/or perforated colon cancer. Perforated cancers had a 9% operative mortality compared with obstructed cancers of 5%. Overall 5-year survival was 33% in each group, approximately 2 times the expected rate based on similar stages in noncomplicated cases.

### Blood Transfusion

Blood transfusions can cause immunosuppression in the postoperative period which may allow for an inability to combat tumor cells shed at the time of surgery and theoretically lead to a worse prognosis. Sibbering et al.<sup>13</sup> reported on 266 patients with colon cancer, some of whom received blood transfusions and others that did not. There was no difference in survival comparing the two groups. However, Chung et al.<sup>14</sup> reviewed 20 papers, representing 5236 patients supporting the hypothesis that perioperative blood transfusions are associated with an increased recurrence and death from colon carcinoma.

### Adjacent Organ Involvement

Local extension of colon carcinoma can involve any structure or organ adjacent to the primary tumor. It occurs in 5%–12% of colorectal cancers. All tumors with local extension would

be considered T4. For right colon cancers, the most frequently involved structures are the liver, duodenum, pancreas, and abdominal wall. Kama et al.<sup>15</sup> reported a 75% disease-free survival of 14–41 months after en bloc pancreaticoduodenectomy and right colectomy. Similarly, Izbicki et al.<sup>16</sup> reported on 83 patients with colorectal cancer undergoing extended en bloc resections. Comparing extended to nonextended resections; mean survival of both groups was around 45 months conferring the benefit of extended resections when necessary to achieve R0 resections. These data were supported by Kroneman et al.<sup>17</sup> who found 4-year survival was 33% after en bloc resection compared with those receiving noncurable resections of 6 months.

## Histologic/Biochemical/Genetic Factors

### Histologic Grade

Broders described classifying adenocarcinomas by the degree of differentiation. He described four grades based on how much of the tumor had differentiated cells within it. Today three grades are used and include Grade 1 with well-differentiated features, Grade 2 moderately differentiated, and Grade 3 poorly differentiated. The vast majority of colon cancers are moderately differentiated (Grade 2) with preservation of gland-forming architecture. However, the amount of preservation of this architecture is variable and when absent leads to sheets of invasive cells classified as poorly differentiated. The degree of differentiation corresponds to prognosis. Poorly differentiated tumors have a worse prognosis stage for stage compared with better differentiated tumors.<sup>18</sup>

### Mucin Production and Microsatellite Instability

Microsatellite instability, known as MSI, is associated with HNPCC. MSI is an alteration in mismatch repair genes which are important to repairing errors in replication. When altered, they can lead to colorectal cancer. Because there is loss of one of the two alleles in HNPCC, these patients tend to present earlier in life, with multiple colonic and extracolonic cancers. Many HNPCC cancers are mucin producing which when present have a better prognosis compared with non-mucin-producing tumors in these patients.

### Signet-cell Histology

Signet-ring or signet-cell tumors have a worse prognosis in many intestinal cancers. Signet-cell tumors tend to be of a more advanced stage when discovered. In a comparison between signet-ring and non-signet-ring colon cancers, it was noted that patients with signet-ring cancers were younger, had more advanced stages, and an increased incidence of liver metastases.<sup>19</sup> In addition, the rate of curative resection was

lower at 35% compared with 79%. This rate was similar to poorly differentiated tumors at 46% at 5 years. In another study, the risk of peritoneal seeding was higher in signet-cell tumors leading to a high incidence of palliative resections and a mean survival of 16 months.<sup>20</sup>

### Venous Invasion

Blood vessel invasion has been linked with poor prognosis both independently as well as with its association with lymph node metastasis. Blood vessel invasion can occur intramurally within the wall of the colon itself or in the surrounding tissue. Although arterial invasion occurs, most series define and describe vascular invasion based on venous invasion. Venous invasion in colon cancer occurs in 42% of patients and increases with increasing grade and stage.<sup>21</sup> Patients with blood vessel invasion had a 74% survival compared with those without it at 85%. In those patients with both intramural and extramural vascular invasion, the prognosis was even worse at 32%.

### Perineural Invasion

The growth of tumor along perineural spaces is known as perineural invasion and, similar to venous invasion, it increases with increasing grade and stage of the tumor. It occurs in 14%–32% of colorectal cancers and can extend to as far away as 10 cm from the primary tumor. Numerous studies have confirmed poorer prognosis when perineural invasion is noted.<sup>22,23</sup>

### Lymph Node Involvement

Lymph node metastasis has been long understood to be one of, if not the most, important prognostic factors in colon cancer outcome. All currently utilized staging systems as described above for colon cancer use and rely on the presence or absence of lymph node metastases. It is therefore important to adequately remove the lymph node bearing tissue associated with the underlying colon cancer. It has been reported by Scott and Grace<sup>25</sup> that, if 13 lymph nodes are not recovered, adequate staging cannot be performed. The main determinant for an adequate lymph node harvest is surgical but a variety of means to enhance the yield have been developed and include fat clearance with xylene, other chemicals, and polymerase chain reaction techniques.<sup>26</sup> Using these techniques, more lymph nodes, or lymph nodes not found by standard techniques, can be discovered, improving the accuracy of staging and allowing for better prognosis and application of adjuvant treatment.

### Carcinoembryonic Antigen

Carcinoembryonic antigen (CEA), a glycoprotein absent in normal colonic mucosa but present in 97% of patients

with colon cancer, was discovered in 1965.<sup>27</sup> CEA increase correlates with either disease that has metastasized to the liver or with very large tumors. Patients with disease confined to the colonic mucosa or submucosa will have increased CEA in 30%–40% of cases. It is therefore not useful for screening but can be used to follow patients with colon cancer. In patients with increased CEA preoperatively and localized disease that is resectable, the CEA should decrease after surgery. If the CEA level does not decrease, then occult metastases may be present and may be an indication for adjuvant therapy. The absolute level of CEA is also important. A CEA of greater than 15 mg/mL predicts an increased risk of metastases in otherwise apparently curable colon cancer.<sup>28</sup> A normal preoperative CEA may become increased with metastatic disease. Controversy exists as to the utility of following CEA postoperatively because it may not allow any advantage to salvage or treatment when compared with symptomatic recurrences.<sup>29</sup> Despite that, the routine periodic CEA measurement is endorsed by the American Society of Colon and Rectal Surgeons in their Practice Parameters.<sup>30</sup>

### Sentinel Node

The idea of a sentinel lymph node being present and if identified be able to predict lymph node metastases has become standard of care in breast cancer and melanoma. Its application to colon cancer is in its infancy and may be less important in colon cancer than these others. The idea that the lymphatic drainage can be mapped and the first node identified has significance in oncologic surgery. In colon cancer, resecting the associated lymphovascular pedicle with the primary cancer is considered paramount to performing an adequate operation; this adds little to no morbidity unlike excising level 3 nodes in breast cancer patients. In an attempt to validate the sentinel lymph node theory in colon cancer, Paramo et al.<sup>31</sup> reported on their experience with 45 patients who underwent intraoperative sentinel lymph node mapping using isosulfan blue dye. Sentinel lymph nodes were identified 82% of the time and predicted regional metastases in 98% of cases, with only a single case of a false-negative sentinel lymph node. Others have agreed that its utility may be marginal in colon cancer.<sup>32</sup>

### DNA Ploidy

Normal cells are made up of diploid cells. Tumors can maintain normal diploid cells or can be aneuploid. Numerous studies show that nondiploid tumors have a worse prognosis and correlate with more advanced Dukes' stage.<sup>33</sup>

### Spreading Patterns

Colon cancer can spread via a variety of pathways. Spread can be local or distant based on these pathways.

### Intramural Spread

Intramural spread is the tumor spreading along the bowel wall either proximally or distally in one of the bowel wall layers. Like rectal cancers, colon cancer rarely spreads this way. In a study of 42 colorectal cancers of which 64% were colonic, the maximum extent of intramural spread was 2 cm.<sup>34</sup> This supports the practice of excising 5 cm or more of colon on either side of a tumor to decrease the risk of anastomotic recurrence.<sup>36</sup>

### Transmural Spread

As they become more advanced, colon cancers invade the colonic wall. Almost all colon cancers start as a mucosal lesion and then penetrate a variable degree into deeper layers of the colonic wall. This colonic wall invasion is the basis of many of the currently used staging systems including the Dukes' and TNM. Transmural spread is the mechanism that produces T4 tumors. T4 tumors penetrate full thickness into the colonic wall and then by direct extension or adherence, invade into other structures in proximity to the primary tumor. When present, en bloc resection is mandatory for an R0 resection. Preoperative evaluation can sometimes predict adjacent organ involvement but often it is an intraoperative finding.

