The traditional body coil MRI studies have ranged in accuracy from 55% to 95%.<sup>15-35</sup> The addition of an endorectal coil to this technique resulted in T stage accuracy rates of 66%–91%.<sup>17,30,32,33,36</sup> These results are listed in Table 29-4. Kim et al.,<sup>27</sup> in the largest published trial to date examining the accuracy of MRI staging of rectal cancer, compared the histopathologic staging with the preoperative staging in 217 patients. The accuracy for the depth of invasion was 81% and for regional lymph node metastasis was 63%. Their technique involved injection of intravenous contrast material and examining T1-weighted spin-echo images and T2-weighted turbo spin-echo images. Brown et al.<sup>28</sup> examined preoperative prognostic factors in 98 patients with rectal cancer using high-resolution MRI with a thin section technique. A whole body scan was performed and only T2 weighted images were examined. The accuracy rate in assessing the T stage was 94%, for lymph node involvement was 84%. In their article, Brown et al.<sup>28</sup> introduced new criteria to define MRI T staging (Table 29-5). MRI identification of metastatic lymph node involvement has not been standardized, which may explain the great variation in accuracy. Kim et al.<sup>27</sup> considered lymph node involvement if they demonstrated heterogeneous texture, irregular margins, or were enlarged to greater than 10 mm. However, Brown et al.<sup>36</sup> demonstrated that lymph node size was not an accurate predictor of metastatic disease and, therefore, they relied on mixed signal intensity and irregular or

ill-defined borders of the lymph nodes. Further studies need to be performed to determine the accurate predictors of lymph node metastasis on MRI.

In recent years, tumor involvement of the circumferential resection margin (CRM) has been identified as an important predictor of locoregional recurrence in rectal cancer patients undergoing a radical proctectomy with total mesorectal excision (TME).<sup>37-40</sup> Postoperative radiation is not effective in reducing the risk of local recurrence in patients with a positive CRM,<sup>41</sup> and a curative operation in these patients will require either tumor downstaging by preoperative chemoradiation, an extended resection, or both. Consequently, the preoperative assessment of the relationship of the tumor with the fascia propria of the rectum, the CRM in patients treated with TME, has become of utmost importance in deciding the type of neoadjuvant therapy and planning the surgical resection. The fascia propria of the rectum is well visualized by phased-array coil or endorectal coil MRI and several studies have suggested that MRI can predict with high degree of accuracy the distance of the tumor to the fascia propria of the rectum.<sup>42-44</sup> Furthermore, because of its multiplanar capabilities, MRI is the most accurate imaging technique in assessing the relationship of the tumor with the levator plate and the sphincter complex. This information may be useful in selecting patients with low rectal

cancer for a sphincter-saving procedure. Therefore, MRI with a surface coil provides useful information in patients with locally advanced rectal cancer.

### Endorectal Ultrasound

Recently, there has been much interest in the technique of ERUS for the preoperative staging of rectal tumors. This approach is proving to be safe, reliable, and relatively inexpensive. It is an outpatient procedure requiring only enema preparation and no sedation or anesthesia. The frequency of the ultrasound transducer determines its focal range and ultrasonographic resolution. Complete circular imaging of the rectal wall can be obtained with the 360-degree rotating endorectal probe. Most investigators are now using a 7.0- or a 10-mHz transducer which provides a five-layer anatomic model of the rectal wall with three hyperechoic circles and two hypoechoic concentric circles (see Chapter 7).<sup>45</sup> Hildebrandt and Feifel<sup>46,47</sup> proposed a preoperative staging classification based on the ultrasonographically determined depth of penetration to the TMN classification system (see Chapter 7).

Table 29-6 lists the results of ERUS in the preoperative staging of rectal cancer.<sup>9,13,25,47-57</sup> The accuracy of the ultrasound in determining the depth of penetration of the tumor through the layers of the rectal wall varied from 60% to 93%. As with all modalities, there is a significant learning curve associated with the interpretation of the ERUS image. Orrom et al.<sup>51</sup> at the University of Minnesota demonstrated an accuracy of 75% in the overall group; however, when they looked at their last 6 months of the study, the authors showed an improvement with a 95% accuracy in determining depth of invasion. Overall, 5% of the tumors were overstaged. This tendency to overstage tumors was a common finding throughout this series because of the inability to differentiate perirectal inflammation from tumor infiltration in the perirectal fat. Orrom et al. also point out some of the pitfalls in performing this examination.<sup>51</sup> These authors routinely use a proctoscope to introduce the ultrasound probe, thereby ensuring that a

TABLE 29-5. MRI T staging as proposed by Brown et al.<sup>28</sup>

MRI T stage
T1: Low signal in the submucosal layer or replacement of the submucosal layer by abnormal signal not extending into circular muscle layer.
T2: Intermediate signal intensity within muscularis propria. Outer muscle coat replaced by tumor of intermediate signal intensity that does not extend beyond the outer rectal muscle into perirectal fat.
T3: Broad-based bulge or nodular projection (not fine speculation) of intermediate signal intensity projecting beyond outer muscle coat.
T4: Extension of abnormal signal into adjacent organ; extension of tumor signal through the peritoneal reflection.

complete image of the tumor is obtained. This eliminates the possibility of error in the situation whereby a tumor is less invasive distally and more invasive proximally. A blind insertion of the endorectal probe has the potential to inadequately visualize the entire tumor and miss a proximal level of deeper invasion.

A longer-term follow-up of the Minnesota series was published in 2002 by Garcia-Aguilar et al.<sup>55</sup> These investigators reported their experience with 1184 patients with rectal carcinoma or villous adenoma that underwent endorectal ultrasonography. Histopathologic correlation was available for the 545 patients who had no prior radiotherapy. The accuracy of ERUS in assessing level of penetration was 69%, with 18% overstaged and 13% understaged. The accuracy for nodal involvement in the 238 patients who had radical surgery was 64% with 25% overstaged and 11% understaged. The overall accuracy in this large series is lower than previously reported. However, in this series, patients with locally advanced tumors that received preoperative radiation were eliminated from the analysis. The accuracy was higher for benign lesions, and for full-thickness lesions. Lower accuracy rates occurred for T1 and T2 lesions.

Preoperative radiation of rectal cancer causes various degrees of tumor regression resulting in scarring and fibrosis that impairs ultrasound imaging interpretation. Napoleon et al.<sup>58</sup> examined the results in determining depth of wall invasion in patients who had received radiotherapy and compared them with a group of patients with no previous radiotherapy. These authors determined that depth of wall invasion was correctly determined in 86% of patients without radiotherapy, but in only 47% of those patients in whom previous radiotherapy had been administered. Therefore, endorectal ultrasonography should be performed in the patient before receiving radiotherapy in order to increase its accuracy rate.

The accuracy in determining lymph node involvement with the ERUS varies from 68% to 83% (Table 29-6). Normal mesorectal nodes are not visualized with ERUS;

visible nodes are considered pathologic. However, ERUS cannot differentiate between inflammatory or neoplastic nodes. Hildebrandt et al.<sup>59</sup> have described different echogenic parameters in nodes that were replaced by tumor as compared with inflammatory lymph nodes. They determined that hypoechoic lymph nodes represented tumor metastases whereas hyperechoic lymph nodes represented inflammatory changes. They reported an overall accuracy rate of 78% and they attributed their errors to micrometastases, mixed lymph nodes, and changing echo patterns within inflammatory nodes.

Andersson and Aus<sup>60</sup> reported a case in which a transrectal ultrasound-guided biopsy of a hypoechoic perirectal lymph node was performed in order to verify metastatic growth in a patient who had already undergone a local excision of a rectal cancer. Harewood et al.<sup>13</sup> investigated the impact of ERUS-guided fine-needle aspiration of perirectal nodes in the preoperative staging of 80 consecutive patients with rectal cancer. In this series, fine-needle aspiration did not significantly improve nodal staging over ERUS.<sup>13</sup> Based on these results, and the potential risk of spreading cancer cells into the mesorectum in patients with metastatic lymph nodes, ultrasound-guided biopsy of enlarged perirectal nodes is not routinely used in clinical practice.

Several prospective studies have compared ERUS and MRI in the preoperative staging of rectal cancer. Surface coil MRI is less accurate than ERUS in assessing rectal wall invasion and is primarily used for the staging of locally advanced rectal cancers. MRI with endorectal coil allows visualization of the different layers of the rectal wall, and can potentially be used for the preoperative staging of early rectal cancers. Kwok et al.<sup>61</sup> performed a systematic review of the literature to compare the accuracy of several imaging techniques in the preoperative staging of rectal cancer. They concluded that ERUS has the highest sensitivity and specificity in assessing wall penetration, but MRI with endorectal coil had higher accuracy than ERUS in assessing nodal metastasis. However, MRI with endorectal coil is cumbersome to the patient, technically difficult, and not widely available.

Three-dimensional ultrasound is a new technique that has recently been developed. Kim et al.<sup>62</sup> compared the accuracy of conventional ultrasound to three-dimensional ultrasound in the staging of rectal cancer. They found no significant difference in accuracy of either depth of invasion or lymph node metastasis. Their study was small and there was a trend to higher accuracy with the three-dimensional ultrasound. Further investigation is required for the evaluation of three-dimensional ultrasound on rectal cancer staging.

## Distant Metastases

The detection of distant metastasis is of prime importance for the accurate staging of rectal cancer. The most common site of distant spread of rectal cancer is the liver.

The most frequently used imaging modalities used today to detect liver metastasis are abdominal ultrasound and CT scans. MRI and intraoperative ultrasound are now used with increasing frequency, particularly in patients with known metastasis that are considered candidates for surgical resection.

Studies that have investigated the use of preoperative ultrasonography and CT in the detection of liver metastases have reported an overall accuracy ranging from 66% to 90%.<sup>63-66</sup> Table 29-7 lists some of the results of these earlier studies. Clarke et al.<sup>67</sup> investigated the accuracy on intraoperative ultrasonography in detecting liver metastasis according to their location by anatomic liver segments. Both techniques were similar in detecting liver metastasis except for lesions located in the lateral segment of the left lobe of the liver where preoperative ultrasonography was accurate (76%) compared with CT scan (29%). The lower resolution of CT scan in the left lateral segment lesions was attributed to artifacts from the stomach and cardiac motion.

Ward et al.<sup>68</sup> from the National Institute of Health reported the results of a study evaluating preoperative CT with various enhancement techniques and MRI of the liver. All patients eventually underwent laparotomy with intraoperative ultrasonography in some cases. Correlation of the imaging techniques with surgical findings was performed to determine the specificity and sensitivity of each test. The authors concluded that the MRI examination had the lowest false-positive rate and proved to be the best hepatic imaging study in the detection of colorectal metastases.

Despite refinements in enhancement techniques of CT<sup>69</sup> and external ultrasounds, along with the addition of MRI, the resolution threshold for liver metastases remains at approximately 1 cm. For lesions in the left lateral segment of the liver, this threshold is larger. Even after preoperative imaging, up to one-third of colorectal cancer patients are found at the time of surgery to have unsuspected additional liver lesions or extrahepatic metastases. Other modalities used to detect metastatic disease not seen with conventional imaging techniques are PET scan and radioimmunoscintigraphy.

PET scans have been shown to have higher sensitivity and specificity in detecting recurrent rectal cancer than both CT and MRI.<sup>70-73</sup> Although sensitivity and specificity in diagnosing tumor recurrence are higher for PET scans, its spacial resolution is not very accurate and therefore other studies such as MRI and/or CT scans are required to define the

precise location of the tumor to important anatomic landmarks. Current scanners are available that fuse CT or MR images with the PET scan images. The ability of these fused images to increase sensitivity or specificity is being investigated. Cohade et al.<sup>74</sup> compared PET scan and PET/CT images in a series of 45 patients with colorectal cancer. They found that the overall staging accuracy increased from 78% to 89% with PET/CT. PET scans when coupled with other studies are also being used to assess the extent of pathologic response of rectal cancers that receive neoadjuvant therapy.<sup>75,76</sup> Further studies are required on this use of PET scans before any definitive conclusions can be drawn.

The impact of PET in the preoperative staging and management of rectal cancer patients has been studied by Heriot et al.<sup>77</sup> in a series of 46 patients who were assessed with PET scans at the time of their initial diagnosis. The surgical management was changed for 17% of the patients because of positive PET scan findings that upstaged the disease. These changes in management included canceling surgery and changing the field of administered radiation.

At the present time, PET scan is primarily used for the diagnosis of local and distant recurrence after curative surgery for colorectal cancer. It is also being used with increased frequency to detect distant metastasis of the time of the primary diagnosis of rectal cancer.

Immunoscintigraphy refers to the use of radiolabeled monoclonal antibodies that bind specifically to tumors to aid in detection and diagnosis. Most studies have primarily examined patients with colon cancer or either colon and rectal cancer. Few have examined primarily rectal cancer. The clinical application of this technique has been limited. Different monoclonal antibodies have been used, making it difficult to compare studies. The accuracy rate of immunoscintigraphy in detecting primary or metastatic colorectal cancers ranges from 63% to 96%.<sup>78-85</sup>

There has not been a defined role for the use of preoperative or intraoperative radiolabeled immunoscintigraphy when dealing with a primary rectal cancer. Likewise, its role in management of recurrent rectal cancer has yet to be well defined. Intraoperatively, it may enhance the surgeon's ability to assess both local and metastatic spread.

## Conclusion

The accurate preoperative tumor staging is essential to select the best therapy for the rectal cancer patient. Presently, the depth of invasion and evidence of perirectal lymph node involvement is best assessed with ERUS. Abdominal and pelvic CT scanning or MRI are also important to detect extrarectal tumor spread and liver metastasis. A chest X-ray is also important to exclude pulmonary metastasis. The role of new imaging modalities such as PET in the staging of rectal cancer patients is currently under investigation.

## Surgical Treatment of Rectal Cancer

Ronald Bleday and Julio Garcia-Aguilar

Approximately 42,000 patients each year are diagnosed with rectal cancer in the United States. Approximately 8500 die of this disease. Despite remarkable recent advances in new oncologic agents for the treatment of colon and rectal cancer, cure is almost never achieved without surgical resection. However, the current management of rectal cancer is now more varied and complex because of the new approaches with multimodality therapy and the refinements in surgical techniques. For example, small distal rectal cancers with minimal invasion can be treated with a local excision with or without adjuvant therapy. More proximal or more invasive tumors require a “radical” resection. The two most common procedures are the low anterior resection (LAR) and the abdominoperineal resection (APR). Extended resections are occasionally required for patients with cancers that invade or adhere to adjoining structures such as the sacrum, pelvic sidewalls, prostate, or bladder.

This Chapter discusses the surgical management of rectal cancer including a basic review of the preoperative evaluation and how it pertains to surgical planning, the preoperative preparation, the surgical procedures, the biology of rectal cancer as it relates to surgery, the issue of margins, and the technical nuances that need to be appreciated for a successful resection.

### Evaluation of the Patient with Rectal Cancer

#### History

The patient with rectal cancer usually presents to the surgeon after a definitive endoscopic diagnosis. The patient’s initial complaint may have been rectal bleeding, a change in bowel habits, or a sense of rectal pressure. However, with the increase in surveillance colonoscopy, many patients are completely asymptomatic on presentation. During the initial history, the surgeon should ask about certain symptoms

because it will aid in selecting the best therapy for the patient. For example, tenesmus (the constant sensation of needing to move the bowels) is often indicative of a large cancer. Constant anal pain or pain with defecation suggests invasion of the anal sphincters or pelvic floor. Preemptive procedures such as a diverting colostomy may be required in patients with these distal painful cancers. Also, cancers growing into the anal sphincter are not candidates for a sphincter-sparing procedure. Questions concerning a patient’s fecal continence should also be discussed before any therapy. Sphincter-sparing procedures can put a tremendous stress on even the most normal of pelvic floors and anal sphincters. A history of significant continence problems should prompt a discussion with the patient concerning quality of life issues. Sphincter-sparing surgery in these patients, even if technically possible, often leads to significant fecal soiling and the patient may be better served with a resection and permanent colostomy.

#### Physical Examination and Rigid Sigmoidoscopic Examination

A digital rectal examination (DRE) and a rigid sigmoidoscopy are essential to the surgical decision-making process. Both a proper examination and rigid sigmoidoscopy should be performed on the initial patient visit unless the patient has a painful invasive lesion. On DRE, fixation of the lesion to the anal sphincter, its relationship to the anorectal ring (the collection of muscles that make up the sphincters), and possible fixation to both the rectal wall and the pelvic wall can be evaluated. For mid rectal or upper rectal lesions, the DRE and rigid sigmoidoscopy can help determine how much normal rectum lies distal to the lower border of the tumor. With the combination of DRE and sigmoidoscopy at the initial visit, the surgeon can often determine whether a patient is a candidate for sphincter-sparing surgery, whether a temporary diverting ostomy is likely, and what anorectal function will be like post-treatment.

## Colonoscopy

A colonoscopy should be performed before surgical resection of a rectal cancer. Colonoscopy allows for confirmation of a malignancy through biopsy and the diagnosis and possible removal of synchronous colonic lesions. Synchronous benign polyps have been reported in 13%–62% of cases and synchronous cancers have been reported in 2%–8% of cases.<sup>1–6</sup> Even if a colonoscopy has been recently performed on a patient, the surgeon should still perform a rigid sigmoidoscopy because estimates of the location of the lesion are often misleading. For example, because of the flexibility of the colonoscope, a lesion that is described as 15 cm from the anal verge can sometimes be as close as 5 cm from the anal verge when evaluated with the rigid scope. Finally, both with a colonoscope and rigid sigmoidoscope, one should describe the distance from the lower border of the lesion to a standard distal landmark. The National Cancer Institute (NCI) consensus group recommends the use of the “anal verge” as the starting point for measuring distance; however, this anatomic landmark is variable. An alternative is to use the dentate line as the zero point and measure the distance from the lower border of the lesion to the proximal border of the anorectal ring. This distance is essentially a measure of the maximal amount of rectum that one can resect before considering an APR.

## Preoperative Staging

Preoperative staging of a patient with a rectal cancer is becoming essential in the decision-making process as adjuvant modalities become increasingly used preoperatively. Also, the range of surgical procedures that can be offered to a patient is in part dependent on the preoperative imaging. For a basic evaluation, all patients should receive a chest X-ray or chest computed tomography (CT) scan to exclude pulmonary metastases. One can obtain a carcinoembryonic antigen (CEA) level. If increased preoperatively, the CEA level should decrease to the normal range after treatment. CEA can then be followed postoperatively to detect a recurrence. Most other laboratory evaluations obtained preoperatively are useful for determining pertinent medical problems but are not very helpful in staging. By far, the most useful staging for rectal cancer is abdominal/pelvic imaging with CT, magnetic resonance imaging (MRI), or ultrasound (US)

## Imaging for Rectal Cancer

Pretreatment abdominal and pelvic imaging of the patient with rectal cancer is necessary in this era because of the increasing value of preoperative adjuvant therapies. Therapy differs depending on stage, depth of invasion into the rectal wall within a stage, size of lesion, and location of the tumor. In particular, distal and mid rectal cancer treatment management will differ depending on the preoperative staging and

imaging. For upper rectal cancers, imaging to determine stage will often not influence the treatment plan. Many of these patients with upper rectal tumors will benefit from an LAR regardless of the stage and may not require neoadjuvant therapy as often as low and mid rectal cancers.

## CT Scans

Differing opinions exist as to whether a CT scan is a useful routine assessment modality in a patient diagnosed with a rectal cancer. Some would argue that for routine, uncomplicated malignancies, a CT scan is generally not necessary, because the information obtained will not usually affect the treatment plan. This concept is probably more applicable to patients with colon cancers versus patients with rectal cancers. For rectal cancer, there may be some merit to a baseline preoperative CT scan for advanced lesions. CT scanning is quite accurate in assessing rectal tumors that have invaded adjacent organs. However, for assessment of small primary lesions, CT scanning has many limitations. CT scans do not effectively visualize the layers of the rectal wall and so do not help in evaluating the extent of rectal wall invasion of an early cancer. The overall accuracy of CT scanning in determining depth of invasion is approximately 70%. Additionally, CT scanning is limited in its ability to determine the presence or absence of lymph node metastases. Overall accuracy with CT scanning for assessing lymph nodes in rectal cancer is only 45%.<sup>7–11</sup>

The most current CT scanning, especially with dynamic contrast infusion, has a high accuracy rate in detecting liver metastases. However, abdominal US, similar to CT scan, can also detect occult liver metastases and should be used when the information obtained would alter therapeutic decisions.<sup>12</sup> MRI is also very useful in evaluating the liver before resection.

## Endoluminal Imaging

Endoluminal imaging in the form of endoluminal US and endoluminal MRI has become extremely useful in the accurate preoperative staging of a rectal cancer. These modalities allow for more precise determination of the depth of invasion and the presence or absence of mesorectal lymph node metastasis. The knowledge of these factors is critical in determining the sequence and type of therapy for any given rectal cancer.

Endoscopic US is performed with a probe that is inserted into the rectum via the anus. The patient usually has taken a small preparation to clear the rectum of stool. A water-filled balloon is inflated and pressed against the rectal lesion. A 7.0- to 10.0-MHz transducer is then used to delineate the layers of the bowel wall into five distinct lines. Localized cancers involving only the mucosa and submucosa can therefore be distinguished from those tumors that penetrate the muscularis propria or extend through the rectal wall into the perirectal fat.<sup>13</sup> A modified TNM classification has been proposed,<sup>14,15</sup>

in which a US stage T1 lesion (uT1) denotes a malignancy confined to the mucosa and submucosa, a uT2 lesion implies penetration of the muscularis propria, but confinement to the rectal wall, a uT3 lesion indicates invasion into the perirectal fat, and a uT4 lesion denotes a primary rectal malignancy that invades an adjacent organ. Studies have compared endorectal US (ERUS)<sup>16,17</sup> to DRE<sup>17</sup> and have found the US much more accurate. In a recent metaanalysis review, endoluminal US was found to be 95% accurate in distinguishing whether a tumor was confined to the rectal wall (T1, T2) versus invasion into the perirectal fat (T3 or greater).<sup>18</sup>

ERUS is less useful in predicting lymph node metastases with 80%–85% accuracy.<sup>19</sup> Endosonographically identified malignant lymph nodes are generally more hypoechoic in perirectal tissues.<sup>20</sup> However, these results are only seen with experienced operators.

Two methods of MRI can be used for the evaluation of rectal cancer. One can use the endorectal coil (ecMRI) or the surface coil MRI. The use of the MRI, either the endorectal or the surface coil, may offer some advantages compared with ERUS. First, it permits a larger field of view. Second, it may be less operator and technique dependent. And third, using the MRI may allow for the study of stenotic tumors.<sup>21–24</sup> Similar to ERUS, endorectal MRI (eMRI) can stage small-volume nodal disease and subtle transmural invasion. In general, eMRI has been more helpful in the assessment of perirectal nodal involvement than T stage. One reason is that MRI can identify involved nodes on the basis of characteristics other than size.<sup>25</sup> Reported accuracy rates of MRI for nodal staging range from 50% to 95%.<sup>24–27</sup>

Several series have compared the preoperative staging accuracy of ecMRI to ERUS in patients with rectal cancer.<sup>24,26–28</sup> In a report of 89 patients, the overall accuracy for T staging was similar (81%) for ecMRI and ERUS compared with only 65% for CT.<sup>29</sup> The accuracy for N staging was equally poor among the three modalities (63%, 64%, and 57% for ecMRI, ERUS, and CT, respectively). Somewhat similar results were noted in a series of 49 patients.<sup>28</sup> Transmural penetration was predicted by ecMRI with equal sensitivity (89%), but higher specificity (65% versus 33%) than ERUS. With both techniques, the predicted N stage had a relatively low correlation with pathologic N stage (45% versus 53%). In one report of 21 patients, ERUS seemed to be superior to ecMRI for determination of pathologic T stage (accuracy 83% versus 40%) because of better differentiation between T1 and T2 tumors. The accuracy for detecting perirectal tumor infiltration was 80% for ecMRI versus 100% for ERUS.<sup>27</sup>

The ecMRI is less operator dependent and in answering the critical question of whether a patient has Stage I versus Stage II or Stage III disease, ecMRI was 88% accurate. Those patients who were not staged correctly were usually overstaged and not understaged.

Double contrast MRI may permit more accurate T staging of rectal cancer by allowing better distinction among mucosa, muscularis, and perirectal tissues.<sup>30,31</sup> The specificity and

sensitivity of ecMRI to predict infiltration of the anal sphincter was 100% and 90%, respectively. However, N staging was not improved with this approach; the sensitivity and specificity for nodal disease being 68% and 24%, respectively.

Phased-array surface coil MRI may prove to be the option of choice for staging of more advanced rectal cancers. The technique has been useful in predicting the likelihood of a tumor-free resection margin by visualizing tumor involvement of the mesorectal fascia.<sup>32</sup>

## Preparation of the Rectal Cancer Patient for Surgery

After the diagnosis and staging of a rectal cancer, a decision needs to be made regarding optimal method of treatment. The surgical approach is dependent on the location of the tumor, its depth of invasion, and whether, in the preoperative evaluation, metastases have been discovered. Whether the patient is a candidate for a local excision or for a radical resection, the patient needs to be prepared for the procedure and the anesthetic so as to minimize perioperative and postoperative complications. Particular attention needs to be given to the patient's medical comorbidities. Unique to colon and rectal surgery is the need for a bowel preparation.

### Bowel Preparation

Before the use of mechanical preparations and perioperative antibiotics, infection rates after colorectal surgery ranged as high as 60%.<sup>33,34</sup> Currently, there are several methods used to mechanically cleanse the large intestine. These include a diet of clear liquids 1–3 days before surgery combined with one of the following: laxatives, enemas, wholegut irrigation with saline via a nasogastric tube, mannitol solutions, polyethylene glycol (PEG) electrolyte lavage solutions, or PEG-based tablets. In a survey of colon and rectal surgeons in 1990, almost two-thirds preferred the PEG solutions for their patients because of the reliability of the cleansing results.<sup>35</sup> Many surgeons today continue to use these PEG solutions as a bowel preparation. There have been two recent metaanalyses that have concluded that mechanical bowel cleansing before colorectal surgery has no significant impact on perioperative infection rates.<sup>36,37</sup> Despite these recent studies, we would still recommend that some type of colonic cleansing occur before surgery because it is easier to manipulate the bowel if it is not filled with stool. It should be emphasized that one should not force a preparation on a patient because the benefits may be minimal. Furthermore, the choice of preparation should be selected depending on the individual. For instance, large-volume lavage solutions should not be used in patients with gastric emptying problems such as gastroparesis caused by diabetes. Saline laxatives are often phosphate- or magnesium-based and should not be used in patients with renal failure.

## Antibiotic Prophylaxis

After mechanical cleansing of the large intestine, antibiotic prophylaxis is used to decrease the incidence of postoperative septic complications, because mechanical cleansing decreases the total volume of stool in the colon but does not affect the concentration of bacteria per milliliter of effluent.<sup>38</sup> Traditional prophylaxis uses an oral regimen known as the Nichols/Condon preparation. This regimen consists of neomycin 1 g and erythromycin base 1 g by mouth at 1:00 PM, 2:00 PM, and 11:00 PM on the day before surgery.<sup>39</sup> Many surgeons have substituted metronidazole 500 mg for the erythromycin base because it is bacteriocidal against a greater percentage of gut anaerobes.

Most surgeons use perioperative systemic antibiotics instead of oral antibiotics for antibiotic prophylaxis. Regimens need to include coverage for both aerobic and anaerobic gut bacteria. For long procedures, redosing should be considered depending on the serum half-life of the antibiotics used. Some have argued that double prophylaxis with both oral and intravenous antibiotics is of benefit in immunocompromised patients or in patients in whom the dissection is below the peritoneal reflection.

## Other Perioperative Issues

Besides the mechanical and antibiotic preparation of the bowel, all patients are prepared in the usual manner for major surgery. Blood loss is usually quite minimal for most elective colorectal surgery and typically patients are not asked to donate autologous blood. Cardiac, pulmonary, and nutritional evaluations are performed when necessary. Perioperative systemic antibiotic coverage is expanded in patients with high-risk cardiac lesions such as prosthetic heart valves, a history of endocarditis, or a surgically constructed systemic-pulmonary shunt, and with intermediate-risk cardiac lesions such as mitral valve prolapse, valvular heart disease, or idiopathic hypertrophic subaortic stenosis.<sup>38</sup> Intravenous ampicillin 2 g and gentamicin 1.5 mg/kg are given 1/2–1 hour before the procedure and for at least one postoperative dose. Oral anticoagulation is stopped, and patients are placed on intravenous anticoagulation or on Lovenox approximately 5 days before surgery. The heparin or Lovenox is then stopped at the appropriate time before surgery (8 or 12 hours, respectively). Depending on the individual risk of the patient and the extent of the operative dissection, anticoagulation is restarted as early as 8 hours postoperatively, but without a bolus. Careful monitoring of the patient's hematocrit and partial thromboplastin time are necessary if early reheparinization is instituted.

## Anatomic and Biologic Issues

### Surgical Anatomy

The type of operation that can be offered to a patient with rectal cancer depends not only on tumor stage, but also on the location of the tumor in relation to the surgical anatomy.

Surgical anatomy refers to the anatomic landmarks that determine resectability and sphincter preservation. The NCI consensus on rectal cancer recommended localizing the tumor relative to the anal verge which is defined as starting at the intersphincteric groove. Another important landmark defining the upper limit of the anal canal is the anorectal ring. From the surgeon's perspective, the top of the anorectal ring is the lower limit of a distal resection margin. A large, full-thickness cancer needs to be located high enough above the top of the anorectal ring to allow for an adequate distal margin if sphincter preservation is contemplated. If the dissection is to be carried lower toward the dentate line, then the tumor must be confined to the mucosa, submucosa, and superficial layer of the internal sphincter.

### Biologic Issues

It is important to understand the clinical biology of rectal cancer. "Clinical" biology, means the typical pattern of growth and natural history of the spread of the disease. Studies have shown that colon cancer frequently arises in adenomatous polyps of the colon or rectum. Also, there is a 13%–62% incidence of polyps in patients with carcinoma of the colon or rectum.<sup>40–43</sup> The variation observed in the incidence of coexisting adenomas with carcinoma of the colon or rectum depends in part on the method of study.<sup>1,2</sup> Whatever method used to study the issue, one can clearly say that the vast majority of carcinomas arise in preexisting adenomas.<sup>44–46</sup> In preparing a patient for surgery, the surgeon should have the colon completely evaluated preoperatively so as to be able to operatively treat any synchronous disease that cannot be removed endoscopically.

The biology of lymph node metastases with invasive rectal cancer is important to note and is somewhat different from that of other solid tumors such as breast cancer. Gabriel et al.<sup>47</sup> reported in 1935 that colorectal cancers tend not to have "skip" metastases. Rectal cancers usually proceeded in an orderly march from the adjacent mesorectal nodes up the lymphatic chain to the upper extent of the mesentery along the inferior mesenteric artery (IMA) and vein systems. From the surgeon's perspective, this means that early intervention along with proper locoregional resection will cure most cancers. As part of a multimodality team that now treats most solid tumors, it must be emphasized to our medical colleagues that a rectal cancer is not a systemic disease from the first abnormal cell division. Aggressive local therapy in the form of an adequate resection is still the "anchor" to any therapy.

Surgical therapy may need to be customized in patients with certain polyposis syndromes or in cancers associated with inflammatory bowel disease. With both of these conditions, a total proctocolectomy needs to be performed. Sphincter preservation can be considered in certain patients but one needs to recognize that any mucosa left intact is at an increased risk of developing cancer. The anal transitional zone needs to be biopsied to identify dysplasia. If dysplasia is

present, then a proctocolectomy with end ileostomy needs to be performed.

## Surgical Procedures: Principles

Resection of the bowel with primary anastomosis was not a common phenomenon until the late 1940s. Before that time, surgery of the colon and rectum usually meant a permanent stoma.<sup>48</sup> Recent advances have been made in the surgical techniques for rectal cancer. The result is that primary resection and anastomosis without a colostomy or ileostomy is now the rule rather than the exception.

Palliation should be the goal in a patient for whom curative resection is not possible. If the patient is a reasonable operative risk and the extent of metastatic disease is minimal, then complete but palliative resection of the primary tumor leads to a better quality of life and prevents many of the distressing symptoms of an advanced primary lesion such as obstruction, bleeding, and pain. If the primary lesion is not resectable, then diversion of the fecal stream can significantly improve the patient's immediate status. Nonoperative therapy should be considered when there is significant metastatic disease and the primary tumor is relatively small and uncomplicated. In this situation, it is likely that the patient will die of metastatic disease before a complication from the primary tumor.

## Variability in Outcome Based on Surgeon and Hospital Volume

The cancer resection margin in the extraperitoneal rectum is limited by the bony confines of the pelvis as well as by the proximity of adjacent anterior organs. In some cases, locoregional recurrence may be inevitable. However, locoregional failure may also result from incomplete surgery. There is accumulating evidence of variability among surgeons in local recurrence rates for stage-matched rectal cancers. McArdle and Hole<sup>49</sup> presented a review of 645 patients undergoing colorectal cancer resection at the Royal Infirmary in Glasgow. They observed significant variability in patients' postoperative morbidity, mortality, and ultimate survival, depending on the surgeon. The proportion of patients undergoing a curative resection varied from 40% to 76%, operative mortality from 8% to 30%, local recurrence from 0% to 21%, and anastomotic leak rates from 0% to 25%.

Hospital volume can also have an impact on colostomy rates, postoperative mortality, and overall survival as shown in a series of 7257 patients diagnosed with Stage I–III rectal cancer between 1994 and 1997.<sup>50</sup> When hospitals with the highest quartile of volume (more than 20 procedures annually) were compared with those with volumes in the lowest quartile (fewer than seven procedures annually), there were

statistically significant differences in colostomy rates (29.5% versus 36.6%), 30-day postoperative mortality (1.6% versus 4.8%), and in overall 2-year survival (83.7% versus 76.6%).

The ability to perform sphincter-sparing surgery is also affected by hospital volume. In the United States Intergroup 0114 trial of 1330 patients with Stage II or III rectal cancer participating in an adjuvant treatment trial, APR rates were significantly higher in low-volume hospitals (46% versus 32% at lowest and highest volume hospitals, respectively).<sup>51</sup> Low hospital surgical volume was only an important predictor of inferior overall or recurrence-free survival in patients who did not complete their planned adjuvant chemoradiotherapy.

## Total Mesorectal Excision

Total mesorectal excision in conjunction with an LAR or an abdominal perineal resection involves precise sharp dissection and removal of the entire rectal mesentery, including that distal to the tumor, as an intact unit.<sup>52</sup> Unlike conventional blunt dissection, the rectal mesentery is removed sharply under direct visualization emphasizing autonomic nerve preservation, complete hemostasis, and avoidance of violation of the mesorectal envelope. Its rationale is underscored by the hypothesis that the field of rectal cancer spread is limited to this envelope and its total removal encompasses virtually every tumor satellite. The reduction of positive radial margins can be reduced from 25% in conventional surgery to 7% in cases resected by TME. Furthermore, Adam et al.<sup>53</sup> showed that patients with positive radial margins were 3 times more likely to die and 12 times more likely to have local recurrence than patients without radial margin involvement.

Conventional surgery violates the circumference of the mesorectum during the blunt dissection along undefined planes. This leaves residual mesorectum in the pelvis. The higher rate of pelvic recurrence in conventional surgery is a reflection of inadequate resection and residual viable tumor burden within the pelvis. Several surgical teams using the TME technique have reported local failure rates ranging from 5% to 7% for Stage II and Stage III cancers.<sup>52–56</sup> By contrast, the North Central Cancer Treatment Group, NCCTG, control arm consisting of surgery plus radiotherapy had a local failure rate of 25% and the addition of chemotherapy only decreased the local failure rate to half that value.<sup>57</sup>

Of greater importance is the fact that improved local control seems to be translatable into improved overall survival. Survival ranges from 68% to 78% are observed among large published series when this technique is applied.

The meticulous dissection, however, is not without consequence. Prolonged operative time and increased anastomotic leak rates are noted. Anastomoses 3–6 cm from the anal verge have led up to 17% leak rates. Some centers are now routinely fashioning a protective diverting ostomy.

Conventional rectal surgery is associated with a significant incidence of sexual and urinary dysfunction. Presumably, this is related to damage to the pelvic autonomic parasympathetic and sympathetic nerves by blunt dissective forces.<sup>58</sup> Postoperative impotence and retrograde ejaculation or both have been observed in 25%–75% of cases particularly if lateral wall lymphadenectomy and splanchnic nerve resection are performed. By contrast, after TME with its careful nerve-sparing dissection, impotence has been reported in only 10%–29% of cases. A recent prospective study confirms that autonomic nerve preservation yields good results in terms of morbidity and functional outcome.<sup>59</sup>

There are well-recognized points during the rectal dissection where nerve injury can occur. The most proximal is the sympathetic nerve plexus surrounding the aorta. These sympathetic nerve trunks are also prone to injury near the pelvic brim as they bifurcate to each side of the pelvis. Intact nerves should look like a “wishbone” near the sacral promontory after a proper dissection. The clinical consequence of an isolated sympathetic nerve injury is retrograde ejaculation. If one proceeds with a dissection beneath the presacral or pelvic fascia from the sacral promontory around to the lateral pelvic sidewall, then one can injure both parasympathetic and sympathetic nerves which can result in impotence and bladder dysfunction. In the lower part of the mid rectum, the hypogastric plexus and *nervi erigentes* can be injured in the anterolateral pelvis. A radial dissection well outside the lymphovascular bundle which lies adjacent to the nerve and nerve plexus can also lead to a mixed parasympathetic and sympathetic injury. This bundle and

the nerve structure are typically located just lateral to the seminal vesicles in a man or the cardinal ligaments in a woman. Finally, a dissection anterior to both layers of Denonvillier’s fascia in a man can also put at risk the nerve and nerve plexus.

To date, all data are from prospectively gathered series and comparisons with historical controls. There are no randomized control data clearly showing benefits in terms of disease-specific and overall survival in patients undergoing TME as opposed to more conventional resection.

Adjuvant therapy has recently been shown to improve the results of TME surgery. In a two-arm, randomized study comparing TME with or without preoperative radiotherapy for resectable rectal cancer, patients receiving the combined therapy had a lower rate of local recurrence at 2 years. Subset analysis showed the most significant benefit in node-positive cancers.<sup>60</sup> The “completeness” of the TME also correlated with prognosis.<sup>61</sup> Adjuvant therapy should therefore be considered in patients undergoing TME surgery with Stage II and Stage III disease.

Figure 30-1 demonstrates schematically how the dissection should proceed. Figure 30-2 shows a cross-section of the rectum, the mesorectal fat, and the associated fascia.

### Distal Margins and Radial Margins

The extent of resection margins in rectal cancer remains controversial. Although the first line of rectal cancer spread is upward along the lymphatic course, tumors below the peritoneal reflection also spread distally by intramural or

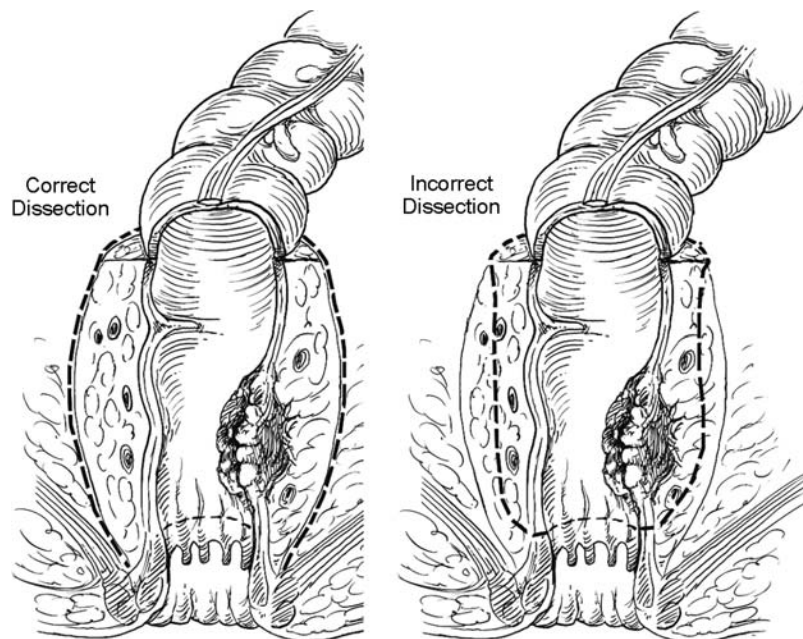

FIGURE 30-1. Schematic representation of the correct TME dissection versus an incorrect dissection. The dissection should proceed between the mesorectal fascia and the pelvic wall fascia to ensure a “complete” TME.

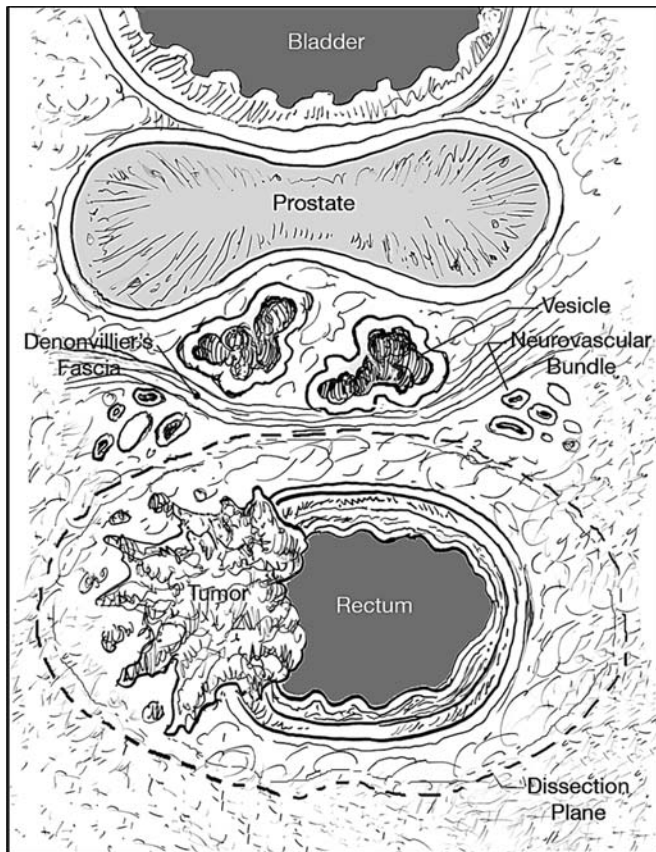

FIGURE 30-2. Transverse diagram of the structures of the mid rectum. The proper dissection proceeds just outside the mesorectal fat and fascia but with sparing of the neurovascular bundle and hypogastric plexus that is located anterolaterally along the pelvic sidewall. One or both layers of Denonvillier's fascia should be included in males and the equivalent fascial dissection along the back of the vagina in females.

extramural lymphatic and vascular routes. When distal intramural spread occurs, it is usually within 2.0 cm of the tumor, unless the lesion is poorly differentiated or widely metastatic.<sup>62-64</sup> Williams et al,<sup>65</sup> in 1983 reported distal intramural spread in 12 of 50 resected rectal cancer surgical patients. It was observed that 10 of the 12 had Stage III lesions. Only 6% had distal intramural spread greater than 2 cm. They concluded a "wet" margin of 2.5 cm was adequate in 94% of the patients. They noted that only five patients (10%) had tumor beyond a 1.5-cm margin, and all five of these had poorly differentiated, node-positive cancers. Also, the mortality in this group of patients was attributable to distant metastases, not local recurrence. All these patients had undergone an APR and had distal margins of greater than 5 cm. Grinnell<sup>62</sup> reported five cases of extramural retrograde lymphatic spread within 1.5 cm in 93 rectal cancers. He also reviewed 28 patients with atypical retrograde lymphatic dissemination. All these patients died within 5 years. He concluded retrograde lymphatic spread was a poor prognostic sign and more radical operations were not advantageous. Pollett and Nicholls<sup>66</sup> observed no differ-

ence in local recurrence rates whether distal margins of <2 cm, 2–5 cm, or >5 cm were achieved. Finally, in two early studies from the British literature, surgical pathology of rectal and rectosigmoid cancer demonstrated the clinical biology of extramural lymphatic spread. In the series by Goligher et al.<sup>67</sup> from 1951, only 6.5% of patients had metastatic glands below the primary tumor, whereas 93.5% had no retrograde spread. Approximately two-thirds of patients with retrograde spread had metastasis limited to within 6 mm of the distal tumor edge, and only 2% had metastasis beyond 2 cm. Dukes<sup>68</sup> published similar results in a study of more than 1500 patients with abdominoperineal cancer.

Further data from a randomized, prospective trial conducted by the National Surgical Adjuvant Breast and Bowel Project demonstrated no significant differences in survival or local recurrence when comparing distal rectal margins of <2 cm, 2–2.9 cm, and >3 cm.<sup>69</sup> As a result, a 2-cm distal margin has become acceptable for resection of rectal carcinoma, although a 5-cm proximal margin is still recommended.<sup>70</sup> The radial margin is more critical for local control.

It seems reasonable to conclude that a 2-cm distal margin is justified over a 5-cm distal margin. Even smaller distal margins may be acceptable in certain patients for whom there is no other option for sphincter preservation. In these cases, a frozen section analysis of the distal margin must be performed to confirm a cancer-free margin.

The discussion concerning the distal margin should not be confused with the issues regarding a TME and the radial margin. It is now clear that the status of the radial margin is perhaps the most critical in determining prognosis. Quirke et al.<sup>71</sup> in 1986 demonstrated tumor spread to the radial margins of 14 of 52 rectal cancers on whole mount specimens (27%). Twelve of these 14 patients subsequently developed local recurrence suggesting that local recurrence is largely a result of radial spread. Cawthorn et al.<sup>55</sup> also documented that tumor involvement of the lateral resection margin correlated with poor prognosis; however, it seemed to correlate more with distant spread and it was not a useful indicator of local recurrence.

### Selection of Appropriate Therapy for Rectal Cancer

The management of rectal cancer has become increasingly complex. Presently, a surgeon has three major curative options: local excision, sphincter-saving abdominal surgery, and APR. Ideal candidates for local therapy that preserves anal sphincter anatomy and function include small T1 lesions (invasion only into the submucosa) and T2 lesions (invasion into the muscularis propria). As will be discussed, patients with T2 lesions probably should not have surgery alone. Recurrence is high. Preoperative or postoperative adjuvant chemoradiation is of benefit. At present, patients with T3 lesions (invasion into the perirectal fat) are not suitable candidates for local therapy and should be treated with an appropriate major resection as well as adjuvant therapy in most cases.

Certain clinical features also may have an impact on decisions about the appropriate therapy. Patients with physical handicaps may have significant difficulty in managing a stoma. Body habitus and patient gender influence the surgeon's ability to perform a sphincter-saving operation because of pelvic anatomy. Whereas a sphincter-saving procedure in a multiparous thin female can be straightforward, performing a low anastomosis in an obese male with a narrow pelvis can be extremely difficult. A history of pelvic irradiation or nonrectal pelvic malignancy can make a rectal resection and sphincter preservation more difficult.

In summary, each patient with rectal cancer should be viewed individually and a technical plan for their resection customized to their stage, gender, age, and body habitus (Figure 30-3). With these issues in mind, the technical choices for a radical resection are discussed below. In all of these resections, a TME should be performed. Local treatments are then described in detail.

## Techniques of Rectal Excision

### Abdominoperineal Resection

The APR was the first radical resection described by Miles in 1908 (reprinted in 1971).<sup>72</sup> Miles set out several principles to be achieved with any radical resection. These principles included:

- Removal of the whole pelvic mesocolon
- Removal of the "zone of upward spread" in the rectal mesentery
- Wide perineal dissection
- An abdominal anus
- Removal of the lymph nodes along the iliacs

Four of five of these principles are the anchor of our technique even today (the dissection along the iliacs is not done routinely).

Candidates for an APR are patients whose tumors are either into the anal sphincter or are so close to the anal sphincter that a safe distal margin cannot be obtained. Also, there is a small subset of patients with mid rectal tumors but with poor continence that benefit from an APR even though they are technically sphincter-preservation candidates. There have been recent reports that obturator/pelvic sidewall lymph nodes are more often involved in patients with very low rectal cancers. It has been suggested that these patients should undergo an extrafascial TME dissection.<sup>73</sup> Although there is some merit to this concept, we describe herein the typical APR with TME, excision of the sphincter and levators, and creation of a permanent colostomy.

### Position

Usually a patient is placed in the lithotomy position. We often elevate the mid and upper sacrum off the bed with a blanket

or a towel so that the coccyx is away from the bed and therefore able to be more easily prepped into the field.

### Incision and Exploration

The abdomen is usually entered through a midline incision. In thin patients, the incision can often be kept below the umbilicus. Low transverse incisions can also be performed as long as the ostomy site is not compromised. The APR is also a good application of laparoscopic-assisted surgery. The abdominal portion of the procedure can be performed using laparoscopic techniques with extraction of the specimen through the perineum. It has yet to be shown, however, whether there is any value added with the laparoscopic-assisted approach.

The exploration of the abdomen and pelvis should be the first step after accessing the abdomen. The liver, aortic lymph nodes, superior hemorrhoidal lymph nodes, iliac lymph nodes, and the pelvis should all be examined. A large tumor burden, particularly multiple peritoneal implants, should lead to a reassessment of the need for resection and perhaps only a colostomy should be performed.

### Mobilization

To excise the whole pelvic mesocolon and "zone of upward spread," the sigmoid colon and left colon need to be mobilized. The mobilization begins along the left pelvic brim. The gonadal vessels, ureter, and iliacs are reflected toward the retroperitoneum and the colon and mesocolon are pulled toward the midline. The left colon is mobilized but the splenic flexure rarely needs to be taken down. The dissection then is started on the right pelvic brim. Often, one can identify the sympathetic nerve trunks behind the superior hemorrhoidal artery (SHA) as one mobilizes the rectal mesocolon away from the sacral promontory.

### Resection and Ligation

After mobilization of the mesentery, the bowel is divided near the sigmoid colon/left colon junction at right angles to the blood supply (Figure 30-4). Because a high ligation of the SHA or of the IMA is planned, the blood supply to most of the sigmoid colon will be compromised. For most cases, a ligation of the SHA flush with the left colic artery should be performed. A higher ligation of the IMA should be performed if there is any question of lymph node involvement outside the pelvis (e.g., palpable nodes along the SHA up to or above the left colic artery). The IMA should be ligated flush with the aorta and the inferior mesenteric vein should be ligated near the ligament of Treitz. A high ligation may also be required for additional colonic mobilization.

After dividing the bowel, sequential clamps of the sigmoid vessels are placed and the mesentery is ligated and divided. A high ligation is performed of the SHA with care being taken

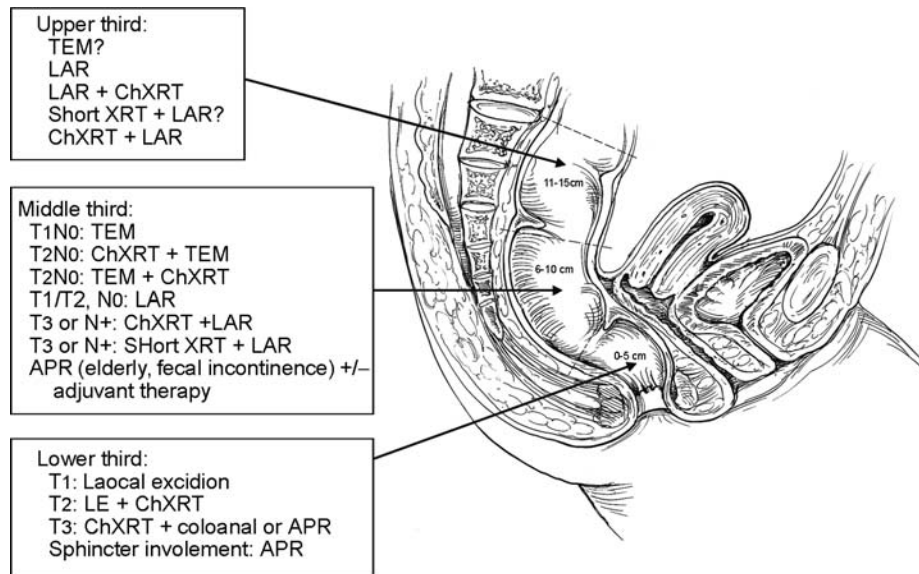

FIGURE 30-3. Treatment options for rectal cancer depending on stage and location.

Stage I (T1N0, T2N0—The cancer is confined to the rectal wall and no nodes are involved)

- Distal rectal cancers: T1 (invasion into the submucosa only)
  - Local excision
  - Radical resection, often an APR
  - Adjuvant therapy is usually not recommended.
- Distal rectal cancers: T2 (invasion into the muscularis propria)
  - Local excision with preoperative or postoperative adjuvant therapy
  - Radical resection without adjuvant therapy, often an APR
- Mid rectal cancer: T1
  - TEM
  - Radical resection, usually an LAR with low anastomosis. A temporary proximal diverting ostomy is often required.
  - Adjuvant therapy is usually not recommended.
- Mid rectal cancer: T2
  - TEM with either preoperative or postoperative adjuvant therapy
  - Radical resection similar to a T1 cancer
  - Adjuvant therapy is not recommended if a radical resection is performed but is recommended after a TEM resection.
- Upper rectal cancers: T1 and T2
  - LAR

Stage II and Stage III cancers [Stage II cancers have invasion into the mesorectal fat (T3) but no involved mesorectal lymph nodes. Stage III cancers are any rectal cancer (T1, T2, or T3) but with involved lymph nodes.]

- Distal rectal cancers
  - Preoperative adjuvant therapy is most often recommended followed by a radical resection, usually an APR.
  - If preoperative imaging does not clearly define the stage of the cancer, resection can be done first followed by postoperative adjuvant therapy.
- Mid rectal cancers
  - Same as above for distal rectal cancers except an LAR is usually performed instead of an APR.
- Upper rectal cancers
  - LAR, with either preoperative or postoperative adjuvant therapy

Stage IV cancers

- Treatment for any cancer is dependent on the extent of metastasis. With better surgical and medical treatments for metastatic disease, locoregional control of the primary should be aggressive and similar to the above recommendations except in the most advanced cases.

(Key: LE, local excision; short XRT, short-course radiation therapy given 2 times a day for 5 days in larger fractions; ChXRT, long-course therapy given in 30 smaller fractions over 6 weeks in combination with chemotherapy)

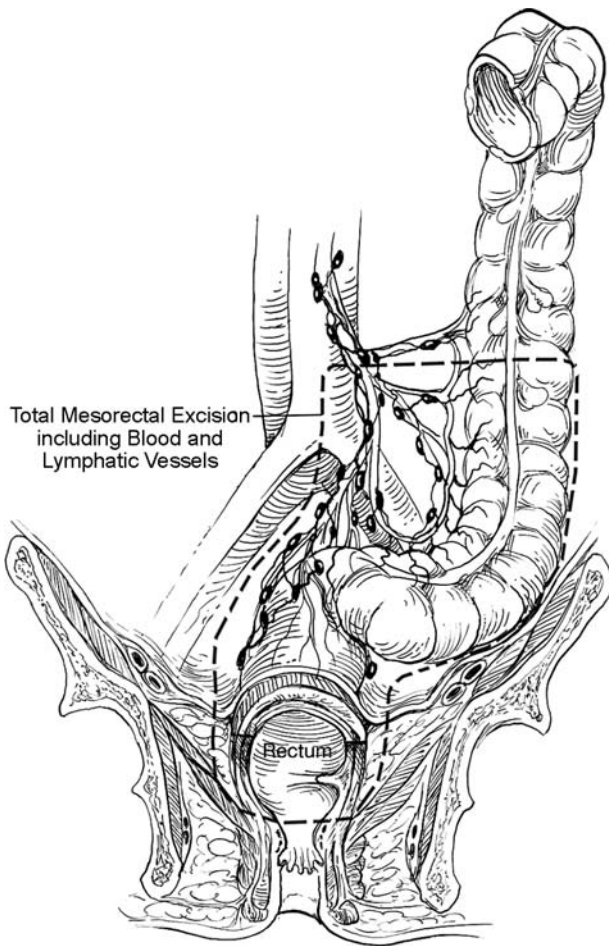

FIGURE 30-4. The vascular supply of the sigmoid and rectum. A typical ligation is performed at the junction of the SHA and left colic artery. In patients with a clinical suspicion of positive nodes at the level of the IMA or if vascular mobilization is needed for the left and transverse colon, then a ligation of the IMA is performed at the aorta.

to not injure the ureters, and also to make sure that the sympathetic nerve trunks are preserved.

### The TME

A successful TME starts with the proper ligation of the SHA or IMA. As one dissects down toward the sacral promontory, the sympathetic nerve trunks are identified. The dissection plane is just anterior or medial to these nerves. Using the cautery or scissors, the nerves are reflected toward the pelvic sidewall while the mesorectal fascia surrounding the mesorectal fat is kept as an intact unit. The dissection starts posteriorly and then at each level proceeds laterally and then anteriorly. In the mid rectal area along the lateral sidewalls, one can sometimes see the parasympathetic nerves tracing anteriorly toward the hypogastric plexus. The plexus is usually on the anterolateral sidewall of the pelvis, just lateral to the seminal vesicles in the man and the cardinal ligaments in the woman. There is

often a tough “ligament” that traverses the mesorectum at this point. It theoretically contains the middle rectal artery. However, in a study by Jones et al.,<sup>74</sup> this artery is only present to any significance about 20% of the time.

The anterior dissection is perhaps the most difficult. In men, one should try to include the two layers of Denonvillier’s fascia. This fascia is composed of peritoneum that has been entrapped between the seminal vesicles and prostate anterior and the rectum posterior (Figure 30-5). In woman, the peritoneum at the base of the pouch of Douglas is incised and the rectovaginal septum is then separated.

If done properly, the mesorectum begins to appear as a bulky bilobed structure. As one progresses distally beyond the mid rectum, the mesorectal fat begins to attenuate. At the pelvic floor there is often only a thin layer of mesorectal fat around the bowel.

### The Perineal Dissection

As the abdominal procedure proceeds distally, the perineal dissection can commence. Before the preparation and draping of the patient, the position of the perineum is ensured so as to allow a wide elliptical incision around the anus. The rectum is usually cleared of any stool or residual preparation and the anus is sewn closed. The incision for the perineal dissection starts anteriorly at the perineal body, goes laterally to the ischiorectal spines, and then finishes posteriorly at the tip of the coccyx. After incising the skin and subcutaneous ischiorectal membrane and fat, the levators are then encountered. The perineal surgeon then coordinates their dissection with the abdominal team in the posterior precoccygeal plane. A pair of long scissors is used to divide the ligaments in the

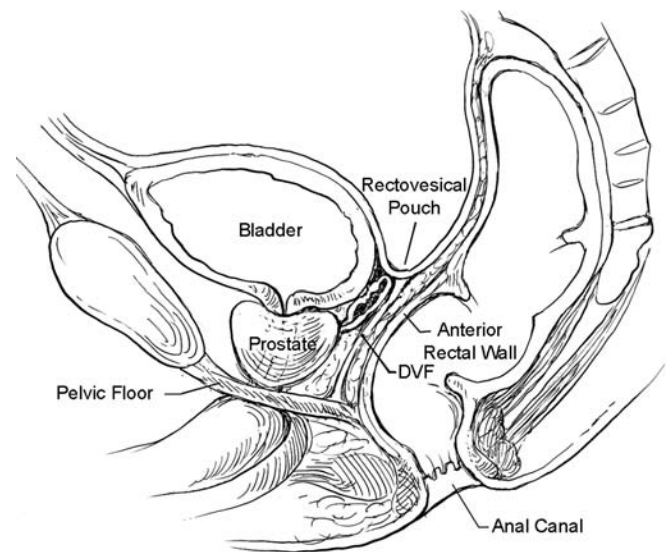

FIGURE 30-5. Sagittal view of the rectum, bladder, Denonvillier’s fascia, and the prostate. The dissection should proceed anterior to one or both layers of Denonvillier’s fascia.

posterior midline behind the rectum. Once a connection has been opened, the perineal surgeon places their finger above the levators and “hooks” them down toward the perineal field. The levators are then divided with the cautery. The dissection starts posteriorly and then proceeds laterally and anteriorly. Often it is best to complete the anterior dissection after the proximal portion of the specimen has been everted out to the perineal surgeon. The remaining attachments in the anterior plane are then divided with the cautery. Once the specimen is removed, hemostasis is ensured with the cautery or absorbable figure-of-8 sutures. Typically there are vessels that need to be ligated in the crease between the lateral prostate and the pelvic floor.

After irrigating the pelvis, one reapproximates the residual levators with absorbable sutures and then the subcutaneous fat, ischioanal fat, and skin are closed in several layers. Drains in the pelvis can be brought out through the pelvis or via the abdomen.

### Closure

With the specimen removed, attention is turned to creating an ostomy. Ideally, the patient has been marked by a certified ostomy therapist preoperatively. The end of the colon is carefully cleaned of any fat. The skin is divided in a circular shape at the ostomy site. A core of fat is removed from the subcutaneous tissues. The fascia is divided in a cruciate manner. The muscle is split but not divided, and then the peritoneum is incised. The hole is made wide enough to accommodate the bowel and the accompanying mesentery. The bowel should then be brought up through the opening so that it is 1–3 cm higher than the skin.

After creating the ostomy, pelvic drains are placed. These keep fluid from leaking through the perineal closure and allow for better healing and a reduced risk of a perineal hernia. The midline fascial opening is then closed and the skin approximated. After skin closure and placement of the dressing, the ostomy is then matured.

### LAR with Sphincter Preservation

Sphincter-sparing procedures for resection of mid and some distal rectal cancers have become increasingly prevalent as their safety and efficacy have been established. The advent of circular stapling devices is largely responsible for their increasing popularity and utilization. An LAR involves dissection and anastomosis below the peritoneal reflection with ligation of the superior and middle hemorrhoidal arteries. An extended LAR indicates complete mobilization of the rectum down to the pelvic floor with division of the lateral ligaments and posterior mobilization through Waldeyer’s fascia to the tip of the coccyx. Additionally, there is dissection of the plane between the anterior rectal wall and the vagina in a female patient and dissection of the plane between the rectum and the prostate in a male patient to a level distal to the

inferior margin of the prostate gland. As long as the surgeon can obtain a distal margin of at least 2 cm, an anastomosis can be considered appropriate if technically feasible. Body habitus, adequacy of the anal sphincter, encroachment of the tumor on the anal sphincters, and adequacy of the distal margin are all factors in determining the applicability of a sphincter-sparing operation.

### Coloanal Anastomosis

The ultimate procedure in sphincter-saving operations is the ultra LAR with coloanal anastomosis. This operation preserves the sphincter mechanism in patients with very low-lying rectal cancer in whom the distal margin is at the minimally acceptable level yet adequate for cancer clearance. These operations are reserved for patients who have a distal rectal cancer that does not invade the sphincter musculature and in whom a standard extended LAR is technically not possible. After an adequate distal margin is achieved, the rectum is transected at the level of the pelvic floor musculature. The remaining anal mucosa between the dentate line and the level of transection of the pelvic floor can then be “stripped” and an anastomosis between the colon and the anus is performed to restore continuity. Alternatively, the procedure can be started at the dentate line with a tubular mobilization of the distal rectum in the intersphincteric groove. This perineal resection can proceed up to the superior margin of the puborectalis muscle before dissecting into the pelvis and connecting with the pelvic and abdominal dissection. The procedure usually requires full mobilization of the splenic flexure, such that the vascular supply of the left colon now based on the middle colic vessels can reach the distal pelvis. The coloanal anastomosis can also be done with a colonic J pouch. Because of the larger capacity of the J pouch construction, anorectal function is thought to be improved, especially early after the surgery. The J pouch is created by folding the distal end of the colon back on itself approximately 5–8 cm and then creating a common channel (Figure 30-6). The actual anastomosis to the anus is then done from the apex of the J in side to end manner. An alternative to the colonic J pouch is the coloplasty. This technique is similar in concept to a stricturoplasty. The distal colon is divided in a longitudinal direction for 8–10 cm starting 4–6 cm from the distal edge of the pedicle. The longitudinal incision is then approximated transversely making a larger reservoir capacity (Figure 30-7). The technique can decrease frequency in the early postoperative period but it has been associated with an increased number of anastomotic leaks. A proximal diverting stoma is advisable because of the potential for an anastomotic leak or vascular compromise of the left colon. Contraindications to the procedure include baseline fecal incontinence from deteriorated anal sphincter muscles; tumor invasion of the anal sphincter musculature or rectovaginal septum; tenesmus; and technical factors such as body habitus, tumor location, and tumor size.

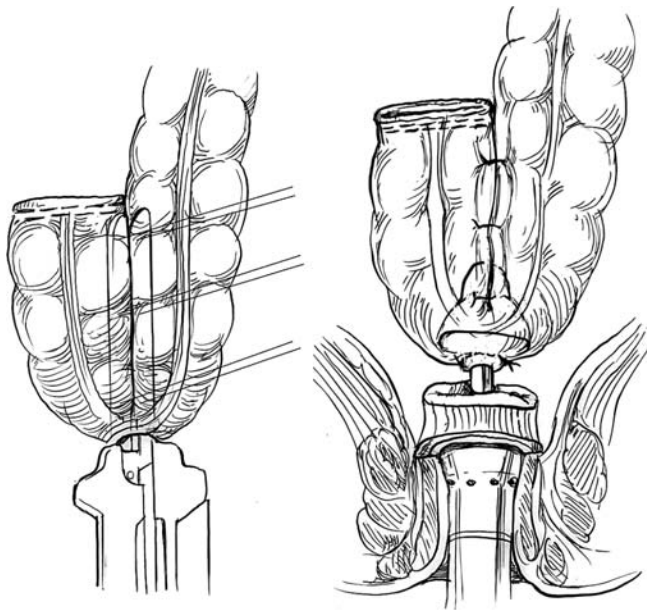

FIGURE 30-6. Construction of a colonic J pouch after an ultra LAR. The distal colon pedicle is folded back on itself to make a “J.” A common channel is then created using a stapling device that will staple and divide. A larger reservoir is then created. The J pouch is then anastomosed to the anus using a circular stapler or in a hand-sewn manner.

### Local Excision

Although the LAR and the APR are the mainstays of therapy for many distal rectal cancers, the radical resection is associated with significant morbidity and mortality. A review of the literature showed that mortality rates for the APR range from 0% to 6.3%,<sup>75,76</sup> with some studies having a 61% incidence of postoperative complications.<sup>77</sup> The majority of these complications are urinary dysfunction and perineal wound infections, with rates as high as 50% and 16%, respectively.<sup>78</sup> In our experience, the incidence of major wound complications was

10%.<sup>79</sup> Radical surgery, especially the APR, leads to a significant change in body image and social habits. In a patient survey performed in 1983 by Williams and Johnston,<sup>80</sup> 66% of patients complained of significant leaks from their stoma appliances, 67% experienced sexual dysfunction, and only 40% of patients who were working preoperatively returned to their jobs after their operation. Also, radical surgery does not guarantee a recurrence-free survival. The 5-year survival rate in the National Cancer Data Base for Stage I disease is 78%.<sup>81</sup> The complication rates, the change in body image with a colostomy, and the improvements in patient selection secondary to innovations in preoperative imaging modalities have led to a renewed interest in local excision of rectal cancers.

### History

The first descriptions of local excision for rectal cancer date back to the late 1800s. At this time, there was little knowledge of the natural history of rectal cancer, and local excisions were viewed as the safest approach. In 1908, Miles<sup>72</sup> noted a high recurrence rate associated with local excision and developed a radical resection that was in keeping with the oncologic principles of the time. It was believed that radical resections such as Miles’ APR provided the best opportunity for cure, and this radical resection quickly became the standard of care despite its increased morbidity and mortality over local excisions.

The first significant series published describing the use of local excision for rectal cancer was by Morson and colleagues<sup>82</sup> at St. Marks Hospital in London. Local excision had been used on patients who had either refused a colostomy or were deemed medically unfit for a radical operation secondary to comorbidities. In this series, they reported at the time of excision 91 patients with negative margins, and in the patients with negative margins only two had local recurrence whereas one had a distal recurrence. However, for the 69 patients with positive margins, 13 had a local recurrence and

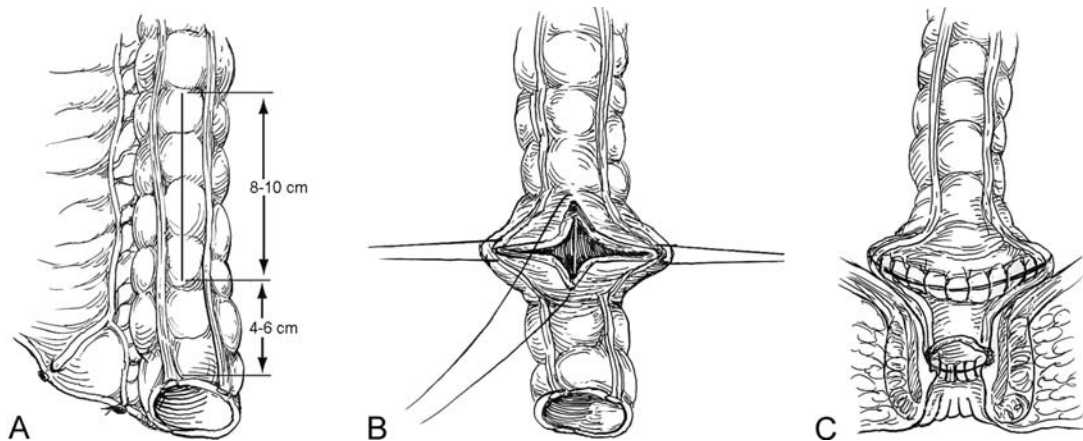

FIGURE 30-7. Construction of a coloplasty. The bowel is divided in a longitudinal manner as shown and resutured transversely to create a larger reservoir capacity.

one had distant recurrence. Most of the patients who underwent a local excision had T1 lesions. With these results, a “policy” was proposed to offer local excision to carefully selected patients with early small distal rectal cancers with well or moderately differentiated tumors.<sup>82</sup> These results prompted a renewed interest in local excision because they showed that local recurrence and survival rates were similar to those of APR for these small distal cancers, whereas the morbidity was greatly reduced.

### Preoperative Evaluation

Proper patient selection remains the key to successful local excision of rectal cancers. The retrospective literature shows that there is a direct correlation between local recurrence and specific pathologic tumor features including depth of invasion, lymphatic invasion, histologic grade, and most importantly clear negative margins at the time of resection. In the past, preoperative evaluation relied solely on the DRE, which was found to have some success in demonstrating depth of invasion.<sup>83,84</sup> Recent studies have refuted this evidence,<sup>85</sup> and there are currently a number of imaging studies that can aid in the preoperative staging of rectal cancers, including ERUS and eMRI.

Preoperative evaluation begins with a thorough history and physical, taking care to note sphincter function, because local excision in the setting of poor preoperative sphincter function may be inappropriate. A digital rectal examination should be performed to assess the distance of the tumor from the anal verge, as well as its size and mobility. Tumors amenable to local excision should be <4 cm in diameter and occupy <40% of the bowel circumference. The distance of the tumor from the dentate line is important, because it will dictate which approach should be taken. Tumors <5 cm from the dentate are amenable to resection via a transanal procedure, whereas tumors in the middle third of the rectum may require a transcoccygeal approach or transanal endoscopic microsurgery (TEM). Immobile tumors are likely transmural, and thus not candidates for local excision. The overall health of the patient must be taken into account, because patients who are considered medically unfit for a major resection are often good candidates for local excision.

Imaging for rectal cancer has already been discussed. Suffice it to say that imaging is especially critical in selecting patients for a local excision. The best candidates have either a T1N0 or a T2N0 lesion. For the T2 lesions, local excision alone is not sufficient as therapy alone, and either preoperative or postoperative adjuvant therapy should be added. The selection criteria for a local excision are summarized in Table 30-1.

### Technique

Historically, there are three approaches to local excision of rectal cancer: transanal, transcoccygeal, and transsphincteric. The transsphincteric approach has been associated with fecal

TABLE 30-1. Properties of distal rectal adenocarcinoma amenable to local excision for curative intent<sup>124</sup>

Physical features
Tumors <4 cm in diameter
Tumor <40% of bowel circumference
Tumor within 10 cm of dentate line
Tumor freely mobile on digital rectal examination
ERUS
T1, T2 lesions
No regional lymph node involvement

incontinence secondary to sphincter dysfunction, and thus has fallen out of favor. Recently, a newer technique, TEM, has provided a minimally invasive option for local excision which also allows the operator to reach lesions that are located more proximally and would have required a transcoccygeal or transsphincteric approach in the past.

### Transanal Excision

Local excision can be accomplished via a transanal approach for the majority of low rectal cancers. In our prospective study of 48 local excisions for rectal cancer, 33 were performed using a transanal approach.<sup>86</sup> Before local excision, all patients should receive a full mechanical and antibiotic bowel preparation. After induction of anesthesia, the patient is flipped over and placed in the prone-jackknife position, with the buttocks taped apart. A pudendal nerve block should then be administered, which aids in postoperative pain control and more importantly relaxes the sphincter complex. An anal retractor alone or in combination with a retractor with self-retaining hooks are then used to dilate the anus and expose the lesion. Once adequate visualization has been obtained, traction sutures are often placed 1–2 cm distal to the tumor, and the line of dissection is marked on the mucosa using electrocautery. This line of dissection should be approximately 1–2 cm from the border of the tumor circumferentially (Figure 30-8). If visualization is not initially adequate, serial traction sutures should be used to prolapse the lesion into the field of view. Next, the electrocautery is used to make a full-thickness incision along the previously marked mucosa (Figure 30-8B). Upon completion of this incision, the perirectal fat should be visible beneath the lesion to confirm a full-thickness excision. In anterior lesions, care must be taken not to injure the back wall of the vagina in females, or the prostate in males. The lesion is then excised leaving visible perirectal fat at the base of the lesion. The defect in the bowel wall is then closed transversely using interrupted 3-0 polyglycolic sutures.

The complications most closely associated with transanal excisions include urinary retention, urinary tract infections, delayed hemorrhage, infections of the perirectal and ischioanal space, and fecal impactions. However, the overall incidence of these complications is quite low, and the mortality rate is 0% in most series.

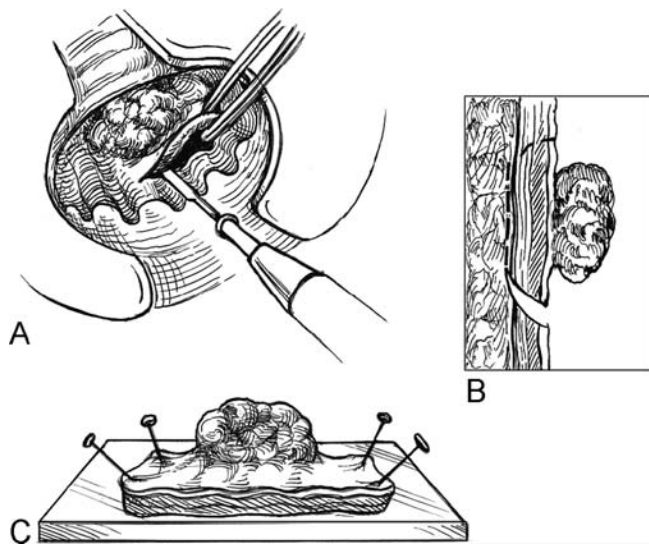

FIGURE 30-8. Transanal excision. **A** A transanal excision is performed by marking out a 1 cm or greater margin around the tumor. **B** A full-thickness excision is then performed to obtain adequate radial as well as lateral margins. **C** The specimen is then oriented accurately for the pathologist.

### Transcoccygeal Excision

The transcoccygeal approach was used historically over the transanal approach for larger, more proximal lesions. It was originally popularized by Kraske who found it beneficial when operating on lesions within the middle or distal third of the rectum. This approach is especially useful for lesions on the posterior wall of the rectum, but can certainly be used for anterior or lateral lesions as well. In our series, the transcoccygeal approach was used where the distal margin was approximately 4.8 cm from the dentate line as compared with 3.0 cm for the transanal approach.<sup>86</sup>

All patients should undergo a full antibiotic and mechanical bowel preparation the day before surgery. The patient is again placed in the prone-jackknife position with the buttocks taped apart after the induction of general anesthesia. The tape will be released for closure to facilitate the approximation of the subcutaneous tissues and skin. Unlike the transanal approach, a pudendal block is not required, because the sphincters do not require relaxation. The patient is prepped and draped in a sterile manner with povidone-iodine solution, and an incision is made in the posterior midline adjacent to the sacrum and coccyx down to the upper border of the posterior aspect of the external sphincter. The coccyx, which along with the anal coccygeal ligament lies immediately deep to the skin and subcutaneous tissue, is removed to improve exposure. To do so, the anal coccygeal ligaments and other attachments are cauterized from each side and from the lower edge of the coccyx. The dissection then proceeds along the undersurface, anterior edge, of the coccyx until a cutting wire can pass through the sacral coccygeal joint. The coccyx is

then removed with occasional bleeding from an extension of the middle sacral artery, which is easily controlled with electrocautery. The levator ani muscles will now be visible at the base of the wound and should be separated in the midline, exposing a membrane that resides just outside of the perirectal fat. Division of this membrane allows for complete mobilization of the rectum within the intraperitoneal pelvis.

For posterior-based lesions, the distal margin of the tumor can be palpated via a rectal examination, and then the mesorectum and rectum are transected at a point 1–1.5 cm distal to the tumor (Figure 30-9). The excision is then completed with a 1-cm margin surrounding the lesion. For posterior lesions, the transcoccygeal approach allows for the removal of perirectal nodes that lie in the surrounding mesorectal tissue. For anterior lesions, a posterior proctotomy is made, and then the lesion is approached under direct vision, again excising the lesion down to the perirectal fat with a 1-cm margin (Figure 30-10). After removal, the specimen is reoriented for the pathologist and all the rectal incisions are closed in either a longitudinal or transverse manner to avoid narrowing of the rectum, using an absorbable suture. An air test should be performed, filling the operative field with sterile saline, and insufflating air in the rectum in order to check for air leaks in the suture line. Once these air leaks are controlled, the levator ani is reapproximated in the midline, and the anal coccygeal ligament is reattached to the sacrum. The operation is completed with closure of the skin and subcutaneous tissue.

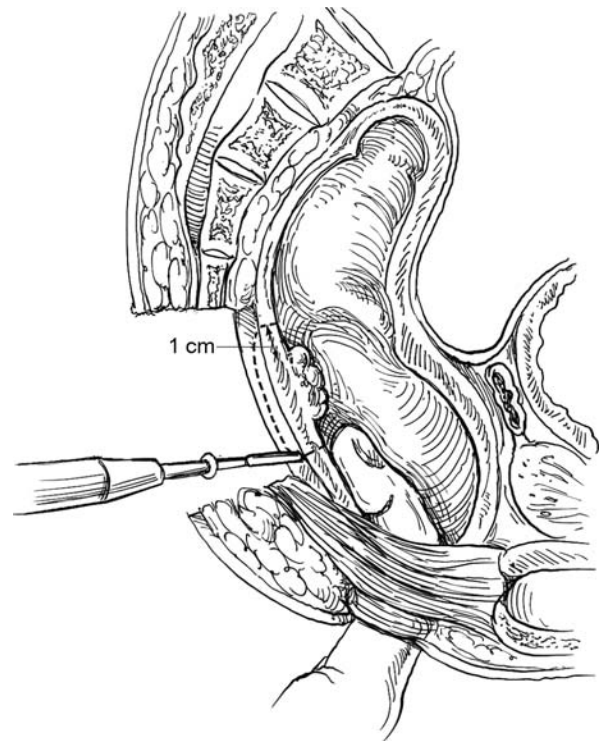

FIGURE 30-9. Transcoccygeal excision. For posterior lesions using a transcoccygeal or “Kraske” approach, one can palpate the lower border of the tumor to ensure an adequate distal margin.

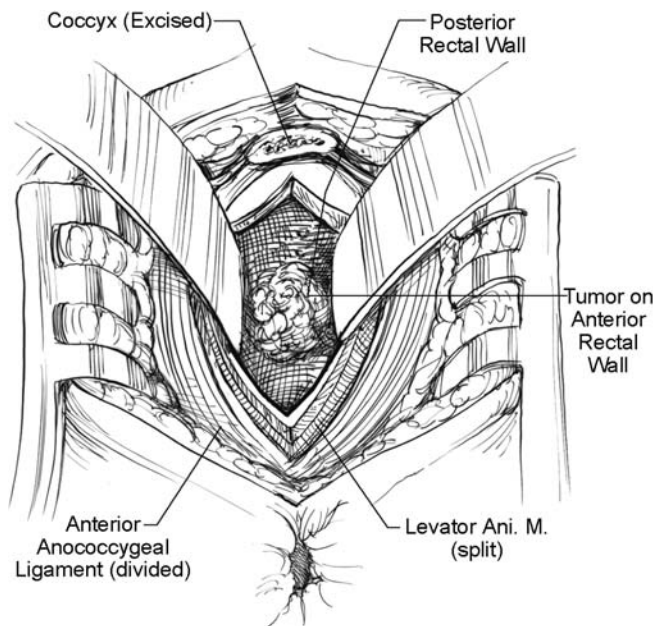

FIGURE 30-10. Transcoccygeal excision. Anterior lesions need to be approached by first making a posterior proctotomy and then excising the lesion through the rectum. The anterior and posterior walls of the rectum then need to be repaired, usually in a transverse manner in order to maintain the lumen diameter.

An unfortunate complication of this procedure is the development of a fecal fistula that extends from the rectum to the posterior midline incision. The incidence of this complication ranges from 5% to 20%,<sup>86-88</sup> and most heal after temporary diversion of the fecal stream via a loop ileostomy or colostomy. For this reason, the Kraske approach is used much less frequently than other methods for local treatment.

### Transsphincteric Excision

The transsphincteric approach developed by York and Mason involves the complete division of the sphincters and the posterior wall of the rectum. The procedure starts similarly to the Kraske transcoccygeal approach, except the levator ani and the external sphincter muscles are divided in the midline. These muscles are carefully tagged so that they can be reapproximated exactly at the end of the procedure. Care must be taken to remain in the midline to avoid the nerve supply to the sphincters that lie in a posterolateral position bilaterally. Once the lesion is removed, the rectum, sphincters, and overlying musculature are closed in a careful stepwise manner. This procedure has an increased risk of incontinence secondary to sphincter dysfunction. Because the exposure provided from this approach is similar to that from the Kraske procedure, which carries less of a risk of incontinence, there are very few indications for this technique.

### Transanal Endoscopic Microsurgery

TEM was first described in 1984 by Gerhard Buess of Tübingen, Germany.<sup>89</sup> The surgery is performed with the use of a special resectoscope which is 4 cm in diameter and available in lengths of both 12 and 20 cm. The scope is inserted with an obturator in place, which is then removed and replaced with an air-tight glass faceplate. The rectum is then manually insufflated, such as in rigid sigmoidoscopy, and the lesion is identified and centered in the field. The scope is then secured in position with the aid of a support arm that is attached to the operating table. The glass faceplate is then removed and replaced with a working adapter that contains four instrument ports and a fifth port for the stereoscope which is connected to a camera and projected onto a monitor. Carbon dioxide is then insufflated at low pressure (10–15 cm H<sub>2</sub>O) to distend the rectum and allow for visualization of the lesion.

Once setup is complete, the operation proceeds in a manner similar to a transanal excision using a variety of special endoscopic instruments, which are introduced through the four ports in the working adapter. We begin with an injection of 1:100,000 solution of epinephrine in the submucosal plane around the lesion to aid with hemostasis. The margin of resection is then marked 1–1.5 cm circumferentially around the lesion using electrocautery. The lesion is then grasped and the excision proceeds along the previously marked line through the full thickness of the rectal wall and into the perirectal fat. The specimen is removed by temporarily removing the faceplate after complete excision. The defect is then closed using 3-0 long-lasting absorbable suture in a continuous or interrupted manner.

TEM allows for local excision of proximal rectal lesions that are not accessible via the transanal, transsphincteric, or transcoccygeal approaches. Despite favorable results of this relatively new technique, it has not gained widespread popularity secondary to the expense of the equipment, lack of familiarity with the equipment and setup, and complexity of the TEM operating system.

### Outcomes: Retrospective Studies

The majority of the literature for local excision of rectal cancer comes from small retrospective reviews from single institutions. These studies are difficult to interpret because there is no uniform approach among the reviews. The length of follow-up varies from study to study, and many combine patients with tumors of different depth, positive margins, and different forms of local therapy including snare cautery and fulguration.

These retrospective reviews report a local recurrence rate of 5%–33% and survival rates of 57%–100%<sup>90-94</sup> (Table 30-2). These studies demonstrate that patients with superficial tumors and negative margins at the time of resection have low recurrence rates and a very good prognosis. Although these studies are not conclusive, they do suggest that local excision

may provide adequate oncologic control with considerably lower morbidity and mortality rates than APR for select distal rectal cancers.

### Local Excision and Adjuvant Therapy

Local recurrence continues to be a major source of morbidity and mortality after both local excisions and radical resections for rectal cancer. The major risk factors for recurrence include the depth of invasion of the primary tumor, positive surgical margins, histologic grade of the tumor, and the presence of tumor in the regional lymph nodes. The addition of adjuvant or neoadjuvant radiation has been shown to decrease these local recurrence rates, and there is increasing evidence that chemoradiation may have a beneficial effect on survival. One of the major shortcomings of local excision is the inability to pathologically assess the regional lymph nodes. Microscopic disease can be present in the regional lymph nodes in up to 12% of T1 lesions, 22% of T2 lesions, and 58% of T3 and T4 lesions.<sup>95,96</sup> This microscopic disease may lead to local recurrence if left untreated. These findings have caused many observers to advocate the use of postoperative radiation after local excision in an attempt to eradicate any nodal disease, especially in more aggressive tumors with some of the risk factors previously mentioned. It also further emphasizes the need for preoperative ERUS or eMRI to identify patients with nodal disease who may be inappropriate for local excision.

Similar to the studies for local excision alone, many of the studies involving local excision combined with pre- or postoperative chemoradiation are small retrospective single-

institution studies, and thus are difficult to interpret (Table 30-3). The patient population, radiation and chemotherapy protocols, and tumor characteristics are highly variable among these studies. The survival rates for these studies range from 33% to 100% depending on tumor stage and the use of adjuvant therapy. However, local recurrence rates are decreased when compared with local excision alone, ranging from 0% to 15% for T1 and T2 lesions, and 0% to 20% for T3 lesions.<sup>76,91,94,97–99</sup>

### Prospective Studies

Unfortunately, there are very few prospective studies that use local excision for distal rectal adenocarcinoma with or without chemoradiotherapy (Table 30-4). We treated 48 patients with rectal adenocarcinoma via local excision, using postoperative chemoradiation for all T2 and T3 lesions. Over a mean follow-up period of 40.5 months, we found an overall survival of 93.8%, with recurrence rates by stage of 0% for T0 lesions, 9.5% for T1 lesions, 0% for T2 lesions, and 40% for T3 lesions. Of note, local recurrence was seen in three of five patients with lymphatic invasion and two of two patients with positive margins at the time of local excision.<sup>86</sup> From our results, we concluded that surgery alone was adequate for T1 lesions, whereas T2 lesions required a combination of surgery and chemoradiation for adequate results, provided that there were negative margins and no lymphatic involvement. If either of these characteristics were present, we recommended the addition of chemoradiation for T1 lesions, and radical resection for T2 lesions.

Ota<sup>100</sup> published results on a study of 46 patients with a median follow-up time of 36 months. In this study, all patients received postoperative radiation, whereas T3 patients also received chemotherapy in addition to their radiation treatments. He reported a 6.5% local recurrence rate and a 3-year survival rate of 93%.

Steele et al. published a multicenter, prospective trial of local excision for rectal cancer in 110 patients.<sup>81</sup> All of these patients were thoroughly screened preoperatively to ensure that their tumors were within 10 cm of the dentate line, <4 cm in size, and involved <40% of the circumference of the bowel wall. Furthermore, all patients had to be N0M0, and statistical analyses were only performed on patients with negative margins at the time of resection. Patients were treated with postoperative chemoradiation only if they had T2 lesions. They published survival rates of 87% and 85% for T1 and T2

lesions, respectively, with an overall survival rate of 85%. They also found an overall disease-free survival rate of 78%, with 84% for T1 lesions, and 71% for T2 lesions. These data compare very favorably with APR, with a 5-year survival rate of 70% for Stage I disease. Unfortunately, the retrospective APR data are not separated into T1 and T2 lesions, making comparison difficult.

### Transanal Endoscopic Microsurgery

Because TEM is still a relatively new technique, the data supporting its use are still being compiled. There are a few small, single-institution, retrospective, and prospective studies describing the use and outcomes of TEM for the excision of rectal cancer.<sup>101–103</sup> In general, these studies show survival and recurrence rates ranging from 83% to 100% and 0% to 27%,

TABLE 30-4. Local excision plus adjuvant therapy (prospective series)

Author	No. of patients	Treatment arms	Follow-up	Local recurrence	Survival
Ota <sup>100</sup>	46	LE Postop XRT (53 Gy) 5-FU for 7 T3's, 1 T2	Median 36 mo (18–73)	3/46 (6.5%) All T3's	Overall 3-y survival 93%

Source: From Ref. 124.

respectively. These rates are equivalent to those seen for transanal excision, but again comparison is difficult because of the differences in patient population, adjuvant therapy, and tumor characteristics (Table 30-5).

## Recommendations

Patient selection is arguably the most important factor for obtaining comparable oncologic results with local excision or TEM versus APR in the treatment of low rectal cancers. All patients should receive a thorough history and physical including a digital rectal examination to assess the distance of the tumor from the anal verge, as well as its size and mobility. Ideally, tumors should be <4 cm in diameter and occupy <40% of the bowel circumference. Tumors within 5 cm from the dentate are amenable to resection via a transanal procedure, whereas more proximal tumors may require a TEM or transcoccygeal approach if an LAR is not feasible. Immobile tumors are not candidates for local excision because they are likely transmural. The overall health of the patient must be taken into account, because medically unfit patients are often good candidates for local excision. Even T2 and T3 lesions in these patients can be locally excised, accepting a higher rate of local recurrence for lower rates of morbidity and mortality. In this setting, these patients should receive adjuvant chemoradiotherapy and close follow-up.

After a thorough history and physical, all patients should undergo preoperative ERUS or eMRI to assess for transmural spread and regional lymphadenopathy. Tumors with evidence of nodal involvement should be considered advanced disease, and should be treated with a radical resection, either an APR or LAR with low pelvic anastomosis. T1 lesions have a very low probability of regional nodal involvement and are excellent candidates for local excision, whereas the opposite is true for T3 and T4 lesions, which should be treated via radical resection. The treatment of T2 lesions is somewhat controversial. Historically, better results have been seen with APR for T2 lesions; however, local excision with postoperative chemoradiation seems to be yielding similar results. If local excisions is offered to patients with T2 lesions, either preoperative or postoperative chemoradiation therapy should be part of the treatment plan.

CT scans of the abdomen and pelvis should be obtained in order to look for any signs of distant spread. PA and lateral

TABLE 30-6. Treatment recommendations after initial resection

T stage	Low risk*	High risk†
T1	No further treatment	Adjuvant chemoradiation
T2	Adjuvant chemoradiation	Radical resection
T3	Radical resection	Radical resection

\*Low risk: well or moderately differentiated with no evidence of lymphatic or vascular invasion.

†High risk: poorly differentiated or lymphatic invasion or vascular invasion.

views of the chest are necessary for similar reasons. In the presence of incurable distant metastases, there is a role for local excision for small T2 and T3 lesions, because these patients are likely to succumb to their distant disease before local recurrence causes any major problems. A full colonoscopy should also be performed preoperatively to assess for any synchronous polyps or carcinomas.

After this thorough preoperative evaluation has been completed, patients may then undergo local excision. Surgical margins should be 1 cm, although the key factor is a negative margin regardless of size. These excisions must be full thickness and include some perirectal fat. Local excisions are still considered total excisional biopsies, because final therapy awaits pathologic evaluation. After excision, these tumors should be evaluated for surgical margins, depth of invasion, histologic grade, and vascular or lymphatic invasion. Tumors with positive margins must be treated with additional therapy, either via reexcision, chemoradiation, or radical resection. Tumors are then categorized into low or high risk based on their level of differentiation and the presence or absence of vascular or lymphatic invasion. Patients with low-risk T1 lesions do not receive any additional therapy, whereas patients with high-risk T1 lesions and low-risk T2 lesions are given adjuvant chemoradiation. Patients with high-risk T2 and any T3 lesions should undergo radical resection (Table 30-6). Close follow-up is essential for all patients in order to detect local recurrence as early as possible.

## Other Local Techniques

Small rectal cancers can be treated definitively using electrocoagulation or endocavitary radiation (ecRT). Electrocoagulation uses standard electric cautery to ablate the tumor, frequently with a specialized operating proctoscope. ecRT is

TABLE 30-5. Transanal endoscopic microsurgery

Author	No. of patients	Treatment arms	Follow-up	Local recurrence	Survival
Lezoche et al. <sup>101</sup>	35 (All T2)	All had preop 50 Gy XRT then TEM	Median 38 mo (24–96 mo)	1/35 (2.85%)	Probability of survival at 96 mo = 83%

a high-dose low-voltage technique applied to a smaller rectal cancer through a special proctoscope. Both techniques have the disadvantage of not providing an intact specimen for histologic analysis. Treatment results using each technique have not been evaluated in any prospective trial; however, recent retrospective reviews<sup>104,105</sup> conclude that these two techniques are good treatment options in carefully selected patients.

### Survival after Rectal Cancer Excision

Overall 5-year survival rates for colorectal cancer have shown improvement over recent decades with the combination of better surgery and adjuvant therapy. Reports from 20 years previous have assured us that a sphincter-sparing surgical approach does not sacrifice survival in selected patients where an adequate margin can be achieved.<sup>106–108</sup> Overall, 5-year survival rates after major surgery for rectal cancer are as follows: Stage I, 85%–100%; Stage II, 60%–80%; and Stage III, 30%–50%.<sup>57,66,106,109–115</sup>

Local excision of cancers confined to the rectal wall without lymphatic or distant spread (T1 and T2N0) can achieve cure rates of 80%–100% as discussed previously; however, the results published in retrospective trials are extremely unreliable because many studies span decades, have no standard entrance criteria, and no standard adjuvant therapy policy. In some retrospective studies, local recurrence seemed high but overall survival was not different than a comparative group of patients who underwent radical resection.<sup>93</sup> Future emphasis on earlier diagnosis, accurate preoperative staging, and appropriate choice of resection procedure, combined with improved adjuvant therapy, should influence favorably overall survival using this conservative technique.

### Laparoscopically Assisted Resections for Rectal Cancer

The application of laparoscopy for the treatment of intraabdominal malignancies including proctectomy for rectal cancer is now being performed. In these operations, part of the procedure is done using the laparoscope and completion of the procedure is in the traditional manner. In particular, exploration and mobilization of the colon and rectum can be done with the laparoscope and laparoscopic instruments. Ligation of the vascular pedicle is performed with laparoscopic clips, vascular stapling devices, or radiofrequency coagulation devices. The pelvic dissection can be performed and well visualized laparoscopically in many patients. Most often, however, the actual resection of the bowel and an anastomosis are still more easily performed in an extracorporeal manner.

The main questions about laparoscopically assisted proctectomy for colorectal cancer are whether it provides the same TME specimen as traditional open techniques, and whether there is any other unique biologic alteration in the laparoscopic procedure that leads to a change in survival or in recurrence patterns. Concerning the latter point, there have been

several reports of unusual wound recurrences at trocar sites in patients undergoing laparoscopic-assisted colectomy. However, a randomized trial of open versus laparoscopically assisted colon resection found no statistically significant differences in survival.<sup>116</sup> In a recent article from the United Kingdom, laparoscopically assisted LAR for rectal cancer revealed an increased risk of a positive circumferential margin compared with open surgery.<sup>117</sup> Going forward, the use of laparoscopy will increase with rectal resection; however, its use will need to be monitored and studied to make sure that the standard principles of a TME are adhered to.

### Synchronous Cancers

Synchronous cancers of the large intestine occur with an incidence of approximately 3.5%.<sup>118</sup> Also, synchronous polyps are common with a primary cancer. If one finds two cancers within the colon and rectum, then one must plan an approach to the surgical resection that depends on the location of the two lesions. Certainly, two resections and two primary anastomoses can be performed in large bowel surgery with a complication rate that is similar to that of just one anastomosis.<sup>119</sup> If a patient has a small rectal cancer that is amenable to local excision along with a synchronous cancer of the colon, one can consider a local excision of the rectal lesion followed by primary resection of the colon lesion. It is important, however, to realize that surveillance after local excision of a rectal cancer needs to be more aggressive in monitoring for local recurrence and metachronous cancers or precancers than after resection of single bowel cancer.

### Extended Resection for Locally Advanced Colon or Rectal Cancer

Carcinoma of the colon and rectum will sometimes invade adjacent organs or the abdominal wall. When this occurs, it has been shown that extended resection of the cancer along with the tissue or organ that it has adhered to can lead to a 5-year survival rate of >50%, provided the surgical margins are tumor free.<sup>120,121</sup> Patients with inflammatory adhesions to contiguous organs have a slightly higher survival rate than patients with malignant infiltration, but the distinction between malignant and inflammatory contiguity often cannot be made until after en bloc resection. The organs that are usually involved with adhesions from colon or rectal cancer include the uterus, small bowel, urinary bladder, and abdominal wall. In general, approximately 5% of patients will present with locally advanced lesions.<sup>121</sup>

### Surgical Treatment of Recurrent Colorectal Carcinoma

Recurrent colorectal cancer affects between 12% and 50% of patients with Dukes B or C (TT2N0 through T3NN1) disease. Although adjuvant treatment has some effect on survival,

surgery remains the mainstay in treatment of recurrent disease. Most often, the intent of surgery for recurrent disease is not curative, but to improve survival or palliate symptoms.

There are three main patterns of recurrence after resection of a primary colorectal cancer. The most common site of recurrence is the liver. However, isolated recurrences can also be seen locoregionally or in the lung. Although 60%–70% of patients who die of colorectal cancer have liver metastasis, the liver is an isolated site of recurrence in <20% of patients. Of the latter group, only 5%–10% will be candidates for curative hepatic resection.<sup>122</sup>

Locoregional recurrence of rectal cancer has been decreasing over the past 2 decades. With the use of adjuvant therapy and the wider application of TME, local failure has been reported as low as 3%. However, when a patient develops a local recurrence, it is often not just a suture line recurrence but a regional recurrence. The workup of these patients requires extensive imaging to identify features of the tumor which would make it unresectable.

Wanebo et al.<sup>123</sup> demonstrated a 25% actuarial 5-year survival after abdominal sacral resection for recurrent colorectal cancer. They concluded that patients presenting after a long disease-free interval could benefit from such a large procedure. Noncurative surgery has only a small role in the treatment of symptomatic pelvic recurrence, particularly with sacral involvement. Newer approaches such as cryoablation of perineal recurrences may replace heroic procedures and may be useful in symptomatic relief of nonresectable pelvic recurrence.

## Appendix: Practice Parameters for the Treatment of Rectal Carcinoma

Prepared by the American Society of Colon and Rectal Surgeons

### Preoperative Evaluation

A patient with a newly diagnosed rectal cancer requires preoperative assessment to identify tumor stage and operative risk factors that may affect the choice of the surgical procedure.

### Examination

Digital rectal examination and sigmoidoscopy allow for the assessment of tumor location, size, and fixation.

Synchronous colon malignancies or coexisting adenomatous polyps should be identified preoperatively, if possible. Colonoscopy is preferred over barium enema.

### Imaging Studies

Identifying the extent of local, regional, or distant metastasis may be useful if the findings would modify the approach to treatment. ERUS may be preferred to assess rectal wall

penetration, MRI to evaluate perirectal tissue involvement, and CT scan to identify hepatic or pulmonary metastasis.

### Laboratory Studies

Laboratory studies should be obtained as indicated by the patient's general condition and anesthetic requirements. The measurement of baseline CEA is useful if postoperative monitoring is planned.

### Treatment Considerations

Where possible, the patient should participate in the treatment selection. They should understand the risks and benefits of therapy including short-term and long-term outcome and treatment alternatives.

### Abdominoperineal Resection

This procedure is generally indicated for lesions of the lower one-third of the rectum or for higher lesions where tumor characteristics and anatomic factors favor such resection. Where possible, preoperative colostomy counseling is recommended.

### Sphincter-preserving Resection

These procedures are possible for the majority of patients with rectal carcinoma. The choice of the anastomotic technique should be left to the discretion of the surgeon.

### Transanal Procedures

Such procedures may be performed for cure in highly selected patients with favorable tumor characteristics or for patients in need of palliative therapy. These procedures include local excision, electrocoagulation, endocavitary irradiation, and laser ablation.

### Hartmann's Procedure

This procedure may be indicated for patients who present with obstructed or perforated carcinoma and for patients in whom colorectal anastomosis is clinically inadvisable.

### Abdominal Transsacral Resection

The indication for this procedure has been largely supplemented by other sphincter-preserving resections. It provides adequate treatment for mid rectal cancers in the hands of surgeons experienced with this approach.

## Adjacent Organ Resection

Contiguous organ resection should be considered in the absence of metastatic disease.

## Palliative Surgical Procedures

Such procedures, which may include contiguous organ resection, may be indicated to alleviate or significantly reduce the patient's symptoms caused by primary or recurrent tumor.

## Adjuvant Therapy

Adjuvant chemotherapy or radiation therapy, preoperatively or postoperatively, may be used in combination with surgical resection to potentially improve results for cure or for palliation.

# Adjuvant Therapy for Colorectal Cancer

Judith L. Trudel and Lars A. Pählman

## Colon Cancer

The stage of disease at presentation remains the most important prognostic factor for colon cancer patients.<sup>1</sup> Stage I disease carries an excellent prognosis of more than 95% 5-year survival rate, and surgical treatment alone is considered sufficient; adjuvant treatment is not indicated. In contrast, adjuvant treatment has repeatedly been shown to improve survival for Stage III disease. The role of adjuvant treatment for Stage II (node-negative) disease remains controversial.

### Adjuvant Chemotherapy for Node-positive Disease (Stage III)

Overall 5-year survival from curative surgery for Stage III colon cancer is 30%–60%.<sup>1</sup> Recurrences are often systemic, hence the need for systemic adjuvant treatment in these high-risk patients. Adjuvant chemotherapy improves survival by approximately 10%–15%.

5-Fluorouracil (5-FU)/leucovorin (LV)-based adjuvant chemotherapy for Stage III disease is the standard of care in the United States today.<sup>2</sup> Historically, single-agent chemotherapeutic agents such as thiotepa or fluoropyrimidines did not prove helpful as adjuvant treatment of colon cancer. Progressively, several combination trials of chemotherapy and immune modulators helped refine the recommendations made for adjuvant treatment. In 1988, the NSABP (National Surgical Adjuvant Breast and Bowel Project) CO-1 trial documented a significant 8% improvement in overall 5-year survival for Stage II and Stage III disease when adjuvant chemotherapy with MOF (semustine, vincristine, and 5-FU) was used.<sup>3</sup> In 1989, the NCCTG (North Central Cancer Treatment Group) published a three-arm randomized study of 401 Dukes' Stage B and C patients comparing surgical resection alone to levamisole and to 5-FU plus levamisole. 5-FU plus levamisole significantly decreased the recurrence rates and improved overall survival, particularly in Dukes' C patients.<sup>4</sup> The large Intergroup 0035 study

confirmed the efficacy of 5-FU plus levamisole in 971 patients with Dukes' Stage C cancer in 1990<sup>5</sup>; death rates were reduced by 33% ( $P = .0007$ ), and recurrence rates by 40% ( $P < .0001$ ). In 1990, the NIH (National Institutes of Health) published a consensus statement establishing 5-FU plus levamisole as the standard adjuvant therapy for Stage III colon cancer.<sup>6</sup> A recent European study has confirmed a significant reduction of 25% in the odds of cancer death in Stage III patients receiving adjuvant 5-FU and levamisole.<sup>7</sup>

While the usefulness of 5-FU/levamisole in Stage III disease was being confirmed, LV emerged as a beneficial agent for the treatment of metastatic disease. Its applicability to Stage II and Stage III disease was confirmed by the IMPACT (International Multicenter Pooled Analyses of Colon Cancer Trials) study of 1526 patients, published in 1995. In this study, 3-year disease-free survival increased from 62% to 71% ( $P = .0001$ ) whereas overall survival increased from 78% to 83% ( $P = .029$ ) in the 5-FU/LV group compared with surgical controls.<sup>8</sup> The NSAPB C-03 randomized trial of 1081 Stage II and Stage III patients comparing MOF to 5-FU/LV had documented a similar advantage of 5-FU/LV, with a 3-year disease-free survival increase from 64% to 73% ( $P = .0004$ ) and an overall survival increase from 77% to 84% ( $P = .003$ ) in the 5-FU/LV group compared with MOF.<sup>9</sup>

The relative merits of levamisole and LV as modulators of 5-FU-based adjuvant chemotherapy, and the optimal duration of treatment were investigated in several studies published between 1998 and 2000. The NCCTG/NCIC (National Cancer Institute of Canada)<sup>10</sup> study of 915 patients compared 6 months 5-FU/levamisole; 6 months 5-FU/LV/levamisole; 1 year 5-FU/levamisole; and 1 year 5-FU/LV/levamisole. Triple therapy for 6 months was as effective as 12 months; and 6-month triple therapy provided superior 5-year overall survival and disease-free survival compared with 5-FU/levamisole. The Intergroup trial 0089 of 3759 patients compared 1 year 5-FU/levamisole; 5-FU/high-dose LV for 32 weeks; and 5-FU/low-dose LV with or without levamisole for six cycles.<sup>11</sup> There were no differences between the four treatment arms

with regard to 5-year disease-free and overall survival. The NSABP CO-4 study<sup>12</sup> and the QUASAR Collaborative Group study<sup>13</sup> have later confirmed the survival advantage provided by LV modulation over levamisole. Based on the results of these studies, the new standard for treatment was changed to 6 months of adjuvant chemotherapy with 5-FU/LV for Stage III, node-positive disease.