### Margins

The acceptable bowel wall margins are dictated by three issues: first, thickness of penetration of the bowel wall margin and the risk based on the distance of local tumor spread intramurally. As described above, colon cancer rarely invades proximally or distally along the bowel wall for more than 2 cm. Convention has led to the recommendation that proximal and distal margins be a minimum of 5 cm. It has been stated that the "ideal extent of a bowel resection is defined by removing the blood supply and the lymphatics at the level of the origin of the primary feeding arterial vessel."<sup>35</sup> These other two factors may modify the length of the proximal and/or distal margins because further resections may be required because of these issues.

### Radial Margins

The circumferential margins are important to both colon and rectal cancer, but most series and studies have been confined to rectal cancers. It has been shown that positive circumferential margins in rectal cancer are associated with local recurrence rates as high as 85%.<sup>36</sup> In colon cancer, the radial margins are less important with the exception of T4 tumors where en bloc resection is required. Typically for colon cancer, the only radial margin that may be involved in a tumor less than T4 are those tumors with serosal involvement. In 279 patients with colon cancer, serosal involvement was not associated with a poorer outcome, and outcome was related only to tumor stage.<sup>37</sup>

## Transperitoneal/Implantation

Tumors with serosal involvement can shed viable tumor cells which can spread throughout the peritoneal cavity and implant on a variety of structures. Usually, tumors will implant on the ovaries, omentum, serosal, or peritoneal surfaces. When widespread, this is known as carcinomatosis. When localized to the ovaries which occurs in 3%–5% of patients, bilateral oophorectomy should be performed. In a recent series, 86% of patients with ovarian metastases had transmural extension of the primary colon cancers.<sup>38</sup>

## Lymphatic

Lymphatic invasion is the most common mechanism leading to metastatic disease. Lymphatics exist within the colonic wall and lymphatic invasion correlates with the depth of penetration of colon cancers. T1 tumors have a risk of lymph node involvement up to 9%, T2 up to 25%, and T3 up to 45%. Most currently used staging systems assign increased stage to increasing T stage and lymph node involvement and prognosis correlates with the overall stage. The lymphatic drainage goes along the venous drainage of the colon, ultimately coursing through the portal vein and into the liver. Metastatic liver disease is believed to occur typically as a result of lymphatic spread.

## Hematogenous

Hematogenous spread of colon cancer is less common than lymphatic spread. Hematogenous spread will bypass the liver and allow tumor cells to go peripherally into the systemic circulation. This is thought to be the mechanism for the development of pulmonary metastases.

## Metastatic Evaluation

Once diagnosed with colon carcinoma, a search for metastatic disease is often performed. This assessment includes a variety of imaging studies, laboratory tests, and endoscopic procedures.

## Detection and Management of Synchronous Lesions

Synchronous polyps and cancers occur in patients with colon cancer. Most colon cancers are diagnosed by colonoscopy and the remainder of the colon is evaluated at the same time by colonoscopy. However, if an obstructing lesion is noted that will not allow a colonoscope to pass, evaluation of the more proximal colon may be jeopardized. Alternatives to evaluating the remainder of the colon in these instances include contrast enemas, virtual colonoscopy, or intraoperative colonoscopy at the time of resection. In a series of 158 patients with incomplete colonoscopies, barium enema was used to examine the

remainder of the colon. Six lesions greater than 1 cm were identified with five of six being proximal cancers or advanced adenomas.<sup>40</sup> Virtual colonoscopy was used in 34 patients suspected of colon cancer with incomplete colonoscopies. Virtual colonoscopy identified all primary and three synchronous tumors proximal to the primary tumor.<sup>40</sup> When a colon cancer is diagnosed by colonoscopy, synchronous cancers occur in 6% or fewer of patients. When present, it should raise the suspicion of possibly HNPCC which is associated with synchronous colon cancer. When synchronous colon cancer is diagnosed, the treatment should consider a subtotal colectomy.

## Distant Metastatic Disease

Distant metastatic disease associated with colon cancer is almost always either liver or lung metastases. Although bone, brain, and other organ involvement can occur, it is rare and therefore the search for these metastases in an asymptomatic patient is unwarranted. The search for liver and lung metastases can be accomplished by a variety of imaging studies including ultrasound, computed tomography (CT) scan, magnetic resonance imaging (MRI), chest X-ray, and positron emission tomography (PET) scans. Each test has different abilities, availabilities, and costs.

## Liver Metastases

The first available test for the evaluation of the liver for metastases is surface ultrasound. Surface ultrasound is available in almost all institutions; however, its accuracy compared with newer modalities is lower in comparative studies comparing it with CT and liver scans.<sup>41,42</sup>

CT scan is the most frequently used method to preoperatively and postoperatively determine the presence or absence of liver metastases associated with colon cancer. There are numerous advantages to cross-sectional imaging such as CT over ultrasound and include the ability to find abdominal wall or contiguous organ invasion as well as liver metastases. Standard CT scan is 64% sensitive in identifying liver lesions larger than 1 cm. MRI of the liver has been poorly studied and is not typically used in the evaluation of liver metastases.

## Lung Metastases

Lung metastases occur in 3.5 % of patients with colon cancer<sup>43</sup>; there are limited data on the utility of plain chest radiographs or CT scans in the initial evaluation of the lungs for metastatic disease. CT scan clearly has advantages over plain radiographs and can identify and characterize lung pathology better than plain X-rays. Given that most patients will undergo CT imaging of the abdomen before surgical intervention, the addition of imaging of the chest via CT seems reasonable. One must be careful about the amount of intravenous contrast when simultaneously scanning multiple regions such as chest, abdomen, and pelvis.

## PET Scans

PET scans are currently approved only for patients with suspected metastatic disease and not for the use in primary staging of colon cancer. However, based on the data from studies looking at patients with metastatic disease, PET scans may have a role in determining if any metastatic disease exists at the time of initial diagnosis.

## Appendix: Practice Parameters for the Detection of Colorectal Neoplasms

Prepared by The Standards Committee, The American Society of Colon and Rectal Surgeons

Drs. Clifford L. Simmang and Peter Senatore, Project Directors; Ann Lowry, Chair; Terry Hicks, Council Representative; Marcus Burnstein, Frederick Dentsman, Victor Fazio, Edward Glennon, Neil Hyman, Bruce Kerner, John Kilkenny, Richard Moore, Walter Peters, Theodore Ross, Paul Savoca, Anthony Vernava, W. Douglas Wong

Colorectal cancer is the most preventable visceral cancer, and its incidence makes it one of the most important. The lifetime probability of an individual developing colorectal cancer is 5%–6%, translating into an estimated 133,500 new cancers of the colon and rectum diagnosed annually. It is further estimated that 54,900 people will die of their cancer each year. Although the incidence was relatively stable during the last half of the 20th century, there seems to have been a decrease during the past decade. Mortality is also decreasing, which suggests greater awareness of the disease and improved detection. Nevertheless, 65% of patients present with advanced disease. It is also reported that when the disease is localized, the 5-year survival rate is approximately 90% for colon cancer and 80% for cancer of the rectum. Most cases are diagnosed after 50 years of age. Although the results of some investigations have not demonstrated a reduction in mortality with screening, those statistics do not reflect the number of patients who are spared from death by early detection and endoscopic removal of polyps, which blunts the adenoma-to-carcinoma sequence.

A consortium of five medical societies (American College of Gastroenterology, American Gastroenterological Association, The American Society of Colon and Rectal Surgeons, American Society for Gastrointestinal Endoscopy, and Society of American Gastrointestinal Endoscopic Surgeons) responded to a request for a proposal from the Agency for Health Care Policy and Research to develop national guidelines for colorectal cancer screening. An interdisciplinary panel of 16 health care professionals from the fields of medicine, nursing, consumer advocacy, health care economics, behavioral sciences, and radiology evaluated the currently available evidence for colorectal cancer screening and made recommendations for physicians and the public. The panel studied 3500 peer-reviewed published articles and analyzed 350 articles in detail specifically assessing the following: 1)

performance of screening tests; 2) effectiveness of screening tests; 3) acceptability to patients; 4) cost effectiveness; and 5) outcome. A computer simulation of the consequences of conducting the various screening strategies in the population was done to determine the risks and benefits of each test. The guidelines made recommendations for people in two groups: average individuals and individuals at increased risk for developing colorectal cancer. All screening strategies, including annual fecal occult blood testing, screening sigmoidoscopy every 5 years, screening by both annual fecal occult blood testing and flexible sigmoidoscopy (every 5 years), double contrast barium enema every 5–10 years, and colonoscopy every 10 years were found to have a net benefit. The panel analyzed an Office of Technology Assessment study for screening average-risk individuals, which demonstrated that costs associated with colorectal cancer screening are within the range of cost effectiveness frequently accepted for other tests, such as mammography.