The newer chemotherapeutic agents currently under study or in use for treatment of metastatic disease (e.g., irinotecan, capecitabine, oxaliplatin) are undergoing evaluation for their usefulness in the adjuvant treatment of patients with Stage II and Stage III disease. Recent data from the multicenter international randomized MOSAIC trial have confirmed that the addition of oxaliplatin to 5-FU/LV (FOLFOX) further decreases the risk of recurrence in Stage II and Stage III disease by 23%, resulting in a significant improvement in 3-year disease-free survival.<sup>14</sup> Another important trial, the PETACC 3 trial, will soon report the results. In that trial 5-FU/leucovorin is compared with irinotecan to 5-FU/LV (FOLFIRI) in both Stage II and Stage III colon cancer.

Several tumor characteristics such as microsatellite instability and the expression of DNA synthesis-associated enzymes have recently been found to predict chemoresistance to 5-FU and irinotecan.<sup>15,16</sup> This is an area of research that is evolving rapidly, and will certainly change the recommendations for adjuvant treatment in both node-positive and node-negative disease.

### Adjuvant Chemotherapy for Node-negative Disease (Stage II)

Whereas the efficacy and benefits of adjuvant chemotherapy for Stage III node-positive disease is unequivocally documented through numerous randomized trials, the role of adjuvant chemotherapy for Stage II node-negative disease is still controversial. The data from the early studies that prompted the NIH recommendation for adjuvant treatment in Stage III disease did not support a similar recommendation for Stage II disease.<sup>4,5</sup> Recent metaanalyses have yielded conflicting results. The IMPACT-B<sub>2</sub> (International Multicenter Pooled Analysis of B<sub>2</sub> Colon Cancer Trials) Group published a pooled analysis of five trials conducted from 1982 to 1989 and regrouping 1016 patients with Stage B<sub>2</sub> colon cancer.<sup>17</sup> Relapse rates, all-cause death rates, 5-year event-free survival and overall survival were similar in patients treated with adjuvant 5-FU/LV compared with controls. Increasing age and poor tumor differentiation were indicators of poor prognosis.<sup>17</sup> A SEER-Medicare cohort analysis of 3700 patients with resected Stage II colon cancer did not reveal any improvement in 5-year survival in patients having received adjuvant chemotherapy compared with controls (74% versus 72%).<sup>18</sup> In contrast, a pooled analysis of four NSABP trials (CO1, CO2, CO3, and CO4) with widely different treatment and control arms regrouping 1565 patients with Dukes' B disease (Stage II) and 2255 patients with Dukes' C disease (Stage III) concluded that patients with Dukes' B

disease (Stage II) should be offered adjuvant chemotherapy.<sup>19</sup> The authors calculated a 30% relative reduction in mortality for Stage II patients having received adjuvant chemotherapy. That metaanalysis has since been widely criticized for its methodologic flaws, and the controversy rages on. The likelihood of reaching a resolution on this subject is remote: to detect a significant survival benefit among Stage II colon cancer patients (who have an estimated 5-year survival of 80%), an adjuvant trial with a no-treatment control arm would require a sample size of 5000–8000 patients.<sup>20</sup> The recent data from the MOSAIC trial showing a significant improvement of 3-year disease-free survival and a 23% reduction of recurrence risk using a combination of 5-FU/LV/oxaliplatin (FOLFOX) in Stage II disease will undoubtedly spur renewed interest in this debate.<sup>14</sup> At this time, the use of adjuvant chemotherapy for Stage II node-negative disease remains an unanswered question, mainly because the prognosis for Stage II node-negative disease is good overall, and many patients would face unnecessary treatment. For the time being, patients with Stage II colon cancer at high risk for tumor recurrence might be considered for adjuvant treatment on an individual basis, or might be entered in a clinical trial.

### Radiotherapy

Local recurrence of rectal cancer after surgery with curative intent has always been recognized as a significant clinical problem. Combined chemoradiotherapy has been shown to increase both local control and survival for patients with locally advanced and node-positive rectal cancer.<sup>21</sup> In contrast, although local failure and recurrence after surgery for colon cancer had been described, there long existed an unwritten consensus that treatment failures in colon cancer surgery were primarily systemic rather than local. Thus, no prospective, randomized study was devised to provide data on the role of external beam radiotherapy in preventing local recurrence or improving survival after colon surgery. The recognition that selected individuals with colon cancer were at a high risk for local recurrence eventually came from retrospective reviews of patterns of failure after surgery with curative intent. Two large retrospective reviews<sup>22,23</sup> helped define the risk factors for local recurrence after surgery for colon cancer. Locoregional failure was identified in 19%<sup>22</sup> to 46%<sup>23</sup> of patients overall; at least half of local recurrences were in the original tumor bed. Only 13% of the local recurrences were salvageable surgically.<sup>22</sup> The most important risk factors for local recurrence were: 1) pathologic staging, with local recurrence rates of 35% in modified Astler-Coller Stages B3, C2, or C3 versus 7% in Stages A, B1, and C1<sup>2</sup>; 2) primary tumor localization in a fixed, nonperitonealized segment of the colon, with the highest failure rates in the cecum, descending colon, hepatic or splenic flexures, and sigmoid colon<sup>22,23</sup>; 3) colon carcinoma complicated by perforation or obstruction, with a two- to three-fold increase in local recurrence for any given pathologic stage.<sup>22</sup>

Identification of individuals at high risk for local recurrence after curative surgery for colon cancer triggered a number of studies on the role of external beam radiotherapy in preventing local recurrence or improving survival after colon surgery. Several disparate single-institutional retrospective studies suggested an improvement in local failure and recurrence rates with adjuvant radiotherapy compared with historical controls.<sup>25–26</sup> Wide variations in radiation techniques and doses, concurrent use and choice of chemotherapy, and patient selection criteria make comparison among studies difficult. Overall, local control rates ranged from 60% to 88%, a significant improvement over controls treated by surgery alone. A single randomized prospective study initiated jointly by the NCCTG and RTOG, comparing chemotherapy alone with F-FU/levamisole versus combined chemotherapy/radiotherapy closed prematurely because of poor accrual; although no differences were observed in overall survival between treatment arms, the study lacked sufficient statistical power to draw valid conclusions.<sup>27</sup>

At this time, the precise role of adjuvant radiotherapy in the treatment of colon cancer remains undefined. There are no data to support a systematic recommendation for therapy or a well-recognized adjuvant regimen. The potential risks of adjuvant radiotherapy for colon cancer, particularly radiation damage to surrounding organs (e.g., small bowel) are significant. Treatment for individuals deemed at high risk for local recurrence after curative surgery for colon cancer should be individualized.

### Immunotherapy, Tumor Vaccines, and Gene Therapy

The goal of cancer immunotherapy treatments is to stimulate the body's immune system in order to improve host defense mechanisms against growing tumors. Colorectal cancer immunotherapy strategies have evolved dramatically over the past 30 years. Nonspecific immune stimulation with bacterial cell products (e.g., BCG) and cytokines (e.g., interleukin-2) has recently been superseded by more specific immune stimulation targeted against colorectal tumor-expressed antigens. Whereas some tumor antigens are present in normal tissues but overexpressed in cancer, other tumor antigens are restricted to cancer tissues. Vaccines stimulate the immune system to recognize and act specifically against these tumor-expressed antigens, through either the humoral or cellular pathway.

More than 25 Phase I and Phase II studies have explored a variety of vaccines based on whole colorectal tumor cells, virus-modified tumor cells, gene-modified tumor cells, tumor antigen-derived peptides, tumor cell lysates, proteins or carbohydrates, monoclonal antibodies, plasmid or viral vectors encoding tumor antigens, and dendritic cell-based vaccines. Promising results were observed in some animal models and Phase I and II studies, prompting ongoing research efforts.

A few Phase III studies have also yielded promising results.<sup>28</sup> Three large studies have looked at the effect of immune stimulation with autologous irradiated tumor vaccine plus BCG in patients with colorectal cancer. Hoover et al.<sup>29</sup> randomized 98 patients with colon or rectal cancer to surgical resection alone or surgical resection followed by vaccination with autologous irradiated tumor plus BCG. There was no difference in disease-free or overall survival in the 80 eligible patients, but subset analysis showed a significant improvement in disease-free survival for colon cancer patients. The Eastern Cooperative Oncology Group (ECOG) randomized Stage II and Stage III colon cancer patients to either observation or vaccination with autologous irradiated tumor plus BCG. There was no survival difference between groups, but patients with a marked delayed cutaneous hypersensitivity showed a trend toward better disease-free and overall survival, suggesting that survival correlated with the patient's immune response to vaccination.<sup>30</sup> Vermoken et al.<sup>31</sup> randomized 254 patients operated for colon cancer to either observation or vaccination with autologous irradiated tumor plus BCG immediately after operation, followed by a vaccine booster 6 months after operation. The overall risk for recurrence was decreased by 44% in all vaccinated patients, with a 61% reduction in Stage II patients. Vaccination significantly increased recurrence-free survival, and there was a trend toward improved overall survival.<sup>31</sup> Because of its marginal efficacy, the complexity in the preparation of the vaccine, and the introduction of more effective chemotherapeutic agents, tumor cell-based immunotherapy is not frequently used in colon cancer patients.

Gene therapy is based on the concept of transferring genetic material into target cells, which would allow for correction of genetic defects in tumor suppressor genes, inactivation of oncogenes, or insertion of treatment-sensitizing genes (such as drug-converting enzymes) or "suicide genes" into the colorectal cells. Correction of p53 mutations, inactivation of k-ras gene product p21, and the delivery of prodrug converting enzymes are currently being studied. The long-term potential for clinical usefulness of these techniques remains to be defined.

### Rectal Cancer

Although surgery remains the central treatment of rectal cancer, the overall approach to treatment has changed dramatically over the last three decades. Surgical technique has been refined to become more focused and precise, with specific attention given to a locally more aggressive and meticulous technique. The modern multimodal therapy approach individualizes rectal cancer care, thus offering the best and most appropriate treatment to every single patient. Local and distant staging guides the decision for adjuvant radiotherapy and/or chemoradiotherapy and for available surgical approaches, i.e., local excision or an abdominal procedure.

Many prospective trials have demonstrated the beneficial effect of preoperative and postoperative radiation therapy in patients with rectal cancer who had surgery with curative intent.

The clinical benefits of radiotherapy in the treatment of rectal cancer can be broadly divided under four categories: first, radiotherapy lowers local failure rates and improves survival in resectable rectal cancer; second, radiotherapy allows surgery in nonresectable rectal cancer; third, it facilitates sphincter-preserving procedures in low-lying rectal cancer; and finally, it may offer a totally curative approach without major surgery.

Radiotherapy can either be used alone or in combination with chemotherapy. The numerous combinations and variations in radiotherapy and chemotherapy regimens make the evaluation and comparison of different multimodal therapy pathways difficult. In this section, we will review the results of various adjuvant treatment modalities in rectal cancer focusing on areas of clinical benefit. We will not discuss the role of curative radiation alone.

### Benefit No. 1: Radiotherapy Lowers the Local Failure Rates and Improves Survival in Resectable Rectal Cancer

According to three recently published metaanalyses, there is no doubt that neoadjuvant treatment is superior to adjuvant treatment with regard to reduction in local failure rates and cancer-specific survival.<sup>32–34</sup> The results of two of three other trials that specifically studied preoperative versus postoperative radiotherapy support the conclusions from the metaanalyses. The first report was the Uppsala trial in which short-course preoperative radiotherapy in all patients was compared with postoperative prolonged course only in patients with advanced cancers (Stages II and III).<sup>35</sup> The other two trials compared neoadjuvant chemoradiotherapy with adjuvant chemoradiotherapy with the same schedules and doses. The results from the NSABP R-03 trial, which closed prematurely because of poor accrual, showed that 44% of patients having undergone preoperative chemoradiation were disease free at 1 year, compared with 34% of patients who had received postoperative chemoradiation.<sup>36</sup> The German CAO/ARO/AIO trial has randomized patients with T3–4, N0, or any T,N1 rectal cancer to neoadjuvant chemoradiation followed by surgery and additional postoperative chemotherapy or postoperative chemoradiation.<sup>37</sup> In this study, surgery was performed according to the principles of sharp mesorectal excision. The rates of complete resection (R0) and sphincter-saving surgery were similar in both groups, but the 5-year cumulative rate of local relapse was 6% for patients assigned to preoperative chemoradiation and 13% for the postoperative chemoradiation group. Survival was similar in both treatment arms. Grade 3 or 4 toxicity occurred in 27% of patients in the preoperative chemoradiation group and 40% of patients in

the postoperative chemoradiation group. The results of this last study suggest that preoperative chemoradiation is the preferred adjuvant treatment in patients with locally advanced rectal cancer.

### *Neoadjuvant Therapy: Radiation Alone Versus Chemoradiation*

The potential advantages of neoadjuvant therapy include increased tumor radiosensitivity with decreased small bowel toxicity, decreased overall radiation-associated complications, and decreased risk of tumor seeding during surgery. The primary disadvantage of neoadjuvant therapy is the risk for overtreatment in patients with early-stage disease. New imaging modalities such as endorectal ultrasound<sup>38</sup> and magnetic resonance imaging<sup>39</sup> now allow for increasingly precise preoperative identification of patients with T2 and T3 tumors, thus minimizing the number of patients who would be overtreated by neoadjuvant therapy. Our ability to identify lymph node metastases preoperatively with any of these imaging modalities remains more limited.

A short course of preoperative radiation, 20–25 Gy given over 1 week is biologically equivalent to the traditional postoperative course of 45–55 Gy given over 5–6 weeks. It was long held that neoadjuvant radiation alone only improved local control but did not improve survival. In 1993, the randomized Swedish Rectal Cancer Trial (SRCT) demonstrated that a short course (25 Gy) of preoperative radiotherapy with surgery within the following week significantly reduced local recurrence from 27% to 12%, and improved 5-year survival rates from 48% to 58% when compared with surgery alone.<sup>40</sup> The main objection to all trials showing improvement in local recurrence and survival rates with radiotherapy, including the SRCT, was the high rate of local recurrence in the control arm that has been attributed to nonstandardized surgical technique.<sup>32–34</sup> Case series from specialized centers have reported lower local recurrence rates with surgery alone using meticulous surgical technique compared with patients treated with radiation and surgery in prospective trials when surgery was not standardized.<sup>41–43</sup> Several reports from different countries have confirmed that surgical skill is of utmost importance, thus opening for discussion the real role of radiotherapy when surgical technique is optimized.<sup>44–47</sup>

The role of preoperative radiation in patients with rectal cancer treated with optimal surgery was addressed in the Dutch Rectal Cancer Trial. All participating surgeons had adopted the technical “gold standard” of total mesorectal excision (TME) before entering patients. In this randomized, multicenter study of 1861 patients with rectal cancer, 2-year local recurrence rates were significantly improved from 8.2% to 2.4% when preoperative radiation was given before TME.<sup>48</sup> Five-year figures confirm a reduction in local recurrence rates from 11.4% after TME alone versus 5.6% for preoperative radiotherapy followed by TME but this does not translate into an improvement in 5-year survival rates (van de Velde,

personal communication). Thus, it seems that neoadjuvant radiotherapy still has a place in the treatment of rectal cancer, even when surgical technique is optimized.

The advisability of adding chemotherapy to preoperative radiation (and therefore to use neoadjuvant combined chemoradiotherapy) is undergoing intense scrutiny. Additional 5-FU-based chemotherapy may theoretically act as a radiosensitizer at the high cost of increased hematologic and gastrointestinal toxicity. Neoadjuvant chemoradiotherapy is recommended for advanced disease (T4, N0-2), but there is no randomized phase III study comparing neoadjuvant radiotherapy versus neoadjuvant chemoradiotherapy in resectable rectal cancer (T2-3, N0-2). Only one study is currently underway to examine this issue. In the EORTC 22921 trial, patients with T3, T4 NX rectal cancer are randomized to one of four treatment arms: preoperative radiotherapy followed by surgery only; preoperative radiotherapy followed by surgery and postoperative adjuvant chemotherapy; neoadjuvant chemoradiation followed by surgery only; and neoadjuvant chemoradiation followed by surgery and additional adjuvant chemotherapy.<sup>49</sup> The trial was closed in 2003 after enrolling 1100 patients. A preliminary analysis of acute toxicity has demonstrated that at the dose recommended in the trial, the addition of chemotherapy during the radiation increased the proportion of patients developing grade 2 diarrhea from 17% to 34%. However, compliance with the adjuvant therapy and the proportion of patients undergoing surgery did not change. The oncologic results of this trial have not yet been published.

#### *Postoperative Adjuvant Therapy: Radiation Alone Versus Chemoradiation*

The advantage of reserving adjuvant treatment for the postoperative setting is the ability to restrict its use to patients who are at identified risk for failure, based on their histopathologic staging. In the German CAO/ARO/AIO trial, 18% of patients diagnosed with Stage II or III rectal cancer based on endorectal ultrasound had pathologic Stage I disease and were probably overtreated. The disadvantages include the higher incidence of radiation-related complications, particularly small bowel radiation injury and a higher number of patients unable to complete the entire course of therapy because of treatment side effects. Other reasons are the relative radioreistance of the hypoxic surgical bed and the risk for repopulation of tumor cells from surgery to the start of radiotherapy.

Postoperative adjuvant radiation therapy alone decreases local recurrence, although not to the same extent as neoadjuvant treatment, and does not improve survival.<sup>50-52</sup> Several early studies revealed that the addition of 5-FU-based chemotherapy to postoperative radiotherapy increased local control (Mayo Clinic/NCCTG 79-47-51<sup>53</sup>) and significantly improved survival by 10%–15% (Gastrointestinal Tumor Study Group<sup>54</sup> and Mayo/NCCTG<sup>55</sup>). Despite the fact that all those trials were heavily underpowered, these findings prompted the National Cancer Institute Consensus

Conference of 1990 to recommend combined modality chemoradiotherapy as the standard postoperative adjuvant treatment for patients with Stage II and Stage III rectal cancer.<sup>55</sup> Although a recently published Norwegian trial confirmed<sup>56</sup> these findings, many countries, especially in Europe, did not follow those recommendations mainly because by then neoadjuvant radiotherapy had been proven to be more efficacious.

#### **Benefit No. 2: Radiotherapy Allows Surgery in Nonresectable Rectal Cancer**

The definition of a nonresectable rectal cancer is controversial. These tumors are clinically tethered or fixed but it is often difficult to predict whether fixation is the result of fibrotic adhesions or tumor infiltration of the pelvic sidewalls or adjacent organs.<sup>57</sup> Such tumors probably involve the fascia propria of the rectum, and a standard surgical resection following the principles of sharp mesorectal excision often results in tumor involvement of the circumferential resection margin. For the purpose of this section, we will define a nonresectable rectal cancer as a tumor that cannot be resected without a very high risk of local recurrence. Magnetic resonance imaging is particularly useful to determine the relationship of the tumor with the fascia propria of the rectum, and it may be the best imaging modality for the preoperative staging of patients with fixed tumors. Based on available data, patients with such locally advanced rectal cancer tumors benefit from preoperative radiotherapy with the aim of downsizing the tumor. Approximately 10%–15% of all patients with rectal cancer fall into this category; half of those patients have no metastases, indicating that there is potential for a curative procedure.<sup>26</sup> Based on tumor characteristics, surgery alone is unlikely to be curative and it is indicated to offer radiotherapy to those patients.

It must be emphasized that short-course radiotherapy is not an option in unresectable rectal cancer; a standard dose of 45–55 Gy over 5–6 weeks must always be given.

Radiotherapy is used to downsize tumors in this group of patients. After completion of standard-dose radiotherapy, a 6- to 8-week waiting period allows the tumor to shrink, increasing the possibility for a curative procedure.

The role of additional chemotherapy remains unclear in this context. There is very little solid evidence from randomized trials using chemoradiotherapy. One old trial (1969) reported positive results from chemoradiotherapy in locally unresectable rectal cancer.<sup>58</sup> Two other negative trials, published in the late 1980s, reported increased toxicity.<sup>59,60</sup> One underpowered Swedish trial (2001) showed improved local recurrence rate and overall survival in patients randomized to chemoradiotherapy versus radiotherapy alone followed by surgery.<sup>61</sup> Several phase II trials have reported a reduction in local recurrence rates and impressive data regarding survival<sup>62,63</sup>; problems with interpretation of case-mix and definition of “nonresectability” make the results of those trials difficult to

interpret. The LARCS Nordic trial, which randomized patients with unresectable rectal cancer to receiving either 50 Gy preoperatively or 50 Gy and chemotherapy preoperatively just closed and will help to shed some light on this question.

At this time, there is no good evidence supporting the use of chemotherapy in addition to radiotherapy for unresectable rectal cancer. Despite the lack of data and scientific evidence, most radiotherapists and medical oncologists have more or less accepted the concept of using chemoradiotherapy for nonresectable rectal cancer patients. It is likely that the trend will continue, until ongoing trials answer that question. The newer chemotherapeutic agents currently in use or under study for treatment of locally advanced and metastatic colon cancer (e.g., irinotecan, capecitabine, and oxaliplatin) will doubtless be evaluated for their usefulness in neoadjuvant and adjuvant treatment of rectal cancer in the near future. Their efficacy and usefulness is unknown at this time.<sup>64</sup>

### Benefit No. 3: Radiotherapy Facilitates Sphincter-preserving Procedures in Low-lying Rectal Cancer

Several series claim that preoperative radiotherapy (and preferably chemoradiotherapy) downsizes tumors to the extent that it is possible to increase the number of patients in whom the sphincters can be preserved.<sup>65-69</sup> There is even a report showing complete response to chemoradiotherapy in some patients with T4 tumors; some of these patients were not operated on and reportedly remain alive and well.<sup>70</sup> Caution must be exercised when reading these studies. First, rates of sphincter preservation do not tell the entire story; second, the main criticism of these studies is that modern therapies are compared with historical controls. The dramatic recent changes in surgical technique (TME, staplers) and the modern approach to rectal cancer treatment may partially explain the increased rate of sphincter preservation. We now accept a 5- to 10-mm distal margin as curative procedure if a stapled anastomosis is done.<sup>71,72</sup> Modern randomized trials must be done to verify the sturdiness of the conclusions. In the French R9001 trial, patients with T2 and T3 tumors received preoperative 39 Gy ( $13 \times 3$  Gy) and were randomized to immediate surgery or surgery 5 weeks after irradiation. Surgeons were asked before any treatment to evaluate the possibility to preserve the sphincters. Delaying surgery for 5 weeks after the end of radiation only slightly increased the rate of sphincter preservation.<sup>73</sup> This small trial indicates that there might be a downstaging and downsizing effect, which in turn might increase the rate of sphincter preservation. Of note, the overall recurrence rate in the trial was 9%, which is considered a high figure; more crucially, the local recurrence rate was 12% among the patients in whom the surgeon had originally planned an abdominoperineal excision but changed intraoperatively to a sphincter-preserving procedure because of the downsizing effect of radiotherapy.<sup>73</sup>

The German trial (CAO/ARO/AIO trial), in which patients were randomized to pre- or postoperative chemoradiotherapy, has shown a clear tendency to more favorable stage in patients having had preoperative treatment compared with postoperative chemoradiotherapy. In a subgroup analysis of patients determined by the surgeon before randomization to require an abdominoperineal resection, the proportion of sphincter preservation rate was 39% in the preoperative chemoradiation group and 18% in the postoperative chemoradiotherapy group.

In a recent Polish study, more than 300 patients were randomized to either short-course radiotherapy (25 Gy) with immediate surgery or long-course chemoradiotherapy and delayed surgery. T3 or resectable T4 tumors located within the reach of the examining finger, without evidence of sphincter involvement, and resectable with a 1-cm macroscopic distal margin were included in the study. Sphincter preservation and local recurrence rates were analyzed. Sphincter preservation rates were identical in both groups (61% in the short-course radiotherapy with immediate surgery versus 59% in the prolonged chemoradiotherapy course and delayed surgery).<sup>74</sup> This trial was conducted to determine whether chemoradiotherapy and delayed surgery had an impact on sphincter preservation. Accordingly, this is not a subset analysis of the data from the trial, indicating the strength of the results. At this time, there is no evidence that prolonged-course radiotherapy combined with chemotherapy with delayed surgery impacts sphincter preservation. It is possible that increasing the waiting time from end of radiotherapy to surgery will achieve further downsizing, which might improve sphincter preservation.

An important consequence of increased sphincter preservation is poor function. Poor quality of life may be the price to pay for intact sphincters: up to 20% of all patients who undergo a low anterior resection are incontinent of solid stool.<sup>68</sup> This contrasts with reports that patients with a stoma had a better quality of life compared with those with an anterior resection.<sup>75</sup> This must be considered when selecting surgical options for individual patients.

### Adjuvant Chemotherapy Alone in Rectal Cancer

In contrast to colon cancer, chemotherapy alone as adjuvant treatment in rectal cancer remains questionable. In the early 1980s, underpowered United States radiotherapy trials concluded that chemotherapy improved survival compared with surgery alone. Two large randomized trials comprising more than 4000 patients have studied the value of chemotherapy versus surgery alone in colon and rectal cancer patients. Combination 5-FU/levamisole and 5-FU/LV were found to improve survival in patients with colon cancer, but showed no benefit in patients with rectal cancer.<sup>76,77</sup> These results underscore the difference in chemotherapy effectiveness for rectal cancer and colon cancer. The reasons for this are unclear:

different tumor profiles or lack of proper surgical technique at the time of these trials may partly explain the results. At this time, adjuvant chemotherapy alone is not acceptable in rectal cancer. However, postoperative chemotherapy is currently used to reduce the risk of distant relapse in patients with rectal cancer treated with pre- or postoperative chemoradiation and radical surgery.

# Colorectal Cancer Surveillance

Brett T. Gemlo and David A. Rothenberger

The majority of colorectal cancers are resected for cure, leaving many patients eligible for ongoing surveillance. The best schema for clinically useful and cost-effective follow-up is still controversial, but the goals are clear. Rational follow-up should detect treatable recurrent cancers, identify and remove metachronous polyps, and identify possible hereditary influences in development of a colorectal cancer. In theory, such follow-up will increase the survival of patients with cancer and improve their quality of life by successfully treating recurrences, preventing metachronous cancers of the colon or rectum, as well as preventing subsequent hereditary cancers from developing in the patient and/or their family members. How to accomplish this is still controversial, but it is clear that accurate risk stratification and patient selection are central to any program of surveillance. The intensity of surveillance should be proportional to the patient's risk of recurrence, and those patients unfit for further surgery because of age or comorbidity may be best served by colonoscopic follow-up only.

## Types of Surveillance

### Metachronous Colorectal Neoplasms

Those patients who have undergone successful treatment of a colorectal malignancy have an increased risk of developing subsequent polyps or cancers compared with the rate at which an age-matched control population would develop their first colorectal neoplasm. The period of risk for the development of metachronous disease seems to be lifelong and cumulative. The risk of developing metachronous polyps ranges between 30% and 56%, and the risk of a second cancer is 2%–8%.<sup>1–3</sup> Because these cancers arise from adenomatous polyps, periodic colonoscopy with polypectomy should prevent the development of subsequent cancers. The starting point and appropriate interval for surveillance colonoscopy in the population of patients undergoing follow-up for colorectal cancer

are controversial and poorly studied. In the past, most clinicians advocated colonoscopic follow-up 1 year after surgery to visualize the anastomosis and look for missed synchronous lesions. Recently, the utility of early follow-up colonoscopy 1 year after surgery compared with delaying colonoscopy until 3 years after surgery has been questioned. The Standards Task Force of the American Society of Colon and Rectal Surgeons (ASCRS) has recommended colonoscopy surveillance to begin 3 years after surgery assuming preoperative or intraoperative clearance was done and was negative.<sup>4</sup> If preoperative or intraoperative clearance examination could not be done, postoperative colonoscopy within 6 months of surgery is recommended. If multiple synchronous polyps are identified, during the clearance examination, it may be reasonable to do the first surveillance examination at 1 year. Otherwise, posttreatment colonoscopy should be performed at 3-year intervals. Follow-up surveillance colonoscopy every 3 years can be continued for the duration of an individual's active life. It is also acceptable to extend follow-up colonoscopy to every 5 years after a negative colonoscopy at 3 years. Once the patient is older than age 80, further examinations may be of limited usefulness although exceptions can be made for individuals who are healthy and active despite their advanced age.

### Recurrent Cancer

The term "recurrent cancer" is a misnomer because the cancer does not disappear and then return. It simply progresses in sites not clinically detectable at the time of the original surgery. Locoregional recurrences are more common in cases of rectal cancer, and may represent inadequate tumor clearance at the time of surgery. Distant disease, typically in the liver or lungs, usually does not cause symptoms until the situation is quite advanced. Options for the detection of asymptomatic recurrences include physical examination, carcinoembryonic antigen (CEA) monitoring, colonoscopy, chest X-ray, (CXR), and various scans. In this high technology era, careful attention to new symptoms such as abdominal pain, change in

bowel habits, weight loss, or anorexia is often lacking, but such symptoms are the first sign of recurrence in many cases. When present, a meticulous physical examination is conducted. This should include a digital rectal and vaginal examination for patients with rectal cancer. CEA testing is most useful in cases in which the level was increased preoperatively but decreased to normal levels after resection. Even in cases in which the preoperative CEA level is normal, serial CEA testing is often the first indication a patient has recurrent disease. Although CEA testing is controversial, the Standards Practice Task Force of the ASCRS recently recommended that CEA testing should be used as a part of follow-up for patients with colorectal cancer. This may be justified if its use is restricted to those who would tolerate reoperation if a recurrence were identified. Endoscopic follow-up is of limited usefulness in looking for recurrences because only 2% of recurrences are visible at colonoscopy. This is especially true for colonic anastomoses where recurrence is rare as compared with rectal anastomoses where mucosal recurrences are more likely to develop. Rigid proctoscopy is an alternative and, some suggest, superior way to assess a rectal anastomosis for recurrence. Patients with rectal cancer, especially those treated with transanal excision, should undergo endorectal ultrasound surveillance (usually every 3 months for the first year). There are currently insufficient data to recommend for or against routine use of CXR to identify an asymptomatic pulmonary metastasis. Its use should be restricted to patients who would tolerate a pulmonary resection. Computerized tomography (CT) and magnetic resonance imaging (MRI) scanning are very sensitive ways to detect liver and lung metastases, but are not recommended as a routine screening procedure. Positron emission tomography (PET) scanning may become the most sensitive way to detect recurrences, but although it is becoming more widely available, data supporting its use are still lacking. Although PET scanning is limited in its usefulness in detecting recurrence, it has been helpful in identifying patients with recurrence who have too many areas of distant recurrence to warrant operative therapy to remove the local, liver, or lung recurrence detected initially. Patients with isolated metastatic disease (fewer than eight liver metastases or 1 or 2 lobe lung involvement) may be candidates for operative treatment (see Chapter 34). As chemotherapy improves, operative therapy to resect residual disease may be more important to extract a cure.

### Hereditary Cancer

Hereditary is thought to be a major factor in 10%–25% of colorectal cancers. Patients who developed their cancer before age 50 years or who have first-degree relatives who developed colorectal or associated cancers such as endometrial, ovarian, ureteral, or bladder cancer or who have multiple family members with varying cancers especially if diagnosed before 50 years of age may have a hereditary cancer. Some inherited syndromes predispose the individual not only to development

of young-age-of-onset colorectal cancer but also other organ cancers. Thus, in addition to informing family members of their risks and need for intensive surveillance, the patient's follow-up plan may need to incorporate surveillance of other potential sites of cancer. Sometimes, genetic counseling and testing is useful and prophylactic surgery may be considered as in the case of hereditary nonpolyposis colon cancer syndrome.

### Risk of Recurrence/Pattern of Recurrence

The risk of recurrence is proportional to the stage of the original disease. Most Stage IV patients have undergone palliative treatment and are not candidates for surveillance unless they were treated by operative removal of metastatic disease. Patients with Stage I colon cancer treated by radical surgery have such a low chance of recurrent disease that routine surveillance may not be justified. However, Stage I rectal cancer patients treated by local therapy are at significant risk of local recurrence and may deserve close follow-up. Patients with Stage II or III disease would seem to benefit most from close surveillance. Other tumor or surgery related factors such as degree of differentiation, presence of lymph node metastases, iatrogenic perforation, and poor primary tumor clearance, influence the risk of recurrence, and could be used to more accurately predict an individual patient's risk of recurrence, and guide the development of a specific follow-up program. To date, there is no standardized formula for doing this but an experienced clinician can individualize follow-up based on the risk of recurrence, the patient's overall health status, the patient's willingness to undergo serial testing and the ability for the patient to undergo aggressive retreatment if recurrence is identified.

The patterns of recurrence reflect the location of the primary tumor.<sup>5</sup> Rectal cancers tend to recur locally in the pelvis, but this tendency has diminished recently with improved mesorectal clearance techniques and the use of neoadjuvant chemoradiation. All colorectal cancers metastasize hematogenously to the liver and lungs as well as to regional lymphatics, and these areas need to be evaluated when looking for recurrent disease.

It is well established that 60%–80% of recurrences occur within 2 years of surgery, and more than 90% of recurrences are found within 5 years. Therefore, follow-up protocols should be most intensive for the first 2 years, and then taper off in frequency of evaluations over the next 3 years. The exception to this timing of recurrence is the patient who has had pelvic radiation. In such cases, recurrence tends to occur later so intensive surveillance may need to extend to 5 or 6 years. Subsequent to that, the risk of recurrence is so low that colonoscopic surveillance for metachronous cancers is all that is warranted. The development of symptoms at any time during follow-up should prompt a thorough diagnostic work-up and specific treatment.

## Surveillance Effectiveness

The utility of a surveillance program should be manifest in an improvement in survival or quality of life when compared with patients who have received little or no follow-up. Several variables confound our ability to evaluate the advantages derived from intensive efforts to detect recurrent cancer before it becomes evident clinically. The first is the lead time bias that results from detecting asymptomatic recurrences. Early detection of such a recurrence for which no effective treatment can be offered will still result in a measured prolongation of survival from the time of diagnosis of the recurrence when compared with those patients treated for symptomatic recurrences because they were identified earlier. Even if the treatment provided does impart some benefit, the bias between groups persists.

The identification of recurrent disease does not necessarily result in improved outcomes. Only about 10% of recurrences are resectable with curative intent and chemotherapy offers little chance of cure. Those patients who are fortunate to have a lesion amenable to surgery are often not suitable surgical candidates as a result of age or comorbidity, and should not be subjected to intense follow-up because any information obtained cannot be acted upon. There is a subset of patients with resectable disease, who may benefit from radical resection, with 5-year survivals of 25%–30% in most series. PET scanning can assist in identifying this small group of individuals.<sup>6</sup>

The results of intensive follow-up programs reported in the literature have been disappointing. A recent review summarized the results of the six randomized, prospective trials of high-intensity versus low-intensity follow-up after surgical resection with curative intent for colorectal cancer.<sup>7–13</sup> Recurrences were not more common in the closely monitored group, but they were found earlier and were more likely to result in reoperation with curative intent. Despite this, only two of the six studies demonstrated a statistically significant improvement in overall survival as a result of intensive surveillance.

Because of the concern that inadequate sample size was in part responsible for the negative results encountered in the above studies, three separate metaanalyses have been conducted on these data.<sup>6,14,15</sup> Although this resulted in a more clearly discerned reduction in death from recurrent cancer, the reduction in absolute risk was only 7%.

## Cost of Surveillance

Offsetting the survival benefits of an intensive surveillance program are the costs associated with such testing. Given the large number of patients involved, cost implications for Medicare and private insurers are significant. The heterogeneity of follow-up regimens results in 5-year Medicare-allowed charges of \$910 to \$26,717 per patient.<sup>16</sup> One of the

above metaanalyses evaluated the cost-associated intensive follow-up in terms of cost per year of life gained and found it to be \$6096.<sup>17</sup> Beart's hypothetical cost analysis of a program to closely follow Stage II and III patients resulted in a cost of \$6558 per patient salvaged by resection.<sup>18</sup> Although these costs are significant, they seem to be below the accepted threshold of \$30,000 per year of life gained.

## Quality of Life

Intensive surveillance may have a negative impact on quality of life secondary to the anxiety, inconvenience, and cost associated with the testing. Conversely, intensive testing may be reassuring to patients and improve their quality of life. Investigators in Denmark found that although patients subjected to closer follow-up expressed greater confidence in their examinations, the increment in quality of life was marginal and did not justify the expense of follow-up.<sup>19</sup> Stiggelbout et al.<sup>20</sup> also showed no differences in health-related quality of life when different intervals of follow-up were studied but they did show patients had a strong preference for follow-up. Additional data are needed to determine methods and settings for follow-up that maximize both survival and the quality of life.

## Recommendations

Recommendations for surveillance of patients who have undergone curative resection of colorectal cancer are as follows.

Virtually all patients can undergo follow-up studies that are focused on excluding hereditary cancer and on prevention of synchronous cancer by every 3- to 5-year surveillance colonoscopies to remove metachronous polyps. If hereditary cancer is likely, work-up appropriately and/or consider referral to experts in hereditary cancers. In addition to counseling the patient about their own risks for other sites of cancer development, the clinician must attempt to educate the patient's family members about their risks and surveillance or treatment options.

The search for treatable recurrent disease is more selective. It is helpful to first determine whether the patient has a significant risk of recurrence. If so, determine whether the patient prefers an aggressive approach to follow-up testing and whether the patient could tolerate retreatment if recurrence is identified. If there is a minimal risk of recurrence and/or the patient refuses or is not a candidate for aggressive follow-up, no additional testing is done. It is comforting for patients to know that should recurrence develop, you are available and palliative treatment can be instituted. Patients should still undergo routine colonoscopic surveillance every 5 years to detect metachronous polyps or cancer.

If there is a significant risk of recurrence and the patient wants aggressive follow-up and would tolerate retreatment,

follow-up will include the search for recurrent disease. Typically this includes: history, physical examination, and serial testing as noted below every 3–6 months for the first 3 years, and then every 6–12 months for an additional 2 years. If pelvic radiation was used for rectal cancer, the closer interval of follow-up may need to be extended to 5 or 6 years. Careful attention to new symptoms and physical finding should be made.

Complete colonoscopy before resection, followed by an examination 1–3 years after surgery and every 3–5 years thereafter for the duration of the patient's productive life.

Serial CEA testing every 3 months for the first postoperative year or two and every 6–12 months thereafter for patients who desire an aggressive follow-up protocol and would tolerate aggressive retreatment for locoregional disease or hepatic or pulmonary metastasis.

Serial CXR every 6–12 months for patients who desire an aggressive follow-up protocol and would tolerate pulmonary resection.

Serial proctoscopy and selective endorectal ultrasound for rectal cancer patients who desire an aggressive follow-up protocol and would tolerate aggressive radical pelvic surgery with or without additional radiation and chemotherapy.

Based on the available evidence, there is no role for the routine use of liver function tests, hemoglobin, CT scanning, MRI, or PET scanning in asymptomatic patients.<sup>4,7</sup>

Future studies may more clearly define the role of these and other surveillance modalities.

# Management of Locally Advanced and Recurrent Rectal Cancer

Robert R. Cima and Heidi Nelson

Of patients with newly diagnosed colorectal cancer who will undergo surgery with curative intent as part of their treatment, approximately 5%–12% will have tumors that have spread beyond the anatomic landmarks of a standard resection and have invaded adjacent organs or structures.<sup>1–3</sup> The goal of surgery in such cases is a wide, en bloc resection of the tumor and any involved adjacent organ or structure. Of patients who undergo resection with curative intent and receive adjuvant therapy, between 7% to 33% develop isolated local or regional recurrences.<sup>4,5</sup> In up to 20% of these recurrences, resection can be curative.<sup>4,6,7</sup>

Although tumor biology must influence the rate and location of recurrence, no tumor-specific characteristics have been clearly associated with local recurrence. The most important factor that influences tumor recurrence is the stage of disease at presentation.<sup>8</sup> Others include obstruction or perforation at presentation, adjacent organ involvement, tumor aneuploidy, increased tumor grade, mucin production, or evidence of venous or perineural invasion. Over the last decade, the adequacy of surgical resection and the use of preoperative chemoradiation have been shown to influence the rate of pelvic recurrence.<sup>9–12</sup> Detailed discussion of these aspects of rectal cancer treatment is addressed elsewhere in the textbook. The focus of this chapter is to discuss the evaluation, operative management, and multimodality treatment of patients with locally advanced rectal cancer. Because the preoperative evaluation, operative approach, and often the perioperative oncologic therapy are similar for primary locally advanced and recurrent rectal cancer, they will be discussed together. The outcomes for the different approaches are evaluated later in the chapter.

Locally advanced primary rectal cancers include tumors that are T4 N1–2 MX at the time of initial presentation. They are often associated with a higher rate of metastatic disease at the time of diagnosis and have a poorer overall prognosis than earlier-stage disease.<sup>8</sup> T4 tumors are found to be fixed by physical examination or to be invading adjacent organs or structures by diagnostic imaging studies. For T4 tumors,

standard surgery alone offers a limited chance of significant local tumor control and/or long-term survival. In cases in which an extended en bloc resection cannot be performed to achieve complete resection, patient survival is dismal: after no treatment or after palliative surgery, mean survival time is less than 1 year.<sup>13</sup>

Multimodality therapy incorporating radiation, chemotherapy, and surgery should be used to achieve local tumor control and to prevent or control systemic tumor dissemination, thereby improving patient survival for patients with locally advanced primary or recurrent colorectal cancers. To achieve these goals, appropriate surgery is combined with external-beam radiation therapy (EBRT), and, under ideal circumstances, intraoperative radiation therapy (IORT) and adjuvant or neoadjuvant chemotherapy.

Patients with isolated hepatic or pulmonary metastasis from a rectal cancer are known to have reasonable survival after surgical treatment; however, survival with an isolated, untreated, locoregional, rectal cancer recurrence is quite poor.<sup>14,15</sup> Most of these patients develop disabling complications, including severe pain from bony or nervous tissue involvement, urinary obstruction, fecal obstruction or incontinence, or persistent bleeding. Nearly 90% of rectal cancer recurrences after surgery alone occur in the central or posterior pelvis, and 19% occur at the anastomosis.<sup>16</sup> Stage T4 primary tumors are significantly associated with relapse in the anterior pelvic region.<sup>16</sup> EBRT alone or combined with systemic chemotherapy may result in temporary improvement of symptoms, but the 5-year survival rate is less than 5%.<sup>14,15</sup> Surgical palliation without the addition of systemic chemotherapy and radiation therapy adds little to the overall survival. For these patients, length of survival is perhaps less important than quality of life.

A patient who presents with a locally advanced primary or recurrent rectal cancer must be thoroughly evaluated for the presence of extrapelvic disease. If extensive extrapelvic disease is found, the degree and scope of surgical resection should be changed from one of curative intent to palliation.

An exception may be considered in younger patients with no significant comorbidities in whom a single, isolated, hepatic metastasis is found that could be surgically resected. However, if a patient has multiple sites of spread or significant comorbidities, extensive surgery involving multiple structures is not warranted, as the chance for cure is quite small. Whether a patient is a candidate for surgery is influenced by a number of factors, including the patient's overall physical condition and comorbid diseases and the extent of spread and fixation of the tumor outside of the rectum.

## Preoperative Evaluation and Patient Selection

Complete resection of a locally advanced primary or recurrent rectal cancer is a significant undertaking. Complete resection may be technically possible in some patients, but if their overall physical condition does not make them an appropriate candidate, surgical palliation combined with chemoradiation is the more prudent course of action. To be considered for a complete resection, the patient should be in generally good health. Any significant cardiac or respiratory conditions should be thoroughly evaluated and treated. Patients who are in poor health, or who will not be able to tolerate multimodality therapy combined with complete surgical resection, or have an ASA classification of IV–V are not considered acceptable surgical candidates. Nearly as important as their physical condition is consideration of the patient's motivation and emotional preparedness for undergoing this extensive treatment. They should be thoroughly informed about and accepting of the short-term and long-term risks associated with the surgery, as well as possible subsequent surgeries or interventions required for postoperative complications.

If the patient is deemed an acceptable candidate for surgery, the next step is evaluation for the extent of local spread and the possibility of extrapelvic spread. A detailed history should be obtained. Symptoms that may suggest metastatic disease, such as back or bone pain outside of the pelvis, new respiratory symptoms, or headaches need to be carefully examined. A thorough physical examination, with particular attention placed on the rectal and vaginal examination, needs to be performed and any fixation of the tumor to rigid pelvic structures needs to be assessed. Complete endoscopic evaluation of the colon needs to be performed, if technically possible, to rule out the presence of a synchronous lesion. Endoluminal ultrasound of the rectum may be combined with this evaluation in cases of recurrent disease to determine if there is a discrete mass adjacent to the intestine that might be amenable to endoscopic biopsy. Imaging should be repeated before surgery is considered and compared with similar previous studies to give some reassurance that there has been no progression or spread of the disease that might change or preclude any surgical intervention. The abdomen and pelvis need to be evaluated with a double contrast (intravenous and oral)

computed tomography (CT) scan to exclude extrapelvic spread and to assess the extent of possible resection. CT scans are generally reliable for identifying the extent of disease and adjacent organ involvement but are less discriminating for predicting local tumor resectability.<sup>17</sup> Any suspicious hepatic lesion should be examined with ultrasound. If the lesion is worrisome for metastatic disease, it should be biopsied. Questionable findings on the chest X-ray film should be further investigated. Any worrisome lesion that is technically accessible should be biopsied percutaneously.

Although the above tests are the standard evaluation for diagnosing recurrence and excluding extrapelvic spread of the tumor, other, more tumor-specific tests have been proposed as adjuncts. Magnetic resonance imaging (MRI) might be more accurate than conventional CT scanning for detecting recurrences in the pelvis or elsewhere in the abdomen because of better image resolution. However, similar to CT scans, MRIs provide only anatomic details and may not be any better at distinguishing tumor recurrence from scar in a postoperative field, particularly after pelvic irradiation. To overcome this limitation, a metabolic-based imaging modality such as positron emission tomography (PET) has been studied.<sup>18–22</sup> Colorectal cancer is known to rapidly metabolize fluorine-18 fluorodeoxyglucose (FDG), which therefore can be used as a metabolic label to detect tumor deposits, not only in the pelvis, but throughout the entire body. Numerous nonrandomized studies have shown that FDG-PET imaging for recurrent colorectal cancer has a significantly higher sensitivity and specificity than CT scanning. When CT scanning was compared with FDG-PET imaging in postoperative patients with colorectal locoregional recurrences, the sensitivity of FDG-PET was significantly higher than CT plus colonoscopy (90% versus 71%, respectively), although the specificities were similar (92% versus 85%, respectively).<sup>23</sup> FDG-PET imaging has been shown to maintain this high sensitivity and specificity, 84% and 88%, respectively, even in the setting of the previously irradiated and postoperative pelvis.<sup>18</sup> Thus, FDG-PET might be a useful tool in the postoperative patient in whom there is a suspicion of recurrence but equivocal CT findings, and in whom extensive reoperative surgery might be extremely high risk.

Even the combination of physical examination and radiographic studies may not be able to prove that there is a pelvic recurrence of a rectal cancer, especially if the patient has undergone a previous pelvic operation or pelvic irradiation. We generally accept three ways of differentiating postoperative changes from tumor. The first is to document a change in the lesion, such as increase in size over time; the second is invasion of the adjacent organs; the third is histologic evidence obtained from endoscopic, CT- or ultrasound-guided biopsies of the suspicious tissue. However, occasionally pelvic disease is suspected from an increasing carcinoembryonic antigen or development of symptoms without any definable anatomic change on examination. In such situations, histologic proof should be vigorously sought. Exploratory

pelvic surgery should be strongly discouraged because it poses an extreme risk to the patient and makes future evaluation of the pelvis even more difficult.

## Determining Resectability

Locally advanced primary or locoregional recurrences of rectal cancers can extend to involve any of the pelvic organs or rigid bony structures of the pelvis. Resectability is based on the anatomic location and what other structures are fixed to the lesion. Although there are other schemes for assessing resectability, we use the following one to classify our patients who are being considered for possible resection. The tumor is classified as F0 when it is not fixed to any pelvic organ or structure, FR when the tumor is fixed but resectable, and FNR when the tumor is fixed and not resectable. FR is further subdivided by noting the anatomic extent of the fixation (anterior, posterior, and lateral).<sup>24</sup> Identifying the anatomic extent provides a better appreciation of the scope of the required resection. For example, anterior fixed lesions may require a hysterectomy, vaginectomy, a partial or complete cystectomy, or prostatectomy, whereas lesions that are fixed posteriorly may require a sacrectomy (Figures 33-1 to 33-3).

Although we have found this classification scheme to be extremely useful, it does not reliably predict resectability before surgery because new findings may be discovered at operation. However, in our experience, some factors are clearly associated with an unresectable tumor (Table 33-1). Any circumferential tumor that extends to the pelvic sidewall is considered unresectable. Evidence of bilateral ureteral obstruction is a very worrisome finding. Unless there is focal infiltration of the bladder trigone causing bilateral ureteral obstruction, this finding usually indicates that a bulky tumor has invaded both lateral pelvic sidewalls. This means that the disease is present at the level of the pelvic inlet, making complete resection impossible. Finally, S1 and S2 nerve root involvement or evidence of invasion of the sacral bone at the level of S1 and S2 indicates an unresectable tumor. A sacrectomy proximal to S2 results in sacroiliac joint instability and although internal fixation is possible, it is not warranted for cases of locally recurrent rectal cancer. Pain from nerve root involvement with tumor occasionally needs to be differentiated from sciatic nerve compression. Nerve compression symptoms may completely resolve after pelvic irradiation and chemotherapy. However, persistent buttock and perineal pain usually resulting from tumor expansion and ingrowth is a more ominous symptom.

FIGURE 33-1. **A** A primary T3N0M0 rectal cancer treated with a low anterior resection without adjuvant therapy. The anterior recurrent tumor fixed at the base of the bladder was treated with preoperative chemoradiation and then resection with IORT. **B** After a primary low anterior resection for T2N0M0 rectal cancer without adjuvant therapy, this patient developed a lateral pelvic recurrence. After preoperative chemoradiation, the patient underwent an abdominal perineal resection with negative margins.

FIGURE 33-1. (Continued) **C** A recurrence after a T3N0M0 lesion treated with postoperative chemoradiation therapy was found to invade the sacrum. After additional EBRT and chemotherapy, IORT combined with an en bloc resection of the tumor and distal sacrum was performed with negative margins. **D** A massive recurrent cancer found in the pelvis after an abdominal perineal resection and postoperative chemoradiation. The tumor was fixed to vital pelvic structures and was deemed unresectable. (Reprinted from Nicholls RJ, Dozois RR, eds. *Surgery of the Colon and Rectum*. TABLE 33-1. Symptoms or findings suggestive of unresectability for cure

Sciatic pain
Bilateral ureteral obstruction
Multiple points of tumor fixation to the pelvic sidewall
Circumferential involvement of the pelvic sidewall
S1 or S2 bony or neural involvement
Extrapelvic disease

## Multimodality Therapy for Advanced or Locally Recurrent Rectal Cancer

Surgery with curative intent is the mainstay of treatment for advanced or locally recurrent rectal cancer. However, surgery alone results in a high rate of local and distant failure.<sup>13</sup> To

improve outcomes, surgery is combined with multimodality therapy, radiation, and chemotherapy. Radiotherapy is used to improve local control and systemic chemotherapy is used to treat possible disseminated disease.

Although EBRT may relieve symptoms and pain resulting from a large primary or recurrent rectal tumor, it alone does not offer a significant chance of cure.<sup>25</sup> However, when it is combined with sensitizing chemotherapy, the probability of achieving a resection with negative margins and the rate of local tumor control increases.<sup>26–29</sup> In the setting of a locally advanced or recurrent rectal cancer, centers have combined multimodality therapy with intraoperative radiotherapy—as electron beam radiation therapy, high-dose-rate brachytherapy, or traditional perioperative brachytherapy to further improve patient outcomes.<sup>30–37</sup> These forms of locally

directed radiation reduce toxicity by limiting normal tissue exposure and deliver a high biologically equivalent dose to the localized area of the tumor.

In general, for patients who never received prior pelvic radiation therapy, a full course of EBRT (5040 cGy) is administered with concurrent 5-fluorouracil chemotherapy. Often, patients with recurrent rectal cancer have previously received a full course of pelvic EBRT. We treat such patients with an additional course of 2000 cGy of EBRT combined with additional 5-fluorouracil chemotherapy before repeating pelvic surgery. Therapeutic synergy between external beam and intraoperative radiation reaches its peak within 8 weeks of completion of external beam therapy. The disease is restaged clinically and radiographically 4 weeks after completion of the external beam and chemotherapy course. If there is no evidence of disease progression in the pelvis or extrapelvic metastasis, the patient is scheduled for surgery within the next 4 weeks.

## Surgery

Before surgery, the magnitude of the operation and the possible complications are discussed in depth with the patient and family members. Very rarely in cases of locally advanced primary rectal cancers can the sphincter mechanism be preserved. In recurrent cancers, there is little role for an attempt at sphincter preservation. Therefore, the patient must be accepting of a permanent colostomy. In addition, the resection of adjacent structures or organs and the functional implications and reconstruction alternatives, such as an ileal conduit, need to be discussed.

Patients are admitted the night before surgery for mechanical and antibiotic bowel preparation, intravenous hydration, and instruction in preoperative incentive spirometry. At our institution, all cases of locally advanced or recurrent rectal cancers are scheduled in a dedicated IORT suite. This suite within the operating room complex houses the standard operating room equipment, a linear accelerator, and special anesthetic equipment that permits the anesthetized patient to be moved from operating to irradiating positions (Figure 33-2). In addition, remote controls are used to monitor the patient outside the suite while radiation is given. The patient is placed in the lithotomy position with both arms tucked and the legs supported in Allen stirrups. Special care is taken to ensure that the arms are well padded and in a neutral position to avoid any nerve injury. The calves are positioned and padded to avoid any pressure from directly resting on the stirrups because the lengthy operation may result in compartment syndrome and/or venous thrombosis.<sup>38</sup> Bilateral ureteral stents are inserted cystoscopically preoperatively.

A midline incision is usually made. Transverse abdominal incisions should be avoided because they compromise the placement of any stomas and may injure the inferior epigastric vessels, the primary blood supply of the rectus muscle.

Preservation of the rectus muscle is important in case a transpelvic rectus abdominis flap is required to reconstruct the pelvic floor. If the patient has had prior abdominal surgery, all adhesions need to be lysed. If any of the small bowel is adhered into the pelvis or in a region that might be indicative of tumor, a sample should be sent for intraoperative biopsy. If the bowel is involved with tumor, then that portion of the small bowel will need to be resected with the rectal tumor en bloc. Once all adhesions have been lysed, the entire abdomen needs to be thoroughly explored for evidence of extrapelvic tumor deposits. The liver, omentum, retroperitoneum, peritoneal lining, and the area of any prior surgical incision need to be carefully examined because they are frequently involved with recurrent disease. Any suspicious finding should be analyzed by frozen section. The presence of extrapelvic disease would be a contraindication to radical resection. Very rarely, exceptions may be made in a young patient who has limited pelvic and liver disease; in such cases, the pelvic recurrence and secondary liver tumor are resected simultaneously.

A self-retaining retractor is placed and the small bowel is packed into the upper abdomen to facilitate pelvic exposure. Because pelvic irradiation or prior pelvic surgery will have induced significant fibrosis in the tissues of the pelvis, we begin the dissection at the level of the aortic bifurcation. Starting at this level allows us to enter a virgin fascial plane, which aids in the posterior dissection to the level of the pelvic floor. Similarly, the ureters are identified before they enter the pelvis and are then mobilized along their length along the pelvic sidewall and into the bladder. Identifying the ureters all the way to their insertion into the bladder is important to ensure adequate length if an ileal conduit is required for urinary tract reconstruction.

For rectal cancer recurrences that are not fixed to any pelvic structure (F0), a completion abdominoperineal resection (APR) is required. The scope of the resection is similar to a standard APR but the pelvic fibrosis induced by any prior surgery will have distorted or eliminated the ideal, relatively bloodless plane between the mesorectum and sacral fascia. The distinction between fibrosis and tumor infiltration into adjacent tissue can be very difficult to discern at the time of the operation. If there is any question about the nature of the tissue, particularly when it occurs outside the realm of planned resection, for example, at the level of the sacral promontory or the lateral pelvic walls, a frozen section should be analyzed. If tumor cells are seen, a complete resection with negative margins is not feasible. As will be discussed later, it is in this setting that the use of IORT improves clinical outcomes.

When the tumor is fixed, either anteriorly or posteriorly, the scope of the operation is much larger than for the non-fixed lesion (F0). If the fixed tumor is considered resectable, we classify it as a FR (fixed, resectable) lesion. For anteriorly fixed tumors there are different operations that need to be considered, whereas for a primary or recurrent posteriorly fixed tumor that is fixed posteriorly, our operation of choice is an en bloc distal sacrectomy.

For the anteriorly fixed lesion, the choice of operation is influenced somewhat by the sex of the patient. In a woman, depending on the level and extent of the tumor, the resection may require only an en bloc excision of the posterior wall of the vagina, with immediate reconstruction. When the upper vagina or lower uterus is involved more extensively, en bloc hysterectomy and posterior vaginectomy would be necessary. A woman who has her uterus usually does not need a cystectomy. However, a man with an anteriorly fixed tumor usually needs a cystectomy or cystoprostatectomy. A partial cystectomy with a wide margin may be an option for an upper rectal lesion, but the functional results may be poor because of a decrease in bladder size and radiation-induced injury to the bladder. In such patients, an ileal conduit at the time of resection may be preferable to subjecting the patient to a second surgery.

Posteriorly fixed lesions require an en bloc distal sacrectomy. The proximal extent of the resection is to S2-3. A more proximal resection would require internal fixation of the sacroiliac joints to stabilize the pelvis. We consider a resection of this magnitude too extensive for primary or recurrent rectal cancer. Furthermore, when the resection is limited to the S2-3 level, it is generally possible to preserve one S3 root, which is usually sufficient to preserve bladder function. The sacrectomy proceeds through four distinct steps: 1) the anterior resection, 2) the posterior resection, 3) the use of IORT if required, and 4) the reconstruction of the pelvic tissue defect. The abdominal dissection is begun as described previously. The dissection in the posterior plane is performed to the level of proximal tumor extent along the sacrum. This permits reevaluation to ensure that the tumor does not extend above the S2-3 level. If it does, then the rectum is dissected free in the anterior and lateral planes, leaving the point of sacral fixation as the only point of attachment. A sacrectomy that needs to include a resection proximal to S3-4 requires bilateral ligation of the internal iliac arteries and veins. This is done to decrease blood loss during the sacrectomy. Once the rectum is completely freed anteriorly and laterally, all required abdominal wall stomas are created and an omental or rectus abdominis flap is mobilized and placed into the pelvis to be used for later reconstruction. The abdominal incision is closed and the patient is repositioned in the prone-jackknife position. A posterior midline incision from the region of the last lumbar vertebra to the coccyx is made. The gluteal muscles are dissected free of the sacrum and the proposed site of transection is identified. The important nervous structures to the lower pelvis and extremities, the pudendal and sciatic nerves, respectively, are identified and preserved. With the assistance of our orthopedic or neurosurgical colleagues, the sacrum is transected and the dural sac is closed. The defect is closed either over an omental flap or the mobilized rectus abdominis flap. Because the resulting tissue defect can be quite sizable, local muscle flaps may need to be mobilized in order to close the defect. Multiple closed suction drains should be used, because any pelvic fluid collection can easily become infected and lead to wound breakdown. The wound compli-

cations and breakdown in this heavily irradiated field are not uncommon and occur in as many as 65% of patients who undergo radical resection with concurrent IORT.<sup>39</sup> These postoperative wounds often require transfer of nonirradiated, well-vascularized tissue like muscle flaps to heal if that transfer was not done at the initial operation.

## Use of IORT

In cases of close margins, known microscopically positive margins, or minimal gross unresectable disease in the pelvis or after the sacrectomy, our policy is to use intraoperative electron-beam radiation therapy (IORT). To give IORT, a lucite cylinder is positioned in the pelvis to target the at-risk area (Figure 33-3A,B). The patient is then positioned under the linear accelerator. Between 1000 to 2000 cGy is delivered, depending on the extent of margin involvement. A dose of 1000 cGy is recommended for minimal residual disease; 1500 cGy is given for gross residual disease less than 2 cm; and 2000 cGy is reserved for unresected or gross residual disease more than 2 cm. The IORT dose that can be given should take into account the total of any prior EBRT that has been administered.

Although we only have experience with EBRT, other institutions have used other ways of delivering intraoperative or prolonged local radiation therapy. At Memorial Sloan-Kettering, a combined-modality treatment protocol uses high-dose intraoperative brachytherapy (HDR-IORT).<sup>30</sup> The radiation is delivered via an array of catheters that are imbedded in a flexible rubber pad. This pad is then sutured to the area of concern and other normal tissue is packed away and protected. The catheters are connected to a high-dose-rate <sup>192</sup>Ir source. After the total dose is delivered, the pad is removed and the operation proceeds. Another approach is to use perioperative brachytherapy as a way to combine local delivery of radiation with extended surgery.<sup>31-34</sup> With this method, brachytherapy catheters are loosely secured to a mesh material that is then secured to the region of interest. The operation is completed and the ends of the catheters are brought out through a separate skin incision and secured to the skin. Then, usually between postoperative day 3 and 5, removable radioactive elements are placed into the brachytherapy catheters. Once the desired total dose is delivered, the catheters are removed at the bedside without the need for sedation or anesthesia. These techniques do not require a dedicated operating room with a linear accelerator to administer radiation regionally and may therefore expand where this type of surgery can be performed. One possible disadvantage with the use of the postoperative brachytherapy catheters is that it is difficult to protect normal tissue, particularly the small intestine, once the operation is complete. However, these alternative methods for delivering local radiation therapy, when combined with extended surgery and chemotherapy, seem to result in morbidity and survival outcomes that are comparable to our experience with intraoperative EBRT.

## Results of Multimodality Treatment for Advanced Primary or Locally Recurrent Rectal Cancer

Disease recurrence and survival in patients with rectal cancer is highly dependent on the stage of disease and the mode of treatment. In recent reports, the combination of preoperative EBRT and total mesorectal excision surgery for resectable rectal cancer resulted in a recurrence-free rate of 94% for Stage II and 85% for Stage III tumors.<sup>40</sup> However, more locally advanced rectal cancers often have a higher recurrence rate.<sup>41</sup> Although the cause of death in these patients is usually attributable to systemic disease, a mortality rate of 16%–44% has been attributed to isolated local failure.<sup>42,43</sup> Also, advanced primary disease and recurrences in the pelvis are associated with significant pain, bleeding, and urinary or neurologic complications that often dominate the clinical picture and affect the patient's quality of life.<sup>14</sup> Traditionally, palliative pelvic radiation has been used, but it often only provides short-term palliation of symptoms or of local disease progression.<sup>14,44</sup> To better address the significant symptoms associated with advanced primary or recurrent rectal cancer and to perhaps improve survival, a number of institutions have used multimodality therapy, including preoperative chemoradiation, extensive surgery, and intraoperative-directed local radiation therapy.

For patients with advanced primary rectal cancer, studies have shown the benefit of combined preoperative chemoradiation followed by radical surgery. In a retrospective review of 60 patients with primary locally advanced rectal cancers,<sup>45</sup> 81% were able to undergo curative resection. Their overall 2-year survival was 91%, and their local regional recurrence rate was 7.5%. In another study, preoperative chemoradiation with extensive surgery improved overall survival and control of pelvic disease compared with preoperative radiation therapy alone.<sup>35</sup> In that study, the use of IORT improved local control in patients with microscopic residual disease or clinically fixed tumors. None of the patients treated with IORT developed local failure in the pelvis. Similar findings of improved local control and survival were reported in a series of patients with primary advanced rectal cancers who were given HDR-IORT.<sup>36</sup> These 22 patients with primary unresectable rectal cancer underwent multimodality therapy including preoperative chemotherapy, external beam irradiation, and extensive surgery with intraoperative brachytherapy, which led to actuarial 2-year local control of 81%. Local tumor control was 92% for patients who underwent resection with negative margins versus 38% for those with microscopic positive margins. The overall 2-year actuarial disease-free survival rates were 77% for patients with negative margins and 38% for patients with positive margins. In sum, series of patients with locally advanced primary rectal cancer who were treated with intraoperative radiation and surgery have shown an overall improvement in local control compared with historical controls.

Surgery alone has been used to treat recurrent rectal cancers. In the series by Garcia-Aguilar et al.<sup>46</sup> of 87 patients with recurrent rectal cancer, 64 patients underwent surgical exploration, and only 42 were able to undergo resection with curative intent. The estimated 5-year survival rate for patients who had curative-intent surgery was significantly better than that for patients who had only palliative or no surgery (35% versus 7%). In most series, recurrence and survival rates for patients with recurrent rectal cancer treated with surgery alone are less than those for patients with primary advanced rectal cancer, but are still better than historical data for patients treated with palliative therapies. In general, patients treated with multimodality therapy including IORT experience 3-year local control rates ranging from 25% to 78%, and long-term survival has been reported to be between 25% and 40%.<sup>47–54</sup>

The institution with the most experience using multimodality therapy including IORT for recurrent rectal cancer is the Mayo Clinic. Between 1981 and 1996, 394 patients were treated, 90 of whom had unresectable local or extrapelvic disease at the time of surgical exploration.<sup>47</sup> Although 304 patients underwent resection of the recurrent tumor, only 138 (45%) underwent a histologically confirmed curative resection. The 166 remaining patients had a palliative operation because of either gross (n = 139) or microscopic (n = 27) residual cancer in the pelvis. Nine percent of the patients who had surgery with curative intent underwent extended resections (i.e., sacrectomy, pelvic exenteration, cystectomy with ileal conduit) because of the advanced nature of the tumor. These patients were prospectively monitored to determine long-term survival and the factors influencing survival.

The 1-, 3-, and 5-year survival rates for the 304 patients were 84%, 43%, and 25%, respectively. The median survival time was 31 months. The 5-year survival rate was greater after curative (i.e., negative histologic margins) than after palliative surgery (37% versus 16%,  $P < .001$ ). The presence of gross residual disease in patients who underwent nonpalliative resections resulted in decreased survival compared with those patients with microscopic residual disease. However, survival for patients who had extended resections was not significantly different than that for patients who had a limited resection (28% versus 21%,  $P = 0.11$ , respectively). Logistic regression analysis found several independent factors that contributed to the ability to perform a curative resection. On univariate analysis, initial surgery with end colostomy or painful recurrence were associated with having palliative surgery. On multivariate analysis, increasing number of tumor fixation sites was associated with a palliative resection. These factors also affected overall survival; patients with pain and more than one site of fixation had significantly lower survival rates. The best 5-year survival rates were in patients who had nonfixed tumors (41%) or asymptomatic recurrences (41%). Other institutions that have used a multimodality approach that included some form of intraoperative radiation have reported similar improvements in local recurrence and survival.<sup>51–54</sup>

Patients whose tumors can be resected with negative margins often have better outcomes. Because of this, some investigators have questioned the routine use of the intraoperative, locally directed radiation therapy.<sup>55</sup> Recently, Wiig and colleagues<sup>56</sup> reported a nonrandomized, prospective study evaluating the value of IORT in reoperative surgery for recurrent rectal cancer. The estimated overall 5-year survival was 30%. However, patients who had an R0 resection had a 60% survival compared with 25% and 0% for R1 and R2, respectively. The use of IORT did not improve survival or local recurrence when controlling for R-stage resection. However, other reports indicate that IORT improves local control and survival even in patients with R1 resections when compared with most control series of patients.<sup>48</sup> In addition, many series report that pelvic recurrences after multimodality therapy that included IORT occurred outside the intraoperative radiation field. In the most recent study to look specifically at the rate of local recurrence after the use of high-dose-rate brachytherapy, significantly more recurrences occurred outside of the IORT field than within the radiation field.<sup>54</sup> In that series, the time to pelvic recurrence was 16 months in patients who had a pelvic recurrence outside the radiation field, and 31 months in patients who had a pelvic recurrence within the radiation field; however, the difference was not statistically significant ( $P = .07$ ). To specifically address the benefit of adding IORT to the combined multimodality treatment of patients with advanced primary or recurrent rectal cancer would require a prospective, randomized trial. However, this would be a difficult undertaking given the relatively few institutions capable of delivering this complex therapy, the variations in different intraoperative radiation techniques, and the relatively limited number of patients for whom this therapy is appropriate. For now, most studies, although retrospective and often based on single institutions, suggest that combined multimodality therapy that includes IORT provides the best chance for cure for patients with locally advanced or recurrent rectal cancer.

Perioperatively related mortality was very low in patients who underwent this multimodality treatment (0.3%).<sup>47</sup> However, treatment-related morbidity was relatively high. In one series of 304 patients who underwent surgery with curative intent, 96 (32%) required prolonged hospitalizations, 78 (26%) of whom required readmissions and/or additional surgical procedures. The most frequent complications included pelvic abscesses (6.6%), bowel obstructions (5.3%), enteric fistulas (4.3%), and perineal wound complications (4.6%).<sup>47</sup> The complication rate was significantly higher in patients who underwent extended surgical resections and in patients who had recurrences fixed in more than two sites in the pelvis. These findings underscore the need for thorough preoperative patient selection to ensure that the patient is fit enough to tolerate the surgery and the potential complications, and that there is no evidence of disease outside of the region of resection.

## Palliative Care for Advanced or Recurrent Rectal Cancer

Patients who present with locally advanced or recurrent rectal cancer must first be evaluated with the intent to cure. An equally important consideration is palliation of symptoms if a cure does not seem to be achievable. The local effect within the pelvis of an advanced or recurrent rectal cancer drives the need to address control of symptoms. These symptoms often include rectal bleeding, rectal obstruction, urinary obstruction caused by local invasion, and severe pain related to invasion of the pelvic sidewall or direct invasion of pelvic nerves. Over the past decade, the choice of palliative options has expanded and choice of option requires careful consideration of the presenting symptoms, possible future symptoms, extent of local and distant spread of the disease, and the overall physical condition of the patient.

Palliative interventions may be broadly classified as noninvasive, minimally invasive, and surgical. The primary noninvasive palliative option is radiotherapy. In patients who have never received pelvic radiation, a full course of external beam irradiation may be a very effective treatment for bleeding, pelvic pain, and near obstruction. The use of external beam radiotherapy may result in palliation of severe pelvic pain in 50%–90% of patients.<sup>57,58</sup> However, virtually all patients will experience progression of the tumor and recurrent symptoms before they die. Lingareddy and colleagues<sup>44</sup> have shown there is a significant use for palliative reirradiation in treating recurrent rectal cancers. In their study of 52 patients with recurrent rectal cancer, pelvic reirradiation resulted in complete palliation of bleeding, pain, and mass effect in 100%, 65%, and 24% of cases, respectively. The median initial radiation dose to the pelvis was 50 cGy; the median reirradiation dose was 30 cGy. Most patients had palliation of their symptoms until their deaths. Grade 3 and 4 toxicity were seen in 23% and 10% of patients, respectively. The 2-year overall actuarial survival was 25%.

Minimally invasive approaches to palliation usually involve mechanical means to reduce symptoms related to pelvic tumors. These include ureteral stents to alleviate urinary obstruction and expandable metal colonic wall stents or the use of lasers to relieve rectal obstruction. Self-expanding metal stents (SEMS) are useful for the nonsurgical management of rectal obstructions, bleeding, and malignant fistulas.<sup>59</sup> In a review of the literature, palliation with SEMS was achieved in 90% of patients.<sup>60</sup> In the largest series to report on SEMS for malignant rectal obstructions, stents could be deployed successfully in 36 of 37 patients with rectal obstructions,<sup>61</sup> and 28 had good long-term results with no need for subsequent intervention.<sup>61</sup>

Endoscopic lasers are an alternative to SEMS. The neodymium yttrium argon garnet (Nd:YAG) laser is the most frequently used. Endoscopic laser treatments remove the tissue intraluminally by coagulative necrosis or immediate

tissue vaporization, depending on the amount of energy applied. Palliation of symptoms and marked improvement in quality of life is achieved after repeated laser sessions (usually 2–5) in 80%–90% of patients.<sup>62,63</sup> Unfortunately, laser therapy does not seem to be a durable treatment. Effective palliation decreases as a patient survives longer; successful palliation at 1 year was only 42%.<sup>64</sup>

There are no data on the use of palliative resections in patients with locally advanced or recurrent rectal cancer. However, a report from Memorial Sloan-Kettering has evaluated the role of palliative resection in 80 patients with Stage IV rectal cancer.<sup>65</sup> Twenty-four percent had clinical evidence of obstruction and 94% had either T3 or T4 lesions. None had received prior surgical or radiation therapy. They underwent radical resection of the primary lesion and surgical treatment of solitary hepatic metastasis, if present. There was one death, a 15% postoperative morbidity, and a 20% colostomy rate. The overall local recurrence rate was 6%, actuarial local control at 2 years was 94%, and median survival was 25 months. This study shows that in appropriately selected patients with Stage IV disease and complicated or advanced rectal cancer, surgical resection of the primary tumors can achieve very reasonable oncologic results and provide good palliation of symptoms related to the tumor.

## Summary

For patients with advanced primary or recurrent rectal cancers, the only hope of cure requires a coordinated multidisciplinary approach to treatment. In general, EBRT, chemotherapy, extensive surgery, and the use of directed IORT seem to improve local control and survival. Surgery in these patients carries a higher morbidity rate than surgery for primary rectal cancer, but one that is acceptable in appropriately selected patients. Before proceeding with multimodality therapy, patients should be thoroughly evaluated for the presence of disseminated extrapelvic or metastatic disease, which would, in most instances, preclude a curative operation. Experience indicates that isolated anterior or posterior fixation of the tumor does not preclude a curative resection. In these cases, en bloc resection of involved organs or bony structures can result in resection with negative margins. However, tumors fixed to the lateral pelvic sidewall, fixed at multiple points, or fixed circumferentially are often unresectable or incurable. Available data from many institutions indicates that multimodality therapy for advanced primary or recurrent rectal cancer results in better local control and higher survival rates than palliative therapy.

# Colorectal Cancer: Metastatic (Palliation)

Michael D'Angelica, Kamran Idrees, Philip B. Paty, and Leslie H. Blumgart

Approximately 20% of patients with colorectal cancer present with established distant metastases.<sup>1</sup> In most cases, the metastases are detectable with noninvasive imaging, and patients can be assigned to AJCC (American Joint Committee on Cancer) Stage IV before any surgical intervention. Among these patients there is enormous heterogeneity with respect to sites of disease, extent of disease, symptoms, performance status, and comorbidities. The clinical spectrum at the time of diagnosis ranges from the asymptomatic patient with a single metastatic lesion to the rapidly deteriorating patient with colon obstruction and advanced, multiorgan metastases. It is therefore difficult to define rigid treatment algorithms that can be widely applied to all clinical settings.

Despite considerable progress in the treatment of advanced colorectal cancer, the vast majority of Stage IV patients are not curable by current treatment protocols. A recent analysis of data from the SEER (surveillance, epidemiology, and end results) population-based database estimates that the 5-year survival rate for Stage IV patients diagnosed between 1991 and 2000 was 8%.<sup>2</sup> However, despite a low overall cure rate, aggressive treatment is indicated for most patients to extend survival and enhance quality of life. Systemic chemotherapy, endoscopic treatments to palliate obstruction, surgical diversion, and surgical resection all have important roles in treatment of Stage IV patients. Treatment approaches must be individualized based on the extent and resectability of local and distant disease, the presence or absence of bowel obstruction, performance status, and comorbidities. For patients with good performance status and minimal symptoms from their primary cancers, standard treatment is systemic chemotherapy, which is well documented to increase survival and quality of life.<sup>3,4</sup> Surgical resection of the primary tumor and, when feasible, of the metastatic lesions can provide excellent palliation and can, in some cases, provide lasting cure.

In the past decade, there has been remarkable improvement in the efficacy of chemotherapy for colorectal cancer. First-line therapy with either FOLFOX or FOLFIRI now yields major responses in up to 50% of previously untreated

patients, and achieves minor responses or stable disease in an additional 20% of patients.<sup>5</sup> Multiple, effective drug combinations are available as well, and second-line chemotherapy has become more effective and more likely to impact survival. Over the past 10 years, the median survival for patients with metastatic disease who are treated with chemotherapy has improved from 12–14 months to 21 months.<sup>6</sup> Although cure from chemotherapy alone remains extremely rare, effective chemotherapy combined with aggressive surgery may be increasing the overall cure rate. In this setting, the care of patients with advanced disease has become quite complex. The goal of this chapter is to provide a reference source for surgeons managing patients who present with Stage IV colorectal cancer.

## Biology of Metastatic Disease

Metastasis is defined as the spread of malignant cells from a primary tumor to a distant organ. It is estimated that 90% of all cancer deaths are a result of metastasis.<sup>7</sup> The process of metastasis is a continuous and inefficient one that begins early in tumor formation and increases as tumors grow.<sup>8</sup> Metastatic foci themselves can go through the metastatic process and spread to other organs (i.e., metastases can metastasize).

Numerous clinical and laboratory studies have attempted to define the complex process of metastasis formation. It is a multistep process, and failure at any step results in failure of the overall process. The process relies on properties of the tumor cells, as well as the microenvironment of the primary and secondary sites.<sup>9,10</sup> A series of major events must occur (Figure 34-1).

The first step is tumorigenesis, which occurs after the initial malignant transformation. The tumor proliferates into a small mass of heterogeneous cells that are of varying metastatic or malignant potential. These tumor cells undergo multiple and sequential genetic changes, characterized by the appearance of oncogenes and a decrease in tumor suppressor genes.

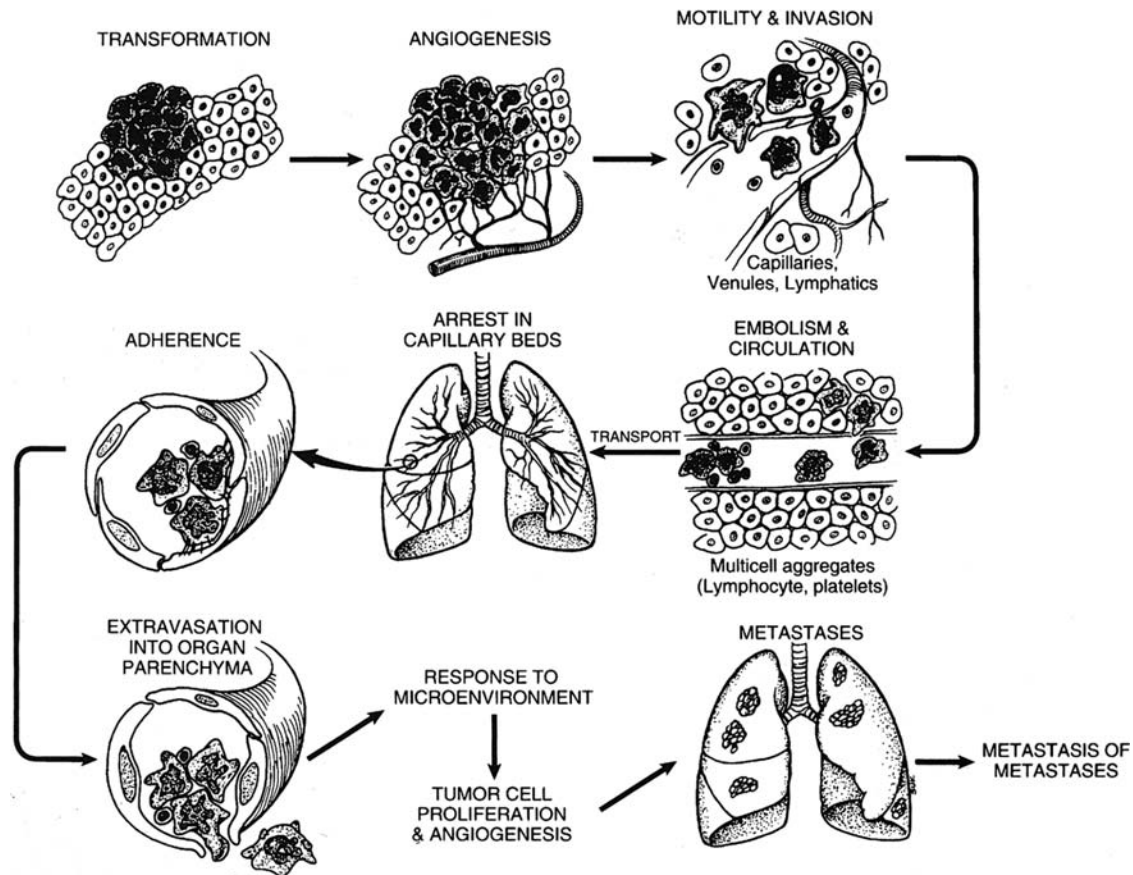

FIGURE 34-1. Schematic illustrating the multistep process involved in the development of metastasis. (Reprinted from DeVita VT Jr, Hellman S, Rosenberg SA. *Cancer: Principles and Practice of Oncology*. 6th ed. copyright 2001, with permission of Lippincott Williams & Wilkins.)

As the tumor grows beyond 1 mm in diameter and becomes relatively hypoxic, angiogenesis is initiated. The process of tumor angiogenesis is tightly regulated by pro- and anti-angiogenic factors secreted by both the tumor and its environment. As tumors successfully grow, suppressors of angiogenesis are inhibited and pro-angiogenic factors predominate, resulting in neovascularity and further growth of the tumor.<sup>11</sup> Some tumors may grow by utilizing other existing blood vessels in nearby tissues.

In the next step, some cells will develop an invasive phenotype. Most researchers believe that there is a selection process resulting in the clonal expansion of certain cell subpopulations with growth advantages and invasive properties. Whether this process represents a property of the whole tumor cell mass or true clonal selection of more invasive cell subpopulations is not known, and is a subject of intense research.<sup>12</sup> Malignant invasion is characterized by down-regulation of cell adhesion, resulting in detachment of the cell from the primary tumor mass and the extracellular matrix. Stromal invasion is accomplished through interactions with the basement membrane, including adhesion, proteolysis, and migration, ultimately resulting in detachment and invasion through the basement membrane. This invasive phenotype

also enables these cells to enter thin-walled lymphatics and vasculature, allowing access to systemic circulation. The neovasculature from tumor-induced angiogenesis seems to be more susceptible to such invasion. This process of invasion is critically related to the expression (up-regulated or down-regulated) of adhesion molecules and factors influencing cell migration.<sup>13,14</sup>

Once inside the vascular system, cells or cell clumps (emboli) are circulated, and must survive hemodynamic filtering as well as immune surveillance. They must then arrest in a distant organ. This probably involves adhesion and/or trapping, based on size, within small capillary beds. There is likely a complex interaction between the malignant cell and the endothelium or exposed basement membrane, allowing cell arrest. Once arrested in a tissue bed, the cells extravasate into the tissue, enabling formation of a metastatic focus. There is debate as to whether proliferation occurs before or after actual extravasation into the tissue; some experimental models have shown that extravasation is not a prerequisite for growth in a secondary organ.<sup>15</sup> Paracrine growth factors, hormones, and the local tissue environment have critical roles in the ultimate outcome of extravasated cells. These metastatic cells can become dormant or proliferate; what determines this

fate is not fully understood. Growth in the distant organ after deposition is a major limiting factor in the formation of metastasis, and some metastatic cells can remain dormant for years. Once deposited in the distant organ, the metastatic focus, if proliferating, must again go through tumorigenesis, angiogenesis, and evasion of the immune system.<sup>16</sup>

This complex multistep process of metastasis formation is related to multiple genetic changes among malignant cells. As the technology of measuring genetic changes improves, we are beginning to appreciate the changes that occur during this process. It seems that there are genes specific to tumorigenesis, invasion, angiogenesis, and other steps. Recently, a number of genes have been identified that suppress metastatic potential and, by their down-regulation, affect a cell's ability to metastasize without affecting tumorigenicity.<sup>17</sup> These discoveries provide a sense of the future challenge in elucidating the multiple, stepwise, and specific changes that regulate a cell's ability to metastasize. Advances in this field will have obvious and profound implications for the treatment of cancer.

## Diagnosis/Staging

The clinical presentation of Stage IV patients is variable. Most present with symptoms referable to the primary tumor. However, symptoms from metastatic disease, asymptomatic metastatic lesions found on imaging studies, abnormalities in routine blood work, and cancers discovered on endoscopic screening procedures may also be the first signs of disease. Initial staging evaluation should include colonoscopy with biopsy, and imaging of the primary tumor, liver, and lungs. When feasible, endorectal ultrasound or magnetic resonance imaging (MRI) is recommended for rectal cancers to document the initial T and N stage. Spiral computed tomographic (CT) scanning of the chest/abdomen/pelvis is a highly accurate and efficient method of detecting metastases. Positron emission tomography (PET) scanning detects occult disease not seen on CT scan in 20% of Stage IV patients, and should be considered if such findings might affect patient management.<sup>18</sup>

Once the extent of disease workup is complete and distant metastases have been documented, the surgeon must make three important judgments. First is whether the patient is fit for aggressive treatment. Patients with poor performance status or serious cardiovascular, pulmonary, renal, neurologic, or gastrointestinal impairment may not tolerate chemotherapy or major surgery. Second is whether the primary tumor presents a clinically significant risk of bowel obstruction. Symptoms, radiographic findings, and endoscopic findings are important considerations. If the proximal colon is not dilated on radiographic studies and a colonoscope can traverse the tumor, it is generally safe to begin treatment with chemotherapy. The third determination is whether the patient's metastases can be surgically resected, and therefore treated with curative intent. If complete resection of all disease can be expected, then surgical intervention should assume a high priority.

## Multidisciplinary Evaluation

Management of patients with advanced disease is often complex, and multidisciplinary evaluation can be helpful in determining initial therapy. The surgeon and medical oncologist should evaluate the patient in consultation with a radiologist and gastroenterologist. The goals, priorities, and expected course of treatment should be discussed. For rectal cancers that are bulky or symptomatic, the advice of a radiation oncologist is often helpful.

## Palliative Management of the Primary Cancer—Stents, Laser

Approximately 8%–29% of patients with colorectal cancer initially present with symptoms of partial or complete bowel obstruction.<sup>19</sup> In a review of 713 obstructing carcinomas, 77% were left-sided and 23% were right-sided cases.<sup>20</sup> Furthermore, a majority of obstructing tumors are either Stage III or Stage IV.<sup>21</sup> Bowel obstruction is insidious in onset, with initial symptoms of mild discomfort and change in bowel habits. With disease progression, the symptoms can become worse, ranging from crampy abdominal pain, abdominal distension, nausea, abdominal tenderness, obstipation, and leukocytosis. Vomiting is a late symptom unless there is an associated small bowel obstruction. Without treatment, the process can progress to complete obstruction, ischemia, and perforation. The risk of cecal perforation is greatest in patients who have a competent ileocecal valve.

In the setting of metastatic cancer, the critical question is whether colon obstruction should be considered a contraindication for systemic chemotherapy or radiotherapy. The degree of symptoms, endoscopic findings, and radiographic findings are all relevant to this decision. When the cancer can be traversed with a colonoscope and there is no radiographic evidence for obstruction, many patients with partially obstructing cancers will tolerate aggressive chemotherapy. Patients must be instructed to monitor their symptoms closely, and to report any signs of worsening obstruction immediately. A liquid diet or pureed diet taken in small portions may help to reduce obstructive symptoms. For patients with advanced obstruction, nonresective palliative options include laser therapy, fulguration, colonic self-expanding metal stents, and creation of a diverting stoma.

Laser therapy has been used for palliation of obstructing rectal cancers for the past two decades.<sup>22–24</sup> In a large series of 272 patients who underwent palliative laser therapy for rectosigmoid cancers, the immediate success rate in treating obstructive symptoms was 85%.<sup>25</sup> Other studies have shown similar success rates, in the range of 80%–90%.<sup>23,24</sup> However, laser therapy is practical only for treating cancers of the distal colon and rectum, and is rarely used to treat proximal lesions. In addition, multiple therapy sessions are required to

achieve lasting relief of symptoms. Serious complications such as bleeding, perforation, and severe pain have been reported in 5%–15% of patients, especially those undergoing multiple treatments.<sup>22,24–26</sup>

Surgical fulguration of rectal cancers is another method of opening the rectal lumen.<sup>27,28</sup> Fulguration, in combination with endoluminal debulking, can remove a large volume of tumor; however, unlike laser therapy, this procedure requires hospital admission and regional or general anesthesia.

Since their introduction in 1991, colonic stents have become an important method of palliation for obstruction in colorectal cancer patients, especially those with unresectable metastatic disease. These self-expanding metallic stents can potentially dilate the lumen to a near-normal diameter, providing quick relief of symptoms and, in some cases, allowing endoscopic assessment of the proximal colon. Stents can be placed in patients using minimal sedation, without need of prior endoscopic dilation and the concomitant increased risk of complications such as perforation or tumor fracture. Moreover, these stents can be placed across relatively long lesions by overlapping stents in a “stent-within-stent” manner.

In a retrospective series of 80 patients who underwent colonic stent placement for malignant large bowel obstruction, stents were successfully placed in 70 patients (87.5% overall technical success rate).<sup>29</sup> Satisfactory symptomatic relief and clinical decompression was achieved in 67 patients (83.7% overall clinical success rate). Two perforations occurred in this series, one of which resulted in death. Other complications included stent migration resulting in expulsion, reobstruction, and intractable tenesmus. Stenting of cancers in the mid and low rectum may result in debilitating urgency and incontinence.

A recent series of 52 patients with malignant obstruction secondary to either primary or recurrent disease, who underwent stent placement by colorectal surgeons, reported that 50 of 52 were successfully palliated.<sup>30</sup> One patient had a perforation, and in another patient obstruction was not relieved because of multiple sites of obstruction. The complication rate in this series was 25%; migration was the most common complication (15.4%), followed by reobstruction secondary to tumor ingrowth (3.8%), perforation, colovesical fistula, and severe tenesmus (2% each). Surgery was required in 17.3%, mostly because of complications or recurrent obstruction. Complications reported in the literature on colonic stents include stent malpositioning, migration, tumor ingrowth (through the stent interstices), tumor overgrowth (beyond the ends of a stent), perforation, stool impaction, bleeding, tenesmus, and postprocedure pain.

Laser therapy has also been used in certain situations, in conjunction with colonic stents, to recanalize and decompress large bowel. Overall, as more experience is gained, these endoscopic palliation therapies increasingly provide effective and durable palliation for patients with malignant obstruction.

## Surgical Management of the Primary Cancer—Resection

The role of bowel resection in patients with unresectable metastases is controversial. It is important to recognize that there are no randomized data demonstrating a survival benefit for bowel resection in Stage IV patients. However, palliative resection of the primary tumor does provide durable local control, is generally well tolerated, and can benefit many Stage IV patients.<sup>31</sup> However, randomized trials of 5-fluorouracil (5-FU)-based chemotherapy versus best supportive care, conducted in the 1990s, have shown that Stage IV patients receiving systemic chemotherapy have increased length and quality of life.<sup>3,4</sup> Moreover, with modern multidrug regimens, the beneficial impact of chemotherapy continues to increase.<sup>5,6</sup> Thus, standard management for patients with unresectable metastatic colorectal cancer is systemic chemotherapy. The proper use of elective colon/rectal resection in nonobstructed patients is a source of continuing debate. Oncologists properly cite loss of performance status, risk of surgical complications, and delay in chemotherapy as major downsides to palliative resection. Surgeons, however, understand that elective operations have a far lower morbidity than emergency surgery and fear having to operate on patients who obstruct while receiving chemotherapy or who present with more advanced disease after multiple cycles of ineffective chemotherapy.

Four retrospective studies have evaluated nonoperative management of Stage IV colorectal cancer by comparing patients who did and did not undergo colorectal resection<sup>32–35</sup> (Table 34-1). The data come from the 1990s, when 5-FU-based chemotherapy was the standard systemic therapy. In all four studies, a strong majority of patients were treated by upfront bowel resection. Patients who were not initially resected were more likely to have rectal cancers, to have more extensive metastatic disease, and to be older. Operative mortality for the patients having upfront resection ranged from 1.6% to 9%. Patients who did not have initial bowel resection underwent a subsequent colorectal operation in 9.3%–32% of cases, although the indications for subsequent operation were often not specified. From these limited data, it is clear that upfront colon resection is frequently practiced, particularly for patients with colon primaries and with less extensive metastatic disease. However, it is not possible to assess the impact of colon resection on symptom control, tolerance to subsequent chemotherapy, quality of life, or survival.

A prospective study of 24 patients with unresectable Stage IV colorectal cancer and minimally symptomatic primary cancers treated by 5-FU-based chemotherapy was reported by Sarela and colleagues.<sup>36</sup> Eleven patients had metastases limited to the liver (six with greater than 50% replacement of the liver), 10 patients had lung metastases, and six patients had peritoneal metastases. In the follow-up period, four patients with sigmoid colon cancer developed bowel obstruction,

TABLE 34-1 Retrospective analysis of bowel resection for patients with unresectable Stage IV colorectal cancer

NR, not reported.

which was treated by operation in two cases and by endoluminal stenting in two cases. Three patients underwent right colectomy for abdominal pain with poor symptom relief. One patient underwent potentially curative resection after disease downstaging by chemotherapy. From this small study, it was concluded that a policy to defer resection of minimally symptomatic primary colorectal cancer is acceptable. However, it is noteworthy that 25% of the primary cancers (and 35% of the colon primaries) were ultimately resected.

Several retrospective studies have specifically examined the impact of rectal resection on patients with Stage IV rectal cancer.<sup>37–40</sup> The goals of radical surgery in this setting are to eliminate bleeding and obstruction, prevent local tumor progression, and prepare the patient for systemic chemotherapy. Moran et al.<sup>37</sup> reported that, among 95 patients undergoing rectal resection, local symptom control was excellent, and only one required subsequent reoperation for local recurrence. Longo et al.<sup>38</sup> reported that, among 103 patients, pelvic pain and sepsis were more common in the nonresected group (15%, 14%) than in the resected group (4%, 9%). Chu and colleagues<sup>39</sup> reported on 21 Stage IV patients treated by abdominoperineal resection. Perioperative morbidity (33%) and mortality (0%) were acceptable, and 20 of 21 patients had complete and durable resolution of local symptoms. Nash and colleagues<sup>40</sup> reported results for 80 patients treated by rectal resection without radiotherapy. There was only one perioperative death, and median hospital stay was 9 days. Only five patients developed local failure. Median survival was 25 months, with greatest survival seen in patients who received and responded to systemic chemotherapy. These studies document that surgical resection can achieve excellent palliation of local symptoms.

There are few published data evaluating the effectiveness of radiotherapy in palliative management of Stage IV rectal cancer. Crane et al.<sup>41</sup> reported on 55 patients who received chemoradiotherapy and 25 patients who received chemoradiotherapy followed by surgery. Both groups received systemic therapy (78% of patients). Pelvic symptom control was high (81%) in the chemoradiotherapy group, but not as high as in the chemoradiotherapy plus surgery group (91%).

There were limited data on the durability of symptom control over time.

To summarize the treatment options for Stage IV patients with unresectable metastases, treatment algorithms are shown for patients with Stage IV colon cancer (Figure 34-2) and Stage IV rectal cancer (Figure 34-3). The algorithms show multiple treatment options, reflecting the heterogeneity of disease presentation. The major variables to consider are location of the primary tumor, degree of colon/rectal obstruction, extent of metastatic disease, and fitness of the patient for surgery. For patients with nonobstructing primary tumors, upfront treatment with chemotherapy is favored because, in this era of increasingly effective chemotherapy, it is important that patients be given the full benefit of aggressive systemic therapy. However, it should be remembered that the goal of therapy is effective palliation, and surgical resection remains the most effective and durable local treatment option.

## Liver Metastasis

Of the 150,000 new cases of primary colorectal cancer diagnosed in the United States each year, approximately 60% of these patients will develop liver metastases and about one-third will have disease limited to the liver.<sup>1</sup> Overall, it has been estimated that about 10% of all patients with colorectal liver metastases are candidates for potentially curative hepatic surgery.<sup>42</sup> Of those able to undergo complete hepatic resection, 25%–35% achieve long-term survival.<sup>43</sup> Therefore, only a small percentage of the overall number of patients with metastatic colorectal cancer are cured by liver surgery; this underlines the paramount importance of patient selection in determining optimal treatment. These statistics also highlight the fact that the majority of patients with liver metastases have unresectable disease, and require evaluation for chemotherapy or supportive care. It should be noted, however, that with improvements in chemotherapy, surgical technique, and ablative techniques, the number of patients eligible for hepatic surgery is on the rise.<sup>44,45</sup>

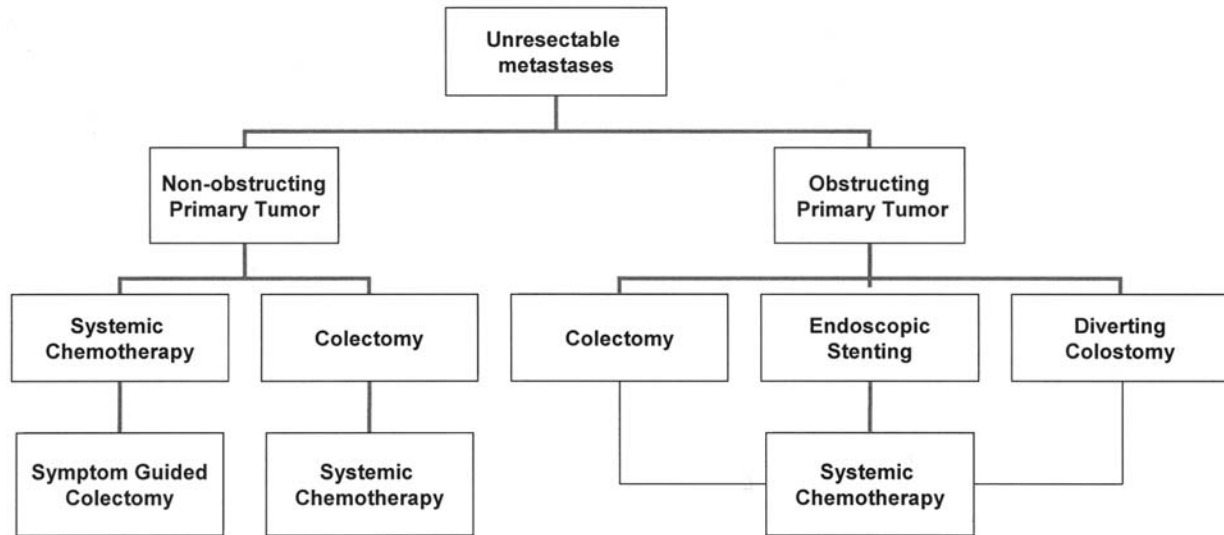

FIGURE 34-2. Treatment algorithms for patients with Stage IV colon cancer: use of palliative colon resection.

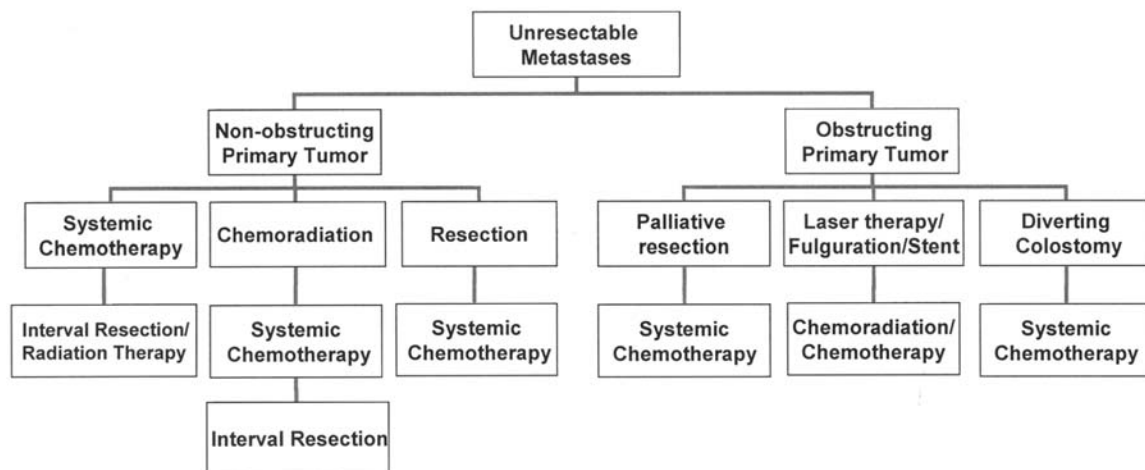

FIGURE 34-3. Treatment algorithms for patients with Stage IV rectal cancer: use of palliative rectal resection.

### Natural History of Untreated Liver Metastases

To understand the impact of any therapy on outcome for patients with hepatic colorectal metastases, the natural history of untreated disease must be reviewed. This is especially relevant in understanding the impact of surgery for hepatic metastases, because there has never been a randomized trial comparing any therapy to surgery (nor is there ever likely to be). Before the 1980s, most hepatic metastases were left untreated. Several investigators have retrospectively studied untreated patients, documenting median survivals of 5–10 months; long-term survival was rarely seen.<sup>46</sup> The majority of these patients, however, had extensive disease, and most had

their primary tumor in place, making comparison to modern surgical series irrelevant. Nonetheless, some investigators retrospectively identified patients with isolated, potentially resectable hepatic metastases who were left untreated. In these patients with limited metastases isolated to the liver, who would otherwise be potential candidates for surgery, 3-year survival was 14%–23% and 5-year survival was 2%–8%.<sup>47,48</sup> Whereas these studies were instrumental in demonstrating the relationship between bulk of disease and survival, they also clearly showed that, even in the best of circumstances, 5-year survival of patients with untreated liver metastases is distinctly uncommon.

## Diagnosis and Patient Evaluation

In the patient who presents with liver metastases, the first consideration must be whether he or she is a potential surgical candidate, because resection remains the only potentially curative modality. A careful extent of disease workup should be initiated. First, a complete evaluation of the colon via colonoscopy should be performed within a year of presentation; this addresses the issue of synchronous and metachronous colonic neoplasms, as well as the issue of local recurrence (especially in rectal cancers). Complete cross-sectional imaging of the abdomen and pelvis with high-quality CT is also essential, to rule out extrahepatic disease. The additional advantage of routine chest CT is low compared with that of a plain chest X-ray, but should be considered in high-risk cases.<sup>49</sup> <sup>18</sup>F-FDG (Fluoro-deoxy-glucose) PET scanning is routinely performed because of early prospective data documenting its utility. The information obtained from PET scanning changes management decisions in patients with recurrent colorectal carcinoma 20%–50% of the time. The major strength of PET scanning seems to be the detection of occult extrahepatic disease.<sup>18</sup> Ongoing larger prospective studies will more clearly define the benefits of PET. A baseline serum carcinoembryonic antigen (CEA) level should also be drawn, as it is of prognostic value (see below), and serves as a baseline to follow after the conclusion of therapeutic interventions.

Once the issue of extrahepatic disease has been addressed, high-quality imaging of the liver is essential in determining bulk of disease and resectability. CT scans are the most common modality used to address liver disease and, with modern dynamic helical scanning techniques, this remains the mainstay of hepatic imaging. Routine CT scans can now evaluate the liver in combination with CT angiography or triphasic imaging of the parenchyma through various phases of intravenous contrast circulation. The most sensitive CT technique is CT portography, which is a CT scan performed after injection of contrast into the superior mesenteric artery. Because liver metastases derive their blood supply from the hepatic artery, when injected contrast enters the portal circulation, metastases appear like filling defects. Although this technique is considered the most sensitive method for evaluating the number of hepatic tumors, it often fails to define the anatomic relationships of tumor to hepatic vasculature, it requires an invasive procedure, and it is costly.<sup>50,51</sup> Additionally, with modern standard CT techniques, the marginal benefit is probably smaller than it once was.

Ultrasound and MRI are additional imaging techniques that can be useful in specific circumstances. Ultrasound is not an accurate method for addressing extrahepatic disease and, indeed, often cannot visualize the entire liver. However, in experienced hands, ultrasound is excellent at distinguishing neoplastic tumors from benign lesions such as cysts, focal nodular hyperplasia, or hemangiomas. Additionally, ultrasound can specifically evaluate the relationship of specific lesions to major vascular structures and the biliary tree. MRI

is an excellent method for characterizing liver lesions. Particularly if there are multiple hepatic lesions, not all of which are suspected to be metastatic tumors, MRI can help distinguish malignant lesions from cysts, hemangiomas, and other benign lesions. MRI is also an excellent modality for evaluating relationships of tumor to the biliary tree (via magnetic resonance cholangiopancreatography—MRCP) and to hepatic vasculature. High-quality MRI and CT are probably equivalent for evaluating extent of liver disease, and as aids in surgical planning.<sup>52</sup> In any patient being considered for hepatic resection, a complete medical workup should be performed to assess the patient's fitness for undergoing a major abdominal operation. Any potential for liver dysfunction, such as alcohol abuse or chronic hepatitis, must be carefully evaluated. Pulmonary function should also be specifically evaluated, because patients undergoing major hepatectomy are at special risk for developing pulmonary complications, because of the upper abdominal transverse incision that is often necessary and the inevitable sympathetic pleural effusion. Likewise, any patient with a history of cardiac disease should be evaluated (as for any major abdominal surgery). We do not use chronologic age as a contraindication to hepatic surgery. We have previously reported that patients older than age 70 did as well as younger patients after hepatectomy.<sup>53</sup> This reflects careful patient selection and emphasizes the fact that physiologic age is more important than chronologic age.