Recently revised colorectal cancer screening guidelines from the American Cancer Society have been announced. The new guidelines divide the population into three categories—average, moderate, and high risk—with specific recommendations for each. The American Society of Colon and Rectal Surgeons endorses the colorectal cancer screening guidelines by the American Cancer Society, which were based in part on “Colorectal Cancer Screening and Surveillance Clinical Guidelines and Rationale” published by the consortium and specialty societies and discussed above. Guidelines governing the detection of colorectal neoplasms as set forth by The American Society of Colon and Rectal Surgeons Task Force are presented in Table 27-1.

## Low-Risk Individuals

For low-risk asymptomatic persons, screening should begin at the age of 50. Low-risk or average-risk patients are those who are asymptomatic, age 50 or older, have a family history of colorectal cancer limited to non-first-degree relatives, and no other risk factors (65%–75% of people). Annual digital rectal examination should be performed. In addition, fecal occult blood testing (FOBT) should be performed annually. Yearly testing is chosen because the randomized trials show that yearly testing is more effective for decreasing mortality than testing every 2 years. Rehydration improves the sensitivity of the test at the expense of specificity. Dietary avoidance of rare meat, turnips, melons, horseradish, salmon, and sardines can decrease the rate of false-positive test results. Aspirin and other nonsteroidal drugs should also be avoided. Diagnostic workup of positive FOBT results should include an evaluation of the entire colon. Double-contrast barium enema can examine the entire colon with relatively high sensitivity and specificity for large polyps (>1 cm) and cancers and is less expensive than colonoscopy. However, it is not possible to biopsy or remove neoplasms during the same procedure, so

TABLE 27-1. Screening guidelines

Risk	Procedure	Onset (age, yr)	Frequency
I. Low or average: 65%–75%	Digital rectal exam <i>and</i> one of the following:	50	Yearly
A. Asymptomatic: no risk factors	Fecal occult blood testing and flexible sigmoidoscopy	50	FOBT yearly, flex-sig every 5 yr
B. Colorectal cancer in no first-degree relatives	Total colon exam (colonoscopy or double contrast barium enema and proctosigmoidoscopy)	50	Every 5–10 yr
II. Moderate risk: 20%–30% of people			
A. Colorectal cancer in first-degree relative, age 55 or younger, or two or more first-degree relatives of any age	Colonoscopy	40 or 10 yr before the youngest case in the family, whichever is earlier	Every 5 yr
B. Colorectal cancer in a first-degree relative older than age 55	Colonoscopy	50 or 10 yr before the age of the case, whichever is earlier	Every 5–10 yr
C. Personal history of large (>1 cm) or multiple colorectal polyps of any size	Colonoscopy	1 yr after polypectomy	If recurrent polyps, 1 yr If normal, 5 yr
D. Personal history of colorectal malignancy, surveillance after resection for curative intent	Colonoscopy	1 yr after resection	If normal, 3 yr If still normal, 5 yr If abnormal, as above
III. High risk (6%–8% of people)			
A. Family history of hereditary adenomatous polyposis	Flexible sigmoidoscopy; consider genetic counseling; consider genetic testing	12–14 (puberty)	Every 1–2 yr
B. Family history of hereditary nonpolyposis colon cancer	Colonoscopy; consider genetic counseling; consider genetic testing	21–40 40	Every 2 yr Every yr
C. Inflammatory bowel disease			
1. Left-side colitis	Colonoscopy	15th	Every 1–2 yr
2. Pancolitis	Colonoscopy	8th	Every 1–2 yr

FOBT, fecal occult blood testing; Flex-sig, flexible sigmoidoscopy.

that patients with abnormalities must undergo an additional examination by colonoscopy to establish the diagnosis and provide treatment. Adding flexible sigmoidoscopy to double-contrast barium enema increases sensitivity, but the magnitude in clinical importance of the additional sensitivity is uncertain. For these reasons, colonoscopy, which can examine the entire colon with few false-negative or false-positive findings and can provide definitive treatment of polyps and some cancers during the same procedure, is usually chosen. For patients who have negative FOBT results, flexible sigmoidoscopy performed every 5 years is recommended. A 5-year interval is chosen because of the observation that few polyps arise and progress to advanced cancer in a 5-year period. If a polyp is identified, it should be biopsied. If the pathologic diagnosis is a hyperplastic polyp, then no additional evaluation is required. If the pathologic diagnosis is an adenoma, then colonoscopy should be recommended.

Colonoscopy permits visualization of the entire colon directly, along with detection and removal of polyps and biopsy of cancers throughout the colon. It can be considered for screening of average-risk individuals. An interval of 10 years has been chosen for asymptomatic, average-risk people because of strong direct evidence that few clinically important

lesions are missed by this examination and that it takes an average of approximately 10 years for an adenomatous polyp, particularly one <1 cm in diameter, to transform into invasive cancer. In addition, a controlled trial has shown a very low incidence of advanced adenomas during surveillance follow-up colonoscopy after an initial examination with negative results.<sup>20</sup> Indirect evidence from the National Polyp Study indicates that few polyps will arise and progress to advanced cancer in less time in patients with no special risk factors.

## Moderate-Risk Individuals

Patients at moderate risk for cancer are those who have one or more first-degree relatives with colorectal cancer or personal history of colorectal neoplasia (20%–30% of people).

## Colorectal Neoplasia in a Close Relative

People with a first-degree relative (sibling, parent, or child) who has a colorectal cancer or adenomatous polyp should be offered the same options as average-risk people, but with

several important differences. Those people with two or more affected close relatives or with an affected close relative younger than age 55 are at even further increased risk, and surveillance should begin at the age of 40 years or 10 years before the youngest case in the family, whichever is earlier. Colonoscopy is the recommended procedure of choice in this situation. If colorectal cancer is detected in a close relative older than age 55, then screening should begin with colonoscopy at the age of 50 or 10 years before the age of the case, whichever is earlier.

## Patients with Other Risk Factors

Patients with prior endometrial, ovarian, or breast cancer and those who have had pelvic radiation, could be followed up according to the guidelines established for patients with a family history of colon cancer. Patients with a ureterocolonic anastomosis should be followed up yearly with flexible sigmoidoscopy as a minimum and colonoscopy if the area of anastomosis cannot be visualized by sigmoidoscopy. Total colonic examination may be recommended for patients with acromegaly, *Streptococcus bovis*, *Streptococcus sanguis*, or a *Clostridium septicum* bacteremia, schistosomiasis, extramammary perianal Paget's disease, and dermatomyositis.

## Polyp Surveillance

For patients who have had a neoplasm identified by sigmoidoscopic examination, a biopsy should be performed. If the pathologic finding is an adenoma, then a colonoscopy should be performed. For a polyp detected during a barium enema examination, a colonoscopy is the recommended procedure. Colonoscopy can directly inspect the entire colon for the presence of synchronous lesions and allow the removal of polyps or biopsy of a larger neoplasm. If a large (>1 cm) polyp is removed, or if multiple polyps of any size are identified and removed, colonoscopy should be repeated 1 year later. If a single, small (<1 cm), tubular adenoma is identified and removed, colonoscopy should be repeated in 3–5 years. If the results of this examination are normal, then colonoscopy should be repeated every 5 years. The finding of an adenoma at any of the follow-up examinations may prompt yearly colonoscopy until the colon is again cleared of polyps. Studies may need to be repeated when the entire colon is not visualized, when there is poor preparation or spasm, when polypectomy is deemed incomplete or complications ensue that require intervention, when there is diagnostic uncertainty, or when tumor debulking is necessary. If the pathologic diagnosis of the initial polyp is a hyperplastic polyp, no diagnostic studies are required at this time and the patient should continue appropriate screening evaluation.

If a polypectomy is performed for curative intent of an invasive cancer, follow-up colonoscopy should be performed

in 6–12 months. If these examination results are normal, colonoscopy should be repeated every 3–5 years as long as the colon remains clear. If, between total colonoscopic examinations, it is necessary to visualize high-risk sites, such as those from which a large, sessile polyp has been removed from the rectum in a piecemeal manner, sigmoidoscopy is a viable alternative.

## Personal History of Colorectal Malignancy

When the colon has been cleared by barium enema or colonoscopy before resection for cancer, colonoscopy or barium enema is performed again approximately 1–3 years after surgical resection. If the colon was not cleared before surgical resection, colonoscopy or barium enema is recommended in 3–6 months. If the follow-up examination results are normal, it is repeated in 3 years and if they are still normal, the interval between colonic surveillance can be extended to every 5 years.