## Treatment Options

### *Chemotherapy*

Until recently, chemotherapy was considered largely ineffective as treatment of unresectable metastatic colorectal cancer. However, with the development of irinotecan, oxaliplatin, hepatic arterial infusional chemotherapy with fluorodeoxyuridine (FUdR), and newer molecular-based therapies, there are now more effective chemotherapeutic options for these patients. For nearly 50 years, 5-FU was the only effective chemotherapeutic regimen for metastatic colorectal cancer. Despite many attempts to modify 5-FU with other agents, response rates generally ranged from 15% to 20%, and survival beyond 1 year was uncommon. The addition of leucovorin (5-FU/LV) and the use of infusional dosing techniques are associated with an increased response rate, and are frequently used despite no improvement in survival.<sup>54</sup>

Irinotecan (CPT-11) in conjunction with 5-FU/LV has been recently shown to be more effective than 5-FU/LV alone for treatment of metastatic colorectal cancer. Two randomized trials established the superiority of single-agent irinotecan over 5-FU/LV alone or best supportive care as second-line therapy.<sup>55,56</sup> Additionally, two randomized trials utilizing combined irinotecan/5-FU/LV as first-line chemotherapy have shown response rates of 40%, with modestly improved survival (median 15–17 months versus 12–14 months).<sup>57,58</sup> The

addition of oxaliplatin has been particularly exciting because of the in vitro sensitivity seen in cisplatin-resistant cell lines, as well as its synergy with 5-FU.<sup>58,59</sup> In a trial comparing oxaliplatin/5-FU/LV (FOLFOX) to 5-FU/LV, response rates for FOLFOX were in excess of 50% (compared with 22% for 5-FU/LV). There was no difference in survival, but this is likely attributable to a 37% crossover from 5-FU/LV to FOLFOX during the trial.<sup>60</sup> Early analyses of comparisons of irinotecan/5-FU/LV to FOLFOX have so far shown FOLFOX to yield superior response rates.<sup>61</sup> Ongoing trials continue to define optimal timing, dosing, and sequence of various combination regimens. As these trials mature, and modern systemic chemotherapy regimens are refined, we are now seeing median survivals in excess of 20 months.<sup>59,62</sup>

Regional hepatic therapy via hepatic artery infusional (HAI) chemotherapy has been studied since the 1970s. This treatment takes advantage of the fact that hepatic metastases derive their blood supply from hepatic arterial branches.<sup>63</sup> Additionally, only a small proportion of systemically administered chemotherapy reaches the liver. The most frequently used agent for HAI is FUDR, which has a 90% hepatic extraction ratio. This permits maximal treatment of liver metastases and minimization of systemic side effects. However, HAI with FUDR limits treatment of occult extrahepatic disease. This can be addressed by giving additional systemic agents, or by using 5-FU via the hepatic artery with a higher “spillover” effect into the systemic circulation.

Early phase II trials of HAI FUDR or 5-FU for unresectable colorectal hepatic metastases demonstrated remarkable response rates ranging from 29% to 88%.<sup>64-67</sup> Subsequently, 10 randomized phase III trials comparing HAI chemotherapy to systemic chemotherapy have been completed (Table 34-2). From 1987 through 1990, five trials were done comparing HAI FUDR to intravenous FUDR or intravenous 5-FU/LV. All of these trials showed significantly increased response rates, but only trials comparing HAI chemotherapy to best supportive care showed improved survival. Most of these trials were underpowered and most allowed crossover, making conclusions about survival difficult. Two metaanalyses of the first seven trials have been performed on the assumption that each was underpowered, in an attempt to detect significant survival differences.<sup>68,69</sup> Both clearly confirmed the increased response rates, and both showed a modest survival benefit.

Since reporting of these seven trials, three more have been performed. The German Cooperative Group compared HAI FUDR to HAI 5-FU/LV to systemic 5-FU/LV. Response rates were significantly higher in patients receiving HAI chemotherapy (43% and 45% versus 20%), but there was no improvement in time to progression or overall survival. Similar to many of the previous trials, this study is difficult to interpret because only 70% of the HAI patients received the intended therapy and 51% of patients crossed over to other groups.<sup>70</sup> Another trial performed by the Medical Research

\*Statistically significant ( $P < .05$ )

Council and the European Organization for the Research and Treatment of Cancer compared HAI 5-FU/LV with systemic 5-FU/LV. This trial did not allow crossover, and showed similar response rates, time to progression, and overall survival. Again, only 66% of those patients assigned to HAI chemotherapy received the assigned therapy; additionally, HAI chemotherapy was with 5-FU rather than FUDR.<sup>71</sup> A Cancer and Leukemia Group B (CALGB) trial comparing HAI FUDR to systemic 5-FU/LV without crossover has recently been completed. Response rates were demonstrated to be significantly higher with HAI FUDR (48% versus 25%), as was overall survival (22.7 months versus 19.8 months).<sup>72</sup>

One of the major lessons learned from trials evaluating HAI chemotherapy was that, although control of hepatic disease was excellent, there was significant extrahepatic failure. Currently, with the explosion of new active systemic agents, a new paradigm has developed in the treatment of hepatic colorectal metastases. Many phase I and II trials are now evaluating combinations of HAI FUDR with systemically administered 5-FU/LV with irinotecan and/or oxaliplatin. Even in pretreated patients, impressive response rates in excess of 80% are being seen.<sup>73</sup> Although recent advances in cytotoxic chemotherapy for colorectal cancer over the last decade have been very exciting, the development of targeted molecular-based therapy provides even greater hope for more effective systemic treatments. Studies continue to focus on immune-based therapy including vaccines, monoclonal antibodies, and immunotoxins. Anti-angiogenic therapy with anti-vascular endothelial growth factor antibodies (bevacizumab) are also currently being evaluated. Inhibitors of the receptor for epidermal growth factor, a tyrosine kinase receptor, has also shown promising results, and drugs such as cetuximab (C225), ZD1839 (Iressa), and OSI774 (Tarceva) are actively being studied. Results of current clinical trials are anxiously awaited to see where these molecular-based targeted therapies will ultimately fit in among the armamentarium of systemic therapy for colorectal cancer.<sup>62</sup>

## Resection

As described above, it is clear that patients with untreated hepatic colorectal metastases have poor survival. Although response rates to chemotherapeutic regimens are improving, the only therapy ever shown to be potentially curative for hepatic colorectal metastases is complete resection. When surgeons began attempting resections for metastatic colorectal cancer they were met with some skepticism.<sup>74</sup> The concept of treating what is generally acknowledged to be a "systemic" problem with "loco-regional" therapy was certainly questionable. Additionally, liver resection performed in the 1970s and 1980s was associated with high morbidity and mortality, making its role in the treatment of advanced cancer suspect at that time.<sup>75</sup> Over the last 20 years, however, large series have demonstrated that liver surgery can now be practiced with acceptable safety, and that patients with isolated and resectable hepatic metastases have the potential for long-term survival.

In modern series, mortality rates for hepatectomy for metastatic colorectal cancer are uniformly 5% or less (Table 34-3). Nonetheless, morbidity for these operations remains substantial, and is usually reported between 20% and 50%. Fortunately, this morbidity does not generally translate into long hospital stays, intensive care unit stays, long-term disability, or early mortality. The most ominous complications, such as liver failure and significant hemorrhage, are now distinctly uncommon, thanks to better surgical technique and postoperative care. A recent review of more than 1800 liver resections (57% of a lobe or greater) over the last decade at our institution found that the median hospital stay was 8 days, morbidity was 45%, and mortality was 3%. Furthermore, of the 1245 hepatectomies performed for metastatic disease, mortality was 2.4%.<sup>76</sup>

Liver resection for metastatic colorectal cancer was performed sporadically in the 1970s, but was an unproven and suspect therapy. Dr. James Foster traveled to medical centers in the United States recording outcomes in patients undergoing

hepatectomy for colorectal metastases and, for the first time, documented 5-year survival rates of 25%.<sup>77</sup> Major institutional and multi-institutional reviews of patients undergoing hepatectomy for metastatic colorectal cancer have now clearly documented that, in well-selected patients, 5-year survival ranges from 25% to 40%, 10-year survival ranges from 20% to 26%, and median survivals range from 24 to 46 months (Table 34-4). These results obviously compare favorably to the results of no treatment (median survival 5–10 months) and to those of chemotherapy (median survival 10–14 months). Despite recent improvements in chemotherapy resulting in median survivals as high as 20 months (see above), complete resection still provides the best outcomes. True long-term cure from chemotherapy is extraordinarily rare, whereas at least half of the long-term survivors after liver resection are disease-free and presumably cured.<sup>78</sup> For these reasons, no trial has ever compared hepatectomy to no treatment or chemotherapy alone. Liver resection for resectable hepatic colorectal metastases is the treatment of choice.

Many studies of patients undergoing liver resection for isolated hepatic metastases have evaluated prognostic factors to help select those patients most likely to benefit from hepatectomy and, conversely, to identify those unlikely to benefit. The two most consistent negative prognostic factors are the presence of extrahepatic disease and the inability to resect all tumor; these two factors remain contraindications to hepatectomy. The exception to this rule is the patient with limited pulmonary metastases or colonic anastomotic recurrence, who may undergo combined resections with some success.<sup>42</sup> Although there are many inconsistencies in the major reported series, a list of other poor prognostic factors exist; these include lymph nodes involved by the primary colorectal tumor, synchronous presentation [or shorter disease-free interval (DFI)], larger number of tumors, bilobar involvement, CEA elevation greater than 200 ng/mL, and involved histologic margins.<sup>79–83</sup> Although it seems to be true that the stage of the primary tumor, the interval in which metastatic disease has developed, and the bulk of tumor in the liver (measured by size, number, and/or CEA level) can provide prognostic information on outcome after hepatectomy, none of these findings in and of themselves preclude the potential for long-term survival. We recently published a multivariate

analysis of 1001 patients who underwent potentially curative hepatectomy, and identified five factors as having the most influence on outcome.<sup>84</sup> These included size greater than 5 cm, DFI of less than 1 year, more than one tumor, lymph node-positive primary, and CEA greater than 200 ng/mL. Utilizing these five factors, we have developed a risk score predictive of recurrence after liver resection (Table 34-4).

Recurrence after hepatectomy for colorectal metastases is common, occurring in more than two-thirds of patients. In fact, long-term survival does not necessarily imply that there has been no recurrence. In a study of 96 actual 5-year survivors, nearly half had experienced a recurrence at some point and received further therapy.<sup>78</sup> In patients who do recur, the liver is the most common site of recurrence and is involved approximately 45% of the time. Most of these recurrences are isolated to the liver. Other common sites are lung, bone, and various intraabdominal sites.<sup>85</sup> Because many recurrences are isolated to the liver, repeat liver resection has been attempted by several surgeons with some success. Unfortunately, only 5%–10% of patients are candidates for a second liver resection, underscoring the importance of patient selection. Currently, at least 14 series reporting on more than 700 patients have documented that repeat hepatectomy for metastatic colorectal cancer is safe and effective in well-selected patients. Mortality is less than 5%, median survival from the time of the second liver resection ranges from 23 to 46 months, and 5-year survival ranges from 30% to 41%.<sup>86</sup> The factors most often associated with a poor outcome after repeat hepatectomy are size and number of tumors, as well as short DFI. Because of the potential for further effective therapeutic interventions after primary liver resection, patients eligible for such treatment should be followed with serial CEA and imaging studies to detect recurrences at an early and potentially treatable phase.

Because recurrence after hepatectomy for metastatic colorectal cancer is common, there is a sound rationale for use of adjuvant therapy. Indeed, adjuvant 5-FU-based systemic chemotherapy after liver resection was often given, but its use was not supported by prospective trials. A number of retrospective comparisons have been performed, but no definitive published data support the routine use of adjuvant postoperative 5-FU-based systemic chemotherapy. The effect of newer,

more effective chemotherapeutic regimens on long-term survival after hepatectomy is not known, but is promising.

Because hepatic metastases derive their blood supply from the hepatic artery and the most common site of recurrence after hepatectomy is within the remnant liver, there is a strong argument for the use of HAI chemotherapy. Three randomized trials have addressed the efficacy of adjuvant HAI chemotherapy. In the German Cooperative multicenter study, HAI 5-FU/LV was compared with no treatment after hepatectomy. No significant differences in outcome were found; however, many patients in the HAI arm did not receive therapy, and 5-FU is not considered the optimal therapeutic for HAI chemotherapy.<sup>87</sup> In the recently published Intergroup study, adjuvant HAI FUDR combined with systemic 5-FU was compared with no treatment. A significant improvement in survival (46% versus 25% 4-year survival,  $P = .04$ ) was demonstrated only when analyzed by actual treatment received. There was no significant difference in outcome when analyzed in an intent-to-treat manner.<sup>88</sup> The third trial, performed at Memorial Sloan-Kettering Cancer Center (MSKCC), compared systemic 5-FU/LV to systemic 5-FU/LV combined with HAI FUDR. Ninety-two percent of patients received therapy as assigned, and there was a significant improvement in 2-year survival (the primary endpoint) favoring the addition of HAI FUDR (86% versus 72%).<sup>89</sup>

Given the growing number of chemotherapeutic options for patients with metastatic colorectal cancer, there are many options for the patient who has had all of his or her liver metastases resected. Because HAI FUDR combined with systemic 5-FU/LV is the only therapy ever shown to improve survival in this setting, there is a strong argument for the use of this modality; however, the surgeon and medical oncologist need to have experience with pump implantation and management. With the advent of more effective systemic chemotherapy, such as irinotecan and oxaliplatin, as well as molecular targeted agents, new trials are needed to assess optimal adjuvant therapy.

Because the majority of patients with hepatic colorectal metastases are technically unresectable, the development of more effective chemotherapy has inspired many oncologists to use a "neoadjuvant" chemotherapy strategy in an attempt to render patients resectable. In a series from France, 701 patients with unresectable liver metastases received chronomodulated 5-FU/LV and oxaliplatin. Ninety-five (14%) of these patients became resectable, secondary to chemotherapeutic response, and underwent staged resection. The resections used techniques such as portal vein embolization and intraoperative ablation to extirpate all tumor, and achieved an actuarial 5-year survival rate of 35%.<sup>44</sup> Another study analyzed 23 previously treated patients with unresectable liver metastases. HAI FUDR was administered, and six patients (26%) were ultimately able to undergo an R0 resection.<sup>45</sup> These early studies suggest that patients with unresectable liver metastases should be treated aggressively with chemotherapy and reevaluated at intervals for the possibility of resection.

Although resection has become the gold standard for treatment of liver metastases, other methods of tumor destruction

using thermal ablation techniques have also been developed. Cryotherapy has been used for decades, and utilizes probes to freeze tumors and surrounding normal hepatic parenchyma. Cryotherapy generally requires a laparotomy, and complications such as bleeding, liver cracking, and a cryoshock phenomena characterized by thrombocytopenia and disseminated intravascular coagulation can occur. More recently, radiofrequency ablation (RFA) probes have been developed that can heat liver tumors and a surrounding margin of tissue to create coagulation necrosis. RFA can be used percutaneously, laparoscopically, and at laparotomy under ultrasound, CT, or MRI guidance. Furthermore, RFA has low morbidity that generally ranges around 10% and is rarely serious. Although RFA can be used near blood vessels, because the heat-sink effect of blood flow protects the endothelium, major bile ducts can be seriously injured, limiting the use of RFA in central tumors situated near major bile ducts. Local recurrence after RFA is a significant problem, and seems to be strongly correlated with tumor size. Generally, recurrence is more common in tumors greater than 4 or 5 cm in diameter and in tumors abutting major blood vessels. With improvements in localization and monitoring of thermal application, however, these therapies are very promising alternatives to surgery. Perhaps the greatest application of ablative techniques will be in their use as additions to resection in patients with multiple bilobar tumors. Ongoing studies are currently evaluating these strategies.<sup>90,91</sup>

## Lung Metastasis

It has been estimated that approximately 10% of patients with colorectal cancer will develop lung metastasis. Of these, only 10% will have metastases isolated to the lung; and of those patients with isolated lung metastases, only a small proportion (probably another 10%) will be considered candidates for pulmonary metastasectomy.<sup>92</sup> These estimates demonstrate that the majority of patients with metastatic colorectal cancer to the lung have advanced disease, and are thus treated with systemic chemotherapy or best supportive care. Few patients will be candidates for metastasectomy; this tiny proportion reflects extremely careful patient selection.

Data on the results of metastasectomy for colorectal lung metastases are inherently flawed because they have been retrospectively collected over long periods of time, and mostly reflect patient selection and tumor biology. There are no adequate control groups to compare survival; therefore, survival statistics are difficult to interpret. However, some patients who undergo pulmonary metastasectomy are cured, and long-term survival without complete resection is very rare, suggesting that patients do occasionally benefit.

Modern series of lung resection for metastatic colorectal cancer uniformly report operative mortalities of less than 2% (Table 34-5). Five-year survival rates range from 16% to 64%, but generally cluster around 30% to 40%. Most studies evaluate factors associated with outcome; however, given the limited number of cases, the statistical power of these studies to

LN, lymph nodes.

detect significant factors is limited. Generally, the pathology of the primary tumor (grade, location, stage) has not been associated with outcome. The most frequently cited significant factors associated with adverse outcome are number and size of lung tumors, short DFI, increased CEA, and incomplete resection.

Although the majority of series evaluate disease limited to the lungs, several series have evaluated patients with both liver and lung metastases. Some authors advocate resection of synchronous limited extrapulmonary disease,<sup>93</sup> but the majority of studies that have analyzed synchronous liver and lung metastases report a uniformly poor outcome after combined resections. Long-term survival is very uncommon in this situation.<sup>94,95</sup> In the setting of isolated pulmonary recurrence after potentially curative partial hepatectomy, outcomes for pulmonary metastasectomy are more favorable and are similar to those for the initial hepatectomy.<sup>94-96</sup>

The surgical approach to patients who are potential candidates for pulmonary metastasectomy has been somewhat controversial. Based on older studies reported in the 1980s citing a 38% yield of contralateral thoracotomy in finding radiographically occult disease, routine bilateral thoracotomy had been advocated.<sup>97</sup> With modern-day CT, such an approach is not justified; indeed, the majority of surgeons perform pulmonary metastasectomy through a unilateral standard thoracotomy. The use of video-assisted thoracoscopic surgery (VATS) has increased in recent years, and is often used in metastasectomy when a minimal parenchymal resection is necessary. One problem with VATS is its inability to palpate the lung parenchyma; a prospective study evaluating confirmatory thoracotomy after VATS showed that 22% of lesions can be missed.<sup>98</sup> However, with improvements in radiology and VATS technique, a minimally invasive approach can be justified.

## Peritoneal Metastasis

The peritoneal surface is involved in approximately 10%–15% of patients with colorectal cancer at time of initial presentation (synchronous metastases) and in 20%–50% of

patients who develop recurrence (metachronous metastases).<sup>99-102</sup> As a site of colorectal cancer metastasis, the peritoneal surface ranks second only to the liver. Peritoneal metastasis occurs by direct implantation of cancer cells via one of four mechanisms: 1) spontaneous intraperitoneal (IP) seeding from a T4 colorectal cancer that has penetrated the serosal surface of the colon<sup>103</sup>; 2) extravasation of tumor cells at the time of colon perforation from an obstructing cancer; 3) iatrogenic tumor perforation through an area of serosal injury or enterotomy at the time of colon resection; 4) leakage of tumor cells from transected lymphatics or veins at the time of colon resection.<sup>104</sup> The risk of peritoneal metastasis is therefore highest in the setting of locally advanced cancers.

Peritoneal metastases are clinically important because of their frequent progression to malignant ascites and/or malignant bowel obstruction. In a French multicenter prospective study to assess the natural history of peritoneal carcinomatosis, 118 patients with T3 or T4 colorectal cancers were among the 370 study patients with nongynecologic malignancies.<sup>105</sup> Synchronous peritoneal carcinomatosis was found in 58.5% of the patients with colorectal cancer. The most frequent symptoms were ascites (29.7%) and bowel obstruction (19.5%).

Preoperative detection of peritoneal metastases is not reliable. Noninvasive imaging frequently misses small peritoneal lesions, even when these are widely disseminated. The sensitivity of CT scanning for lesions smaller than 5 mm is only 28%, as compared with 70% for lesions 2 cm or greater.<sup>106</sup> Thus, indirect signs such as bulky primary tumor, ascites, or bowel obstruction are important clues.

The extent of carcinomatosis is a major prognostic factor, and is best assessed by either laparoscopic or open exploration. Two different peritoneal carcinomatosis staging systems (Gilly's classification and Peritoneal Cancer Index of Sugarbaker) can be used to assess the extent of carcinomatosis.<sup>107,108</sup> These staging systems have both shown utility in determining the prognosis and treatment of patients with peritoneal carcinomatosis. By Gilly's classification, carcinomatosis is classified principally by the dimensions of the peritoneal tumor implants: Stage I, tumor nodules <5 mm in diameter

localized in one part of the abdomen; Stage II, tumor nodules <5mm disseminated widely through the abdomen; Stage III, tumor nodules 5 mm to 2 cm in diameter; Stage IV, tumor nodules >2 cm. The Peritoneal Cancer Index scores the extent of carcinomatosis on the basis of tumor size and location within 13 regions of the abdomen and pelvis. The lesion with the largest size in each abdominopelvic region is scored on a scale of 0–3 (0, no tumor; 1, tumor up to 0.5 cm; 2, tumor up to 5.0 cm; 3, >5 cm or confluence). The total score of the Peritoneal Cancer Index can vary from 0 to 39. The Peritoneal Cancer Index is shown to correlate with survival. Median survival and 5-year survival after surgical debulking and IP chemotherapy were 48 months and 50% for peritoneal index <10, compared with 12 months and 0% for index >20.<sup>109</sup>

Standard management of patients known to have peritoneal metastases at initial presentation is systemic chemotherapy. Colon resection has an important role for patients with obstructing primary cancers, and also for patients with occult metastases that are first detected in the operating room. Historically, the median survival for patients with unresected peritoneal metastasis treated with 5-FU-based systemic chemotherapy was very poor (6–8 months).<sup>102,105,110</sup> However, patient survival is highly variable, depending on the extent of metastatic disease and response to chemotherapy.<sup>111,112</sup> Contemporary combination chemotherapy regimens have significantly greater efficacy, and can produce long periods of disease control in certain patients.<sup>6</sup>

In the past decade, a more aggressive treatment approach utilizing cytoreductive surgery and IP chemotherapy has been pioneered by Sugarbaker.<sup>113</sup> The goal of cytoreductive surgery is to remove all macroscopic disease with peritonectomy procedures and visceral resections. Perioperative IP chemotherapy is then used to destroy residual microscopic disease. IP delivery offers a pharmacokinetic advantage over standard intravenous delivery by producing high regional concentrations of drug while simultaneously minimizing systemic toxicities.<sup>114,115</sup> The most widely reported method of IP chemotherapy is intraoperative delivery of mitomycin in a hyperthermic (41C) circuit for 90 minutes.<sup>116</sup> An alternative approach is postoperative infusion of FUDR via an implanted IP catheter.<sup>117</sup>

Although few prospective trials have been completed for colorectal carcinomatosis, the available evidence suggests a survival benefit for cytoreductive surgery and IP chemotherapy. Phase II studies report 5-year survival rates ranging between 19% and 28%.<sup>117,118</sup> The most consistent and important prognostic factor in these studies is the ability to achieve complete resection of all gross disease. Five-year survival rates reported for patients with completely resected disease range from 27% to 54%.<sup>117,119</sup>

A phase III study conducted by the Netherlands Cancer Institute randomized 105 colorectal cancer patients with peritoneal carcinomatosis to either standard treatment (systemic 5-FU/LV with or without palliative colectomy) or experimental therapy (aggressive cytoreductive surgery, hyperthermic IP

mitomycin, and systemic 5-FU/LV).<sup>120</sup> In the experimental arm, median operation time was 585 minutes, treatment toxicity was high, and treatment-related mortality was 8%. After a median follow-up of 22 months, median survival was 12.6 months in the standard therapy arm and 22.3 months in the experimental therapy arm. It is not known if the survival benefit observed in the experimental therapy arm is attributable to surgical debulking, IP chemotherapy, or both.

In summary, the standard therapy for patients with peritoneal metastases is systemic chemotherapy. However, there is evidence that aggressive surgical cytoreduction and IP chemotherapy will benefit patients with limited peritoneal tumor burden. Additional clinical trials are needed to define optimal use of this aggressive treatment approach.

## Ovarian Metastasis

Approximately 7%–30% of ovarian neoplasms are metastatic cancers, the most common being colorectal and breast cancer.<sup>121–124</sup> In approximately 1%–7% of all women with primary colorectal cancer, ovarian metastases are discovered either at the time of colon surgery or during follow-up.<sup>125–127</sup> However, the risk of developing ovarian metastasis is substantially higher in woman with Stage IV disease, and approaches 90% in women with established peritoneal metastases. In addition, women with adenocarcinoma of the vermiform appendix have a very high risk of ovarian metastasis. Thus, in a woman with recent diagnosis of advanced colorectal cancer, any ovarian mass should be considered a metastasis from colorectal cancer until proven otherwise.

The pathogenesis of colorectal cancer ovarian metastasis is variable. Metastatic spread occurs primarily through the peritoneum, but can also occur via the blood stream, through lymphatic vessels, or by direct extension. Careful intraoperative assessment of the ovaries at the time of colon cancer surgery is essential. Synchronous metastases occur in 0%–8.6% of patients in various clinical studies,<sup>128–132</sup> whereas metachronous metastases develop in 1.4%–6.8% of colorectal cancer cases,<sup>126,127,133,134</sup> usually within 2 years after the primary resection.<sup>129,135,136</sup> Most often these metastatic lesions are large, and at least half of the cases have bilateral ovarian involvement.<sup>136,137</sup> Approximately 40% of these patients also have associated extraovarian pelvic metastasis.<sup>136</sup> Distinguishing a metastatic colorectal cancer from primary ovarian tumor is difficult by gross assessment alone, but a correct diagnosis can generally be determined through integration of clinicopathologic, immunohistochemical, and cytogenetic features. Most metastatic colorectal lesions are CK20<sup>+</sup>/CEA<sup>+</sup>/CK7<sup>-</sup> on staining, whereas primary ovarian neoplasms are CK20<sup>-</sup>/CEA<sup>-</sup>/CK7<sup>+</sup>.<sup>138–141</sup>

Clinical studies attempting to document the benefit of ovarian metastasectomy in patients with colorectal cancer are small and retrospective.<sup>126,127,142,143</sup> Although generally asymptomatic when first detected in the operating room or on

CT scan, ovarian metastases can compress or invade adjacent organs (ureter, bladder, bowel), rupture, and on rare occasions bleed. Survival of women with synchronous ovarian colorectal metastases is significantly worse than that of patients without such metastases.<sup>126,144</sup> In addition, ovarian metastases are frequently resistant to systemic chemotherapy even when other sites of metastatic disease are responding. Therefore, resection of synchronous ovarian metastases should be performed when encountered in the operating room. Bilateral oophorectomy and complete resection of gross disease is recommended. Reoperation for metachronous metastases should be considered in selected patients with good performance status and limited tumor burden elsewhere. The goal of metastasectomy is to prevent local tumor progression. Therefore, an aggressive surgical approach should be undertaken to achieve complete resection when possible, especially if disease is confined to the pelvis. The survival benefit of removing ovarian metastases has never been well documented. Complete metastasectomy is associated with significantly better outcome when compared with palliative debulking, especially in the setting of metastatic disease confined to the pelvis only. However, complete resection is only possible in 50% of these cases. For women with isolated ovarian metastases, median postresection survival is 18 months.<sup>145</sup> Women with other sites of disease have shorter survival, however, and 5-year survival after resection of established ovarian metastases is rare.<sup>146,147</sup> Although postresection chemotherapy with 5-FU was considered ineffective in studies done in the 1970s and 1980s, systemic chemotherapy should be strongly considered, particularly when residual disease is present. With the availability of stronger chemotherapeutic regimens containing oxaliplatin, irinotecan, and/or bevacizumab, better survival can be expected.<sup>6,57,59,61</sup>

The role of prophylactic oophorectomy in the absence of macroscopic disease is not well defined. Several clinical studies have failed to show a survival advantage, although the majority of evaluated patients were postmenopausal.<sup>128,129,148,149</sup> A randomized, prospective study comparing prophylactic oophorectomy versus no oophorectomy in Stage II or III colorectal cancer demonstrated an improvement in 5-year disease-free survival for the oophorectomy group (80%) compared with no oophorectomy (65%), but the benefit was not statistically significant ( $P = .16$ ).<sup>149</sup> Some justification and benefits for prophylactic oophorectomy can be found in retrospective studies.<sup>150–152</sup> These studies have shown reduction in the incidence of ovarian carcinoma, resection of synchronous microscopic ovarian metastases, and prevention of metachronous ovarian metastases in the future. Based on the available data, it is reasonable to offer prophylactic oophorectomy to all postmenopausal patients. For premenopausal patients, only those with established peritoneal metastases, those with a clearly increased risk of developing ovarian carcinoma (strong family history, known carriers of breast cancer [BRCA] or hereditary nonpolyposis colorectal cancer [HNPCC] mutation), or those who have already

completed their families should be considered for prophylactic oophorectomy.

## Bone and Brain Metastases

Bone metastases from colorectal cancer reportedly occur in 7%–9% of cases, and most often present in the context of widespread metastatic disease.<sup>153–155</sup> Routine diagnostic bone imaging is not indicated in colorectal cancer patients, however, unless there are specific bone-related symptoms. There are no curative modalities, but palliation of pain, fractures, or spinal cord involvement are important issues for these patients. Symptomatic relief from bony metastases can usually be accomplished with radiation and medical therapy. However, pathologic fractures are best treated by operative internal fixation. The systemic issues related to bone metastases are serious and include debilitation, immobility, hypercalcemia, and thromboembolic disease.

Cerebral metastases from colorectal cancer are uncommon, occurring in 1%–4% of colorectal cancer cases.<sup>156,157</sup> Colorectal tumors account for approximately 3% of all metastatic brain tumors.<sup>158</sup> These are generally found in the context of widespread metastases to multiple organ sites, but on rare occasion can present as an isolated brain metastasis. There is no role for routine brain imaging at primary presentation or at presentation with metastases elsewhere, unless there are specific neurologic symptoms. Once brain metastases occur, symptoms are common; palliative therapies include steroids to decrease swelling and anticonvulsants to control seizures. Definitive therapy of colorectal brain metastases usually involves surgery, radiation, or a combination of the two. For isolated, single brain metastases, resection can result in survival beyond 1–2 years.<sup>159,160</sup>

## Anal Cancer

Mark Lane Welton and Madhulika G. Varma

This chapter, reviews the anatomy that defines anal and perianal squamous cell carcinomas (SCCs), discusses the cancers and precursor lesions that are most frequently found in these regions, and concludes with brief discussions of the less common malignancies of the anus and perineum.

### New Anatomic Considerations

There are approximately 4200 new cases of anal cancer per year in the United States. This number may actually somewhat overestimate the true incidence because it is our impression that perianal or anal margin cancers are often classified as anal canal cancers because of proximity to the anus without actual involvement of the anal canal. As colorectal surgeons, the authors and editors are quite familiar with the landmarks that define the anal canal and anal margin. However, many caregivers involved in the diagnosis and treatment of this disease are less familiar with these landmarks in that their primary practices are internal medicine, gastroenterology, radiation oncology, medical oncology, dermatology, human immunodeficiency virus (HIV) medicine, etc. Many practitioners in these fields are not clear on the distinction between the dentate line and the anal verge and often lack the tools in their offices to visualize the anal landmarks. Given these limitations, we suggest a new terminology based on landmarks that all healthcare providers can easily visualize and understand. The new terminology is necessary because true anal canal lesions may have a more aggressive biology requiring chemoradiotherapy whereas lesions of the perianal skin may simply be treated with local excision. Thus, if the two classes of lesions are unwittingly grouped together, the response rates of anal cancer to chemoradiation therapy may be overstated.

The authors have proposed a new classification that may prove more useful to all caregivers who diagnose or treat patients with anal cancers. The classification system divides the region into three easily identifiable regions: intraanal, perianal, and skin (Figure 35-1).<sup>1</sup> **Intraanal** lesions are lesions that cannot be visualized at all, or are incompletely

visualized, while gentle traction is placed on the buttocks. In contrast, **perianal** lesions are completely visible and fall within a 5-cm radius of the anal opening when gentle traction is placed on the buttocks (Figure 35-2). Finally, **skin** lesions fall outside of the 5-cm radius of the anal opening. A key component of this classification system is that all clinicians, including gastroenterologists, surgeons, nurse practitioners, and medical and radiation oncologists can perform this simple examination in their offices without the aide of an anoscope or a clear understanding of the anatomic landmarks (dentate line and anal verge) of the region.

Identification of a new zone, the transformation zone, is also proposed to help clinicians and pathologists understand how intraanal SCCs may be found 6, 8, or even 10 cm proximal to the dentate line in the anatomic rectum. The transition zone is a well-known region. It is an area 0 to 12 mm in length beginning at the dentate line where a “transitional urothelium-like” epithelium may be found in the rectal mucosa instead of the standard columnar mucosa of the rectum. A “transformation zone” is a common finding in the cervix. This transformation zone, which we would propose for the anorectum, is a region in which squamous metaplasia may be found overlying the normal columnar mucosa. This immature metaplastic tissue may extend up the rectum in a fluid and dynamic manner involving at times 10 cm or more of distal rectal mucosa. The “transformation zone” is an important region where metaplastic tissue susceptible to human papillomavirus (HPV) infection, in particular HPV 16, may be found.

Finally, the locations of all lesions within these zones should be clearly reported. Frequently, accurate reconstruction of the exact location of a lesion removed by a referring caregiver is not possible. This may lead to overtreatment of perianal and even skin lesions. In the distal rectum, it may still be necessary to refer to one established anatomic landmark, the dentate line (mucocutaneous junction), to accurately reflect how far proximally in the rectum a lesion was found. In contrast to the dentate line, the anal verge is poorly understood, poorly visualized, and often confused with anal margin, which represents a region, not an anatomic boundary.

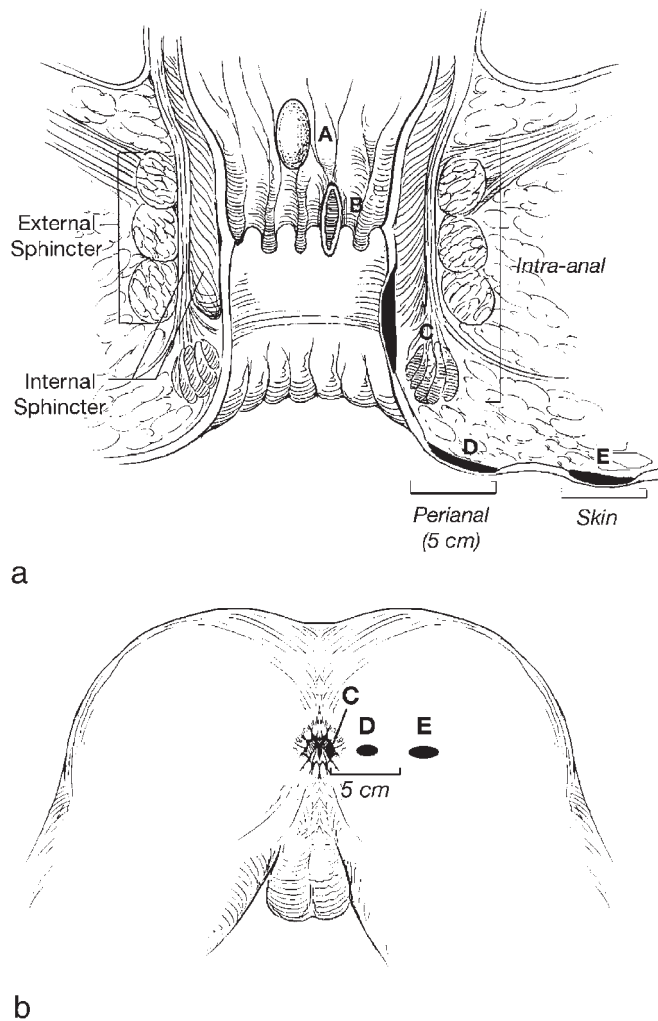

FIGURE 35-1. Classification system of anal cancers: a) coronal section. b) perianal view; A-C. intranal (anal canal) lesions, D. perianal (anal margin) lesions, E. skin lesions.

By adopting this new terminology, abandoning the use of some terms, and recording lesion locations clearly, we may begin to understand which lesions are amenable to local excision and which lesions require more radical intervention.

## Terminology

The terminology used by pathologists when reporting premalignant lesions of the anus and perineum is often confusing to the treating clinicians. The terms SCC in situ (CIS), anal intraepithelial neoplasia (AIN), anal dysplasia, squamous intraepithelial lesion (SIL), and Bowen's disease may all be used to refer to the same histopathology. The training of the pathologist dictates the term chosen. AIN and anal dysplasia have both historically been broken into AIN I, II, and III and low-, moderate-, and high-grade dysplasia. However, as with other pathologic staging systems, the intra- and interobserver variability are too high with this many categories. Therefore,

FIGURE 35-2. Perianal squamous cell carcinoma. (From Nivatvongs,<sup>79</sup> copyright © 1999. Reproduced by permission of Routledge/Taylor & Francis Group, LLC).

it has been suggested that when referring to intraanal, perianal, and skin lesions of the buttock that the tissue be classified as normal, low-grade squamous intraepithelial lesions (LSIL), high-grade squamous intraepithelial lesions (HSIL), or invasive cancer. Throughout the remainder of the chapter we will use this terminology and avoid CIS and Bowen's disease.

## Lymphatic Drainage

Lymphatic drainage above the dentate line occurs via the superior rectal lymphatics to the inferior mesenteric lymph nodes and laterally to the internal iliac nodes. Below the dentate line, drainage is primarily to the inguinal nodes but may also involve the inferior or superior rectal lymph nodes.

## Etiology and Pathogenesis of Anal Dysplasia and Anal SCC

The HPV is a necessary but not sufficient cause for the development of anal SCC (SCCA) and SILs.<sup>2,3</sup> HPV is a DNA papovavirus with an 8-kb genome and is the most common viral sexually transmitted infection.<sup>4-6</sup> Although most patients clear the virus with only 1% of the patients developing genital warts with low oncogenic potential (HPV serotypes 6 and

11),<sup>7-9</sup> an estimated 10%–46% of patients will develop sub-clinical infections that may harbor malignant potential (HPV serotypes 16, 18, 31, 33, 35).<sup>10-13</sup>

Transmission is not prevented by condoms because the virus pools at the base of the penis and scrotum thus abstinence is the only effective means of prevention. In women, the virus may pool and extend from the vagina to the anus. Anoreceptive intercourse may be associated with the development of intraanal disease but the presence of condylomata or dysplasia within the anus does not mandate that anoreceptive intercourse has occurred.<sup>14</sup>

In the rare patient who develops chronic infection, a variety of events must occur starting with the virus entering the basal and parabasal cells. This may occur through a disruption in the normal mucosal barrier that developed as a result of anoreceptive intercourse, other sexually transmitted diseases (ulcers from syphilis, gonorrhea), friable prolapsing hemorrhoidal tissues, or a firm bowel movement. As noted above, the squamous metaplastic tissue above the dentate line is a relatively “immature” incompletely developed squamous epithelium overlying the columnar epithelium and may not require trauma to disrupt an intact “barrier” making it particularly susceptible to HPV infection.<sup>15</sup> If high-risk viral DNA eludes immune surveillance and gains access to the nucleus of replicating cells (wound repair or metaplasia), the infection can become widespread and persistent lasting for decades resulting in an increased risk of cancer.

Cell-mediated immunity seems to be important to the cellular response prohibiting the virus from establishing a prolonged presence. This hypothesis is supported by the observation that cervical dysplasia patients with established high-risk lesions had a decreased ability to mount a T helper cell type 1 (Th1 IL-2) response in contrast to those patients with low-risk lesions.<sup>16</sup> Further support comes from the increased anal cancer rates observed in kidney transplant and HIV (+) patients, both populations with blunted cell-mediated responses.<sup>17-22</sup>

Oncogenic viruses lead to cellular proliferation in the latency phase by interfering with cell cycle control mechanisms.<sup>15,23</sup> Two “early region” viral genes, E6 and E7, inhibit cell cycle control resulting in increased proliferation. E7 binds directly to the retinoblastoma (Rb) tumor suppressor protein products p105, p107, and p130 related proteins leading to a complicated cascade of events involving E2F transcription factors, cyclin complexes, and other regulatory proteins allowing the cell to progress through G1 into S phase.<sup>24</sup> Cell cycle release by E7 allows for immortalization of the cells but is not sufficient for transformation of the infected cell. Accumulation of genetic errors seems necessary for transformation which is consistent with the clinical scenario of a longstanding low-grade infection preceding the development of malignancy.<sup>25</sup> The genetic errors may accumulate as a result of the E6 protein which binds to p53 with E6 associated protein (E6AP) leading to degradation of the complex through the ubiquitin pathway.<sup>24,26</sup> The unblocked

p53 protein is an important cell cycle regulating protein that leads to cell cycle arrest and apoptosis when genetic errors have accumulated, thus allowing for DNA repair and avoidance of replication of errors.

The E2 protein allows the HPV DNA to avoid intracellular detection by facilitating the attachment of the HPV DNA to the host chromatin. This also assures replication in a steady state with each cell division.<sup>15,27-29</sup> In uninfected epithelium, division occurs in the basal layers and maturation results in pyknotic condensed cells that slough from the tissue surface. In infected tissues, the viral DNA replication process is reactivated leading to the presence of specific proteins and viral particles that can be detected in the upper cell layers. In summary, through the combined effect of E7, E6, and E2, cells with genetic errors may proliferate, accumulate, and involve the entire thickness of the epithelium.<sup>15</sup> This may result in carcinogenesis.

As the infection with oncogenic viruses persists, the anal tissues may progress through low-grade to high-grade dysplasia and cancer. With this disease progression is an associated increased proliferation and angiogenesis, and decreased apoptosis.<sup>30</sup> In contrast to the mechanisms responsible for the increased proliferation and decreased apoptosis outlined in the above discussion, the mechanisms involved in increased angiogenesis are less well defined. However, in the cervix, angiogenic changes have long been recognized as an important and visible step in the progression of dysplasia to cancer. Colposcopy, a magnified view of the cervix, with the aid of acetic acid and Lugol’s solution, allows for direct visualization of characteristic vascular patterns seen with LSIL and HSIL. Gynecologists are trained to recognize these vascular patterns and target their therapeutic destruction in the cervix accordingly. This therapeutic intervention, in combination with screening Pap smears, has led to the belief that cervical cancer is a largely preventable cancer.

Fortunately, the angiogenic changes associated with development of anal HSIL can also be visualized with the aid of acetic acid and Lugol’s solution in the perianal skin, anus, and distal rectum through an operative microscope, colposcope, or loops in the office or operating room.<sup>13</sup> Targeted destruction is safe and may result in the same decrease in anal cancer incidence as was seen with cervical cancer when cervical Pap smears and targeted destruction was introduced for cervical disease.<sup>31</sup>

The cost effectiveness of such an anal cytology screening system to prevent anal cancer has been demonstrated using an economic model in both HIV-positive<sup>32</sup> and HIV-negative men who have sex with men (MSM).<sup>33</sup> These studies demonstrated that screening to identify patients with HSIL to be referred for treatment would be cost effective if performed annually for HIV-positive MSM and every 2–3 years for HIV-negative MSM.

Although the association of MSM and anal cancer is clear,<sup>14,34,35</sup> the association of HIV with the development and progression of anal cancer has been hard to separate from

other confounding factors. Initial studies accumulating anal cancer rates from the pre-HAART (highly active antiretroviral therapy) era failed to show a correlation presumably because patients succumbed to complications of the HIV.<sup>36,37</sup> HPV is an indolent infection that leads to cancer in a minority of patients who generally suffer from a long-term infection. Thus, as might be expected, more recent studies reporting anal cancer rates in patients who are now surviving longer with effective HAART suggest an association with HIV and anal cancer.<sup>17,18,38–40</sup> The increase in anal cancer and dysplasia rates is seen in HIV-positive MSM, and HIV-positive heterosexual men and women who do not report anoreceptive intercourse.<sup>17–19</sup> Furthermore, HIV-positive patients are more likely to have HSIL, are more likely to progress from LSIL to HSIL over a 2-year time period, and both of these findings are increased in the patients with a lower CD4 count (<200 cells/mm).<sup>38–40</sup> Low CD4 counts are a surrogate measure for immunosuppression from the HIV infection and it is therefore suggested that HIV infection is associated with an increased risk of progression of anal disease.

Although the above articles suggest a permissive role for HIV in the development of anal cancer in HIV-positive men and women, a recent cancer registry report compared anal cancer rates from the pre-AIDS era to the post-AIDS era and found no correlation.<sup>41</sup> Nonetheless, data are accumulating that suggest that as men and women live longer in the HAART era, the indolent HPV infection will result in an increased risk for the development of anal cancer and this effect will be most significant in the most immunocompromised patients.

## Epidemiology

The incidence of SCCA has been increasing in frequency over the last 30 years in the United States, Europe, and South America. This increase was noted to be quite pronounced in a recent 4-year review in which an increase from 3400 new cases for 1999 to 3900 new cases for 2002 was noted in the United States.<sup>42,43</sup> The California Cancer Registry found a statewide increase in anal cancers in non-Hispanic white men of approximately 2% per year between 1988 to 1999 with 1.0 case per 100,000 population in 1988 and 1.4 cases per population in 1999.<sup>20</sup> There was not a comparable increase for women over the same time period. Most alarming was the increase in the age-adjusted incidence for San Francisco white men aged 40–64 where the rates increased from 3.7 per 100,000 for 1973–1978, to 8.6 per 100,000 in 1984–1990 and ultimately to 20.6 per 100,000 in 1996–1999. This is the first report ever of anal cancer rates higher among men under age 40 compared with women of the same age group.<sup>20</sup> Previous reports have consistently shown a higher rate in women in all age groups.<sup>44</sup>

In Denmark during the years 1943–1987 there was a 1.5 fold increase in men and a 3-fold increase in women.<sup>45</sup> A significant decrease in the mean age of men diagnosed with

SCCA from 68 to 63 years of age was also found. An even greater increase was found in city populations where a 3-fold increase in the incidence of anal cancers in Copenhagen and its suburbs was observed. A significant increase in incidence for the entire male population was still seen with the incidence observed between the years 1983–1987 representing an increase of 30%–40% of that seen in the 5-year span of 1943–1947. The rates in Copenhagen and surrounding areas were equal to the national level in 1943–1947 but in 1983–1987 the incidence in the city was 2.5-fold higher than that seen in the rest of the country. The average age of women patients with SCCA did not change but the incidence did increase 3-fold over the entire country with a significantly greater increase in Copenhagen when compared with the entire country. Men with anal cancer were significantly less likely to have been married when compared with men with colon cancer and stomach cancer. The same was not true of women with anal cancer. Similar findings were reported from Sweden where a dramatic increase in incidence of anal cancer was observed around 1960, with a greater change in women than men (2:1), and the steepest increase in the heavily populated cities.<sup>44</sup>

In another Copenhagen study, women with anal cancer were noted to have a higher risk of having had cervical neoplasia or cancer.<sup>46</sup> Risk factors for developing HSIL and anal cancer also included HIV seropositivity, low CD4 count, persistent infection with high-risk HPV genotypes (16, 18, 31, 33, 35), infection with multiple genotypes, cigarette smoking, anal receptive intercourse, and immunosuppression for organ allograft. Unlike cervical cancer, multiple partners was not a significant independent risk factor.<sup>25,38,39,47–53</sup>

## Bowen's Disease

As mentioned above, the distinction between Bowen's disease and HSIL is unclear and seems to have more to do with the pathologist's training, cytopathology versus histopathology, than any biologic difference. Bowen's disease is both SCCA in situ and HSIL. The term Bowen's disease is applied to SCC in situ in both keratinizing and nonkeratinizing tissues. Thus, we believe the term is archaic and confusing, and should be abandoned in favor of HSIL. For purposes of this section of the chapter, we will use the term because it is in common usage.

Bowen's disease is frequently found as an incidental histologic finding after surgery for an unrelated problem, often hemorrhoids. The lesion is clinically unapparent but histologic assessment of the specimen reveals SCC in situ. Alternatively, patients may present with complaints of perianal burning, pruritus, or pain. Physical examination may reveal scaly, discrete, erythematous, or pigmented lesions.

The natural history of Bowen's disease is poorly defined. In the immunocompetent, fewer than 10% will progress to cancer.<sup>54</sup> However, in immunocompromised patients, the

progression rate seems greater as evidenced by the higher rates of anal cancers observed in the HIV (+), and immunosuppressed transplant patients.<sup>17-22</sup> Because we are as yet unable to identify those patients that will progress, we favor treatment of Bowen's disease. An exception to this recommendation would be patients with advanced AIDS with poor performance statuses despite maximal medical therapy. This was a common problem in the early 1990s but since the advent of HAART, the vast majority of our AIDS patients are candidates for surgical intervention. The other exception might be the elderly patient with an asymptomatic lesion and a short life expectancy. Unlike perianal Paget's disease, there is no association with other visceral malignancies.<sup>55</sup>

The preferred treatment is fairly controversial but should be tailored to the given patient. The standard recommendation for the unsuspected lesion found after hemorrhoidectomy is to return the patient to the operating room for random biopsies taken at 1-cm intervals starting at the dentate line and around the anus in a clock-like manner. Frozen sections establish the presence of Bowen's disease and these areas are widely locally excised with 1-cm margins. Large defects are covered with flaps of gluteal and perianal skin. Bowen's recurrence rates in one series were as high as 23% despite this radical approach.<sup>56</sup> No cancers developed in this group, but complications including continence, stenoses, and sexual function, and HIV status were not reported. In another study of wide local excision, the authors noted a 63% persistence rate at 1 year and a 13% recurrence rate at 3 years. Eleven percent of the patients developed incontinence or stenosis.<sup>57</sup>

A less radical approach involves taking patients to the operating room and with the aide of an operating microscope, acetic acid, and Lugol's solution the lesions are visualized and targeted for electrocautery destruction. Similar to cervical disease, the Bowen's disease is visible because of its characteristic vascular pattern identifying the at-risk tissue for selective destruction.<sup>13</sup> This technique minimizes the morbidity of the procedure and saves the normal anal mucosa and perianal skin that would otherwise be sacrificed. Postoperative pain is significant as would be expected with any perianal procedure but in HIV (-) and otherwise immunocompetent patients there have been no recurrences and no progression to cancer. No patients developed incontinence or anal stenosis. In the HIV (+) patients, the recurrence rate is high but re-treatment is well tolerated and no cancers have developed in patients sent for surgical intervention.<sup>31</sup> Bowen's disease identified with the operative microscope and acetic acid may also simply be locally excised taking care to stay close to the lesion margin which is directly visualized with the operative microscope. The deep margin is kept equally close because wide local excision seems of limited benefit and increases morbidity. The resulting minimal defects heal in secondarily. High-risk patients, the immunocompromised, and patients practicing receptive anal intercourse, should be followed with Pap smears at yearly and three yearly intervals for the immunocompromised and immunocompetent, respectively.<sup>32,33</sup>

Other therapeutic modalities include topical 5-fluorouracil (5-FU) cream, imiquimod, photodynamic therapy, radiation therapy, laser therapy, and combinations of the above. The reports are generally small series with limited follow-up but there may be anecdotal success with each approach and the options may be kept in mind for challenging cases. Initial reports of the use of 5-FU cream were generally disappointing<sup>58</sup> but a recent report has suggested that Erbium:YAG laser pretreatment may improve the response of Bowen's disease.<sup>59</sup> Reports of the use of vidarabine and cidofovir support their consideration but the series are small with limited follow-up.<sup>60,61</sup> Imiquimod has been reported to be of benefit alone<sup>62</sup> and in combination with 5% 5-FU therapy in the immunosuppressed transplant and HIV (+) patient population.<sup>63,64</sup> Radiotherapy with a special skin patch or conventional external beam have also been reported.<sup>65,66</sup> Photodynamic therapy has been tried with success<sup>67,68</sup> and compared favorably to topical 5-FU in a randomized comparison.<sup>69</sup>

## SCC of the Anal Margin

SCC arises from both the anal margin and the anal canal, although it is much less common in the former group. The distinction between the two locations has become more important as they are increasingly considered different entities with separate treatments and prognosis. Immunohistochemical studies of squamous cell tumors from the anal margin and anal canal demonstrate differences in expression of cadherin, cytokeratins, and p53 confirming that these tumors are of distinct histogenetic origin.<sup>70</sup> The anal margin is defined as the skin starting at the distal end of the anal canal to a 5-cm margin surrounding the anal verge.<sup>71</sup>

## Clinical Characteristics

Tumors of the anal margin resemble SCC of other areas of skin and are therefore staged and often treated in a similar manner.<sup>72</sup> They have rolled, everted edges with central ulceration, and may have a palpable component in the subcutaneous tissues although the sphincter complex is not usually involved. Patients present in the seventh decade of life with equal incidence in men and women.<sup>73,74</sup> Presenting symptoms include a painful lump, bleeding, pruritus, tenesmus, discharge, or even fecal incontinence.<sup>75</sup> In general, anal margin tumors are characterized by a delay in diagnosis because of their location and indistinct features, and SCC is no exception. Patients have been noted to have symptoms anywhere from 0 to 144 months before diagnosis (median of 3 months),<sup>76</sup> and almost one-third are misdiagnosed at their first physician visit.<sup>75</sup> Patients were given erroneous diagnoses of hemorrhoids, anal fissures, fistulas, eczema, abscesses, or benign tumors. For anal margin tumors, however, there was no significant difference in survival between correctly diagnosed and misdiagnosed patients.<sup>75</sup>

TABLE 35-1. AJCC staging of SCC

Anal margin		Anal canal		
Primary tumor (T)				
Tx	Tumor cannot be assessed	Tumor cannot be assessed		
T0	No evidence of primary tumor	No evidence of primary tumor		
Tis	Carcinoma in situ	Carcinoma in situ		
T1	Tumor ≤2 cm in greatest dimension	Tumor ≤2 cm in greatest dimension		
T2	Tumor 2–5 cm in greatest dimension	Tumor 2–5 cm in greatest dimension		
T3	Tumor ≥5 cm in greatest dimension	Tumor ≥5 cm in greatest dimension		
T4	Tumor invades deep structures (muscle, bone, cartilage)	Tumor invades deep structures (vagina, urethra, bladder, but not sphincter)

Stage 4	Any T	Any N	M1	

## Staging

The staging of anal margin SCC is based on size of the tumor and lymph node involvement, both of which correlate with prognosis. Lymphatic drainage of the anal margin extends to the femoral and inguinal nodes and then to the external and common iliac nodes. Venous drainage occurs through the inferior rectal vein. Lymph node involvement is associated with the size and differentiation of the tumor.<sup>76–78</sup> In one study, the incidence of inguinal lymph node metastasis was noted to be 0% for tumors <2 cm, 23% for tumors 2–5 cm in size, and 67% in tumors >5 cm.<sup>78</sup> Distal visceral metastasis at presentation is rare but should be evaluated with a computed tomography (CT) scan of the abdomen and pelvis, to assess for liver metastases, as well as the presence of nodal disease. A chest X-ray can be performed to evaluate for lung metastasis. These tumors are generally slow growing and histologically are well differentiated with well-developed patterns of keratinization.<sup>73,79</sup> The American Joint Committee on Cancer (AJCC) staging system is described in Table 35-1.<sup>71</sup>

## Treatment Options

Treatment of anal margin SCC traditionally consisted of surgical resection with wide local excision for smaller-sized tumors and abdominoperineal resection (APR) for larger, invasive tumors. However, it is well documented that wide local excision alone results in high locoregional recurrence

rates (18%–63%) (Table 35-2)<sup>73,80–84</sup> and should be reserved for those lesions that can be excised with a 1-cm margin, are Tis or T1, and do not involve enough sphincter to compromise function.<sup>74</sup> A series of 27 patients with Tis and T1 lesions treated with wide local excision had a 100% 5-year survival<sup>85</sup> and in another study, all patients with small or superficial tumors locally excised had a survival of 100% whereas those with deep invasion did not survive 5 years.<sup>83</sup> Since it was introduced in the early 1970s, radiation therapy has become the mainstay of therapy for SCC of the anal canal and its application to tumors of the anal margin is increasing. In patients with T1 or early T2 lesions, local excision or radiation therapy provides similar local control rates (60%–100%),<sup>78,86,87</sup> but for less favorable lesions, chemoradiation is now used as the first-line therapy using a perineal field and inguinal fields, even without clinically detectable disease in the groin.<sup>78,87</sup> Pelvic lymph nodes are also treated for those patients with T3 and T4 tumors.<sup>73,74,78,88</sup> Local

TABLE 35-2. Results of local excision of anal margin tumors

Author	Year	N	Local recurrence (%)	Survival (%)
Beahrs and Wilson <sup>85</sup>	1976	27	0	100

Schraut et al. <sup>83</sup>	1983	11	18	80
Greenall et al. <sup>81</sup>	1985	31	42	68
Jensen et al. <sup>80</sup>	1988	32	63	—
Pintor et al. <sup>84</sup>	1989	41	—	68

control rates for radiation therapy reported by T stage are as follows: T1, 50%–100%; T2, 60%–100%; T3, 37%–100%<sup>78,86,87,89,90</sup> (Table 35-3). In one study, the T3 lesions were separated into tumors 5–10 cm in size and those >10 cm with local control rates of 70% versus 40%, respectively.<sup>89</sup> Patients with persistent tumor can be treated with local excision or APR with a 50% salvage rate.<sup>80,91</sup> Those with recurrence after successful radiation can also be salvaged for cure.<sup>92–95</sup> The absolute 5-year survival rate for patients treated with local excision or APR ranges from 60% to 100% but is lower in patients with larger tumors.<sup>81,82,96</sup> Similarly, absolute 5-year survival in patients treated with radiation ranges from 52% to 90% with sphincter preservation in about 80%.<sup>74</sup> The use of chemoradiation specifically pertaining to SCC of the anal margin has not been well examined. However, one study did show an improvement in local control (64% versus 88%) with the addition of 5-FU and mitomycin to radiation.<sup>89</sup> In extrapolation of data from a randomized, multicenter study including early stage tumors, those of the anal margin and anal canal, it would be postulated that chemoradiation is superior.<sup>93</sup>

In summary, the choice of treatment is dependent on the stage of tumor, the anticipated functional result as a result of therapy, and the risk of complications. Although surgery may result in alteration of sphincter function, or a permanent colostomy, radiation therapy may also cause skin changes or proctitis that produces urgency, incontinence, or the need for diversion. For T1 and early T2 tumors, wide local excision may be less morbid and time consuming than radiation therapy and therefore a superior choice. However, if the excision will result in damage to the sphincters with impairment of fecal function, radiation provides similar local control and survival. T2 tumors should be treated with radiation therapy to the primary lesion and inguinal fields because of poor local control with excision and the significant risk of lymph node metastasis. This treatment modality is much less morbid than resection of the primary and bilateral lymph node dissection with similar control rates.<sup>77</sup> Those with T3, T4, or poorly differentiated tumors should receive radiation to the primary lesion and include inguinal and pelvic fields to treat regional nodes in these areas. APR should be reserved for those patients with persistent or recurrent disease after radiation therapy.<sup>74,88</sup>

## SCC of the Anal Canal

SCC incorporates all large-cell keratinizing, large-cell nonkeratinizing (transitional), and basaloid histologies. The terms epidermoid, cloacogenic, and mucoepidermoid carcinoma are all encompassed in the SCC group.<sup>97</sup> SCC of the anal canal is 5 times more common than SCC of the anal margin but its incidence is one-tenth that of rectal cancer. The incidence, epidemiology, and etiology have been described above.

### Clinical Characteristics

The most common presenting symptom is bleeding, which occurs in >50% of patients with many complaining of anal pain. Other symptoms include palpable lump, pruritus, discharge, tenesmus, change in bowel habits, fecal incontinence, and rarely, inguinal lymphadenopathy.<sup>75,98,99</sup> A small number of patients will be asymptomatic. Unfortunately, most patients are diagnosed late, with up to 55% of patients being misdiagnosed at the time of presentation.<sup>75</sup> In another study of 172 patients with SCC, only 17 were diagnosed with tumors confined to the epithelium and subepithelial connective tissue.<sup>100</sup>

### Evaluation

Physical examination should include a complete anorectal examination with external inspection of the anoderm, digital examination, anoscopy and proctoscopy, in addition to examination of inguinal areas. Careful notation should be made of the size, location, and mobility of the mass, associated perirectal lymphadenopathy, and in women, a pelvic examination should be performed to look for any associated lesions or invasion of tumor into the vagina. Complete examination and biopsy may require anesthesia for those patients with significant pain. Additional workup should include an endoanal/endorectal ultrasound to assess the depth of the tumor, presence of perirectal lymph nodes, and invasion of adjacent organs as an adjunct to the physical examination.<sup>101–104</sup> Ultrasound has been found to be superior to physical examination in assessing the involvement of internal and external anal sphincter muscle and perirectal lymph nodes. This has an impact on staging because physical examination often understages tumors. One study demonstrated that endorectal ultrasound T and N stage were significant predictors of relapse whereas the corresponding clinical staging was not.<sup>103</sup> Recently, a study of three-dimensional ultrasound has demonstrated improved accuracy in detecting perirectal lymph nodes and some suggestion of improved evaluation of tumor invasion.<sup>105</sup> Inguinal nodal involvement at the time of presentation can be difficult to determine. The sensitivity of radiologic imaging and clinical examination are poor.<sup>106</sup> Enlarged lymph nodes can be reactive to secondary inflammation in some cases and therefore should be biopsied with

direct FNA (fine-needle aspiration) or ultrasound-guided FNA if detected by imaging. Excisional lymph node biopsy is rarely required but may be done if FNA is inconclusive. Studies of sentinel lymph node biopsy have demonstrated that the technique is safe and may result in more accurate staging<sup>107</sup> but the actual impact on initial and subsequent management remains unclear as long as inguinal fields are included during radiation therapy. CT scan or magnetic resonance imaging (MRI) of the abdomen and pelvis can add to locoregional staging as well as evaluating for liver metastasis. A chest X-ray is used as a screening tool for lung lesions and, if suspicious, a chest CT should be performed. Positron emission tomography (PET) scans are primarily useful for assessing persistent or residual disease after treatment. Colonoscopy can exclude any associated lesions proximal to the anal canal. Lastly, an HIV test should be performed for those at higher risk. HIV-positive patients with CD4 counts <200 need better monitoring of opportunistic infections, closer attention to toxic effects of chemoradiation with possible alterations in dosage, and management of antiretroviral therapy.<sup>98,99,108,109</sup>

## Staging

The staging of anal canal SCC is based on the size of the tumor and lymph node metastasis. The TNM (tumor-node-metastasis) staging is listed in Table 35-1. The risk of nodal metastasis correlates with the size, depth of invasion, and the histologic grade of the tumor. In a series of 305 patients with SCC, lymph node metastasis was present in 16%. Nodal metastasis by T stage was as follows: T1 (0%), T2 (8.5%), T3 (29%), T4 (35%). Lymph node metastasis occurred in 47% of patients with T4 tumors >5 cm in size.<sup>110</sup> Inguinal metastases have been detected in 10%–30% of patients at the time of diagnosis<sup>84,100,111,112</sup> with an additional 5%–22% of patients developing clinically apparent lymph node metastases over time.<sup>112</sup> Nodal metastasis was almost double (58% versus 30%) in those tumors invading beyond the external sphincter compared with invasion of the internal sphincter.<sup>113</sup> Lymphatic drainage of the anal canal above the dentate line proceeds along the superior rectal vessels. At the dentate line, the drainage basin includes the internal pudendal, internal iliac, and obturator nodes. Below the dentate line, the lymphatic drainage is through the inguinal, femoral, and external iliac lymph nodes.<sup>114</sup> Mesenteric lymph nodes are more common in tumors of the proximal anal canal (50%) than the distal anal canal (14%).<sup>98</sup> An anatomic study of lymph node metastasis demonstrated that they most often occur above the peritoneal reflection and not in the perianal area. Additionally, almost half of the positive lymph nodes were <5 mm in size.<sup>114</sup> Distant visceral metastasis occurs in 10%–17% of patients at presentation and can be found in the liver, lung, bone, and subcutaneous tissues.<sup>92,93</sup> Subsequent metastasis is more common and was the cause of 40% of cancer-specific deaths in one series.<sup>93</sup>

## Treatment

### Surgery

The treatment of anal canal SCC was historically operative with APR being the standard of care. Unfortunately, local recurrence rates ranged from 27% to 47% and 5-year survival was 40%–70%.<sup>83,84,97,98,100,106,115</sup> The presence of pelvic lymph nodes decreased the 5-year survival to <20%.<sup>99</sup> Local excision was performed in those patients who could not tolerate an abdominal operation, refused a permanent colostomy, or had small, well-differentiated tumors. The recurrence rates and 5-year survival ranged from 20% to 80% and 45% to 85%, respectively.<sup>79,80</sup> However, in well-selected patients with early tumors, the 5-year survival was 100%.<sup>83,84,100</sup>

### Radiation Therapy

Primary radiation therapy is quite effective in treating SCC because this tumor is extremely radiosensitive. It can be given as external beam radiation, brachytherapy, or in combination. Response is dose dependent with the best chance of tumor eradication occurring with at least 54 Gy of external beam radiation (Table 35-4).<sup>116,117</sup> However, this benefit is lost when radiation is administered in a split-course manner.<sup>118,119</sup> Local control and cure can be achieved in 70%–90% of selected patients with 60%–70% retaining sphincter function.<sup>111,116</sup> However, when tumors are larger than 5 cm or lymph nodes are involved, the cure rate decreases to 50%.<sup>72,92,111,116</sup> Better results with higher doses of radiation must be exchanged with increased radiation-induced complications when more than 40 Gy is administered. Serious late complications include anal necrosis, stenosis, and ulcerations, diarrhea, urgency, and fecal incontinence, cystitis, urethral stenosis, and small bowel obstruction. Significant impairment of fecal function caused by anal complications can lead to the placement of a colostomy. Most studies have found a dose-dependent effect on morbidity with the requirement of a colostomy in 6%–12% of patients.<sup>95,111,120</sup> However, a recent study examining risk factors predictive of requiring a colostomy for management of anal cancers found that tumor size was the only risk factor. Although radiation toxicities did occur, patients were not at an increased risk for requiring a stoma.<sup>121</sup> Brachytherapy used alone or in conjunction with external beam radiation is also effective with local control rates of 75%–79% and 5-year survival of 61%–65%, but 3%–6% of patients had serious complications that required surgery. The high rate of anal necrosis seen when both modalities are used has dampened

the enthusiasm for this approach.<sup>122,123</sup> At this time, radiation therapy alone is not frequently used but may have a role in treating T1 tumors.<sup>120,124</sup>

### Chemoradiation Therapy

The introduction of chemoradiation therapy by Nigro et al. in 1974 revolutionized the treatment of anal canal SCC by demonstrating equivalent local control and survival rates with preservation of sphincter function and thus avoidance of a colostomy.<sup>125–127</sup> Since that time, multiple studies have confirmed these results and now chemoradiation has become the standard therapy for SCC of the anal canal. Nigro et al. described using 30-Gy external beam radiation with 5-FU and mitomycin C, and demonstrated a complete pathologic response in 21 of 26 patients treated (81%). Since that time, various radiation doses (30–60 Gy) and chemotherapeutic regimens have been used with similar complete pathologic responses (45%–100%) and survival rates (70%–90%) (Table 35-5). As a result, operative treatment for anal canal SCC was largely abandoned and reserved for those patients with persistent or recurrent disease after chemoradiation. Although much controversy existed as to the benefit of chemoradiation therapy compared with primary radiation therapy, two randomized, controlled studies have been completed which demonstrate the superiority of chemoradiation therapy using

5-FU and mitomycin C to radiation alone.<sup>92,93</sup> Using 45 Gy with a boost for good response, both studies exhibited better local control rates with chemoradiation (Table 35-6) but no significant difference in survival. However, one study resulted in a higher complete response rate (80% versus 54%) and an improvement in colostomy-free survival (72% versus 47% at 3 years) which is significant.<sup>92</sup> Chemotherapy-related deaths occurred in 5.4% of patients in one series, and changes were made to the protocol which included a reduction of the dose for patients older than 70, bed-bound, frail, or with evidence of tumor-related sepsis.<sup>93</sup> The role of mitomycin C was also examined in a randomized trial which demonstrated better complete pathologic response rate (92% versus 85%), local control rate (84% versus 66%), colostomy-free survival rate (71% versus 59%), and disease-free survival (73% versus 51%) when mitomycin C was used in conjunction with 5-FU and radiation compared with 5-FU and radiation alone.<sup>128</sup> However, treatment toxicity was increased in the mitomycin C group (23% versus 7%) with a 4% chemotherapy-related mortality and overall survival was equivalent.

Although the use of mitomycin C has provided excellent results, cisplatin has gained favor because it is a radiation sensitizer, is less myelosuppressive than mitomycin C, and has been used for those patients who failed to respond to mitomycin C. In series of patients treated with 45–55Gy of radiation, 5-FU, and cisplatin, the reported rates of local control

TABLE 35-6. Results of two randomized trials examining radiation therapy alone and radiation therapy with chemotherapy for anal canal SCC

	N	Follow-up (y)	Local control (%)			Overall survival (%)		
			XRT	Chemo XRT	P value	XRT	Chemo XRT	P value
EORTC	110	5	50	68	.02	57	52	.17
UKCCCR	585	3	39	61	<.001	58	65	.25

(80%–83%), disease-free survival (77%–90%), and colostomy-free survival (71%–82%) were comparable to the best results obtained from mitomycin C regimens. Additionally, there were fewer severe toxicities reported.<sup>129,130</sup> A pilot study of the CALGB (Cancer and Leukemia Group B) using cisplatin demonstrated a complete response rate of 80%, colostomy-free survival of 56%, and overall survival of 78%. A randomized trial (RTOG 98-11) comparing cisplatin, 5-FU, 45 Gy to mitomycin C, 5-FU, 45 Gy is currently underway.<sup>99,109</sup>

Although the presence of inguinal metastasis at presentation indicates a worse prognosis, the overall 5-year survival is 48% (range, 30%–66%). Those with lymph nodes >2 cm in size, T3 or T4 tumors, or anal margin involvement had a worse survival (29%–32%).<sup>112</sup> For patients with obvious evidence of inguinal node metastasis, local control can be achieved in 90% of patients receiving chemoradiation compared with 65% receiving radiation alone. Surgical management with radical groin dissection can lead to significant complications and may be successful only 15% of the time.<sup>106</sup> The management of synchronous inguinal node metastasis is not standardized and different centers will use primary radiation therapy (45–65 Gy), chemoradiation, and selective lymph node dissection followed by radiation which has been reported to maintain disease-free intervals in up to 60% of patients.<sup>73</sup> For those with subclinical lymph nodes in the groin, chemoradiation is advocated with doses as low as 30–34 Gy. This minimizes toxicity but is effective in treating small-volume disease based on previous studies of small-sized tumors.<sup>99</sup> Whether or not inguinal fields should always be included when treating patients for anal canal SCC remains controversial.

### Follow-up

No consensus has been reached on appropriate follow-up after treatment of SCC. It is generally agreed that early intervention for persistent disease and recurrent locoregional disease can lead to successful salvage therapy. Routine examination with digital rectal examination and proctoscopy every 2 months in the first year, every 3 months in the second year, and every 6 months thereafter has been recommended. Ultrasound examination has also become popular in detecting recurrence although the literature is mixed on its benefit.<sup>103,131</sup> CT scan or MRI performed after completion of chemoradiation may also be useful as a baseline for future comparison. MRI is useful for distinguishing surrounding tissues and detecting persistent or recurrent disease.

### Treatment of Residual or Recurrent Disease

Persistent or recurrent disease localized to the pelvis after chemoradiation can be treated with salvage therapy. Patients need to be restaged with a CT of the chest, abdomen, and pelvis. MRI may be useful to assess resectability of pelvic

recurrence and PET scan may help to differentiate tumor from radiation-induced tissue changes or other undetectable metastases. APR can be performed for tumor localized to the pelvis with a 5-year survival of 24%–47%.<sup>132–137</sup> Those with positive margins, nodal disease at salvage, and persistent disease after chemoradiation have poorer outcomes.<sup>137,138</sup> Morbidity for APR in this setting is significant with an increased risk of perineal wound complications. This has prompted the use of plastic surgery reconstruction using rotational or advancement flaps to promote healing. The benefit of adjuvant chemotherapy after APR is currently unknown. Clinically evident inguinal disease after chemoradiation of the primary tumor can be treated with radical groin dissection if radiation has already been administered. Additional radiotherapy can be considered if maximal doses of radiation were not delivered. Radical groin dissection in selected patients can result in a 5-year survival of 55%.<sup>139</sup> Distant metastases have been found in 10%–17% of patients treated with chemoradiation,<sup>92,93</sup> and are usually treated with systemic chemotherapy such as cisplatin or 5-FU for palliation. If the metastases are isolated in the liver or lung and the primary disease is controlled, resection can be considered. The role of adjuvant maintenance chemotherapy is still under investigation in a Phase 3 randomized study in the United Kingdom.<sup>109</sup>

## Uncommon Anal Canal Neoplasms

### Adenocarcinoma

Anal canal adenocarcinomas are classified into three types. The first group may arise from the mucosa of the transitional zone in the upper canal and are indistinguishable from rectal adenocarcinoma. The second derives from the base of the anal glands which are lined with mucin-secreting columnar epithelium. The last can develop in the setting of a chronic anorectal fistula.<sup>79</sup> Adenocarcinomas account for 5%–19% of all anal cancers,<sup>140–142</sup> and have a more aggressive natural history than SCCs.<sup>143</sup>

The average age at presentation ranges from 59 to 71 years with equal gender distribution.<sup>141,144</sup> Patients may present with pain, induration, abscess/fistula, or a palpable mass. Other symptoms include bleeding, pruritus, seepage, prolapse, and weight loss.<sup>79</sup>

Because of the rarity and heterogeneity of this tumor, the role of surgery and chemoradiation has been difficult to assess, thus making definitive recommendations for treatment impossible. Many patients present with advanced local or metastatic disease making curative treatment challenging. The local disease may tend to be more advanced in those that arise in glands and fistulous tracts because these locations are outside the bowel wall and therefore the disease originates in a locally advanced location. Wide local excision may be feasible for those patients with a “rectal-type” tumor that is small, well differentiated, and does not invade the sphincter

complex. All other tumors require APR. Chemoradiation alone has not been shown to be as effective for adenocarcinoma compared with SCC because of high local recurrence rates (54% versus 18%) and poor survival rates (64% versus 85%).<sup>143</sup> However, in another study analyzing treatments for anal canal adenocarcinoma including APR, surgery with radiation, and chemoradiation, similar locoregional recurrence rates (20%, 37%, 36%) and better overall survival was seen in the chemoradiation group (21%, 29%, 58%).<sup>144</sup> Other studies have suggested that a combined modality approach of surgery with chemoradiation does improve outcome with survival rates exceeding 60%.<sup>140,141</sup> Although no large series of patients has been treated in any uniform manner to substantiate the approach of chemoradiation therapy followed by surgery, the success of this approach for rectal adenocarcinoma would support its use.

## Melanoma

Anorectal melanoma is characterized by unusual lesions that are often difficult to differentiate from benign pathology. For this reason, and its rarity, many patients present with advanced-stage disease. Although the anorectum is the most common site for primary melanoma of the gastrointestinal tract, it comprises only 0.5%–5% of all malignancies there. Fewer than 500 cases have been reported in the literature.<sup>145</sup> Patients are frequently female, Caucasian, and in their 60s. Isolated cases have been reported in African-American and Asian populations.<sup>72,146,147</sup>

Anorectal bleeding is the most common symptom described. However, anal pain, change in bowel habits, or tenesmus may also be reported. Weight loss and malaise may be indicative of advanced disease. A mass in the anal canal is the most frequent sign with a high likelihood of palpable inguinal lymph nodes. These tumors arise from the transitional epithelium of the anal canal, the anoderm, or the mucocutaneous junction. Although some lesions may seem to arise within the rectal mucosa, it is postulated that this is attributable to heterotopic epithelium within the rectum or mucosal spread from a primary foci within the anal canal.<sup>146</sup>

Most lesions are pigmented, with early lesions appearing polypoid and larger lesions having ulcerations, raised edges, or significant growth into the rectal vault. An early lesion may be indistinguishable from a thrombosed hemorrhoid and some cases have been incidentally diagnosed from a hemorrhoidectomy specimen. Approximately two-thirds of the lesions will be grossly pigmented or show histologic evidence of melanin.<sup>148</sup> Amelanotic lesions can be difficult to differentiate from undifferentiated SCC.

Surgical management of anorectal melanoma provides the only chance for cure. However, the choice of operation continues to be controversial because the prognosis is so poor. Up to 35% of patients present with metastatic disease,<sup>149,150</sup> and those patients with tumors >10 mm in thickness are not cured by any treatment.<sup>150</sup> Additionally, long-term survival rates,

which range from 0% to 29%,<sup>145,148–152</sup> do not seem to differ when wide local excision or APR is performed. However, some studies have shown fewer locoregional recurrences with a more radical operation,<sup>148,149,153</sup> thereby supporting the use of APR for earlier-stage tumors. In a recent study of anorectal melanomas stratified by tumor thickness, tumors >4 mm had inadequate local tumor control with wide local excision alone and APR was advocated.<sup>150</sup> Despite this, anorectal melanoma is largely a fatal disease and so the choice of treatment has little influence on the eventual outcome. Therefore, many authors advocate local excision to spare patients the morbidity of an APR and a colostomy. If the tumor is bulky and negative margins (1–2 cm) cannot be achieved, it involves the sphincter complex, or local resection will result in incontinence, then an APR is the recommended treatment option. If the patient already has signs of regional or systemic metastasis, radical excision should not be performed. The use of endoanal ultrasound and sentinel lymph node biopsies may further guide treatment for this disease.<sup>145,151</sup>

Adjuvant therapy for cutaneous melanoma has been studied extensively; however, the applicability of these data to anorectal melanoma remains uncertain. Many immunotherapeutic and chemotherapeutic agents such as dacarbazine, bacillus Calmette-Guerin, levamisole, and interferon- $\alpha$  have demonstrated no benefit.<sup>151</sup> Cytotoxic chemotherapy including cisplatin, vinblastine, and dacarbazine, combined with interleukin-2 or interferon- $\alpha$ 2b has shown some improvement in survival; however, patients experienced significant treatment-related toxicity.<sup>154</sup> Radiation therapy has also been used to improve local and regional control, yet because of the small numbers of patients with anorectal melanoma, its efficacy is unknown. Because of its predilection for developing systemic metastasis, it is unclear whether efforts to achieve better local control are useful.

## Gastrointestinal Stromal Tumors

Gastrointestinal stromal tumors (GISTs) of the anus are extremely uncommon with only 17 cases reported in the literature up to 2003.<sup>155</sup> GISTs are tumors of mesenchymal origin that are not derived from smooth muscle or Schwann cells. They are identified by immunohistochemical studies that stain positive for CD34 and CD117 antigens. It is important to differentiate them from true smooth muscle tumors, with which they were previously combined, as they have a different pathogenesis and biologic outcome. However, most series that have reported on leiomyomas and leiomyosarcomas in the past did not make this distinction, but in fact, reflect a large proportion of GISTs.<sup>155,156</sup> Because of the rarity of anal GISTs, they have only been studied with lesions of the rectum as a single entity.

Patients present in the fifth to seventh decade of life and are more often men. Most patients are asymptomatic but bleeding, anal pain, change in bowel habits, or urinary symptoms can occur. Pathologic factors implicated in aggressive tumors

with metastatic potential are size >5 cm in diameter and high mitotic counts, pleomorphism, infiltration of muscularis propria, and coagulative necrosis. The presence of symptoms is also associated with a worse prognosis.

Treatment involves local excision for tumors <2 cm and APR for those with larger tumors or worse pathologic features.<sup>155</sup> In a study of anorectal stromal tumors, recurrence rates for local excision and radical resection were 60% and 0%, respectively.<sup>157</sup> The natural history of GISTs is indolent with a long latency period (>4 years) to recurrence or metastasis, which is usually by a hematogenous route.<sup>156</sup> The role of adjuvant therapy is still uncertain.

### Small Cell Carcinoma/Neuroendocrine Tumors

Small cell or neuroendocrine tumors comprise less than 1% of all colorectal malignancies and are extremely rare in the anal canal. In a recent series of neuroendocrine carcinomas of the lower gastrointestinal tract, 16% were found in the anal canal.<sup>158</sup> Diagnosis involves identification of the classic histopathologic pattern. Hyperchromatic nuclei, pale nucleoli, high mitotic count, in addition to tumor growth in loose, non-cohesive sheets are seen, similar to small cell or oat cell carcinoma of the lung. Sixty-five to eighty percent of patients with extrapulmonary small cell tumors present with metastatic disease; therefore, it is important to stage them accurately. Those with disease limited to the anal canal are treated in a similar manner to those with adenocarcinoma, including chemoradiation and radical surgery. Those with disseminated disease may benefit from combination chemotherapy regimens used for small cell lung cancer such as cisplatin and etoposide.<sup>146,158</sup>

## Uncommon Anal Margin/Perianal Neoplasms

### Basal Cell Carcinoma

The incidence of basal cell carcinomas (BCCs) of the anus, in comparison to sun-exposed areas of the body, is extremely low. It comprises about 0.1% of all BCCs diagnosed and fewer than 200 cases of BCC have been reported on the perianal and genital area.<sup>159</sup> BCCs of the anal margin account for only 0.2% of all anorectal cancers. The largest series of perianal BCCs thus far reported includes only 34 cases.<sup>160</sup>

The etiology of perianal BCC is likely different from BCC arising in sun-exposed skin. Although preexisting skin conditions such as basal cell nevus syndrome and xeroderma pigmentosum, immunodeficiency, and genetics may contribute to both types, radiation, chronic irritation or infection, history of trauma or burn have all been implicated in perianal lesions.<sup>159,161</sup> The majority of these carcinomas occur in men (60%–80%) and the average age at presentation is 65–75 years. Approximately one-third have a previous or concomitant history of BCC at other skin sites.<sup>159,160,162</sup>

The average size at presentation is <2 cm, although they can be as large as 10 cm and extend into the anal canal.<sup>160</sup> The clinical appearance can range from erythematous papules to nodules, plaques, and ulcers.<sup>159</sup> They tend to be mobile and superficial with little invasive or metastatic potential. Histologically they are similar to BCCs of other areas of the body and do not contain HPV.<sup>159</sup> It is extremely important to differentiate BCC from basaloid carcinoma histologically because these entities behave in a different manner.

It was previously thought that anorectal BCC was more aggressive than other cutaneous BCCs,<sup>162</sup> but it is likely that perianal BCC was not adequately differentiated from the more aggressive basaloid tumors thus suggesting a worse prognosis.

Treatment is wide local excision ensuring adequate margins which is possible in lesions <2 cm. Larger lesions may require excision with skin grafting or use of Mohs micrographic surgery to preserve uninvolved tissue. Recurrence rates for local excision range from 0% to 29%.<sup>160,162</sup> Cancer-specific survival in both series was 100% at 5 years. Recurrences can be treated with reexcision. Large lesions extending into the anal canal may be better treated with radiation or APR.

### Paget's Disease

Paget's disease can be divided into two groups, mammary and extramammary. The former was identified on the nipple of the female breast with an underlying carcinoma by Sir James Paget in 1847.<sup>163</sup> The latter was described specifically in the perianal area by Darier and Couillaud in 1893<sup>164</sup> and comprises about 20% of the extramammary type.<sup>146</sup> Other sites of Paget's disease include the axilla, scrotum, penis, vulva, groin, thigh, and buttock where apocrine glands are found.

It is currently believed that Paget's cells represent an intraepithelial adenocarcinoma with a prolonged preinvasive phase that eventually develops into an adenocarcinoma of the underlying apocrine gland given enough time. The origin of these cells is not completely understood. One theory suggests that a pluripotent basal cell is the progenitor of the Paget's cell with the adenocarcinoma arising in the epidermis and extending into the dermis. The other theory supports the origin of Paget's cells from the apocrine glands that spreads into the overlying epidermis. The latter hypothesis may be more likely given the fact that the lesions tend to occur in areas of high-density apocrine glands.<sup>73,146,165</sup>

This is a rare condition with fewer than 200 cases reported in the literature to date.<sup>166</sup> Patients present in the seventh decade of life with equal distribution among men and women. The most common presenting symptom is intractable itching followed by bleeding, palpable mass, inguinal lymphadenopathy, weight loss, anal discharge and constipation. The median duration of symptoms is 3 years.<sup>167,168</sup> The lesions themselves often have an erythematous, eczematous appearance with well-demarcated borders mimicking a rash.

They may look ulcerated or plaque-like with oozing or scaling. A third of cases involve the entire anus.<sup>169</sup> These lesions are often misdiagnosed because of their similarity to other conditions. The differential includes Bowen's disease, Crohn's disease, condyloma acuminatum, hidradenitis suppurativa, pruritus ani, and SCC. Biopsy is essential to confirm the diagnosis.

Histologically, Paget's cells have large, round, eccentric, hyperchromic nuclei with pale-staining, vacuolated cytoplasm. The cytoplasm stains positive with periodic acid-Schiff stain because of the abundance of mucin and also stains positive for mucicarmine, cytokeratin 7, and Alcian blue, which stain mucoproteins, and differentiates it from Bowen's disease. Both mammary and extramammary Paget's disease have similar histologic features but mammary Paget's consistently presents with an associated invasive carcinoma, whereas in perianal Paget's disease, less than half (30%–44%) present with invasive adenocarcinoma.<sup>165,169,170</sup> However, the incidence of associated visceral malignancies in perianal Paget's disease is increased with various series reporting rates of 30%–50%. The most common sites include the gastrointestinal tract, anus, skin, prostate, neck, and nasopharynx.<sup>165,169–171</sup> There may also be synchronous lesions in the axillary or anogenital area in patients diagnosed with perianal disease, therefore a careful survey of other sites for malignancy and secondary disease is necessary.<sup>146</sup>

The treatment for perianal Paget's disease depends on the presence of invasion and other associated anorectal malignancies. For noninvasive lesions, wide local excision is the procedure of choice. In addition to resecting the lesion with grossly negative margins, it is important to map the extent of involvement of the lesion microscopically. This can be performed either by taking random biopsies 1 cm from the edge of the lesion in all four quadrants, including the dentate line, anal verge, and perineum<sup>166,171</sup> or by using toluidine blue and acetic acid to stain the Paget's cells, thereby directing the site for biopsy.<sup>73</sup> The use of intraoperative frozen sections ensures that any disease that extends beyond the gross lesion will be excised to reduce the chance of recurrence. Positive margins requiring reexcision are not uncommon when this technique is not used. In a recently reported series of 27 patients, 9 had positive margins and 12 required further surgery. Of the five patients who had mapping with 1-cm biopsies, none developed recurrence.<sup>165</sup> Another study reported positive margins in 53% of patients.<sup>172</sup> Preoperative mapping can also be performed using dermatologic punch biopsies. If the defect is small, the skin may be closed primarily. For larger lesions that require circumferential excision of the perianal skin, split-thickness skin grafts or sliding and rotational flaps may be required. Recurrence rates range from 37% to 100%.<sup>165,170,173</sup> Most recurrences were treated with wide reexcision with excellent results. For those who developed invasion, more radical surgery or adjuvant therapy was used.

Patients who have an invasive component or an associated anorectal malignancy should be considered for radical

excision with APR. If positive inguinal lymph nodes are present, an inguinal lymphadenectomy should be added. Unfortunately, patients with invasive disease present with metastasis 25% of the time and all patients who die of this disease have an invasive component.<sup>73,165</sup> Too few cases of perianal Paget's disease exist to allow for a comparison of invasive and noninvasive groups. Disease-specific survival for all perianal Paget's disease at 5 years ranges from 54% to 70%<sup>165,169–171</sup> and at 10 years decreases to 39%–45%.<sup>165,169</sup>

The role of adjuvant chemoradiation therapy remains uncertain. It is currently used in some cases of invasive or aggressive recurrent disease. Concurrent anorectal malignancies may be another indication. Radiation has been associated with an increased rate of local complications when used for perianal Paget's disease<sup>172</sup> and is therefore reserved for patients who are not candidates for further surgical resection.<sup>165</sup>

### Verrucous Carcinoma

The term verrucous carcinoma was initially coined in 1948 to describe a low-grade carcinoma of the oral mucosa that resembled viral warts. It has now been expanded to include those lesions described as giant condyloma acuminatum or Buschke–Lowenstein tumors. The latter was first described by Abraham Buschke in 1896 with respect to two invasive condylomata of the penis. Buschke and Lowenstein then further delineated these lesions of the anus in 1925.<sup>174</sup> These tumors were characterized by condylomatous features with growth to a large size, local invasion, and destruction of surrounding tissues and the absence of metastases. Although it is a well recognized entity, only 51 cases have been reported in the literature to date.<sup>175</sup> HPV is frequently detected.

These tumors are more frequently found in men with a 2.7:1 male to female ratio. The average age of patients is 45 years and is slowly decreasing. Patients usually present with complaint of an anal growth. Pain, perianal discharge/abscess, anorectal bleeding, pruritus, and a change in bowel habits may also occur.<sup>175,176</sup> The lesions themselves are generally slow growing with a soft, cauliflower-like appearance that can become nodular as it penetrates the underlying tissues. This direct expansion of the tumor causes erosion and even necrosis of the surrounding tissues thereby predisposing it to developing fistulas that drain purulent fluid. They usually arise from the perianal skin but can also present in the anal canal and distal rectum. At presentation they tend to be quite large measuring anywhere from 1.5 to 30 cm.<sup>175</sup> Regional lymphadenopathy may also occur secondary to infection.

The tumor, which is clinically difficult to distinguish from a malignancy, is histologically benign. Papillomatosis, acanthosis with hyperplasia of the prickle cell layer, variable hyperkeratosis, parakeratosis, and underlying inflammation are often found.<sup>174</sup> However, of all the cases of giant condyloma acuminatum reported, only 42% were histologically diagnosed as condyloma without any invasion. A malignant transformation was identified in 58% of the tumors; 8% had

carcinoma in situ, and 50% had invasion that was termed verrucous carcinoma, SCC, or basaloid carcinoma.

The standard treatment for verrucous carcinoma is radical local excision. For those patients with extensive deep tissue involvement, multiple fistulas, or involvement of the anal sphincter, APR is indicated. Cure can be achieved only by radical excision. Neoadjuvant radiation therapy may be useful for those tumors with invasive carcinoma and to render a tumor resectable because of its large size; however, some controversy exists as to whether radiation promotes malignant transformation of the tumors. The most current studies do not support this concept, because the incidence of invasive lesions after radiation is extremely low.<sup>176</sup> It has been hypothesized that the high recurrence rates after radical excision may be attributable to spillage of residual tumor, which could potentially be prevented by reducing the tumor size with preoperative chemoradiation. Certainly, size and local extent of tumor invasion, not malignant histology, has the greatest impact on morbidity, recurrence, and mortality. Unfortunately, the rarity of this condition makes it difficult to study this issue prospectively.

## HIV-related Anal Cancer

### Kaposi's Sarcoma

Although Kaposi's sarcoma is the most common cutaneous malignancy in patients with AIDS,<sup>177</sup> the incidence of perianal lesions is quite small and decreasing with the increasingly effective antiretroviral therapy available today.<sup>178</sup> A study of 180 consecutive HIV-seropositive patients seen for anorectal symptoms revealed two perianal Kaposi's sarcomas. They were both small, round, purplish lesions that could easily have been mistaken for hemorrhoids. Both were treated with chemotherapy although radiation has been used for localized cutaneous lesions.<sup>179</sup>

### Lymphoma

The incidence of non-Hodgkin's lymphoma (NHL) has been increasing in AIDS patients as treatment improves and life expectancy increases. NHL is the second most common AIDS-related neoplasm after Kaposi's sarcoma. Compared with lymphomas found in the general population, these tumors are characterized by B cells of a higher histologic grade that originates from extranodal tissue. They are also more aggressive, prone to dissemination, and resistant to treatment. Most lymphomas are found in the central nervous system and the gastrointestinal tract. However, anorectal lymphomas are extremely rare, comprising less than 1% of all anorectal neoplasms in the general population.<sup>180</sup> Although the anorectal area is devoid of lymphoid tissue, it is postulated that the exposure to chronic infections from anal receptive intercourse or an immunocompromised state may result in an "acquired" mucosa-associated lymphoid tissue.

The most common presenting symptoms are pain, pruritus, drainage, or a palpable mass. Some patients may have more constitutional symptoms such as fever, night sweats, or weight loss.<sup>180</sup> After appropriate staging, patients are treated with a standard regimen for NHL of chemotherapy and radiation therapy of the affected area.

There is no role for surgical treatment. Usual chemotherapeutic agents include cyclophosphamide, actinomycin, vincristine, and corticosteroids (CHOP). There are too few cases of anorectal lymphoma reported to discuss overall prognosis. However, younger patients without constitutional symptoms may fare better. Additionally, low CD4 counts and performance status may affect a patient's ability to endure aggressive therapy.<sup>146</sup> Isolated reports of immunocompetent patients with anorectal lymphoma have been reported with excellent response to treatment.<sup>181</sup>

## Presacral Tumors

Eric J. Dozois, David J. Jacofsky, and Roger R. Dozois

The presacral or retrorectal space may be the site of a group of heterogeneous, and rare tumors that are often indolent and produce ill-defined symptoms. Because detection is often difficult and delayed, patients frequently present with tumors that have reached considerable size and involve multiple organ systems, complicating their treatment. The diagnosis and management of these tumors has evolved in recent years because of improved imaging modalities, a better understanding of tumor biology, adjuvant chemoradiation therapy, and a more aggressive surgical approach. Few surgeons have the opportunity to treat these complex lesions, and the care of these patients can be greatly optimized by an experienced, multidisciplinary team.

### Anatomy and Neurophysiology

A thorough understanding of pelvic anatomy including soft tissue, neurologic, and osseous structures is essential in the evaluation and management of presacral tumors. The boundaries of the retrorectal region include the posterior wall of the rectum anteriorly and the sacrum posteriorly (Figure 36-1). This space extends superiorly to the peritoneal reflection and inferiorly to the rectosacral fascia and the supralelevator space. Laterally, the area is bordered by the ureters, the iliac vessels, and the sacral nerve roots (Figure 36-2A). Several important vascular and neural structures are located in this area and injury to them may have important physiologic rectoanal sequelae, as well as neurologic and musculoskeletal consequences. If all sacral roots on one side of the sacrum are sacrificed, the patient will continue to have normal anorectal function. Likewise, if the upper three sacral nerve roots are left intact on either side of the sacrum, the patient's ability to defecate spontaneously and to control anorectal contents will remain essentially intact. If, however, both S-3 nerve roots are sacrificed, the external anal sphincter will no longer contract in response to gradual balloon dilation of the rectum and this will translate clinically into variable degrees of anorectal incontinence and difficult defecation.<sup>1</sup> If sacrectomy is to be

performed, the surgeon must be familiar with the relationship between the thecal sac, sacral nerve roots, sciatic nerve, piriformis muscle, and sacrotuberous and sacrospinous ligaments (Figure 36-2B). From a structural standpoint, the majority of the sacrum can be resected. If more than half of the S-1 vertebral body remains intact, pelvic stability will be maintained. However, preoperative radiation to the sacrum may ultimately lead to stress fractures if only S-1 remains. As such, spinopelvic stability may be augmented with fusion in select patients. Knowledge of anatomy of the thigh and lower extremity is required in complex cases requiring muscle or soft tissue flaps. It is important to discuss with patients preoperatively the potential neuromuscular and visceral losses that may occur during the operation and how this will influence their function and quality of life.

### Classification

#### General Considerations

Presacral lesions are rare. Reports from various large referral centers would indicate that their incidence may be as low as 1 in 40,000 hospital admissions (0.014%).<sup>2</sup> Spencer and Jackman<sup>3</sup> found precoccygeal cysts in only 3 of 20,851 proctologic examinations. Jao et al.<sup>4</sup> reported 120 patients over a 19-year period. Lesions found in the presacral space can be broadly classified as congenital or acquired, benign or malignant. Two-thirds of lesions are congenital and of these, two-thirds are benign and one-third are neoplastic. The presacral space has a complex embryologic development, and this potential space is composed primarily of connective tissue, nerves, fat, and blood vessels. Because this area contains totipotential cells that differentiate into three germ cell layers, a multitude of tumor types may be encountered. The classification first described by Uhlig and Johnson<sup>5</sup> has been used for many years by several authors and divides tumors into the broad categories: congenital, neurogenic, osseous, and miscellaneous. We have modified and updated this system to

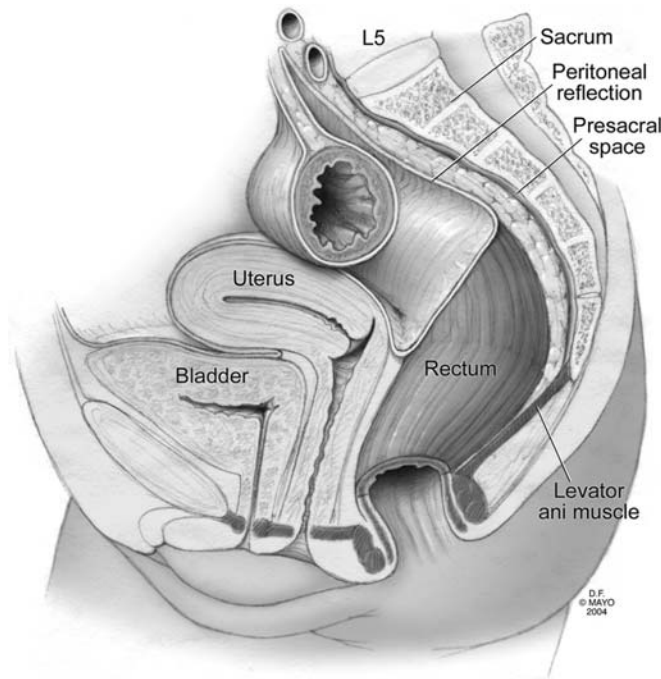

FIGURE 36-1. Relationship of pelvic structures to presacral space.

subcategorize tumors into malignant and benign entities, because this greatly impacts therapeutic approaches (Table 1).

### Gross and Histologic Appearance

*Epidermoid cysts* result from closure defects of the ectodermal tube. They are histologically composed of stratified squamous cells, do not contain skin appendages, and are typically benign.

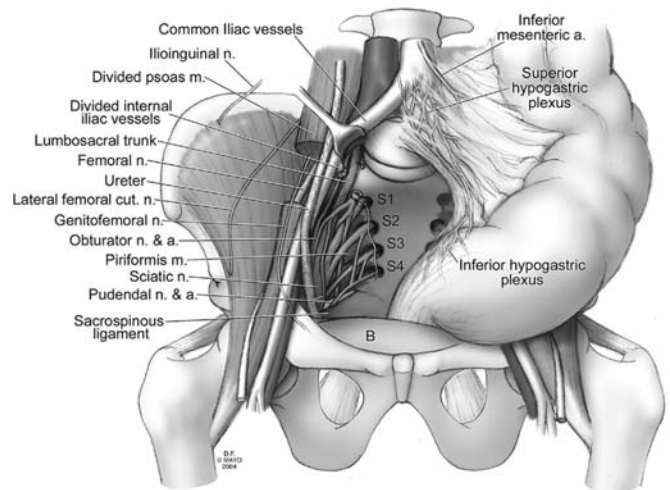

*Dermoid cysts* also arise from the ectoderm, but histologically they contain stratified squamous cells and skin appendages. These are also generally benign. Epidermoid and dermoid cysts tend to be well circumscribed and round and have a thin outer layer. Occasionally they communicate with the skin surface producing a characteristic postanal dimple. They are most common in females and the infection rate may be high because they are often misdiagnosed as a perirectal abscess and manipulated operatively.

*Enterogenous cysts* are lesions thought to originate from sequestration of the developing hindgut. Because they originate from endodermal tissue, they can be lined with squamous, cuboidal, or columnar epithelium. Transitional epithelium may also be found. These lesions tend to be multilobular with one dominant lesion and smaller satellite cysts. Similar to dermoid and epidermoid cysts, they can become infected and are more common in women. These are generally benign, but case reports have described malignant transformation within rectal duplications.<sup>6</sup>

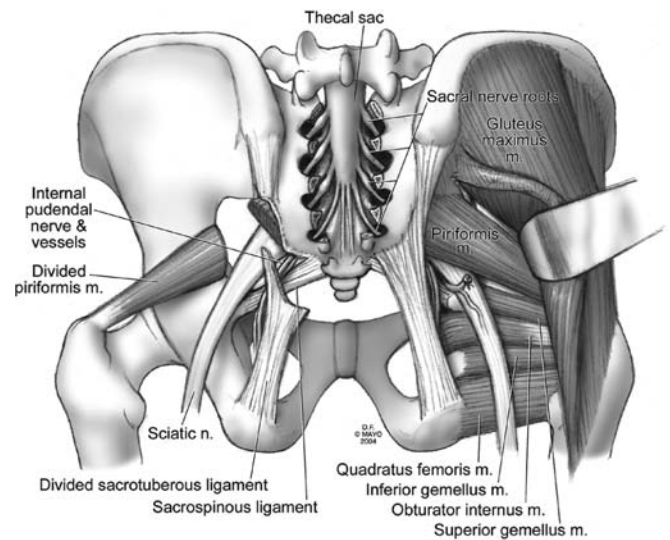

*Tailgut cysts*, which are sometimes referred to as cystic hamartomas, are also multilobular cysts. These cysts are composed of squamous, columnar, or transitional epithelium that

may have a morphologic appearance similar to that of the adult or fetal intestinal tract. The presence of glandular or transitional epithelium will differentiate this lesion from an epidermoid or dermoid cyst. Malignant transformation is rare.<sup>7</sup>

*Teratomas* are true neoplasms derived from totipotential cells and include all three germ layers. They may undergo malignant transformation to squamous cell carcinoma arising from the ectodermal tissue, or rhabdomyosarcoma arising from the mesenchymal cells. Anaplastic tumors are also seen in which the tissue of origin may not be distinguishable. Histologically, these tumors are referred to as either “mature” or “immature” reflecting the degree of cellular differentiation. Teratomas are more common in females and in the pediatric age group, and are often associated with other anomalies of the vertebrae, urinary tract, or anorectum.<sup>8</sup> In adults, malignant degeneration can occur in 40%–50%.<sup>9</sup> Incomplete

or intralesional resection increases the likelihood of malignant degeneration.<sup>10</sup> These also can become infected and be misdiagnosed as a perirectal abscess or fistula. Diagnosis is often delayed and these tumors may reach considerable size.

*Sacroccygeal chordoma* is the most common malignancy in the presacral space. These tumors are believed to originate from the primitive notochord which embryologically extends from the base of the occiput to the caudal limit in the embryo. They can occur anywhere along the spinal column, but have a predilection for the pheno-occipital region at the base of the

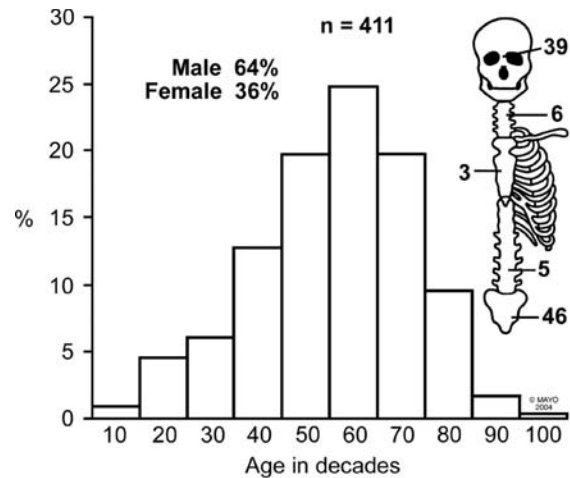

FIGURE 36-3. Distribution of chordomas. (Mayo Clinic orthopedic database.)

skull and for the sacroccygeal region in the pelvis. More than half occur in the sacrum (Figure 36-3). They predominate in men and are rarely encountered in patients younger than 30 years of age. These tumors may be soft, gelatinous, or firm and may invade, distend, or destroy bone and soft tissue. The center of these tumors contains extracellular mucin. Hemorrhage and necrosis within tumors may lead to secondary calcification and pseudocapsule formation. Common symptoms include pelvic, buttock, and lower back pain aggravated by sitting and alleviated by standing or walking. Diagnosis is often delayed and these tumors may reach a considerable size.

*Anterior sacral meningoceles* are a result of a defect in the thecal sac and may be seen in combination with presacral cysts or lipomas. Typical symptoms include constipation, low back pain, and headache that is exacerbated by straining or coughing. It may be associated with other congenital anomalies such as spina bifida, tethered spinal cord, uterine and vaginal duplication, or urinary tract or anal malformations. Surgical management consists of ligation of the dural defect.

*Neurogenic tumors* include neurilemmas, ganglioneuromas, ganglioneuroblastomas, neurofibromas, neuroblastomas, ependymomas, and malignant peripheral nerve sheath tumors (neurofibrosarcoma, malignant schwannomas, neurogenic sarcomas). The most common malignant neurogenic lesion in the Mayo series was neurilemoma, which is more common in males and may occur at any age.<sup>4</sup> Neurogenic tumors tend to grow slowly and may reach considerable size. Differentiating between benign and malignant pathology preoperatively can be difficult, but is of paramount importance to guide operative approach.

*Osseous tumors* include chondrosarcoma, osteosarcoma, myeloma, and Ewing's sarcoma. These tumors arise from bone, cartilage, fibrous tissue, and marrow. Because of relatively rapid growth, these often reach considerable size. The lungs are a common sight of metastasis. All osseous tumors of the presacral space are associated with sacral destruction. Although

benign, giant cell tumors are locally destructive and can metastasize to the lungs (“benign metastasizing giant cell tumor”).

*Miscellaneous lesions* in this region include metastatic deposits, inflammatory lesions related to Crohn’s disease or diverticulitis, hematomas, and anomalous pelvic ectopic kidneys.

Overall, most presacral tumors occur in females and are cystic. Most solid tumors are chordomas and more often seen in males. Benign lesions are frequently asymptomatic and discovered incidentally during routine gynecologic examinations which may explain the greater incidence in females. By contrast, malignant tumors are more often symptomatic, but still frequently found late because of their vague symptomatology.