## High-risk Individuals

Patients at high risk for developing colorectal cancer are those with a hereditary or genetic predisposition for development of colorectal cancer, and those patients with inflammatory bowel disease (6%–8% of people).

## Family History of FAP

FAP is characterized by the development of multiple (more than 100) adenomatous polyps in the colon and rectum. Inheritance is by an autosomal dominant manner with high penetrance.

It is recommended that endoscopic examination of the rectum and sigmoid colon be performed every 12 months beginning at the age of puberty (12–14 years). For those patients with familial adenomatous polyposis who have undergone a total abdominal colectomy with an ileorectal anastomosis, it may be desirable to examine the rectum every 6–12 months.

Definitive data regarding appropriate duration of screening is not available. As a general guideline, intense surveillance could change to routine screening at age 40 in families with uniformly severe disease. In families with variability in the severity of polyposis, screening should continue until age 60, although the interval might be increased to 2 years after age 40.

People with a family history of FAP should also be considered for genetic counseling and consider genetic testing to see if they are gene carriers. A negative genetic test result rules out FAP only if an affected family member has an identified mutation. Gene carriers or indeterminate cases should be offered flexible sigmoidoscopy as recommended above. If polyposis is present, colonoscopy is not a reliable screening

test for malignancy and prophylactic surgery is indicated, preferably before the patient is 20 years old. If genetic test results are negative, screening should be the same as for low-risk individuals.

## Family History of HNPCC

HNPCC is an autosomal dominant disease characterized by early-onset colorectal tumors, primarily in the right colon, that are frequently associated with other cancers. A common standard for the diagnosis of HNPCC, referred to as the Amsterdam criteria, is the existence of three or more relatives with colorectal cancer, one of whom is a first-degree relative and involves at least two generations, with one or more cases diagnosed before the age of 50. The Amsterdam criteria have been criticized as being too rigid, failing to take into account small families where a dominant pattern of inheritance may not be obvious and extracolonic cancers that make up the syndrome of HNPCC. When a strong family history is present, the possibility of HNPCC must be considered.

People with a family history of colorectal cancer in multiple close relatives and across generations, especially if the cancers occurred at a young age, should receive genetic counseling and consider genetic testing for HNPCC. When performed, genetic test results are positive in approximately 80% of these families. It is recommended that individuals considering genetic testing be counseled regarding the unknown efficacy of measures to reduce risks and associated issues and that care for individuals with cancer-predisposing mutations be provided whenever possible within the context of research protocols designed to evaluate clinical outcomes.

Endoscopic examination should begin between the ages of 20 and 25 years or at least 10 years younger than the family member who had colorectal cancer. The endoscopic procedure of choice is colonoscopy and this should be performed every 2 years until the age of 40 years. After the age of 40 years, colonoscopy should be performed annually. Unless genetic testing results are negative, surveillance should be performed as long as the patient's overall medical condition warrants it. Colonoscopy is selected because the cancers and precursor adenomatous polyps are both predominantly proximal to the splenic flexure.

## Inflammatory Bowel Disease

### Ulcerative Colitis

The increased risk of developing colorectal cancer in patients with inflammatory bowel disease is well established, with a lifetime incidence of 6% in patients with ulcerative colitis (UC). Up to 1% of all cases of colorectal cancers seen in the general population may be associated with inflammatory bowel disease. The risk of developing colorectal cancer is low

until 8 years of disease duration, after which the risk increases exponentially to reach as high as 56 times that of the general population by the fourth decade of disease. The degree of risk also depends on extent of involvement and age of onset. The strongest predisposing factor for cancer is the anatomic extent of the inflammation, with patients at most risk if they have pancolitis or ulceration extending proximally to the splenic flexure and least risk if the disease is limited to the rectum and sigmoid colon. Because the risk of developing dysplasia or cancer increases with longer disease duration, efficient surveillance calls for more frequent testing as the risk increases with duration. It is common practice to perform surveillance colonoscopy every 1–2 years after 8 years of disease in patients with pancolitis or after 15 years in patients with colitis limited to the left colon.<sup>6</sup> Ulcerative proctitis does not need extraordinary cancer surveillance.

### Crohn's Disease

Patients with Crohn's disease have a 20-fold increased risk of colon carcinoma over the general population; however, less than the increased risk seen with UC. Compared with sporadic colorectal cancer, colorectal cancers in Crohn's disease occur at an earlier age (48 versus 60 years), are more often located in the right colon, and are more frequently multiple. In particular, sites of stricture and fistula formation seem particularly prone to the development of carcinomas. It is clear that Crohn's disease warrants attention to risk of cancer; however, evidence for the most appropriate surveillance program is lacking. We recommend a moderate program, such as recommended for left-sided UC with surveillance colonoscopy every 1–2 years after 15 years of disease.

# Surgical Management of Colon Cancer

Anthony J. Senagore and Robert Fry

All colorectal adenocarcinomas develop from a single transformed cell which through numerous cell divisions unimpeded by cell death forms a macroscopic lesion involving the lumen of the bowel. The staging of colorectal cancer assesses the depth of penetration of the bowel wall, the involvement of regional lymph nodes, the involvement of adjacent organs, and the presence or absence of distant metastases. An increasingly wide variety of putative molecular markers for aggressiveness and metastatic potential have been analyzed; however, the most accurate prognostic indicator remains the true stage of the cancer. This fact is the basis for recognizing adequate locoregional oncologic principles when performing curative resections of colon cancer. The purpose of this chapter is to primarily address issues directly related to the safe and oncologically sound methods of performing a curative resection of a colonic carcinoma. Important and related issues, such as clinicopathologic staging systems, the role of adjuvant or neoadjuvant treatments, and molecular markers are addressed in detail in other sections of this text.

## Preoperative Preparation

Planning an operation for a patient with colon cancer requires the surgeon to have as much understanding as possible of the tumor's location in the bowel, the stage of the cancer, and the patient's physiologic status.

A variety of scoring systems are available for grading operative risk of surgical patients. The most widely applied scoring system is the American Society of Anesthesia score (1–4); however, this tool only provides information regarding the risk of an anesthesia complication given a certain physiologic status.<sup>1,2</sup> A more recent tool is the POSSUM and the modified p-POSSUM which include the additional risks related to underlying nutritional status and the performance of a colectomy.<sup>3–5</sup> These tools, although of limited specificity for the individual patient, do provide an estimation of the relative risks for both the patient and the entire surgical team.

Localization of the tumor and the histopathology are important data elements that allow preoperative selection of an operative plan and selection of the optimal resection margins. The presence of a lesion at watershed areas of vascular supply such as the hepatic and splenic flexures may require more extensive resection of colonic length for a safe and complete oncologic procedure. An extended right or left colectomy may be indicated to remove all contributing vascular supplies. In addition, information consistent with the hereditary nonpolyposis colon cancer (HNPCC) (right-sided lesion, Crohn's-like inflammatory response, young patient, and positive family history) would support the resection of the abdominal colon rather than a simple segmental resection. This diagnosis may also be supported by special stains of the biopsy specimen which demonstrate microsatellite instability, the hallmark of the disease which develops from mutations in the DNA mismatch repair system.

Colonoscopy is widely used today and represents the optimal means of diagnosing the lesion, identifying location, providing histopathologic material, and tattooing for intraoperative localization when required. Contrast enema is another means of localizing the lesion anatomically which should be considered to localize a lesion when colonoscopy fails to clearly define the portion of bowel involved. Computed tomography (CT) allows the localization of larger lesions, identification of local organ invasion, and provides important staging information regarding the presence of extracolonic disease, particularly liver involvement. Although intraoperative ultrasound may provide this information, most surgeons will obtain a CT as a screening tool (see Practice Parameters). Although positron emission tomography has recently been approved for colon cancer staging, in isolation its role in assessing the majority of primary, curable lesions remains speculative. It may be very useful for recurrent cancer, where it is essential to determine the presence of disease outside the scope of resection and may provide evidence of widely metastatic disease when planning a radical resection. Thus, an unnecessary noncurative operation with high morbidity may be avoided.