## Diagnosis and Management

### History and Physical Examination

Because of their indolent course, presacral tumors are often found incidentally at the time of periodic pelvic or rectal examination. Symptomatic patients typically complain of vague, longstanding pain in the perineum or low back. Pain may be aggravated by sitting and improved by standing or walking. In the Mayo Clinic series, pain was more common when the tumor was malignant as compared with benign (88% versus 39%).<sup>4</sup> Occasionally, patients complain of longstanding perineal discharge and their symptoms may be confused with anal fistula or pilonidal disease.<sup>11</sup> Several clues may alert the clinician to the presence of a retrorectal cystic lesion, including repeated operations for anal fistula, the inability of the examiner to uncover the primary source of infection at the level of the dentate line, a postanal dimple, or fullness and fixation of the precoccygeal area. All patients in the Mayo series with osseous tumors complained of low back pain, perineal pain, or both.<sup>4</sup> Some patients may give a history of referral to a psychiatrist because of a clinician’s inability to ascertain the origin of the patient’s chronic, ill-defined pain. Patients with larger tumors may complain of constipation and/or rectal and urinary incontinence, and sexual dysfunction because of the sacral nerve root involvement. Patients should be examined carefully, focusing on the perineum, rectal examination, and assessing for a postanal dimple. In the Mayo series, 97% of presacral tumors could be palpated on rectal examination.<sup>4</sup> Digital rectal examination will typically reveal the presence of an extrarectal mass displacing the rectum anteriorly with a smooth and intact overlying mucosa. Rectal examination is also critical in assessing the level of the uppermost portion of the lesion, degree and extent of fixation, and relationship to other pelvic organs such as the prostate. Rigid or flexible sigmoidoscopy can be used to assess the overlying mucosa and rule out transmural penetration of the tumor. A careful neurologic examination focusing on the sacral nerves and musculoskeletal reflexes is mandatory, and may also aid in the diagnosis of extensive local tumor invasion.

### Diagnostic Tests

The presence of a presacral tumor can be confirmed with plain radiographs of the sacrum, or with more sophisticated imaging modalities such as computerized tomography (CT), magnetic resonance imaging (MRI), and endorectal ultrasound (ERUS). Simple anterior–posterior and lateral radiographs of the sacrum identify osseous expansion, destruction, and/or calcification of soft tissue masses, but are typically not helpful in rendering a specific diagnosis. A chordoma is the most common tumor causing these findings, but sarcomas or benign, locally aggressive tumors, such as giant cell tumor, neurilemoma, and aneurysmal bone cysts, may also cause extensive bony destruction. The characteristic “scimitar sign” denotes the presence of an anterior sacral meningocele, a diagnosis that can be confirmed with conventional myelography or MRI with gadolinium.<sup>12</sup>

In recent years, state of the art imaging such as CT, MRI, and positron emission tomography (PET) scan has dramatically changed the way in which these tumors should be evaluated. CT and MRI complement each other and are the most important radiographic studies in evaluating a patient with a presacral lesion. CT can determine whether a lesion is solid or cystic and whether adjacent structures such as the bladder, ureters, and rectum are involved (Figure 36-4A–C). CT is also the best study to evaluate cortical bone destruction. MRI is highly recommended because of its multiplanar capacity and improved soft tissue resolution that will be essential for planning specific lines of resection (Figure 36-5A,B). Sagittal views will assist in decision making in regard to need for and level of sacrectomy (Figure 36-5C). MRI is also more sensitive than CT in spinal imaging, showing associated cord anomalies such as a meningocele, nerve root, and foraminal encroachment by tumor, or thecal sac compression.<sup>13</sup> MRI is superior to CT in evaluating the extent of marrow involvement in bone. Angiogram and venogram can be added to the MRI (MR angiogram, venogram) to delineate vascular involvement and anatomy grossly distorted by tumor mass effect. This information is helpful to the vascular, plastic, and orthopedic surgeons for operative planning. Gadolinium-enhanced MRI imaging before, during, and/or after neoadjuvant therapy may also show the effectiveness of this treatment in terms of volume of tumor that appears vascularized and viable.

In patients with presacral cystic lesions thought to be the source of a chronically draining sinus, fistulogram may help clarify the diagnosis. ERUS has been used by some to characterize retrorectal tumors and their relationship to the muscularis propria of the rectum.<sup>14</sup>

### Preoperative Biopsy

Historically, the role of preoperative biopsy of presacral tumors has been a controversial topic in the general surgical literature. Its necessity and how it is performed varies from author to author. In the past, some authors have considered any

FIGURE 36-4. Massive cystic teratoma with sacral appendage **A**, CT image of teratoma, intrapelvic portion **B**, extrapelvic portion **C**, including fully developed phalanx.

presacral tumor deemed resectable a contraindication to preoperative biopsy,<sup>4,15-17</sup> with only a minority stating that all solid tumors should be sampled preoperatively by biopsy.<sup>18</sup> This, in part, may have to do with the fact that the literature on this topic is sparse and outdated, especially when one considers the availability of modern imaging, better knowledge of tumor biology, and new opportunities for neoadjuvant therapy. Indeed, some patients will substantially benefit from preoperative chemotherapy and radiation, especially in osseous tumors such as Ewing's sarcoma, osteogenic sarcoma, and

neurofibrosarcoma. Likewise, very large tumors such as pelvic desmoids can be more easily removed after reducing their size with radiation. We consider preoperative tissue diagnosis essential to the management of solid and heterogeneously cystic presacral tumors. For example, the surgical approach and necessary margins are dramatically different when faced with a neurofibroma as compared with a neurofibrosarcoma. When performed correctly, preoperative biopsy can only improve the overall management, not harm it. What is clear about preoperative biopsies of presacral tumors is that they should never be

FIGURE 36-5. MRI of pelvic neurofibroma displacing the rectum anterior and lateral. **A** T1 weighted coronal image. **B** T2 weighted coronal image. **C** Sagittal view with tumor exiting the third sacral foramen.

performed transrectally or transvaginally. In the presence of a cystic lesion, such an approach is likely to result in infection rendering its future complete excision more difficult and increasing the likelihood of postoperative complications and recurrence. More importantly, inadvertent transrectal needling of a meningocele may lead to disastrous sequelae such as meningitis and even subsequent death. Moreover, because the

biopsy tract needs to be removed en bloc with the specimen, transrectal biopsy would mandate proctectomy in a patient whose rectum may otherwise have been spared.

There is rarely an indication to biopsy a purely cystic presacral lesion. From a technical standpoint, a presacral tumor biopsy should be done by a radiologist with experience in the evaluation and management of pelvic tumors. In planning the

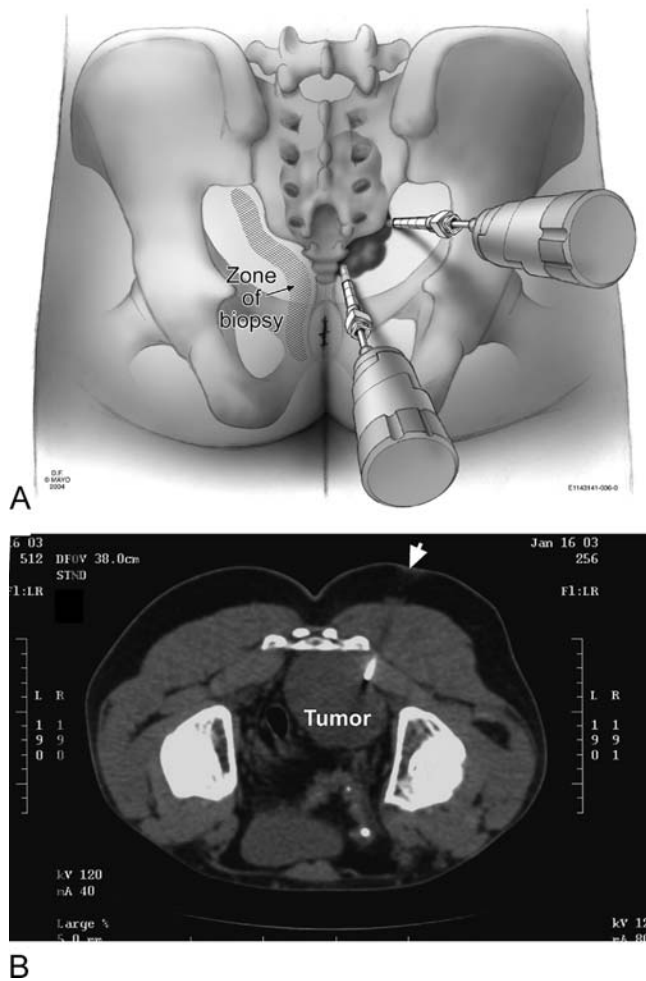

FIGURE 36-6. **A** Preoperative biopsy technique using CT guidance. **B** Parasacral approach to presacral neurogenic tumor.

approach for a biopsy, the surgeon should always consider the resection margins so that the needle tract can be removed en bloc with the specimen. The transperineal or parasacral approach is usually ideal and falls within the field of the pending surgical resection (Figure 36-6A,B). Transperitoneal, transretroperitoneal, transvaginal, and transrectal biopsy should be avoided. Biopsy tracts should never traverse neurovascular planes. Normal coagulation studies are required before biopsy, because hematoma formation and/or bleeding will potentially contaminate involved areas. PET-CT scan can be useful to guide biopsy needles into small focal areas of high tumor density.

### Role of Preoperative Neoadjuvant Therapy

Modern protocols and the wide availability of neoadjuvant tumor irradiation and systemic chemotherapy has revolutionized the management of patients with complex malignancies. It is in large part because of these new treatment modalities before surgery that a preoperative diagnosis is of paramount

importance. Although some tumors, such as chondrosarcoma and chordoma, are poorly responsive to both chemotherapy and irradiation, there are a number of tumors seen in the presacral space whose rate of local recurrence can be markedly decreased with the addition of irradiation. Preoperative, as opposed to postoperative, irradiation can be extremely helpful in the face of large pelvic tumors. One of the significant advantages of preoperative irradiation is that it allows treatment to a smaller radiation field. Postoperative irradiation for a pelvic tumor would require irradiation of the entire surgical bed, previous tumor site, all contaminated surgical planes, and the sites of all skin incisions. This increased radiation exposure is associated with increased morbidity. Furthermore, should “spillage” occur during resection of a radiosensitive tumor, this contamination may be with previously irradiated necrotic, nonviable cells. A third, and perhaps most important, advantage of preoperative irradiation in sensitive tumors, is the fact that decreased tumor size is often observed. A decrease in tumor size in a pelvic tumor may allow the surgeon to spare vital structures that would have had to be sacrificed in order for wide margins to be achieved without prior radiation. Additionally, a smaller tumor often means a surgery of a lesser magnitude and therefore less risk for intraoperative complications.

Large tumors in the presacral space, especially sarcomas, are notorious for systemic metastasis. Neoadjuvant chemotherapy is the cornerstone of treatment for diagnoses such as Ewing’s sarcoma and osteogenic sarcoma. A wide resection of a pelvic tumor of this type, which would cause a delay in systemic chemotherapy treatment, is not in the patient’s best interest. Micrometastatic disease must be treated in patients with diagnoses such as these preoperatively, unless the tumor has caused an immediate complication that requires emergent surgery. Furthermore, one could argue that lymphoma or Ewing’s sarcoma can be completely treated with chemoradiation, and that surgery may not be necessary at all.

As with extremity sarcomas, there are clearly some cases in which irradiation and chemotherapy are not required. Small, low-grade malignancies without metastatic disease that can be completely excised with a histologically negative wide margin may likely be observed without adjuvant treatment. This, however, implies that any subsequent recurrence would again be amenable to excision. If a recurrence would no longer be amenable to re-resection, then most oncologic surgeons would favor adjuvant treatment to minimize the risk of this recurrence. Most authorities advocate irradiation, either before or after resection, of nonextremity low-grade sarcomas with “marginal” or positive margins or for any patient with an intermediate or high-grade malignancy.

The efficacy of adjuvant chemotherapy for patients with nonextremity sarcomas has not been established firmly to date. One randomized trial examined the efficacy of adjuvant chemotherapy in patients with soft tissue sarcomas of the head and neck, breast and trunk, all of whom received postoperative radiotherapy.<sup>19</sup> Adjuvant chemotherapy consisted of

doxorubicin, cyclophosphamide, and methotrexate, a regimen that admittedly is no longer commonly used for sarcoma management. However, the three-year actuarial disease-free survival rate in the chemotherapy group was 72% compared with 60% in the group without chemotherapy. These differences showed a trend, but were not statistically significant. However, one must understand that as improvements in local therapy continue, fewer patients will succumb to local recurrence and more patients will succumb to distant disease. It is in this setting that neoadjuvant chemotherapy may be of most benefit.

## Surgical Treatment

### Rationale for Aggressive Approach

The rationale for an aggressive surgical approach for presacral tumors is based on several arguments. The lesion may already be malignant or transform into a malignant state if left in place. In patients with teratomas, especially those in the pediatric age group, the risk of malignant transformation is considerable and continues to increase dramatically if removal is delayed or incomplete.<sup>9</sup> Untreated anterior sacral meningoceles may become infected and lead to meningitis, which is associated with high mortality.<sup>20</sup> Cystic lesions may become infected making their excision difficult and increasing the possibility of postoperative infection and future recurrence. A presacral mass in a young woman may cause dystocia at the time of delivery. Lastly, benign and malignant tumors left untreated may grow to considerable size, making surgical resection much more complicated.

Unfortunately, in the past, many surgeons have adopted a rather defeatist attitude toward sacrococcygeal chordomas and other tumors in this area based on a number of erroneous misconceptions. Chordomas are slow-growing tumors producing vague symptoms which leads to a delay in diagnosis for months or even years. Thus, patients may seek medical treatment late in the course of their disease and the presence of a large mass in this often unfamiliar and complex anatomic area makes some surgeons reluctant to consider aggressive surgical approach for fear of serious operative and postoperative complications. This same reluctance to operate may apply to other types of lesions as well. Moreover, chordomas have all too often been considered to have a benign clinical behavior characterized by slow local growth. We now know that these tumors will metastasize and that the longer the diagnosis is delayed, the greater risk of distant spread. Finally, and most importantly, tumors in this area have been treated inadequately in the past because of tumor violation, their large size and location, and fear of neurologic complication and/or musculoskeletal instability. Tumor violation can take place preoperatively when such tumors are biopsied transrectally, or intraoperatively when margins of resection are inadequate or tumor cells are spilled in an effort to be too conservative. When a surgeon is attempting to avoid injury to

the rectal wall or important neurologic structures, they may inappropriately restrict excision and compromise oncologic outcome. For malignant lesions, wide margins and oncologic cure should be the primary goal of these procedures.

### Role of Multidisciplinary Team

It is of great importance that an experienced team consisting of a colorectal surgeon, orthopedic oncologic surgeon, spine surgeon, urologist, plastic surgeon, vascular surgeon, musculoskeletal radiologist, medical oncologist, radiation oncologist, and specialized anesthesiologist evaluate and surgically treat tumors that are large and extend to or destroy the hemipelvis or the upper half of the sacrum. The importance of a multispecialty approach for presacral tumors was first described in 1953 by a Mayo Clinic team of surgeons. They found an improvement in outcome in this difficult to manage group of patients with the combined effort of multiple specialists.<sup>21</sup> This quote from their publication describes their convictions:

The surgical management of presacral and sacral tumors has been in general unsatisfactory. We feel that progress in treating these lesions may have been impeded rather than enhanced by the individual surgical specialists who came into contact with these lesions. Consequently, we have united our efforts in solving the problem and thereby utilizing the special assets of the three surgical specialties—neurologic, orthopedic and general surgery—in meeting this problem.

### Surgical Approach

Careful surgical planning is important in deciding how to approach these tumors whether it be an anterior approach (abdominal), posterior approach (perineal), or a combined abdominoperineal approach. CT and MRI will help define the margins of resection and the relationship of the tumor to the sacral level (Figure 36-7). Small and low-lying lesions can be removed transperineally through a parasacral incision, whereas tumors extending above the S-3 level, especially if large, often require a combined anterior and posterior approach.

For large, malignant lesions requiring extended resection, a plastic surgeon has a significant role, because adequate soft tissue coverage can often be difficult. Most often, we use the transabdominal rectus abdominus myocutaneous (TRAM) flap, which fills dead space and can cover large cutaneous defects left by the resection. Healthy, well-vascularized tissue flaps, placed in the surgical bed, markedly decrease the incidence of wound-related complications.

### Preoperative Considerations

Optimizing patients for surgery is of extreme importance in a majority of these cases. Adequate nutritional repletion with total parenteral nutrition or with a feeding tube, may be necessary in patients who present severely debilitated. In technically complex cases, when we expect a long operative time and significant debilitation postoperatively, we consider

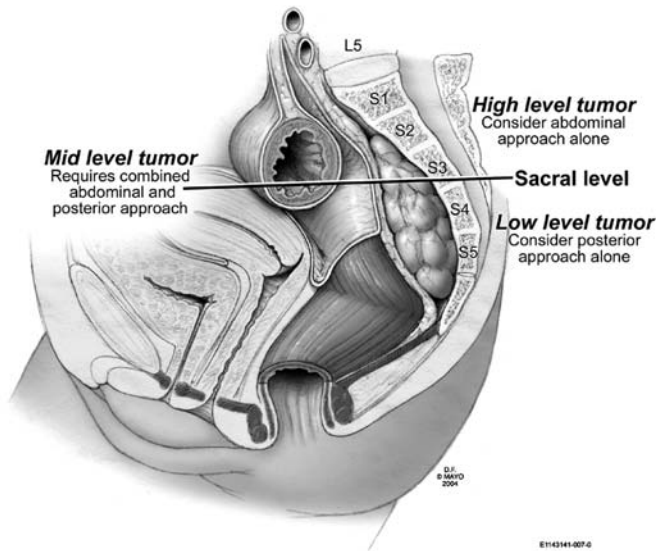

FIGURE 36-7. Relationship of tumor to sacral level and proposed approach.

placement of a temporary intravenacaval filter, because the risk of deep venous thrombosis and pulmonary embolus is high and postoperative anticoagulation may be contraindicated. Availability of blood products should be assessed. A multidisciplinary team meeting preoperatively, to review films and plan surgical strategy, avoids confusion during the day of surgery. An operating theater capable of managing massive transfusion requirements is mandatory, as is an anesthesiologist comfortable with the physiologic management needed during the procedure.

### Posterior Approach

For low-lying tumors, the patient is placed in the prone jackknife position with the buttocks spread with tape (Figure 36-8A). An incision is made over the lower portion of the sacrum and coccyx down to the anus taking care to avoid damage to the external sphincter. Resection of the tumor may be facilitated by transection of the anococcygeal ligament and coccyx (Figure 36-8B). The lesion can then be dissected from the surrounding tissues including the rectal wall, in a plane between the retrorectal fat and the tumor mass itself. In the case of very small lesions, the surgeon may double-glove the left hand and, with the index finger in the anal canal and lower rectum, push the lesion outward, away from the depths of the wound (Figure 36-8C) facilitating dissection of the lesion off the wall of the rectum without injury. If necessary, the lower sacrum or coccyx or both can be excised en bloc with the lesion to facilitate excision.

### Combined Abdominal and Perineal Approach

If the upper pole of the tumor extends clearly above the S-3 level, an anterior and posterior approach is usually indicated. Patients may be placed in the supine or lateral

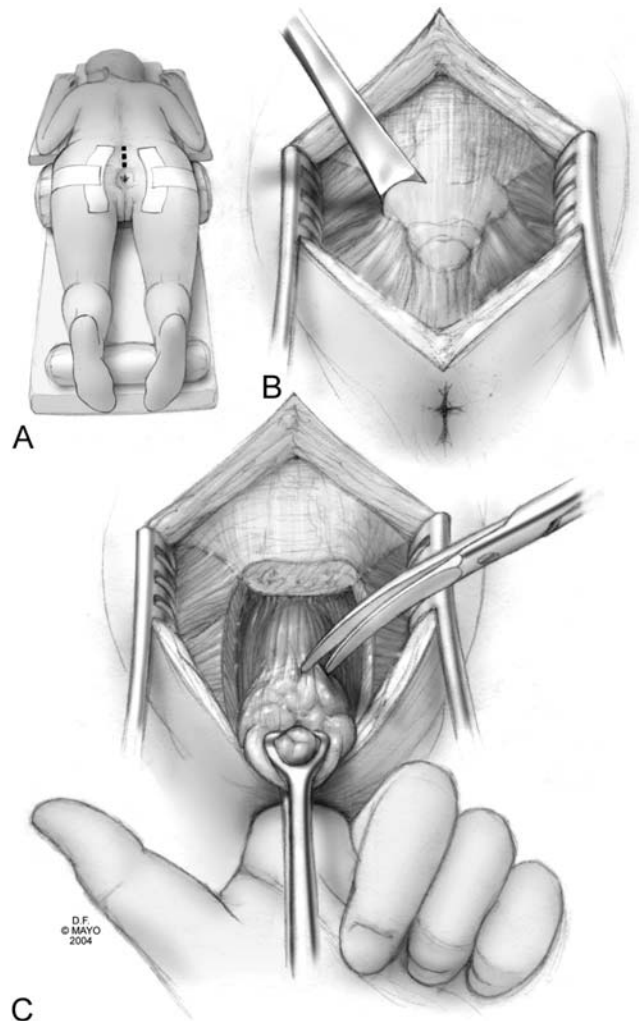

FIGURE 36-8. **A** Positioning for posterior approach. **B** Coccygectomy. **C** Index finger in anal canal to “push” tumor outward facilitating dissection.

position, depending on the surgeon’s preference and previous experience. A variety of techniques and positioning to the abdominal perineal approach have been described.<sup>22</sup> If an anterior–posterior approach is necessary, the patient can be placed in a “sloppy-lateral” position to facilitate a simultaneous two-team approach (Figure 36-9A–C). We always recommend cystoscopy and bilateral ureteral stent placement before laparotomy. Through a midline incision, the abdomen should be carefully examined to rule out metastasis or other important pathology. After the lateral attachments to the sigmoid have been mobilized and the presacral space is entered just below the promontory, the posterior rectum can be dissected from the upper sacrum down to the upper extension of the tumor. The ureters are identified and protected. The rectum can then be mobilized laterally, and if necessary, anteriorly.

If a malignant tumor can be safely separated from the posterior wall of the rectum without compromising a wide

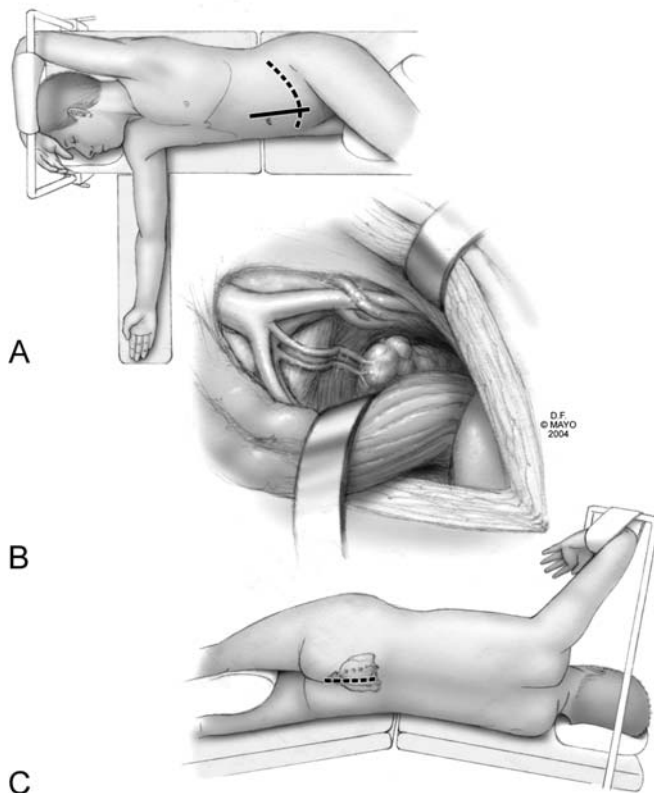

FIGURE 36-9. **A** Modified lateral position for anterior exposure via a midline (solid line) or ilioinguinal (dotted line) incision. **B** Anterior exposure of vessels and tumor. **C** Posterior approach to sacrum.

margin, the lesion can be dissected in a plane between its capsule and the mesorectal fat to preserve the rectum. If the tumor is extremely large, markedly compressing and displacing the rectum, making dissection between the rectal vault and the tumor hazardous, one should remove the rectum en bloc with the tumor and the involved segments of the sacrum. It is mandatory in malignant cases that no structures attached to the specimen be separated with dissection and that they be removed en bloc with the primary tumor mass. In this situation, the upper rectum is transected with a stapler at the level of the promontory. Under these circumstances, it is imperative that the anterior wall of the rectum be completely freed from the seminal vesicles and prostate in men and the upper two-thirds of the vagina in women. The pelvic floor can then be reconstructed over the anal remnant and the sigmoid colostomy established in the left lower abdominal wall.

In the presence of very large tumors, blood loss during the procedure can be substantial. This may be minimized by ligating the middle and lateral sacral vessels and both internal iliac arteries and veins (Figure 36-10). When ligating the internal iliac artery, it is best to preserve the anterior division, which gives off the inferior gluteal artery, thereby reducing the risk of perineal necrosis. This is often performed in conjunction with permissive hypotension. A vascular surgeon

FIGURE 36-10. Ligation of middle sacral and internal iliac vessel.

can be helpful during this portion of the procedure especially in patients who have had prior irradiation or have distorted vascular anatomy. In a situation in which a large tissue defect is expected, one may elect to mobilize one rectus muscle (preferably the right if possible), on its vascular pedicle and place it in the presacral area for later use in the closure of the perineal wound when the patient is prone. In the anterior-posterior approach, when a flap will be used, a thick piece of silastic mesh is placed posterior to the vital structures and anterior to the bony structures to protect vital structures from injury during bony resection while in the prone or lateral position. After the abdominal incision is closed and the colostomy is matured, the anesthetized patient can then be moved from the supine to the prone position. The perineal approach is similar to that used for benign low-lying cystic or solid tumors, except that wider and more proximal dissection will be necessary. After an incision has been made over the sacrum and coccyx down to the anus, the anococcygeal ligament is transected and the levator muscles are retracted laterally. If the rectum is to be preserved, the tumor can be separated from the rectum by careful dissection of the plane between the rectum and the tumor. The orthopedic surgeon can then proceed with separation of gluteus maximus muscles on both sides, detachment of the sacrospinous and sacrotuberous ligaments, and division of the piriformis muscles bilaterally to protect the sciatic nerves (Figure 36-11A). A posterior laminectomy may be required to expose and ligate nerve roots to be sacrificed and/or the thecal sac (Figure 36-11B,C). In this manner the lesion can be removed en bloc with the lower sacrum and coccyx and involved sacral roots. If the surgeon previously

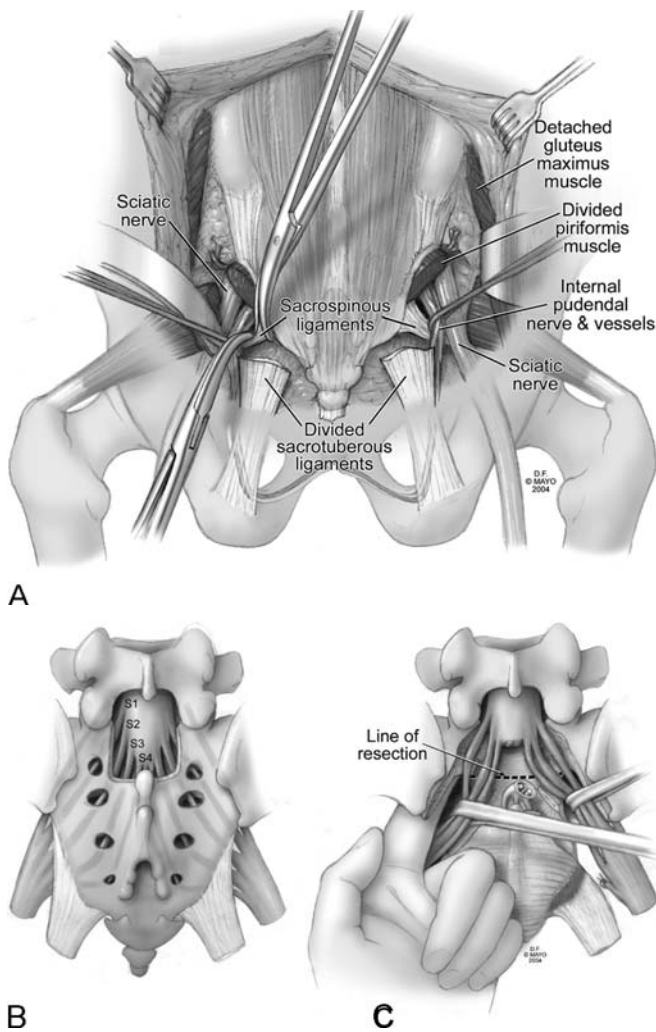

FIGURE 36-11. Posterior approach and exposure of sciatic nerves **A**, sacral nerve roots **B**, and ligation of thecal sac **C**.

ected to excise the rectum en bloc, it is preferable to remove the anus and anal canal with the rectal specimen. The wound is then closed in layers over suction silastic drain, or a TRAM flap is inserted and sewn into place by the plastic surgeon. More complex soft tissue procedures may be required if the tumor involves the posterior soft tissue elements.

## Results of Treatment

### Malignant Lesions

The results of surgical treatment of malignant presacral neoplasms and cysts depends on the natural behavior of the lesion and the adequacy of resection. In malignant cases, if wide margins are not achieved or if the tumor is violated, one can expect a high local recurrence rate and a poor overall outcome. In general, most malignant tumors reported in the

literature have had a rather poor prognosis, but many such tumors had been incompletely resected or excised piecemeal, breaking oncologic principles. Kaiser et al.<sup>23</sup> found that local recurrence rate increased from 28% to 64% if the tumor was violated perioperatively.

In the literature, the prognosis for patients with chordomas has been variable, ranging from 15% to 76% at 10 years after surgical therapy. At the Mayo Clinic, the 5-year survival rate in 1976 was reported to be 75%; more recently we have found 5- and 10-year survivals of 80% and 50%, respectively [Chiu et al. An update of the Mayo Clinic experience 1980–1992 (unpublished data)].<sup>4</sup> Of 16 patients with chordomas that were completely resected, nine had no clinical or radiologic evidence of recurrence 4–14 years later. Isolated metastases to the lungs, ribs, spine, and long bones can sometimes be excised successfully and provide patients with symptomatic relief and a substantial prolongation of life. The 5-year survival for patients with malignant tumors other than chordomas was 17%. Only one patient with a neuroblastoma, one with a neurofibrosarcoma, and one with Ewing's sarcoma were alive without recurrence at 3, 5, and 7 years, respectively. However, these results likely were related to the lack of, or poor quality of, the adjuvant therapies available.

Cody et al.<sup>24</sup> reported their experience with malignant presacral tumors, 9 (38%) of which had chordomas. Excision of these tumors was described as “en bloc” or “in fragments.” Forty-eight percent developed local recurrence; 60% of patients underwent open biopsy. For all treated patients, survival at 5, 10, 15, and 20 years was 69%, 50%, 37%, and 20%, respectively.

Lev-Chelouche et al.<sup>15</sup> reported on 21 patients with malignant presacral tumors, nine of which were chordomas. No patients underwent preoperative biopsy. Nearly all patients had a palpable lesion on rectal examination. Fifteen of 21 malignant lesions were completely excised. Most recurrences were seen in patients with incomplete resection and 50% of these died of disease.

Wang et al.<sup>25</sup> reported their series of 22 patients with malignant presacral tumors, five of which were chordomas and seven were leiomyosarcomas. Tumor size ranged from 1.5 to 40 cm. The average size of malignant tumors was 17 cm; 96% were palpable by rectal examination. CT was believed to be the best test to identify the lesions and define extent and degree of tumor invasion, but the diagnosis remained nonspecific. No patients underwent preoperative biopsy. Five patients had complete resection and 17 had incomplete resection. The overall 5-year survival rate for malignant tumors was 41%. No patients underwent preoperative adjuvant therapy. Postoperative chemotherapy and radiotherapy was used in selected patients with malignant tumors.

Bohm et al.<sup>17</sup> reported their series of 24 patients with congenital presacral tumors. They had four patients with chordomas and 20 with developmental cysts. All patients with chordoma

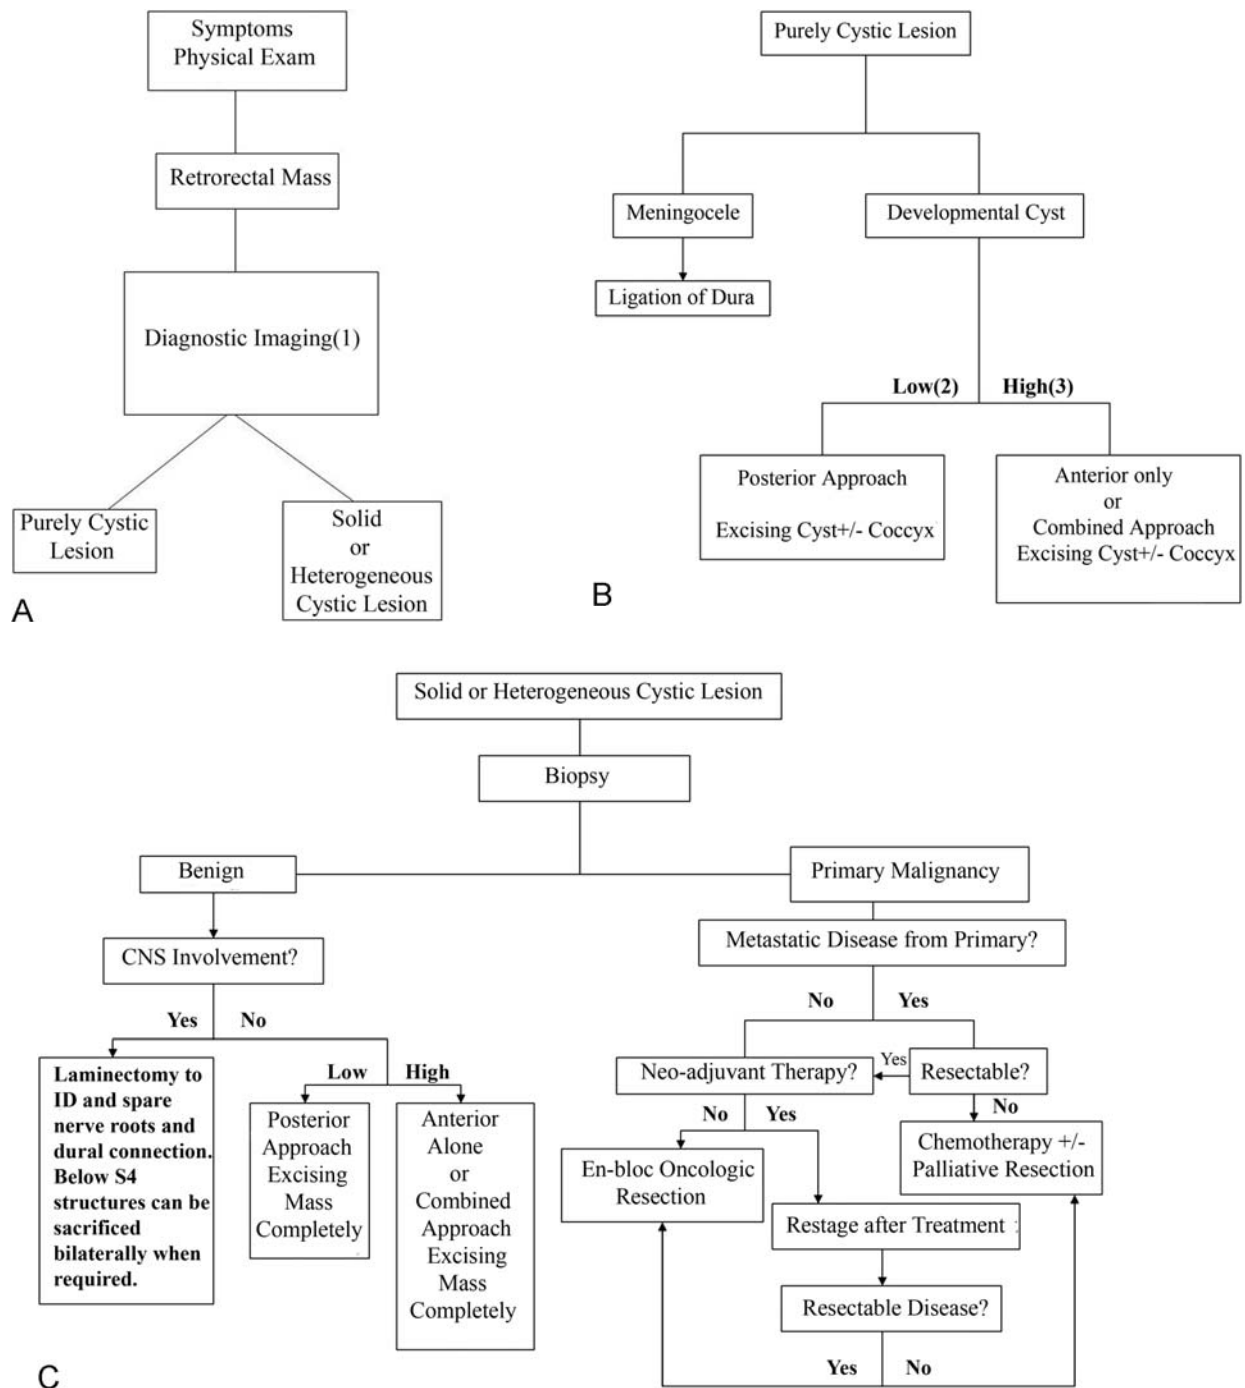

FIGURE 36-12. Proposed treatment algorithm. Notes: 1) conventional radiographs of pelvis, CT scan, MRI with gadolinium, ERUS, intraluminal contrast studies of rectum, PET, myelogram; 2) lower than the third sacral vertebra; 3) higher than the third sacral vertebra.

underwent excision. Three of four chordoma patients had recurrence at 25, 32, and 55 months. Patients with recurrence presented with pain and neurologic disturbance. Complete local reexcision was done in the three patients with recurrence. Only 3 of 20 patients with developmental cysts developed recurrence, all of which underwent successful reexcision.

### Congenital Cystic Lesions

In general, cystic lesions can be treated adequately by complete excision via a posterior approach. Large cystic lesions such as teratomas extending high into the pelvis can be excised via a combined abdominal–perineal approach. There continues to be some debate as to whether or not a coccygectomy needs to

be done for all resections of congenital cystic lesions.<sup>11</sup> Some believe that the coccyx harbors totipotential cells that will lead to a high recurrence rate if not excised.<sup>26</sup> It should be remembered also that 10%–38% of patients with cystic lesions harbor a malignancy and that oncologic principles must be followed.<sup>27</sup>

In the Mayo series, 49 congenital cystic lesions were described including 15 epidermoid cysts, 16 mucus-secreting cysts, 15 teratomas, and 2 meningoceles.<sup>4</sup> Three teratocarcinomas were seen. Most lesions were in females with only three in males. Average size of cysts was 4–7 cm. Almost all cystic lesions were treated with a posterior approach. Of 66 patients with benign tumors, 10 had recurrence (four had giant cell tumors, six had congenital benign cysts), most of which were treated successfully with reexcision.

Lev-Chelouche et al.<sup>15</sup> reported 21 benign presacral lesions. Complete excision of benign lesions was possible in all cases with no recurrences during the 10-year follow-up.

Singer et al.<sup>11</sup> reported on seven patients with presacral cysts (six females, one male). All patients had previously been misdiagnosed and treated for pilonidal cysts, perirectal abscesses, fistula in ano, psychogenic disorder, proctalgia fugax, and posttraumatic or postpartum pain before the correct diagnosis was made. Patients underwent an average of 4.1 prior operative procedures. All patients were successfully treated with resection through a parasacrococcygeal approach after the correct diagnosis was made with CT fistulogram.

## Algorithm

Based on the experience at our institution, we have established a decision-making algorithm to guide the management of presacral tumors (Figure 36-12).

## Conclusion

Presacral tumors are rare, the differential diagnosis is extensive, and their discovery is notoriously difficult and late. A high index of suspicion is needed to identify these patients. Once a benign or malignant presacral lesion is discovered and histologically diagnosed, it should be treated, even if the patient is asymptomatic. CT and MRI imaging can help differentiate between benign and malignant, cystic and solid and accurately define extent of adjacent organ and bony involvement to guide operative planning. Completely cystic lesions, in general, do not require preoperative biopsy unless malignancy is suspected. All solid tumors and heterogeneous cysts should be considered for biopsy to rule out malignancy, guide neoadjuvant therapy, and plan extent of resection. Biopsies should be done transperineally or parasacrally.

An aggressive approach, by an experienced, multidisciplinary team, that can achieve a tumor-free, en bloc resection, avoid tumor violation, restore spinopelvic stability, and minimize

intraoperative and postoperative complications, should decrease the risk of local recurrence and improve survival.

## Miscellaneous Neoplasms

Richard Devine and Marc Brand

### Carcinoids

Carcinoid tumors originate from enterochromaffin cells, part of the diffuse endocrine system. Thus, they are considered to belong in the neuroendocrine group of tumors.<sup>1</sup> They are a confusing group of tumors with a wide range of behavior. Carcinoid tumors may be located in any of a number of locations within and outside the gastrointestinal (GI) tract, may be single or multiple, may produce a wide array of biochemical products, may produce symptoms from the biochemical products or the tumor itself, and exhibit varying degrees of biochemical and aggressive behavior relative to their location. This section will focus on carcinoid tumors of the small bowel, appendix, colon, and rectum.

### History and Terminology<sup>1,2</sup>

The clinical and histologic recognition of carcinoid tumors was first described in 1888 by Lubarsch. He had noted two patients with multiple small tumors of the ileum at autopsy. The term carcinoid (“karzinoid”) was first applied to these tumors in 1907 by Oberndorfer. The term implies that these tumors are similar to carcinoma, but behave somewhat differently. Specifically, carcinoid tumors are histologically similar to carcinoma, but have a more benign clinical course. Gossett and Masson described the argentaffin-reducing properties of appendiceal carcinoids in 1914, and the tumors became known as “argentaffinomas.” The argentaffin reaction is characterized by reduction of silver salts to a black metallic silver stain.

The association between carcinoid tumors and serotonin production was first described by Lembeck in 1953. Around the same time, the first description of the carcinoid syndrome was published by Waldenstrom’s group (1954). Within a few years, Sandler and Snow first recognized a variable nature of carcinoids. They described an “atypical” *gastric* carcinoid which only produced a serotonin *precursor* and had staining and flushing patterns different from “typical” carcinoids. The

staining pattern is described as “argyrophilic,” implying that the reduction of silver salts to the black metallic silver stain occurs only in the presence of pretreatment with a reducing agent.

The amine precursor uptake and decarboxylation (APUD) abilities of these tumors were recognized by Pearse in 1969, and carcinoid tumors became known as “APUDomas.” APUDomas, including carcinoid tumors, are now considered part of a group of tumors known as neuroendocrine tumors. Neuroendocrine tumors are derived from the diffuse neuroendocrine system. As such, carcinoid tumors share some characteristics with melanomas, pheochromocytomas, medullary carcinoma of thyroid, and pancreatic endocrine tumors.<sup>3</sup>

### Pathology<sup>3</sup>

The light microscopic appearance of carcinoid tumors is rather bland. They are composed of monotonous sheets of small round cells. The cells themselves demonstrate uniform nuclei and cytoplasm. The ultrastructural appearance of carcinoid tumors demonstrates electron-dense neurosecretory granules which contain small clear vesicles. These neurosecretory granules correspond to the synaptic vesicles found in neurons.

The staining pattern of carcinoid tumors is related to the amines and peptides they produce as well as cytoplasmic proteins they contain. Silver staining was initially used to identify these tumors. Carcinoid tumors that are capable of taking up *and* reducing silver stains are described as “argentaffin positive,” and this is attributed to the silver reducing ability of serotonin. Tumors that are only capable of silver uptake, and not silver reduction, may be demonstrated by addition of an external reducing agent. These tumors are described as “argyrophilic.”

Silver staining has been supplanted by immunohistochemical stains for cytoplasmic proteins. Chromogranin, neuron-specific enolase, and synaptophysin are frequently used to identify a tumor as being a neuroendocrine tumor.

Carcinoid tumors have been described to grow in one of five histologic patterns. These histologic patterns have been

TABLE 37-1. Carcinoid tumor growth patterns

Sogo and Tazawa <sup>4</sup>	Martin and Potet <sup>5</sup>	Pattern	Description	Frequency	Prognosis
Type A	Type I	Insular	Solid nests with peripheral palisading	Most frequent pattern	Favorable
B	II	Trabecular	Ribbon-like anastomosing pattern	Second-most frequent pattern	Favorable
C	III	Glandular	Tubular, acinar, or rosette pattern	Least frequent pattern	Poor
D	IV	Undifferentiated	No recognizable pattern	Third-most frequent pattern	Poor
Mixed	Mixed	Any combination of the above	Any combination of the above	A + C most frequent mix A + B next most frequent	Most favorable Favorable

designated as A-D<sup>4</sup> or I-IV,<sup>5</sup> with the fifth pattern in each system being a combination of several patterns. These growth patterns are described in Table 37-1.

## Pathophysiology

Carcinoid tumors are known to produce at least 30 bioactive compounds.<sup>2</sup> These compounds may be amines (including serotonin and histamine), proteins (a wide variety of hormones and kinins), and prostaglandins. Serotonin, an amine, is the most well-known of these compounds.

Serotonin is derived from tryptophan, an essential amino acid. The production of serotonin is a two-step process: hydroxylation of tryptophan to 5-hydroxytryptophan (5-HTP), followed by decarboxylation of 5-HTP to 5-hydroxytryptamine (5-HT, or serotonin). Serotonin is then stored and transported in platelets. Metabolism of serotonin occurs in the liver (monoamine oxidase) and then the kidney (aldehyde dehydrogenase) to produce 5-hydroxy-indole-acetic acid (5-HIAA) which is excreted in the urine.

Normally, less than 1% of tryptophan is converted into serotonin. The remainder is used for synthesis of proteins, niacin (vitamin B<sub>3</sub>), and nicotinamide (vitamin B<sub>3</sub>). Protein malnutrition, hypoproteinemia, and pellagra (vitamin B<sub>3</sub> deficiency) may develop if large quantities of tryptophan are diverted to serotonin production by carcinoid tumors.

## Classification

Numerous classification schemes have been devised to categorize carcinoid tumors. These have been based on several features including site of origin and histologic growth pattern. The prognosis of carcinoid tumors is somewhat related to these classifications.

Carcinoid tumors are grouped by their site of origin into foregut, midgut, and hindgut tumors. Foregut tumors originate in the thymus, respiratory tract, stomach, duodenum, pancreas, and ovaries. Midgut tumors originate in the jejunum, ileum, appendix, and proximal colon. Hindgut tumors originate in the distal colon or rectum. The histologic classification pattern has already been described (Table 37-1).

Several studies have reviewed the distribution of site of origin of carcinoid tumors. Godwin<sup>6</sup> reported the most frequent

sites of origin as the appendix, ileum, rectum, and bronchus (38%, 23%, 13%, 11.5%, respectively) in a series of 4349 carcinoid tumors. In another large series, Modlin and Sandor<sup>7</sup> reported the most frequent sites of origin as the bronchus, ileum, rectum, and appendix (32.5%, 17.6%, 10%, 7.6%, respectively) in 5468 carcinoid tumors.

## Clinical Presentation<sup>3</sup>

Carcinoid tumors may be found incidentally or may present as a result of the production of local or systemic symptoms. Local symptoms are related to the site of origin or site of metastasis, whereas systemic symptoms are related to production of bioactive compounds.

### Local Symptoms

Small bowel carcinoids may produce local symptoms of periodic abdominal pain, small bowel obstruction (caused by intussusception or mesenteric fibrosis and small bowel kinking), intestinal ischemia, and GI hemorrhage. Appendiceal carcinoids are often found incidentally at the time of appendectomy. Rectal carcinoids are often found incidentally at the time of colorectal cancer screening examinations. The symptoms of rectal carcinoids, when present, are related to bleeding and change in bowel habits. Liver metastases may be the initial presentation, manifested by hepatomegaly and right upper quadrant pain.

### Systemic Symptoms and the Carcinoid Syndrome<sup>2</sup>

Systemic symptoms produced by carcinoid tumors are referred to as the carcinoid syndrome. These consist of a combination of vasomotor symptoms (flushing and blood pressure changes), diarrhea, and bronchospasm. These symptoms are brought on by release of active tumor products into the circulation. The liver is capable of metabolizing and inactivating large quantities of tumor products. Therefore, the carcinoid syndrome occurs only in the presence of liver metastases (for GI carcinoids), or a primary carcinoid tumor located outside the portal venous system. Episodes of symptoms of the carcinoid syndrome may be precipitated by routine daily experiences such as emotional stress, heat, alcohol consumption, or straining at stool.

Flushing symptoms and hypotension are thought to be caused by a variety of bioactive tumor products. These include catecholamines, histamine, tachykinins, and kallikrein. Four different patterns of flushing have been described, and each is related to a specific site of origin. Type 1 flushing is a diffuse, erythematous rash, which may last up to 5 minutes, and is associated with the early stage of metastases from midgut carcinoid tumors. Type 2 flushing is a violaceous rash with telangiectasias, which may also last up to 5 minutes, and is associated with the later stages of metastases from midgut carcinoid tumors. Type 3 and 4 flushing is associated with bronchial and gastric carcinoid tumors, respectively.

The heart may be affected by carcinoid tumor products, particularly in those patients with midgut carcinoids and liver metastases. It is thought to be caused by the effects of serotonin on the heart. Specifically, serotonin has an effect on myofibroblasts resulting in fibroplasia, increased vascular tone, bronchoconstriction, and platelet aggregation. Together, these effects may cause pulmonary hypertension, tricuspid and pulmonary valve stenosis, and right ventricular hypertrophy and fibrosis. The left side of the heart is typically protected from the effects of carcinoid products by the lungs, which are capable of inactivating these substances.

Carcinoid crisis is a life-threatening condition. It may be brought on by anesthesia, embolization or manipulation of the tumor, administration of chemotherapy, or occur spontaneously. Life-threatening manifestations of the carcinoid crisis include profound flushing and hypotension, bronchoconstriction, arrhythmias, and hyperthermia. Other manifestations include diarrhea, confusion, and stupor. The crisis may be limited or avoided by pretreatment with somatostatin and histamine blockade (both  $H_1$ - and  $H_2$ -receptors) before treatments known to induce a crisis.

## Diagnostic Studies

### Biochemical Studies

Carcinoid tumors are often difficult to diagnose preoperatively, particularly those in the small bowel and appendix. In a study by Thompson and von Heerden,<sup>8</sup> less than 10% of 145 patients with GI carcinoids were accurately diagnosed before surgery, and all had carcinoid syndrome at presentation.

The diagnosis of carcinoid tumor before surgery relies on biopsy of an accessible lesion (in the foregut, hindgut, or liver), or the identification of biochemical products from the tumor. Although carcinoid tumors may produce many substances, the most widely used tests are related to serotonin. The most widely accepted test currently used to diagnose the presence of a carcinoid tumor is a 24-hour urine specimen analyzed for 5-HIAA (a serotonin metabolite). Urinary 5-HIAA excretion under normal circumstances is between 2–8 mg/24 hours. Excretion exceeding these levels has shown high sensitivity and specificity (73% and 100%,

TABLE 37-2. Dietary and medicinal intake affecting urinary 5-HIAA<sup>70-72</sup>

Foods rich in serotonin	Medicines affecting urine 5-HIAA
Bananas	Guaifenesin
Plantains	Acetaminophen
Pineapples	Salicylates
Plums	L-Dopa
Kiwi	
Walnuts	
Hickory nuts	
Pecans	
Avocados	
Tomatoes	

respectively) in diagnosing carcinoid syndrome.<sup>9</sup> It is important to avoid foods and medications that can produce a false-positive result by affecting urinary 5-HIAA levels. These are listed in Table 37-2.