Bowel preparation has historically been considered an essential component of the preoperative preparation of the patient with colon cancer. The performance of mechanical cleansing combined with oral antibiotics reduces the concentration of aerobic and anaerobic bacteria within the colon and has been shown to decrease the incidence of wound infection from 35% to 9%.<sup>6-8</sup> However, more recent prospective, randomized studies have questioned the additional benefit of luminal preparation, compared with the use of appropriate intravenous antibiotics administered in a timely manner. A recent metaanalysis by Bucher et al.<sup>9</sup> reviewed 565 patients with a mechanical bowel preparation versus 579 without a preparation. Interestingly, all but one study demonstrated a higher anastomotic leak rate in the mechanical preparation group with an odds ratio of 1.8.<sup>10,11</sup> Other surgical site infectious complications were also more frequent in the mechanical preparation group. However, most of these studies included high-volume polyethylene glycol in the preparation group. Similar conditions may or may not apply to bowel preparation with the lower volume sodium phosphate preparation. Selective use of mechanical bowel preparation in combination with systemic antibiotics may be justified. A mechanical bowel preparation is still advantageous for laparoscopic colectomy because the reduction in stool volume within the colon makes manipulation of the bowel easier with the small instruments and reduces the size of the extraction site.

## Surgical Technique

There are many approaches to the technical performance of each segmental colonic resection. This description will provide general technical methods and document standard anatomic landmarks that should be common to all patients.

### Right Colectomy

The patient is placed supine on the operating table. The modified lithotomy position may be useful in cases in which intraoperative endoscopy is necessary. A vertical midline incision is made sufficiently long to allow complete visualization of the operative field. A self-retaining retractor should be placed so as to allow the entire surgical team free hands to conduct the procedure. Thorough examination of the abdominal and pelvic contents should be performed. Particular attention should be given to potential metastatic sites, especially the liver. The increasing use of intraoperative ultrasound has demonstrated the superiority of liver assessment of this modality compared with clinical examination or CT. In the female patient, the ovaries should be examined not only for the risk of metastatic deposits, but also for primary neoplasms. The resectability of the tumor should be assessed with minimal manipulation of the lesion. It is important to determine the presence of disease adherent to adjacent viscera

which should be included with an en bloc resection. It is rare for cancer of the right colon to be unresectable; however, extensive involvement of the vena cava, superior mesenteric artery, or the pancreas may necessitate a palliative resection or bypass procedure.

The key to an oncologically safe and effective resection of a colon cancer requires clear lateral margins, resection of the locoregional lymph node bearing mesentery for both cure and staging, and fashioning of an accurate and well-vascularized anastomosis. Therefore, a right colectomy is required for a tumor at any location in the ascending colon. The author prefers the medial to lateral “no touch” technique. However, the section senior editor prefers the lateral to medial technique. Thus, as can be seen, both approaches are acceptable alternatives.

### *The Medial Approach*

The resection begins with exposure of the right colon mesentery by reflecting the small bowel to the left side of the abdomen. The right colic artery (present in 50% of cases) and the ileocolic vessels can be elevated from the retroperitoneum. A vertical incision is made at the root of the right colon mesentery just caudal to the third portion of the duodenum to the right of the superior mesenteric artery (see Figure 28-1). The vessel(s) is elevated off the retroperitoneum and a proximal ligation is performed at the origin off the superior mesenteric

FIGURE 28-1. The drawing demonstrates the incision made at the root of the right colon mesentery just caudal to the third portion of the duodenum to the right of the superior mesenteric artery.

artery (see Figure 28-2). The right colon mesentery is then dissected off the retroperitoneum. This will allow identification of the hepatic branch of the middle colic artery (MCA) as the transverse colon is approached rostrally. Dissection caudally toward the terminal ileum permits ligation of the ileal vascular branches. The right colon can then be released from its peritoneal attachments laterally along the right gutter and transversely over the right iliac artery and brought to the midline. The hepatic flexure suspensory ligaments should be carefully divided to avoid injury to the common bile duct and should be secured with energy or ligatures because of large veins in the ligament. The terminal ileum should be divided 5–15 cm proximal to the ileocecal valve to ensure good vascular supply (see Figure 28-3 for extent of resection). The transverse colon is divided just to the right of the main trunk of the MCA. The right branch of the MCA may be taken, if required. The attached omentum over the right side of the transverse colon should be resected with the specimen. The ileocolic anastomosis can be fashioned according to the desire of the operating surgeon. The author prefers to divide the ileum and colon with linear staplers and perform a functional end-to-end anastomosis by anastomosing the antimesenteric surfaces of the bowel segments with a linear cutting stapler and closing the remaining colotomy with a transverse application of the linear stapler. Closure of the mesenteric defect is optional but may be appropriate to prevent trusion of the small intestine around the terminal ileal vascular pedicle.

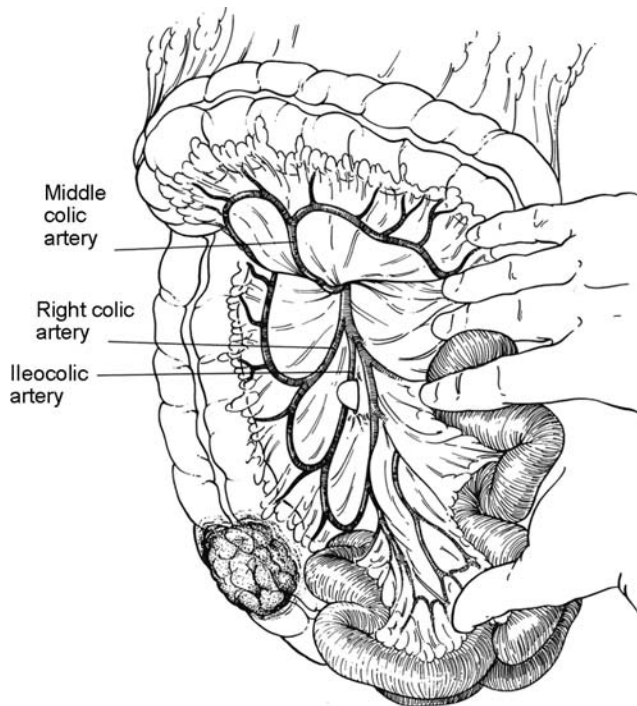

FIGURE 28-2. The vessel(s) is elevated off the retroperitoneum and a proximal ligation is performed at the origin off the superior mesenteric artery. The surgeon's finger is used to demonstrate the vascular origin for accurate placement of the ligation.

FIGURE 28-3. The drawing demonstrates the appropriate levels for vascular ligation and colonic transition for a right hemicolectomy. Notably, the transverse colon is divided just to the right of the main trunk of the MCA, although the right branch of the MCA may be taken, if required. The middle colic vessels are demonstrated and may be ligated during the performance of an extended right hemicolectomy. This leaves the descending colon in place supported by the left colic artery.

### *Lateral Approach*

Dissection of the right colon may begin laterally along the peritoneal reflection fold which attaches colon to retroperitoneum. The avascular plane between mesentery and retroperitoneum should lead the dissection over the kidney and duodenum from the lateral aspect to make the right colon a midline structure. Vascular ligation can be performed as the final step in the same sites as for the medial approach.

### *Extended Right Colectomy*

An extended right colectomy should be performed for any lesion involving the transverse colon including the hepatic and splenic flexure. This procedure requires proximal ligation of the middle colic vessels which are preserved in a standard right hemicolectomy (see Figure 28-3). Once again this accomplishes complete resection, lymph node clearance, and most importantly two well-vascularized bowel segments for anastomosis.

The operation proceeds in similar manner as the right colectomy described above. However, rather than proceeding through the transverse colon mesentery to ligate and divide the right branch of the MCA, dissection continues in the retroperitoneal plane to identify the main middle colic arterial trunk anterior to the pancreas. This vessel is ligated and

divided. The right colon is then mobilized medially as before and then the lesser sac is entered through the gastrocolic ligament outside the gastroepiploic artery so that the omentum can be resected with the transverse colon. The splenic flexure is released from the tail of the pancreas, tip of the spleen, and anterior surface of the left kidney. The left colon and mesentery are divided just proximal to the left colic artery which is preserved for right-sided lesions. The left ascending colic may be sacrificed for left transverse colon lesions preserving the left descending and sigmoid vessels, where a more distal colonic (ileosigmoid) anastomosis is desired. The ileocolic anastomosis is then constructed based on surgeon preference with functional end-to-end/side-to-side technique or end-to-end technique.

## Left Colectomy

### *The Medial Approach*

The small bowel mesentery is mobilized to the right upper quadrant to expose the origin of the inferior mesenteric artery (IMA) (Figure 28-4) located just caudal to the third portion of the duodenum (see Figure 28-4). An incision running along the base of the left colic and sigmoid mesentery from the sacral promontory to the ligament of Treitz, exposes the aorta, bifurcation of the common iliac arteries, and IMA vein. The IMA is ligated and divided proximal to the origin of the left colic artery and the inferior mesenteric vein (IMV) is ligated at the base of the pancreas. The avascular plane filled with areolar tissue is developed beneath mesentery and left colon along the entire left gutter. The left ureter is easily identified at this stage and should be freed from overlying mesentery to avoid injury before vascular ligation. The mesentery is elevated off the retroperitoneum and the sigmoid colon mobilized from the pelvic ileum. The left colon is finally mobilized medially from its lateral abdominal wall attachments and the splenic flexure is released. The attachments to the left kidney, tail of the pancreas, and tip of the spleen can be released bloodlessly. Once again, the omentum should be taken with the left transverse colon. The left MCA in the base of the transverse colon mesentery is divided to preserve blood flow to the right transverse colon from the right MCA. Occasionally, it may be necessary to divide the right MCA to allow the right transverse colon to reach the sigmoid for an anastomosis. However, an extended right colectomy and ileosigmoid or ileorectal anastomosis may be preferable if there is any concern related to the blood supply of the distal right colon as the proximal component of the anastomosis. Another alternative is to perform a retroileal right colon to rectum anastomosis if maintenance of the right colon is desired. This is performed by swinging the fully mobilized colon in a counterclockwise direction down into the pelvis to place the cut edge of the right colon mesentery across the pelvic brim (Figure 28-5). Once again the anastomosis is left to the discretion of the surgeon.

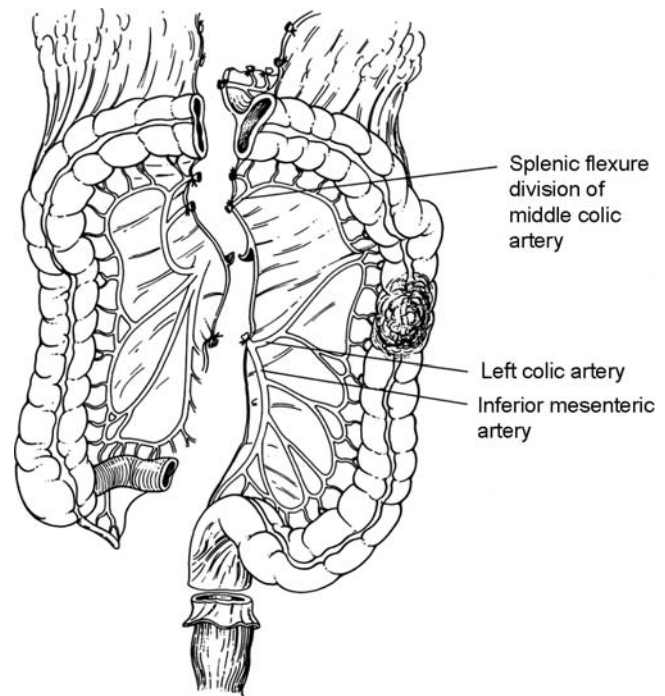

FIGURE 28-4. The small bowel mesentery is mobilized to the right upper quadrant to expose the origin of the IMA located just caudal to the third portion of the duodenum (see Figure 28-4). An incision running along the base of the left colic and sigmoid mesentery from the sacral promontory to the ligament of Treitz, exposes the aorta, bifurcation of the common iliac arteries, and IMA vein. The IMA is ligated and divided proximal to the take-off of the left colic artery. The left branch of the middle colic vessels will require ligation and division for a formal left colectomy.

### *The Lateral Approach*

An incision is made first at the attachments of the sigmoid colon at the pelvic brim and then along the left gutter medial to the white line of Toldt. An areolar tissue plane is found between the mesentery of the left colon and retroperitoneal structures which can be bluntly dissected as far as the midline. The splenic flexure is mobilized with this plane as the guide. Finally, the medial incision is made along the base of the left colon mesentery to expose the IMA and IMV as described above. The procedure proceeds as for the medial approach.

## Sigmoid Colectomy

High ligation of the IMA (Figure 28-4) is necessary when performing a sigmoid colectomy to remove all of the lymphatic drainage, and more importantly to ensure construction of a tension-free anastomosis. The ascending branch of the left colic artery should be preserved to allow retrograde blood flow via the marginal artery from the middle colic arterial supply. The splenic flexure should be released to avoid anastomotic

FIGURE 28-5. An alternative method of reconstruction that preserves the right colon is a retroileal right colon to rectum anastomosis. This is performed by swinging the fully mobilized colon in a counter-clockwise direction down into the pelvis to place the cut edge of the right colon mesentery across the pelvic brim.

tension. The sigmoid colon is mobilized to the level of the middle colic vessels medial to lateral or lateral to medial and the proximal rectum is mobilized from the sacral promontory. The patient is always in modified lithotomy position to allow transanal access for the anastomosis. An end-to-end circular stapled anastomosis can be performed between proximal left colon and rectum, after dividing the rectosigmoid junction with a transverse linear stapler. A leak test with air insufflation of a submerged anastomotic segment should be performed in all cases using either an endoscope or bulb syringe.

### Total Abdominal Colectomy with Ileorectal Anastomosis

This procedure may be required for circumstances in which the patient has been diagnosed with HNPCC, attenuated familial adenomatous polyposis, metachronous cancers in separate colon segments, and frequently in acute malignant distal colon obstructions with unknown status of the proximal bowel. The access to vascular supply and mesenteric dissection has been

described above. The terminal ileum should be sufficiently mobilized to allow easy reach to the rectum. A circular stapled end-to-end anastomosis or functional end-to-side/side-to-side anastomosis are both appropriate. Proper sizing of the circular stapler is needed to avoid ischemia and stricture.

## Special Circumstances

### Acute Obstruction

Acute colonic obstruction produces dilated bowel with a large amount of fecal loading proximal to the blockage. The associated bacterial overgrowth coupled with possible impairment of blood flow in the proximal bowel, have been the primary factors that have classically dictated resection and proximal diversion. Lee et al.<sup>12</sup> compared left- and right-sided resections managed by primary anastomosis and found similar leak rates (left 6.9% versus right 5.2%) and mortality rates (left 8.9% versus right 7.3%) when compared with historical nonobstructed controls (<2% and <1%, respectively).<sup>12-16</sup> On-table colonic lavage has been advocated as an alternative means of dealing with the obstructed colon. Several cohort studies have demonstrated the safety and efficacy of this approach for avoiding a colostomy without increasing leak rates (<5%) or sepsis.<sup>14-16</sup> Another approach at attempting to protect at-risk anastomoses has been omental wrapping. A large prospective randomized trial by Merad et al.<sup>17</sup> did not demonstrate any significant difference in anastomotic leak rates or the sequelae of those leaks. A complete resection of the tumor and obstructed proximal bowel with primary ileocolic anastomosis has been shown to be safe and carry low leak rates.<sup>18</sup>

### Prophylactic Oophorectomy

The debate continues regarding the relative risks and benefits of a prophylactic bilateral oophorectomy in women with colon cancer. The potential benefits are removal of an ovary seeded by colon cancer cells which will manifest as a delayed metastatic site and reduction in the risk of primary ovarian cancer in this age group. The data are limited for both issues. A randomized trial of prophylactic oophorectomy has shown no benefit to survival.<sup>19</sup> The risk of micrometastatic implants in the ovary increases with Dukes' stage and approaches 10%.<sup>20,21</sup> A comparison of cohorts of women with and without prophylactic oophorectomy could not demonstrate a survival advantage but a 3.2% versus 0% risk of primary ovarian cancer in survivors with ovaries not resected.<sup>22</sup> In general, prophylactic oophorectomy is not performed.

### Colon Cancer and Abdominal Aortic Aneurysm

The simultaneous presence of a colorectal cancer and abdominal aortic aneurysm which requires surgical management causes a clinical dilemma in many situations. A survey of

general surgery program directors revealed that vascular surgeons preferred to repair the aneurysm first, whereas the non-vascular surgeons preferred colectomy.<sup>23</sup> The primary risk is that performing either operation first may cause complications that significantly delay the second procedure. The risk of performing a colectomy synchronously with placement of graft material is a graft infection; however, this risk does not seem excessive based on the small data sets available.<sup>23–27</sup> In all likelihood, the best guidance suggests that any aneurysm >6 cm should be repaired first or synchronously in the face of an associated colon cancer to avoid the risk of rupture.<sup>25</sup> Endoluminal grafting of an appropriate aneurysm may eliminate the majority of these quandaries in the future.<sup>25</sup>

### Synchronous Management of Colon Cancer and Liver Metastases

The potential benefit of simultaneous colectomy and hepatectomy is the avoidance of two laparotomies and possible reduction in operative risk. Conversely, delayed management of colonic hepatic metastases offers the ability to accurately stage patients and avoid the risk of hepatectomy in a group of patients who will prove to have more widely metastatic disease in several months. Selection of patients who have limited hepatic involvement and who are positron emission tomography negative for distant disease has resulted in increased resectability and 5-year survival after hepatectomy.<sup>28</sup> The risks of simultaneous colectomy and hepatectomy do not seem to be excessive in select patients operated by expert groups.<sup>29–31</sup> However, the risks may be less with smaller nonanatomic liver resections coupled with right colectomy. Radiofrequency ablation will be discussed in Chapter 34.<sup>32,33</sup>

### Sentinel Node Assessment

Sentinel node assessment was first described as a means of improving staging and treatment for melanoma patients and is currently considered standard of care for breast cancer patients.<sup>34,35</sup> Saha described the application of sentinel node identification for colorectal cancer patients with proposed benefits of a high rate of node identification and pathologic upstaging.<sup>36</sup> The technique involves either *in vivo* injection of 0.5–1 cc of isosulfan blue dye subserosally at the periphery of the tumor (node visualization within 30–60 seconds), or *ex vivo* injection of 1–2 cc in a similar manner after the bowel has been resected.<sup>35</sup> Subsequent evaluation of the technique, including some modifications, has demonstrated false-negative rates approaching 60%, and limitations in rectal cancers.<sup>36–38</sup>

There are several concerns that restrict routine implementation of sentinel node assessment in colorectal cancer. First, there is no consensus of opinion regarding the prognostic significance of micrometastatic lymph nodes in colorectal cancer, particularly those identified by immunohistochemistry

or polymerase chain reaction.<sup>39–45</sup> Second, the relatively high false-negative rates and/or lack of node visualization mentioned previously, limit the confidence in restricting microsectioning and use of special stains to the group with stained nodes. Finally, there is insufficient evidence that the technique is sufficiently accurate to alter the extent of surgical resection.<sup>46</sup> Before sentinel node assessment can be routinely recommended, two hurdles must be overcome: 1) provision of incontrovertible evidence that micrometastatic disease identified by any technique correlates with survival; and 2) that the survival rates can be favorably impacted by an adjuvant chemotherapy regimen. Therefore, at the present time, routine lymph node mapping cannot be recommended.

### Outcome of Colectomy for Colon Cancer

In general, the operative outcome and long-term survival after resection of curable colon cancer parallels the TNM and Dukes' stage (A1, well above 90%; B2, 65%–90%; C3, 45%–75%) which may be modulated by adjuvant chemotherapy.<sup>47,48</sup> The risk of locoregional recurrence after colectomy is a rare occurrence and should be less than 5%.<sup>49–51</sup> However, the impact of the surgeon's experience and the associated expertise of the institution have recently been found to have a profound effect on outcome. High-volume surgeons, particularly those at high-volume institutions, have demonstrated significantly lower perioperative complications and an improved survival after colectomy for colon cancer.<sup>52–55</sup> A colectomy for palliation should rarely be performed and only in patients with life-threatening comorbidities or advanced incurable disease. Local extension of colon cancer may be treated with chemoradiation initially to allow eventual resection and primary anastomosis.

In addition to experience, the overall surgical approach to management of margins and extent of resection has a significant effect on outcome after colon cancer resection. The margins to be considered included proximal and distal bowel margins, radial margins, and extent of mesenteric resection which encompasses the nodal resection and proximal vascular ligation. The adequacy of proximal and distal bowel margins is primarily defined by the vascular ligation and hence the adequacy of vascular supply to the intended anastomotic segments. Although not clearly defined, it is generally agreed that 5 cm proximal and distal bowel margins are sufficient to allow resection of mural tumor spread. Grinnell originally evaluated the patterns of mural spread of tumor in the colon via lymphatics and found no instance of spread greater than 4 cm in the most advanced cases.<sup>56</sup> More recent data would suggest that mural tumor migration is rarely greater than 2 cm either proximal or distal to the palpable tumor edge.<sup>57</sup> Similarly, there is no need to resect any specific amount of terminal ileum, other than defined by vascular supply because mural spread to the ileum is a very rare event. Vascular ligation is generally performed at the origin of the primary feeder

vessel to a colonic segment. For resection of the right colon and transverse colon, the debate is relatively moot because of the constraints of the arterial origin of the right colic and middle colic arteries. Ligation for left-sided resections has been debated, primarily in sigmoid or anterior resections because ligation of the IMA may be performed at the aorta, or just distal to the left colic artery takeoff. A report from St. Marks assessed this issue in 1370 patients and found that survival was equivalent for all stages for the ligation options except for the most advanced node positive cases who fared worse with ligation at the aorta.<sup>58</sup> This counter-intuitive finding was more likely related to the higher stage of patients identified by the wider lymphatic resection. A comparison of left hemicolectomy and segmental colectomy (ligation of the IMA versus more distal) by the French Association for Surgical Research could not discern either a different survival rate or pattern based on the ligation or resection performed.<sup>59</sup> Jagoditsch et al.<sup>47</sup> demonstrated the benefits of careful surgical technique which resulted in a complete resection of all tumor (R0).<sup>49</sup> Their data demonstrated an operative mortality of 1.3% and a 5-year survival rate of 71.8% for curative operations in Stage I–III disease.

## Summary

Surgery for colonic cancer has been increasingly better defined and the data clearly support the benefits of wide mesenteric resection, clear radial margins, and resection of adherent adjacent organs. Although the precise level of proximal vascular ligation may remain debatable, it is equally clear that the major trunk vessel and the entire supporting mesentery should comprise the specimen. Attention to surgical detail coupled with improved perioperative care strategies are essential to minimizing operative morbidity and mortality.

## Appendix: Practice Parameters for Colon Cancer

Prepared by The Standards Practice Task Force, The American Society of Colon and Rectal Surgeons

Neal Ellis, MD, John W. Kilkenny III, MD, Clifford Ko, MD, Richard Moore, MD, Charles Orsay, MD, Ronald Place, MD, Janice Rafferty, MD, Jan Rakinic, MD, Paul Savoca, MD, Joe Tjandra, MD, Mark Whiteford, MD

### I. Diagnostic evaluation

### II. Preoperative assessment

Guideline—Preoperative, carcinoembryonic antigen level should be obtained. Level of evidence (Class II, Grade A)

Guideline—Evaluation with preoperative CT scanning of selected patients is indicated and routine preoperative CT scanning is optional. Level of evidence (Class II, Grade B)

Guideline—Routine performance of preoperative chest X-rays is acceptable. Level of evidence (Class III, Grade C)

### III. Preparation for operation

#### A. Informed consent

Guideline—Informed consent should be obtained preoperatively. Level of evidence (Class III, Grade C)

#### B. Mechanical bowel preparation

Guideline—Mechanical bowel preparation is nearly universally used in elective surgery. Level of evidence (Class II, Grade A)

Guideline—Outpatient bowel preparation is generally safe and cost effective. Level of evidence (Class II, Grade A)

#### C. Prophylactic antibiotics

Guideline—Prophylactic antibiotics are recommended for patients undergoing colon resection. Level of evidence (Class I, Grade A)

#### D. Blood cross-match and transfusion

Guideline—Blood transfusion should be based on physiologic need. Level of evidence (Class III, Grade C)

#### E. Thromboembolism prophylaxis

Guideline—All patients undergoing surgery for colon cancer should receive prophylaxis against thromboembolic disease. Level of evidence (Class I, Grade A)

### IV. Operative issues

#### A. Operative technique

Guideline—The extent of resection of the colon should correspond to the lymphovascular drainage of the site of the colon cancer. Level of evidence (Class II, Grade B)

#### B. Synchronous colon cancer

Guideline—Synchronous colon cancers can be treated by two separate resections or subtotal colectomy. Level of evidence (Class II, Grade B)

#### C. Contiguous organ attachment

Guideline—Colon cancers adherent to adjacent structures should be resected en bloc. Level of evidence (Class II, Grade A)

#### D. Synchronous resection of liver metastases

Guideline—Resection of synchronous liver metastases may be reasonable to perform at the time of the initial colon resection. Level of evidence (Class III, Grade B)

#### E. Role of oophorectomy

Guideline—Bilateral oophorectomy is advised when one or both ovaries are grossly abnormal or involved with contiguous extension of the colon cancer. However, prophylactic oophorectomy is not recommended. Level of evidence (Class II, Grade B)

#### F. Role of laparoscopic resection

Guideline—Relative merits of laparoscopic versus open resection for colon cancer remain unproved at this time. Level of evidence (Class II, Grade B)

### V. Operative issues—emergent

#### A. Obstructing colon cancer

Guideline—Patients with an obstructing right or transverse colon cancer should undergo a right or extended right colectomy. A primary ileocolic anastomosis can be performed in the appropriate clinical setting. Level of evidence (Class II, Grade C)

Guideline—For the patient with a left-sided colonic obstruction, the procedure selected should be individualized from a variety of appropriate operative approaches. Level of evidence (Class II, Grade C)

#### B. Colonic perforation

Guidelines—The site of a colonic perforation caused by colon cancer should be resected, if at all possible. Level of evidence (Class III, Grade C)

#### C. Massive colonic bleeding

Guideline—Acutely bleeding colon cancers that require emergent resection should be removed following the same principles as in elective resection. Level of evidence (Class III, Grade C)

#### VI. Staging of colon cancer

Guideline—Colon cancers should be staged using the TNM staging system. Level of evidence (Class II, Grade B)

Guideline—To be properly evaluated, one should strive to have a minimum of 15 lymph nodes examined microscopically. Level of evidence (Class II, Grade B)

#### VII. Adjuvant therapy

##### A. Chemotherapy

Guideline—Postoperative adjuvant systemic chemotherapy has a proven benefit in Stage III colon cancer and may be beneficial in certain high-risk Stage II patients. Level of evidence (Class I, Grade A)

##### B. Immunotherapy

Guideline—The value of immunotherapy for colon cancer is undetermined. Its use is recommended within the setting of a clinical trial. Level of evidence (Class II, Grade C)

##### C. Intraperitoneal/Intraportal Chemotherapy

Guideline—Intraperitoneal and intraportal infusions of chemotherapy are recommended only in the confines of a clinical trial. Level of evidence (Class II, Grade C)

##### D. Radiation therapy

Guideline—The role for radiation therapy in colon cancer is limited. Level of evidence (Class II, Grade C)

# The Preoperative Staging of Rectal Cancer

Jonathan E. Efron and Juan J. Nogueras

The classification of cancers of the rectum into a staging system with both therapeutic and prognostic applications has been the goal of pathologists and clinicians for the greater part of the last century. Different staging systems for colorectal cancer are in use today; however, the majority are modifications of a common framework using similar nomenclature with the unfortunate results of inconsistencies and confusion. Most staging systems rely on examination of the pathologic specimen as well as information gained during surgery. Thus, they are useful only in the postoperative setting and have little use for the purpose of preoperative therapy. Cuthbert Dukes<sup>1</sup> declared in 1932 “if it would be possible to decide the category of the case before operating, this would be very useful information.” As the therapeutic options available for the treatment of rectal cancer increase, the ability to accurately stage a rectal tumor preoperatively takes on greater importance. Accurate and reproducible preoperative staging provides uniformity among numerous investigative centers; specifically those involved in adjuvant preoperative therapy trials. Finally, the ability to stage the tumor preoperatively permits the physician to convey more accurate information to the patient and the family with regard to therapeutic options and prognosis.

The tumor-related factors of prognostic significance that are most useful in the preoperative staging of rectal cancers include the depth of penetration of the tumor through the rectal wall, the presence or absence of metastasis to the regional lymph nodes, and the presence of distant metastases. Clinicians have a variety of diagnostic tools at their disposal that can aid in delineating these aforementioned factors. The most frequently used modalities for the preoperative staging of rectal tumors available today are clinical examination, computed tomography (CT), magnetic resonance imaging (MRI), endorectal ultrasonography (ERUS), and positron emission tomography (PET).

At the time of history and physical examination, other initial evaluations are ordered. Laboratory tests including CEA

(carcinoembryonic antigen) levels and liver function tests may also provide useful information in patients with rectal cancer. There is a small risk of metastatic spread of rectal cancer to the lung, bypassing the liver, therefore a baseline chest X-ray should also be obtained.

## Clinical Evaluation

Because of its anatomic location, clinical examination of the rectum can be performed with minimal discomfort to the patient. Careful digital assessment of the rectal tumor may yield valuable information. Table 29-1 lists some of the important parameters that should be recorded during the physical examination of a rectal tumor. A clinical staging system based on tumor mobility was first established by York-Mason<sup>2</sup> in 1976 and subsequently modified in 1982.<sup>3</sup> In this clinical staging system, tumor mobility is correlated with the level of tumor penetration in the different layers of the rectal wall (Table 29-2). Nicholls et al.<sup>3</sup> evaluated this clinical staging system and discovered that senior examiners had an 80% accuracy in distinguishing CS1 and CS2 tumors from CS3 and CS4 tumors, but only a 50% accuracy in detecting lymph node metastasis. The accuracy was directly proportional to the experience of the examiner. Factors that facilitated clinical assessment were the number of quadrants involved, the mobility of the tumor, and palpable extrarectal growths. This study clearly showed that useful information can be obtained from digital examination of rectal tumors. However, certain limitations of a digital examination must be recognized. The accurate assessment of early invasion into the rectal wall has been disappointing, especially in selecting patients for local excision of such a tumor. Clinical staging is more accurate in correctly assessing the stage of more advanced lesions where local excision is not an option. Finally, only tumors of the mid and distal rectum can be assessed by digital examination.

TABLE 29-1. Tumor characteristics to assess on digital examination

Location
Morphology
Number of quadrants involved
Degree of fixation
Mobility
Extrarectal growths
Direct continuity
Separate

TABLE 29-2. Clinical staging system

Clinical stage	Mobility	Pathologic correlation (level of invasion)
CS1	Freely mobile	Submucosa
CS2	Mobile with rectal wall	Muscularis propria
CS3	Tethered mobility	Perirectal fat
CS4	Fixed/tethered fixation	Adjacent tissues

## Local and Regional Staging

### CT Scan

CT scan is helpful in providing an image of the entire pelvis and the relationship of the tumor to surrounding pelvic structures especially for advanced tumors. However, CT scan has not proven to be very accurate in determining the depth of penetration of the tumor through rectal wall or assessing involved perirectal lymph node metastasis.

Table 29-3 summarizes the results of several studies in which CT scan was used to delineate the penetration of the tumor through the rectal wall and the presence or absence of involved perirectal lymphadenopathy.<sup>4-13</sup>

The reported accuracy rate of CT scan in determining tumor penetration through the rectal wall ranges from 52% to 100%. CT scan is unable to depict the layers of the rectal wall. Thus, for tumors that are confined to the rectal wall, CT scan cannot distinguish tumors that are confined to the submucosa from those that have breached the submucosa and involve the muscularis propria. In cases of advanced tumor growth, CT scan

TABLE 29-3. Accuracy of CT scan in preoperative staging of rectal cancer

	No. of patients	T staging (%)	N staging (%)
Dixon et al., 1981 <sup>4</sup>	47	78	49
Grabbe et al., 1983 <sup>5</sup>	54	79	56
Freeny et al., 1986 <sup>7</sup>	80	62	35
Thompson et al., 1986 <sup>6</sup>	25	70	35
Holdsworth et al., 1988 <sup>8</sup>	17	94	70
Goldman et al., 1991 <sup>9</sup>	30	52	64
Zerhouni et al., 1996 <sup>10</sup>	365	74	62
Matsuoka et al., 2002 <sup>11</sup>	20	100	70
Chiesura-Corona et al., 2001 <sup>12</sup>	105	82	79
Harewood et al., 2002 <sup>13</sup>	80	71	76

does provides valuable information about the relationship of the tumor to the surrounding viscera and pelvic structures.

The accuracy of CT scan in determining lymph node involvement ranges from 35% to 70%. One drawback of CT scan is its inability to detect lymph nodes smaller than its resolution threshold of 1 cm. A second drawback of CT scan for the assessment of perirectal lymph node metastasis is its inability to differentiate between tumor metastasis and inflammation in enlarged lymph nodes.

New technology such as the multidetector-row CT (MDRCT) may significantly improve the ability of CT scans to accurately determine the depth of invasion and lymph node metastasis in rectal cancer. MDRCT utilizes four detectors which result in a much higher resolution and better multiplanar reformation of the images. Matsuoka et al.<sup>14</sup> compared 21 patients who had MDRCT with 21 patients that had MRI evaluations of the pelvis for rectal cancer. They reported an accuracy rate of 95% on depth of invasion for MDRCT versus 100% for MRI, whereas lymph node accuracy was 70% versus 61% for MDRCT and MRI, respectively.

### Magnetic Resonance Imaging

MRI is a relatively new modality for the staging of rectal cancer. Since its original description in 1986,<sup>15,16</sup> multiple studies have compared the accuracy of MRI in staging rectal cancers with other imaging modalities such as CT scan and ERUS. Accuracy rates for MRI in the preoperative staging of rectal cancer have varied according to technique.