Carcinoid tumors vary in their ability to produce serotonin. Midgut tumors typically produce high levels of serotonin and its metabolites. Foregut tumors typically lack the ability to convert (decarboxylate) 5-HTP (5-hydroxytryptophan) into 5-HT (serotonin), resulting in low urinary levels of 5-HIAA. However, the kidney may decarboxylate sufficient 5-HTP into 5-HT, thus increasing urinary serotonin levels. Hindgut carcinoids rarely produce 5-HTP or 5-HT, and urine and blood tests are typically negative. Platelet serotonin levels may be more sensitive than urine or blood tests. The results of three different tests in a series of 44 patients with carcinoid tumors is shown in Table 37-3.<sup>10</sup>

### Imaging Studies

Localization of primary carcinoids in the GI tract is often difficult. Carcinoids in the foregut and hindgut are frequently diagnosed by endoscopy and biopsy.<sup>11</sup> However, ileal and appendiceal carcinoids are more common and less easily localized. These primary sites often remain unknown, despite small bowel contrast studies or computed tomographic (CT) scanning, until surgical exploration identifies the primary site.<sup>12</sup> If these studies are positive, it is usually the mesenteric kinking and fibrosis that is evident rather than the mass itself. Contrast studies may show small bowel obstruction, extrinsic filling defects, or kinking, angulation, and separation of small bowel loops.<sup>11</sup>

TABLE 37-3. Comparison of urine and platelet biochemical studies in carcinoid patients

	Number	Platelet 5-HT (%)	Urine 5-HIAA (%)	Urine Serotonin (%)
Foregut	14	50	29	55
Midgut	25	100	92	82
Hindgut	5	20	0	60

Multiple newer imaging techniques have been used in an attempt to identify both the primary tumor as well as metastases. These may be categorized as morphologic and functional imaging studies. Morphologic studies include ultrasound, CT, and magnetic resonance imaging (MRI). These studies may be useful, as they are in many types of cancers, in identifying distant metastases. In addition, CT scans may show a characteristic stellate soft-tissue stranding in the mesentery.<sup>13</sup> Functional studies are based on tumor uptake and scintigraphic imaging of various isotopes. The first of these was metaiodobenzylguanidine (MIBG),<sup>14</sup> but this has since been replaced by newer agents and techniques. The two scintigraphic imaging techniques currently in use are somatostatin receptor scintigraphy (SRS) and positron emission tomography (PET). Both techniques rely on differential uptake of the radiotracer by the tumor relative to normal tissue. SRS relies on somatostatin receptors on the cell surface, whereas PET relies on metabolic utilization of the localizing agent. A recent study by Hoegerle et al.<sup>15</sup> compared both morphologic and functional imaging modalities in localizing primary and metastatic carcinoid tumors in 17 patients. The results are summarized in Table 37-4, and suggest that the two approaches are complementary. <sup>18</sup>F-Dopa-PET imaging is more sensitive in localizing primary tumors and lymph node involvement, whereas CT or MRI is more sensitive in identifying distant disease.

### Prognosis

The behavior and prognosis of carcinoid tumors are highly variable and are affected by multiple factors including tumor size, depth, presence and location of metastases, and primary tumor location.

TABLE 37-4. Morphologic and functional imaging in carcinoid tumors

Tumor site	PET		SRS	CT/MRI
	<sup>18</sup> F-Dopa	<sup>18</sup> FDG		
Primary	7/8	2/8	4/8	2/8
Lymph nodes	41/47	14/47	27/47	29/47
Distant metastases	12/37	11/37	21/37	36/37

<sup>18</sup>FDG, <sup>18</sup>F-fluorodeoxyglucose; SRS, somatostatin receptor scintigraphy.

The TNM staging of carcinoid tumors is similar to that of GI adenocarcinomas. T-stage is related to depth of penetration, and nodal and metastatic staging are related to its absence or presence. Prognosis is affected by the TNM stage, as shown in Table 37-5. The effect of primary tumor location on prognosis (survival, likelihood of carcinoid syndrome, and additional tumors) is shown in Table 37-6.

### Treatment

#### Tumor-directed Therapy<sup>16,17</sup>

The mainstay of treatment for carcinoid tumors is surgical resection. Difficulty arises in selecting the extent of surgery relative to the extent of disease, magnified by two considerations: 1) carcinoid tumors are often located in an area where “local excision” is an option (appendix, rectum), and 2) the benefit of debulking procedures. The surgical decision is based on the likelihood of residual primary disease, lymph node metastases, and the benefit of debulking the tumor burden to reduce the symptoms of the carcinoid syndrome. Guidelines for extent of surgical resection are summarized in Table 37-7.<sup>16,17</sup>

TABLE 37-5. TNM staging and survival of GI carcinoid tumors<sup>73</sup>

TNM stage	Definition	5-y survival (%)	Comment
T	1 Submucosa	82	Survival differences related to tumor depth in absence of metastases
	2 Muscularis propria		
	3 Subserosa		
	4 Perforated or invading neighboring structure		
N	0 Absent	95	Survival differences related to presence and proximity of metastases
	1 Present	83	
M	0 Absent	—	
	1 Present	38	

TABLE 37-6. Effect of primary carcinoid location on prognosis<sup>16</sup>

Primary carcinoid location	Overall 5-y survival (%)	Incidence of metastases (%)	Carcinoid syndrome	Multiplicity of carcinoid tumors (%)	Second primary cancer (%)
Appendix	99	<1 cm, 0 1–1.9 cm, 11 >2 cm, 30–60	Rare	4.2	13
Small bowel	Related to metastasis (see Table 37-4)	<1 cm, 20–30 1–2 cm, 80 LN 20 liver >2 cm, >80 LN 40–50 liver	Common	30–50	20–30

LN, lymph node.

TABLE 37-7. Guidelines for extent of surgical resection

Primary tumor	Factor	Extent of resection
Appendix	<1 cm	Appendectomy
	1–1.9 cm	Individualize, appendectomy, or right hemicolectomy
	>2 cm	Right hemicolectomy
Small bowel	Locally limited disease	Resection of primary and metastatic tumors
	Extensive disease	Resection or bypass of primary tumor Debulking of metastases
Colon		Colectomy
Rectum	<1 cm	Local excision
	1–1.9 cm	Individualize, local excision, or proctectomy
	>2 cm	Proctectomy

Small bowel carcinoid tumors are frequently associated with lymph node metastases and structural abnormalities (intussusception, mesenteric fibrosis, and small bowel kinking). Lymph node metastases are common, even when the tumors are small. Lesions less than 1 cm in diameter have a 20%–30% incidence of lymph node involvement. Additionally, there are often multiple small bowel lesions. Therefore, surgical management involves formal resection and wide mesenteric excision of the associated region of lymph node drainage as well as thorough exploration for additional lesions.<sup>16,17</sup>

Appendiceal carcinoids typically behave differently than small bowel carcinoids. They are frequently found during appendectomy, are less likely to have lymph node metastases (0% for lesions less than 1 cm, 11% for lesions between 1 and 1.9 cm, and 30%–60% for lesions greater than 2 cm in diameter) and multicentric disease is rare. Therefore, appendectomy is adequate treatment for lesions less than 1 cm, whereas lesions greater than 2 cm are treated by formal resection (right hemicolectomy). Treatment for intermediate-size appendiceal carcinoids (1–1.9 cm) must be individualized, balancing the risk of a more extensive surgery against the risk of residual disease. Factors that suggest an increased likelihood of residual disease, and are thus used to indicate a formal right hemicolectomy, include lymphovascular invasion, involvement of the mesoappendix (by direct extension or in lymph nodes), or a positive surgical margin.<sup>16,17</sup>

Colonic carcinoid tumors generally behave in an aggressive manner and frequently have lymph node metastases and a poor prognosis. Therefore, they are treated with formal resection.<sup>16,17</sup>

Rectal carcinoid tumors are minimally aggressive lesions, and behave in a manner similar to appendiceal carcinoids. They have a similar rate of lymph node metastases and multiple lesions are uncommon. Surgical treatment also shows similarity in that local (transanal) excision is adequate for lesions less than 1 cm in diameter whereas formal proctectomy is advised for lesions larger than 2 cm in diameter. Treatment for intermediate-size rectal carcinoids (1–1.9 cm) must be individualized, balancing the risk of a more extensive

surgery against the risk of residual disease. Muscular invasion is the factor that suggests an increased likelihood of residual disease, and is thus used to indicate a formal proctectomy.<sup>16,17</sup>

Treatment of hepatic metastases is of significant benefit, especially when metastatic disease is confined to the liver.<sup>18</sup> Tumor debulking may be in the form of hepatic resection, ablative therapy (cryotherapy, radiofrequency ablation), radiolabeled octreotide, or hepatic artery embolization and chemoembolization. The expected 5-year survival rate for patients with carcinoid liver metastases is 20%. Death is often related to liver failure from local tumor progression or carcinoid heart disease. However, several studies have demonstrated a 5-year survival rate approximating 70% when these metastases are treated with a combination of the listed techniques. Similar survival rates have been achieved with the use of liver transplantation in a small number of patients.<sup>19</sup>

## Systemic Therapy

Medical treatment for patients with carcinoid tumors has two purposes: palliation of systemic symptoms of the carcinoid syndrome, and treatment of metastases. The palliation of symptoms may use medications directed at specific symptoms, or medications causing a generalized reduction in hormone production. Specific agents that may help control symptoms of the carcinoid syndrome are listed in Table 37-8. Somatostatin analogs are helpful in controlling many of the symptoms of the carcinoid syndrome by reducing synthesis and systemic release of hormone products. Octreotide is a long-acting somatostatin analog with a half-life of 90 minutes. In doses of 400 µg/day, octreotide improved the major symptoms of flushing and diarrhea in more than 80% of patients.<sup>3</sup> Lanreotide is another somatostatin analog with a longer half-life than octreotide, and both agents are available in long-acting depot forms.

Chemotherapy has largely been ineffective in patients with metastatic carcinoid tumor.<sup>20</sup> Single agent regimens using 5-fluorouracil, streptozotocin, dacarbazine, dactinomycin, doxorubicin, etoposide, cisplatin, and carboplatin have had objective tumor response rates between 0%–30% in small series of patients. Similarly poor results have been found when combination chemotherapy has been used in the adjuvant

TABLE 37-8. Medical treatment of carcinoid syndrome symptoms<sup>2-3</sup>

Symptom	Drug category	Specific agents
Flushing	H <sub>2</sub> -Blockade	Cimetidine, ranitidine, famotidine
	α <sub>1</sub> -Blockade	Doxazosin, phenoxybenzamine
	Phenothiazine	Chlorpromazine
	Corticosteroid	Prednisone
Diarrhea	Serotonin blockade	Ketanserin, ondansetron, cyproheptadine, methysergide
	Opiate blockade	Codeine, loperamide
Bronchospasm	Phenothiazine	Chlorpromazine
	Bronchodilator	Salbutamol
	Corticosteroid	Prednisone

setting or to treat metastatic carcinoid tumor. Interferon has been used in the treatment of metastatic carcinoid tumors with some success. Patients have experienced an objective response rate near 50%, with a duration of 2.5 years. However, interferon therapy produces significant side effects of a flu-like syndrome, fatigue, and fever which may limit its use.

## GI Stromal Tumors

In the past, most spindle cell sarcomas arising from the mesenchymal elements of the GI tract were considered smooth muscle neoplasms and were considered leiomyomas, leiomyosarcomas, and leiomyoblastomas. With advances in electron microscopy and immunohistochemistry, it was discovered that many of these tumors lacked structural or immunophenotypic features associated with smooth muscle differentiation and the more generic term "stromal tumor" was introduced.<sup>21</sup> Further advances in immunohistochemistry allowed pathologists to separate these tumors into those that are true smooth muscle tumors (leiomyomas) and those that are thought to arise from GI pacemaker cells (GI stromal tumors).

GI stromal cell tumors (GISTs) are mesenchymal tumors arising from the intestinal wall, omentum, or retroperitoneum that stain positive for the CD117 antigen, a marker for the KIT oncoprotein. Sixty to seventy percent of GISTs also stain positive for CD34, a hematopoietic progenitor cell antigen.<sup>22</sup> Leiomyomas are stain negative for KIT and CD34 and positive for desmin or smooth muscle actin.<sup>23</sup>

Because of structural and immunohistochemical similarities between GISTs and the interstitial cells of Cajal, it is thought GISTs arise from these cells or other pluripotential mesenchymal stem cells. The interstitial cells of Cajal are located in the muscle layer of the GI tract and form a complex network that regulates intestinal motility.

The stomach is the most common location of GISTs (45%–55%) with small bowel the next most common location (25%–35%). Only 10%–20% of GISTs are located in the colon and rectum. The gender distribution is close to equal in all locations.

GISTs occur throughout the colon but are most often located in the rectum. Miettinen et al.<sup>23,24</sup> retrieved all cases coded as leiomyomas, leiomyosarcomas, smooth muscle tumors, or stromal tumors at the Armed Forces Institute of Pathology and the University of Helsinki from 1970 to 1996 for rectal tumors and 1970 to 1998 for colon tumors. The most common location was the rectum and anus (80%). Older reports of colorectal leiomyosarcomas (the majority of which were probably GISTs) also show an increased incidence in the anorectal area with about 1/3 occurring in the colon and 2/3 in the anorectal area.<sup>25</sup>

The most common clinical presentation is hematochezia, abdominal or rectal pain, or a mass found incidentally on physical examination or endoscopically. As might be

expected, how patients present is largely related to the size of the tumor.<sup>26–28</sup>

Complete surgical excision, if possible, continues to be the treatment of choice. Because GISTs rarely spread to the lymphatic system, removal of the regional lymph nodes is not necessary or recommended.<sup>29</sup> Wide margins are not necessary, but complete en bloc removal of the tumor and its pseudocapsule should be performed. Because of high local recurrence rates, enucleation of the tumor (leaving the pseudocapsule) or cutting across tumor should be avoided.

The use of imatinib mesylate (Gleevec in the United States, Glivec in Europe, Novartis Pharmaceuticals) has significantly impacted the treatment of GISTs. The KIT oncoprotein, detected in almost all GIST tumors by positive immunohistochemical staining for the CD117 antigen, is a transmembrane receptor tyrosine kinase encoded for by the C-kit protooncogene.<sup>29,30</sup> In GIST tumors, abnormal activation of the KIT oncoprotein results from a mutation in the C-kit gene. This abnormal activation results in unregulated cellular proliferation. Imatinib is a selective tyrosine kinase inhibitor and acts by blocking the abnormal activation of the KIT oncoprotein.

Demetri et al.<sup>31</sup> used imatinib in 147 patients with metastatic or unresectable GIST tumors. Fifty-four percent had a partial response with shrinkage of their tumors and 41% of the patients had stable disease. Van Oosterom et al.<sup>32</sup> found an objective response in 70% (25 of 36 patients) of patients with KIT-positive metastatic GIST tumors.

The use of imatinib as a postoperative adjuvant to surgery is currently being investigated and patients who have a resected primary GIST should be considered for entry into a clinical trial.<sup>29</sup> Patients who present with marginally resectable or unresectable tumors should be considered for a course of preoperative imatinib. Katz et al.<sup>30</sup> reported two cases of patients with unresectable GIST tumors treated with imatinib. In both cases there was a dramatic decrease in the size of the tumors and both patients eventually had surgical excision of their tumors.

The incidence of local recurrence or metastatic disease after complete surgical excision is high. About 50% of patients with potentially curative resection will develop a recurrence.<sup>29</sup> Of 40 patients with rectal tumors reported by Yeh et al.,<sup>27</sup> 48% developed a recurrence or metastasis. They also found local recurrences were higher in the group that had wide local excision compared with those who had a more radical resection, such as an abdominoperineal resection or anterior resection (55% versus 24%).

## Leiomyomas

Leiomyomas of the colon and rectum are usually small (less than 1 cm) nodules arising from the smooth muscle of the muscularis mucosa. They are differentiated from GISTs by staining negative for CD117 (KIT) and positive for desmin and smooth muscle actin.<sup>33</sup> They are almost always found

incidentally on endoscopy or in surgical resections done for other pathology. Of 88 cases reported by Miettinen et al.,<sup>33</sup> 29% were in the rectum and 49% in the sigmoid colon. The leiomyomas in this series were almost all removed by snare polypectomy. There were no recurrences. Walsh and Mann<sup>34</sup> also reported a series of 26 patients who had leiomyomas arising from the muscularis mucosa. Twenty-two tumors had some sort of local excision (12 by biopsy forceps). No recurrence was noted in any of these patients. Small incidental leiomyomas found on endoscopy are benign tumors that are adequately treated by snare polypectomy alone.

## Squamous and Adenosquamous Carcinoma

Squamous and adenosquamous carcinomas of the colon are thought to be variants of the same tumor.<sup>35</sup> Squamous cell cancers have pure epithelial features without glandular elements; adenosquamous cancers have both epithelial and glandular features. A review of the National Cancer Institute's database found approximately one in 2000 cases of colorectal cancer was adenosquamous.<sup>36</sup> By 1999, only 59 cases of squamous cell carcinoma and 56 cases of adenosquamous cell cancer had been published. A review of the National Cancer Institute database added 145 cases of adenosquamous cancer in 1999.

To be considered a primary colon rectal tumor, these tumors should be located proximal to the distal rectum to exclude anal canal cancers that have extended proximally. Patients with a history of squamous cell cancer elsewhere are also excluded because of the possibility this may represent metastatic disease.

The mean age of patients in reported cases of pure squamous cell cancer is 58<sup>37</sup> and 66 for a large series of patients with adenosquamous cancer. The anatomic location seems to be similar to that of adenocarcinoma with most lesions found in the proximal and distal colon and few in the middle colon (transverse and descending).<sup>36,37</sup>

Patients tend to present with advanced disease. Cagie et al.<sup>36</sup> reviewed 145 patients with adenosquamous disease and found only 11% presented with node negative, superficially invasive cancer (Astler-Coller Stage A and B). Forty-four percent had tumors with full-thickness invasion or positive lymph nodes and 40% had distant metastasis. Those patients with T<sub>1</sub>, or T<sub>2</sub>, N0, M0 lesions appeared to have a prognosis similar to that of patients with adenocarcinoma. Patients with T<sub>3</sub> lesions, positive lymph nodes, or metastatic disease have a worse prognosis.<sup>36</sup> In a combined series of squamous and adenosquamous cancer, Frizelle et al.<sup>35</sup> reported a 5-year survival rate of 86% for patients with Stage II disease and only 24% for patients with Stage III.

The primary treatment of these tumors is surgical. Because, by definition, these tumors are located in the colon or proximal to mid rectum, a segmental resection with anastomosis should be feasible. In rectal tumors, preoperative adjuvant chemoradiation should be considered. This recommendation

is based on improved control of local disease with preoperative adjuvant therapy in patients with adenocarcinoma and the good response to chemoradiation in patients with squamous cell cancer of the anus.<sup>35</sup> No recommendations based on data can be made concerning postoperative adjuvant chemotherapy in patients with these tumors. The prognosis, however, is so poor in patients with nodal disease that adjuvant chemotherapy seems a reasonable option. At the very least, these patients deserve to have a consultation with an oncologist.

## Lymphomas

Most primary GI lymphomas are located in the stomach or small bowel; only 6%–12% of primary GI lymphomas occur in the colon. Primary colonic lymphomas represent less than 1% of large bowel malignancies.<sup>38</sup> Approximately 70% involve the cecum or ascending colon.<sup>39,40</sup> The most common presenting symptoms are abdominal pain, palpable abdominal mass, hematochezia or melena, and weight loss.<sup>39,41</sup>

Several authors use Dawson's criteria to establish a diagnosis of primary intestinal lymphoma as opposed to generalized lymphoma secondarily involving the GI tract. Dawson's criteria are: 1) absence of enlarged superficial lymph nodes when the patient is first seen; 2) no enlargement of mediastinal lymph nodes; 3) the total and differential white count are normal; 4) at laparotomy, only regional lymph nodes have metastatic disease; 5) the liver and spleen are unaffected.<sup>42</sup>

The majority of lymphomas in the colon and rectum are non-Hodgkin's lymphomas of B cell origin, diffuse large cell type. In a series of 32 patients reported by Myung et al.,<sup>41</sup> 22 were of diffuse large cell type and 27 of B cell origin. Other pathologic types that occur in the colon include low-grade lymphoma tissue (MALT lymphomas), mantle cell lymphoma, and T cell lymphoma.<sup>38,43,44</sup>

GI lymphoid tissue exists in intestinal mucosa, submucosa, and lamina propria. Low-grade B cell lymphomas arising from these specialized lymphoid tissues are referred to as MALT (mucosa-associated lymphoid tissue) tumors. MALT tumors are low-grade tumors with an indolent course and are usually located in the stomach, but cases of colonic involvement have been reported.<sup>45–47</sup> Currently, gastric MALT tumors are thought to arise in response to *Helicobacter pylori* infection and it has been shown that eradication of the *H. pylori* infection will lead to complete regression in the majority of cases.<sup>48</sup> MALT tumors in the colon are usually solitary lesions, but can also present as multiple polypoid lesions. In a series of 17 colonic MALT tumors reported by Yatabe et al.,<sup>49</sup> treatment consisted of endoscopic (three patients) or surgical excision (14 patients); three of the patients also had chemotherapy. There are two case reports of complete regression of a colonic MALT with either chemotherapy or treatment of a concomitant *H. pylori* infection.<sup>47,50</sup>

Multiple lymphomatous polyposis is a mantle cell lymphoma that involves the GI tract. Multiple lymphomatous

polyps can involve the GI tract from the stomach to the rectum, but can also involve the colon alone. The most common presenting symptoms are weight loss, diarrhea, abdominal pain, rectal bleeding, and anemia. On endoscopic examination, it can be confused with familial adenomatous polyposis or nodular lymphoid hyperplasia. The treatment is chemotherapy.<sup>51,52</sup>

Treatment of localized, primary colonic lymphoma is primarily surgical excision.<sup>40,45</sup> Aviles et al.<sup>45</sup> followed surgical excision with adjuvant chemotherapy consisting of cyclophosphamide, doxorubicin, vincristine, prednisone, and bleomycin. In 40% of their cases, epirubicin was used in place of doxorubicin. In node negative patients, their event-free survival rate at 10 years was 80%. In two other series of more advanced lesions, the 5-year survival rate was only 33% and 39% in patients treated with both surgery and chemotherapy.<sup>39,40</sup>

## Extramedullary Plasmacytoma

The most common type of plasma cell neoplasm is multiple myeloma. Of 1272 patients with a plasma cell neoplasm seen at M.D. Anderson Cancer Center, 94% had multiple myeloma and only 2% (22 patients) had an extramedullary plasmacytoma (EMP).<sup>53</sup> More than 75% of EMPs occur in the upper respiratory tract, and when they do occur in the GI tract, they are usually found in the stomach or small intestine.<sup>53,54</sup> Therefore, EMPs occurring in the colon are very rare and by 2004, only 22 have been reported in the English language.<sup>55</sup>

To be considered an EMP, metastatic multiple myeloma must be excluded by evaluating the urine for Bence-Jones protein, serum electrophoresis, and bone marrow biopsy. Pathologic diagnosis is established by histologic and immunohistochemical findings consistent with a localized collection of monoclonal plasma cells.<sup>55,56</sup>

Hashiguchi et al.<sup>55</sup> recently reviewed all the reported cases of colonic EMPs. Patient ages ranged from 15 to 90 with a mean of 52.3. The cecum (36.4%) and rectum (22.7%) were the most common sites involved. Treatment consisted of surgery alone in 18 cases (81.8%), radiotherapy in two cases (9%), and both surgery and radiotherapy in one case. In the 22 plasmacytoma cases report by the M.D. Anderson group, only two were in the colon. Radiation treatment alone was used in 18 of the 22 cases with good results. In seven of the 22 cases (32%), multiple myeloma developed after a median of 1.8 years, including one of the two colon cases.<sup>56</sup>

## Melanoma

Primary melanomas of the GI tract are rare and the majority are located in either the anorectal area or the esophagus.<sup>57</sup> An electronic search of the medical literature from 1966 to 2004 found only four reports of primary colonic melanoma.<sup>58,59</sup>

Malignant melanoma will often metastasize to the GI tract, and autopsy studies have shown malignant melanoma is one of the most common metastatic lesions to involve the GI tract. Up to 60% of patients dying of melanoma will have metastasis to the GI tract.<sup>60</sup> It is unusual, however, for colonic metastasis to be diagnosed while the patient is alive.

In a recent Mayo Clinic review, 2965 patients were treated between 1960 and 2000 with metastatic melanoma. Only 24 patients (0.8%) had symptoms from metastatic melanoma to the colon. The mean age at diagnosis of metastatic disease was 60.4 and the average time between diagnosis of the primary and metastasis was 8.47 years. The presenting symptoms were bleeding (50%), pain (20%), obstruction (20%), and weight loss (17%). Eighteen of the 24 had segmental resection and the 1-year survival was 37%. The 5-year survival was 21%.<sup>60</sup>

Long-term survival from literature review of patients with isolated colonic metastasis was 58.7 months. Therefore, surgery for metastatic melanoma to the colon with either palliative or curative intent is indicated.

## Colonic Complications of Leukemia

Colonic complications of leukemia may be broadly divided into two categories: complications caused by leukemic invasion of the bowel and complications caused by the profound immunocompromise, as a result of the disease and its treatment.

Leukemic infiltration of the colon is not common. In a paper by Hunter and Bjelland,<sup>61</sup> 13 of 142 leukemic patients had a significant GI complication and only one had evidence of colonic infiltration. In an autopsy study, 16 of 148 patients who died of leukemia had evidence of leukemia infiltrates in the colon.<sup>62</sup>

Endoscopic and radiologic findings are varied; a small localized ulceration,<sup>63</sup> diffuse polyposis,<sup>64</sup> a colitis-like appearance,<sup>65</sup> and plaque-like bowel thickening have all been described. The most common CT finding is a diffuse thickening of the bowel wall.<sup>66</sup>

Symptoms of leukemic infiltration are nonspecific, such as abdominal pain, bloating, diarrhea, and hematochezia.<sup>67</sup> The treatment consists of treating the underlying leukemia. Surgery is indicated only if complications arise.

Neutropenic enterocolitis is a serious life-threatening complication of the chemotherapeutic treatment of leukemias. Cartoni et al.<sup>68</sup> reported a 6% incidence of neutropenic colitis in 1450 consecutive patients treated for leukemia with a mortality rate of 15%. Hogan et al.<sup>69</sup> reported a 15% incidence of neutropenic colitis in a group of 78 patients treated for acute myelogenous leukemia. In the report by Hogan et al., the median onset of symptoms (fever, pain, diarrhea) was 10 days after the start of chemotherapy and all patients had absolute neutrophil counts of less than  $0.5 \times 10^9/L$ . CT and ultrasound findings consist of thickening of the bowel wall in the ileocecal region. Cartoni et al. showed that detection of bowel wall

thickening on ultrasound was associated with a worst prognosis than if no thickening was detected (a 29% mortality versus 0% mortality).

Treatment consists of bowel rest, parenteral nutrition, and broad spectrum antibiotics. Surgery should be reserved for complications such as documented evidence of bowel perforation or massive bleeding.

## Hereditary Nonpolyposis Colon Cancer

Lawrence C. Rusin and Susan Galandiuk

Colorectal cancer affects 148,300 patients in the United States annually (72,600 males and 75,700 females) causing 56,600 deaths each year.<sup>1</sup> Those patients who have two or more first- and/or second-degree relatives with colorectal cancer have a potentially definable inheritable disorder. Approximately 5%–6% of colorectal cancers have a known germline genetic mutation. Hereditary nonpolyposis colon cancer (HNPCC) is one of the syndromes and accounts for 3% of newly diagnosed colorectal cancer cases.<sup>2</sup>

HNPCC is characterized by the early onset of colorectal cancer (mean age, 45 years), with multiple generations affected. These cancers tend to be proximal to the splenic flexure, poorly differentiated, and have an increased frequency of synchronous and metachronous cancers. There is also an excess of extracolonic cancers, including endometrial, ovarian, gastric, small bowel, hepatobiliary, and transitional cell carcinomas. Over a patient's lifetime, there is an 80% risk of cancer, with colon cancer being the most frequently diagnosed cancer.<sup>3</sup> The syndrome is characterized by an autosomal dominant mode of inheritance. Germline mutations in mismatch repair (MMR) genes, which normally repair mistakes in DNA replication, are responsible for HNPCC.

### Historical Perspectives

Alfred Warthin, a pathologist at the University of Michigan, first described a family with inherited intestinal cancer in 1895. Detailed descriptions of this family (known as “Family G”) as well as other families were published in 1913. Gastric cancer was the predominant cancer.<sup>4</sup> Nearly 50 years later, after spending time at the University of Michigan, Henry Lynch published the pedigrees of two large midwestern families (“Family N” from Nebraska and “Family M” from Michigan). In his article, he commented on the wide spectrum of cancers diagnosed and the probability of an inheritable gene. By the mid-1980s, after further studies, two patterns of disease presentation became apparent, so-called Lynch I (colorectal cancer only) and Lynch II (colorectal and other malignancies). Concurrent observations determined that there was

a paucity of colonic polyps in these patients, and that there was considerable overlap between Lynch I and II syndromes. The syndrome became known as HNPCC.<sup>5</sup>

To promote research collaborative studies, the International Collaborative Group on HNPCC met in Amsterdam in 1990.<sup>6</sup> A set of diagnostic guidelines was agreed on that would allow researchers to gather homogenous populations to be studied. Once HNPCC was well categorized, rapid progress was made elucidating the genetic defect as well as in diagnosis and treatment of the disease. Colorectal tumors were found to have multiple mismatched nucleotides. This unique genetic abnormality was termed replication error phenotype or RER+. Most of these mismatched bases were in areas of the gene called “microsatellites,” so the term microsatellite instability (MSI) became prevalent.<sup>7</sup> Extensive research in yeast and *Escherichia coli* had identified a group of genes referred to as MMR genes. Using linkage studies, the first human homolog, MSH2, was identified in 1993 by Fishel.<sup>8</sup>

### Genetics

#### What Are Microsatellites?

Microsatellites are short tandem repeating base sequences that are usually mononucleotide or dinucleotide base repeats. Most often, the repeats are found in the noncoding or intronic portion of the gene. However, microsatellites can occur anywhere within the gene. There are well over 200 polymorphic microsatellite loci identified.<sup>9</sup> The most common sequences are repeats of adenine or thymine or the dinucleotide repeats of cytosine/adenine (CA<sub>n</sub>) or guanine/thymine (GT<sub>n</sub>). When the number of repeats in a microsatellite sequence in a cancer cell is different from the surrounding normal tissue, this is termed “microsatellite instability.”

#### Different Types of DNA Repair

There are several intracellular mechanisms that repair DNA damage and maintain genomic stability and fidelity. “Base excision repair” (BER) repairs mutations caused by reactive

oxygen species related to aerobic metabolism. Oxidative DNA damage produces a stable 8oxo 7-8 dihydro-2' deoxyguanosine (8 oxoG), which readily misrepairs with adenine residues resulting in G:C→T:A transversion mutations. "Nucleotide excision repair" (NER) repairs damage caused by exogenous agents such as mutagenic and carcinogenic chemicals as well as ultraviolet radiation. Several genes have been cloned XPA through XPG. MMR genes repair single base mismatches as well as insertion/deletion loops (IDL) of up to 10 nucleotides. MMR gene dysfunction is characterized by MSI and is responsible for HNPCC. The so-called mutator phenotype of HNPCC is characterized by an increased genome-wide mutation rate. This is in contradistinction to sporadic colon cancer or familial polyposis, which is characterized by loss of whole portions of chromosome alleles known as loss of heterozygosity (LOH).<sup>10</sup>

### MMR Function in Single Cells

This MMR repair system has been well studied and elucidated in single cell organisms. There are three main components of this repair system, namely, MutS, MutL, and MutH.

MutS recognizes base mismatches and IDL. Acting as an adenosine triphosphatase (ATPase) homodimer, MutS attaches to the abnormal DNA, undergoes a conformational change, and translocates or slides along the DNA, allowing the formation of a large DNA loop. As the DNA is being shortened into the loop, the abnormal mismatches are included in the DNA loop. MutL, another ATPase, again acting as a homodimer, identifies the loop segment of DNA that includes the mismatch. The loop continues to enlarge, and a DNA-methylated (DAM) GATC base sequence is encountered. The new DNA strand is recognized because it is not methylated. At this point, MutH, an endonuclease, is activated and a nick in the DNA strand is made. This can occur on either the 3' or 5' side of the DNA strand. Bidirectional exonucleases excise the abnormal DNA strand and DNA polymerase resynthesizes a new strand.<sup>11</sup>

### MMR Function in Humans

MMR genes have been found in every organism studied and are homologous with yeast and bacterial MMR genes. In humans, five MutS genes have been identified (*MSH2*, *MSH3*, *MSH4*, *MSH5*, *MSH6*) and four MutL genes (*MLH1*, *PMS1*, *PMS2*, *MLH3*). No MutH gene equivalent has been discovered. In humans, MutS and MutL presumably directly activate exonucleases without the need for a MutH gene.

Unlike single cell MMR genes that function as a homodimer, human MMR genes function as a heteroduplex (Figure 38-1). MSH2 acts as a "scout" and identifies the mismatches in the new DNA strand. It then complexes with MSH6 to form the MutS $\alpha$  complex that identifies single nucleotide misrepairs. Alternatively, MSH2 can complex with hMSH3 forming MutS $\beta$  complex that repairs IDL with up to 10 base pairs.

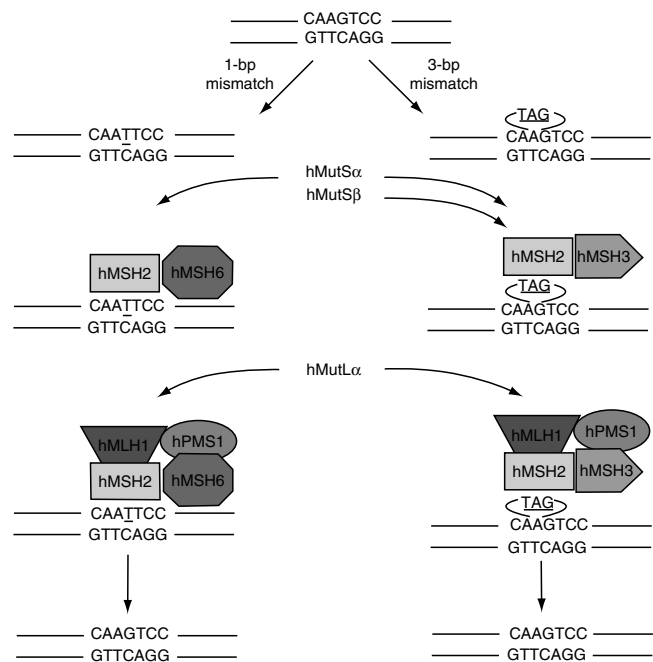

FIGURE 38-1. The DNA MMR system can correct either single base-pair mismatches or larger loops of mismatched DNA. hMSH2 serves as the "scout" that recognizes mismatched DNA. It forms a complex with either hMSH6 or hMSH3, depending on the number of mismatched nucleotides. A second heterodimeric complex (hMLH1/hPMS1) is then recruited to excise the mispaired nucleotides. hMUTS $\alpha$  = hMSH2/hMSH6; hMUTS $\beta$  = hMSH2/hMSH3; hMUTL $\alpha$  = hMLH1/hPMS1. bp = base pair. (Reprinted with permission from Chung and Rustgi.<sup>29</sup>)

These pathways are not mutually exclusive as MutS $\alpha$  can recognize 2–4 base IDL, but there is less affinity. Likewise, MutS $\beta$  can recognize single base pair insertions and deletions. Both MSH3 and MSH6 must be abnormal to have complete loss of hMSH2-dependent MMR.<sup>12</sup>

MLH1 and PMS2 bind to form a second heteroduplex that interacts with the MutS duplex, stimulating excision and resynthesis. The exact mechanism of action of the human MutL MMR genes is not known. The most frequently mutated genes in HNPCC are *MLH1* (33%) and *MLH2* (31%) and rarely *PMS2* or *PMS1*.<sup>13</sup> Of the mutations identified, 90% occurred in *MLH1* and *MSH2*.<sup>14</sup> Recently, a metaanalysis of index families fulfilling the Amsterdam criteria, worldwide, revealed that a mutation in *MLH1* is found in 25.5%–29.6% of families, and *MSH2* is found in 14.8%–21.6% of families. In general, the overall mutation discovery rate is less than 50%.<sup>14</sup>

MutS has two functions—mismatch recognition and ATPase activity. Both functions are essential for repair in 7 of 8 possible single-base mismatches. The C:C misrepair is not recognized, but fortunately occurs least frequently.<sup>10</sup> It is generally agreed that mismatched DNA stimulates ATP hydrolysis as part of the repair mechanism, but there is disagreement as to the role this has in MMR gene function. It is agreed that

the MutS with adenosine 5'-diphosphate (ADP) has the highest affinity for the mismatch.

In the translocation model, ATP enables MutS $\alpha$  or  $\beta$  to move like a motor protein away from the mismatch. This allows formation of an  $\alpha$  loop similar to that described in the *E. coli* model. When the MutS ADP is attracted to the MMR, it is converted to MutS ATP, which has reduced affinity for the mismatch and activates the binding sites for translocation along the newly synthesized DNA. This draws flanking DNA toward the mismatch, causing it to form into an  $\alpha$  loop.<sup>15</sup>

The molecular switch theory proposes that this transposition from ADP to ATP in the MutS gene switches the repair complex on and off. MutS ADP has a high affinity for the misrepaired gene and then it binds to it. When this occurs, ADP is transformed to ATP and causes a conformational change in the MutS complex. A clamp is formed around the mismatched DNA. Several of these clamps surround the misrepair and signal either a repair process or induce apoptosis via a P53 independent pathway. When ATP is hydrolyzed to ADP, the clamp is switched off and is released from the DNA strand. The MutS complex is now recycled and can recognize a new mismatch. The ATP hydrolysis in this model turns the MMR switch off and on but is not intrinsically involved in the actual repair.<sup>16</sup>

The third theory is called "transactivation." MutS binds both ATP and the mismatch DNA simultaneously in order to activate MMR. The ATPase in this model functions as a proofreader and binds only to heteroduplex DNA. Once the mismatch and the ATP are bound, it is believed that a signal is produced to authorize DNA repair.<sup>17</sup>

### Genes Implicated in HNPCC Carcinogenesis

When MMR genes are dysfunctional, the myriad genes that have microsatellites in their coding region can become inactivated, causing acceleration of tumorigenesis. Transforming growth factor beta Type II receptor gene (*TGF $\beta$ RII*) has a 10 adenine-repeating tract in its coding area. *TGF $\beta$ RII* was found to be mutated in 70%–90% of cancers with MSI.<sup>18,19</sup> *TGF $\beta$ RII* acts as a tumor suppressor gene and is a strong inhibitor of epithelial growth. Insulin-like growth factor II receptor gene (*IGFRII*) binds insulin-like growth factor I, thus antagonizing its growth stimulating effects. IGFRII also activates TGF $\beta$ I from its latent to active form. There is a long 8 repeat guanine tract in *IGFRII*. In 90% of tumors studied, either *TGFRII* or *IGFRII* was abnormal but not both. This suggests that the genes are part of the same tumorigenesis pathway.<sup>20</sup>

The *BAX* gene is another gene found to be mutated in up to 54% of MSI-H colorectal tumors.<sup>19</sup> It is involved in apoptosis and is a downstream gene often activated by the P53 gene. It is of note that MSI-H tumors have wild-type *P53*. In the coding region of the *BAX* gene, there is an 8 guanine repeating tract spanning codons 38–41 that is highly susceptible to frameshift mutations.<sup>21</sup> Other genes with microsatellites in

the coding region are *MSH3*, *MSH6*, *TCF4*, *BLM* (19), *Capase-5*,<sup>22</sup> and the *PTEN* gene and *APC*.<sup>23</sup>

Because only 50% of HNPCC tumors have mutations in known MMR genes, a search for other unique gene pathways that could affect DNA repair is ongoing. *RAF* oncogenes are a family of genes that encode kinases and mediate cellular responses to growth signals. *BRAF* is a *RAF* gene that is common in MMR-deficient tumors and in colorectal tumors that have a normal *KRAS* gene. Both *BRAF* and *KRAS* mutations are found in all stages of colon cancer and in adenomas greater than 1 cm.<sup>24</sup> Another DNA repair gene is *MED1* that has endonuclease activity and could function as a MutH gene. It has four hypermutable tracts of adenine repeats. *MED1* alteration may contribute to progressive MSI as part of "mutators mutation" phenomena.<sup>25</sup>

### Pathologic Features

There are unique pathologic features associated with the mutator phenotype of HNPCC. Cancers are often mucinous or poorly differentiated with signet ring cells.<sup>26</sup> Despite what appears to be unfavorable histology, the incidence of lymph nodes is 35% compared with 65% in sporadic colon cancer.<sup>27</sup> In 9% of patients, there is an extensive peritumoral lymphocytic infiltration that may be the result of an enhanced immunologic response (Figure 38-2A). Others have described a Crohn's-like lymphocytic reaction with the accumulation of both B and T lymphocytes around the tumor (Figure 38-2B).<sup>28</sup> Flow cytometry showed most HNPCC tumors to be diploid. Because HNPCC cancers have small unstable tracts, large chromosomes are not lost. This is in contradistinction to the frequent aneuploidy of sporadic colon cancer where tumorigenesis is related to the LOH.<sup>29</sup>

### Clinical Features of HNPCC

Affected individuals in HNPCC have an increased risk of colon cancer and other extracolonic cancers as demonstrated in Table 38-1. Colon cancer is the most frequently diagnosed cancer in HNPCC (80%) and endometrial cancer is the most frequent extracolonic cancer (50%–60%).<sup>29</sup> Colorectal cancers in HNPCC are proximal to the splenic flexure (68% in HNPCC versus 49% of sporadic cancers), are more likely to have associated synchronous cancers (7% HNPCC versus 1% sporadic colon cancer), and will have increased metachronous cancers at 10 years (29% HNPCC versus 5% sporadic cancers).<sup>30</sup> Similarly, women with HNPCC-related endometrial cancer have a 75% risk of a second cancer during a 26-year follow-up. The median age of onset of colon cancer is 42 years and for endometrial cancer it is 49 years.<sup>31</sup>

Despite being termed hereditary nonpolyposis colon cancer, a polyp is still the precursor lesion for a colorectal cancer. The phenotype is not the extensive polyposis as seen in familial

Petras, MD, National Director Gastrointestinal Pathology Services, Ameripath Inc., Oakwood Village, OH and Associate Professor of Pathology, Northeastern Ohio University College of Medicine).

adenomatous polyposis (FAP). In a Danish surveillance study, 70% of mutation carriers developed adenoma by age 60 as opposed to 37% in the control group. The adenomas in the mutation carrier group were larger and had a higher proportion of villous components and high-grade dysplasia. Adenomas were located in the proximal colon and 70% of the polyps had absent MMR genes on immunohistochemistry.<sup>32</sup> One cancer is prevented for every 2.8 polyps removed in HNPCC patients<sup>33</sup> compared with one cancer being removed for every 41–119 polypectomies in the general population.<sup>34</sup> It is estimated that malignant transformation occurs in 3 years in HNPCC as opposed to 10 years in sporadic colon cancer.

TABLE 38-1. Lifetime risks for cancer associated with the hereditary nonpolyposis colorectal cancer syndrome

Type of cancer	Persons with HNPCC	General population
Colorectal	80–82	5–6
Endometrial	50–60	2–3
Gastric	13	1
Ovarian	12	1–2
Small bowel	1–4	0.01
Bladder	4	1–3
Brain	4	0.6
Kidney, renal, pelvis	3	1
Biliary tract	2	0.6

In other studies, HNPCC polyps are found throughout the colon and not necessarily clustered near the proximal colon where the predominance of cancers are seen.<sup>35</sup>

Two other types of polyps—the flat adenoma and serrated adenoma—have been implicated as possible precursors of the HNPCC cancers. Flat adenomas are found proximally in up to 50% of HNPCC patients<sup>36</sup> (Figure 38-3A and B). Approximately 20% of flat adenomas will be MSI-H and will also have a mutation in the *TGF $\beta$ R2* gene.<sup>36</sup> These polyps are difficult to detect during colonoscopy without dye spray techniques (e.g., methylene blue). Furthermore, flat adenomas with advanced histology (high-grade dysplasia or cancer) are significantly smaller (10.75 mm) than comparable polypoid lesions (20 mm).<sup>37</sup> It has been proposed that hyperplastic polyps, serrated adenomas, and serrated adenocarcinomas form a morphologic continuum. Carcinomas associated with serrated adenomas have a predilection for the cecum and the rectum and are often mucinous in nature. MSI is found in 37% of the cases.<sup>38</sup>

## Genotype–Phenotype Relationships

There are very few studies that evaluate phenotype–genotype correlations. One study of 35 families found the *MSH2* mutation to be associated with a late age onset of rectal cancer and more extracolonic cancers than in the *MLH1* mutation-positive group.<sup>39</sup> Mutations in *MSH2* were associated with an increased risk of rare extracolonic cancers in another study.<sup>40</sup> Amsterdam-positive families with known mutations were compared with Amsterdam-positive families without a known mutation. The subgroup without mutations had an increased risk of rectal cancer, fewer HNPCC-related cancers, a lower frequency of multiple colorectal cancers, and a later age of onset.<sup>41</sup>

The Muir-Torre syndrome is characterized by sebaceous adenomas, sebaceous carcinomas, and keratoacanthomas associated with multiple visceral tumors. Colorectal cancers are most frequently found (51%) and are often proximal to the splenic flexure (60%). Although only 25% of Muir-Torre patients develop a polyp, 90% of patients who develop polyps

FIGURE 38-3. **A** Colonoscopic view of a flat adenoma in the cecum that could easily be overlooked. Such polyps are more easily seen using dye-spraying techniques. **B** Microscopic view of same polyp after endoscopic removal, showing severe dysplasia,  $\times 100$  magnification. Petras, MD, National Director Gastrointestinal Pathology Services, Ameripath Inc., Oakwood Village, OH and Associate Professor of Pathology, Northeastern Ohio University College of Medicine).

will develop colon cancer. The second most frequent tumors are genitourinary (24%).<sup>42</sup>

Germline mutations in *MLH1*<sup>43</sup> and *MSH2*<sup>39</sup> have been identified. As expected, many of the tumors exhibit MSI. The visceral tumors are often low grade, and prolonged survival in the presence of metastatic disease has been reported. The median age of diagnosis is 55 years and only 60% will have a positive family history.<sup>42</sup> Aggressive screening and surveillance for colorectal and genitourinary cancers as recommended for HNPCC are warranted.

MUTS $\alpha$  (a heterodimer of MSH6 and MSH2) senses and repairs single base mismatches. In a study of 91 familial

non-HNPCC patients, six patients (7.0%) were found to have *MSH6* mutations but none were found in 58 HNPCC patients. These tumors were microsatellite low (MSI-L), had a median onset of 61 years, and did not fulfill classic Amsterdam criteria.<sup>44</sup> Other studies of 90 mutation-negative HNPCC families and HNPCC-like families found only one *MSH6* mutation.<sup>45</sup>

Despite this discrepancy, the International Collaborative Group has collected more than 30 potentially pathogenic *MSH6* mutations. Thirty-five percent of these mutations involve only one amino acid.<sup>46</sup> *MSH6* is the third most frequently affected gene in HNPCC. Because MutS $\beta$  (heterodimer of MSH2 and MLH1) can act redundantly to repair single base mismatches, and insertion–deletions of large dinucleotide sequences is intact, there are less frame shifts. This results in less loss of function in affected genes. A weaker phenotype occurs with slower tumorigenesis and cancers that are MSI-L.<sup>45</sup> *MSH6* knockout mice display an MSI-L phenotype and the majority of tumors in mice are endometrial or cutaneous with few intestinal cancers.<sup>47</sup>

Colorectal cancers are more frequently left-sided in *MSH6* carriers.<sup>48</sup> The risk of endometrial cancer is increased over *MSH2* or *MLH1* carriers (76% versus 30%) and colon cancer is decreased (32% versus 80%). The median age of onset is 55 years.<sup>49</sup> Therefore, a distinct phenotype has emerged, characterized by a clustering of endometrial cancer, a decreased frequency of colorectal cancer, later age of onset, and MSI-L cancers. Some *MSH6* cancers are MSI-H. Combined MSI testing and immunohistochemistry, as well as a distinct phenotype, are used to select families for *MSH6* mutation analysis.<sup>49</sup>

## Diagnosis

The key to the diagnosis of HNPCC is a detailed family history and subsequent construction of a family pedigree. Amsterdam criteria (Table 38-2) were created to define clinical criteria to identify patients with a high probability of

TABLE 38-2. Amsterdam criteria

### Amsterdam criteria

- At least three family members with colorectal cancer, one of whom is first-degree relative of the other two.
- At least two generations with colorectal cancer.
- At least one individual <50 y at diagnosis of colorectal cancer.

### Amsterdam criteria II

- At least three family members with HNPCC-related cancer, one of whom is first-degree relative of the other two.
- At least two generations with HNPCC-related cancer.
- At least one individual <50 y at diagnosis of HNPCC-related cancer.

### Modified Amsterdam criteria

- Two first-degree relatives with colorectal cancer involving two generations.
- At least one case diagnosed before 55 y *or*
- Two first-degree relatives with colorectal cancer and a third relative with endometrial cancer or another HNPCC-related cancer.

Source: Modified with permission from Chung and Rustgi.<sup>29</sup>

having an inheritable form of colon cancer not associated with diffuse polyposis. For day-to-day clinical purposes, the original definition was too restrictive because it did not account for the extracolonic malignancies associated with HNPCC, the decrease in the average family size, the late onset variants of HNPCC, and the problems with incomplete data recovery. Modifications of the Amsterdam criteria have occurred and are known as Amsterdam II and modified Amsterdam criteria (Table 38-2). A National Cancer Institute workshop on HNPCC was held in 1996. Out of this meeting, a broader, less-specific set of guidelines was introduced (Table 38-3).<sup>50</sup> These criteria, known as the Bethesda criteria, were formulated to increase sensitivity at the expense of specificity and focused on individual patients. Because MSI status is linked to HNPCC and the clinical criteria were broadened, MSI testing of this population can define a sub-population for genetic testing.

It is important to remember that HNPCC is a clinical diagnosis and genetic testing cannot prove a family does *not* have HNPCC. Gene testing can potentially decrease the cost and morbidity of screening and surveillance, help with surgical decisions, stratify patients for chemoprevention, and help patients cope with job and family planning.

Table 38-4 compares the sensitivity and specificity of several of the clinical criteria for identifying a pathologic mutation. This table is derived from a cohort of 70 families. Only 18 families had a mutation found and six of these were inconclusive.<sup>51</sup>

## Genetic Testing

Gene sequencing of *MSH2* and *MLH1* is now commercially available. This testing may not be covered by insurance companies and the cost is approximately \$1750. Furthermore, interpretation of gene testing is complicated because mutations are spread diffusely throughout *MSH2* and *MLH1*. Mutations themselves are a broad spectrum of truncating, frameshift, and missense mutations. A missense mutation results in the substitution of a single amino acid, and the effect on protein function may be negligible. This type of missense mutation is often reported as a mutation of unknown significance. Approximately 31% of *MLH1* mutations are this

TABLE 38-3. Modified Bethesda guidelines

### Amsterdam criteria

- Patient with two HNPCC-related tumors.
- Patient with colorectal cancer with first-degree relative with HNPCC-related cancer; one of the cancers at <50 y or adenoma at <40 y.
- Patient with colorectal cancer or endometrial cancer at <50 y.
- Patient with right-sided, undifferentiated colorectal cancer at <50 y.
- Patient with signet ring colorectal cancer at <50 y.
- Patient with adenoma at <40 y.

type.<sup>52</sup> Missense mutations must meet strict criteria to be considered pathologic: Is the amino acid change conserved across species? What is the mutation population frequency? Does the mutation segregate with cancer in kindreds? Finally, does the alteration affect gene function? A data bank of known mutations is kept by the International Collaborative Group of HNPCC now known as InSiGHT.

Only half of well-characterized HNPCC families have a mutation identified. This suggests that there are other unknown MMR genes or that current techniques are lacking in sensitivity. Before genes are sequenced, they are amplified by polymerase chain reaction (PCR) and both alleles are sequenced simultaneously. A wild-type allele may mask a very short mutated allele. A technique called conversion has been used to detect these hidden mutations. Patient mononuclear cells are fused with a specially designed rodent cell line. One quarter of the hybrids contain a single copy of the human genes, thus the human gene is now haploid and can be analyzed and characterized.<sup>53</sup> In a series of 10 suspected HNPCC families, no mutations were found on initial gene sequencing, but a mutation was found in all 10 when the conversion technique was used.<sup>54</sup>

Once criteria to identify HNPCC families had been broadened, direct gene testing by sequencing was less effective (Table 38-4). Two techniques that are more cost effective—MSI testing and immunohistochemistry—are performed before gene sequencing if the strict Amsterdam criteria or the Bethesda 1–3 criteria are not fulfilled. MSI testing is done on tissue. An international workshop was held and five validated microsatellite markers were selected to ensure uniformity of diagnosis between different laboratories. These microsatellite loci include two polyadenine sequences (BAT25 and BAT26) and three dinucleotide repeat sequences (D2S123, D5S346, D172S250).<sup>55</sup> Microsatellite testing can be done on fresh tissue or paraffin blocks. A typical test for MSI is seen in Figure 38-4. If none of the markers are unstable, the tumor is called microsatellite stable (MSS). When only one marker is unstable, this is termed MSI low (MSI-L), and microsatellite high (MSI-H) will have two or more markers positive. When a tumor is MSI-H, then gene sequencing of *MSH2* or *MLH1* can be performed. The cost of MSI testing is \$700.

Immunohistochemistry is a technique using antibodies to *MSH2* and *MLH1*. This is a standard laboratory procedure (Figures 38-5 and 38-6) to identify which MMR gene is abnormal so that only one MMR gene needs to be sequenced.

FIGURE 38-4. Detection of MSI with the use of fluorescent labeling of PCR products analyzed in an automatic sequencer. Two markers are analyzed in the same track: the mononucleotide repeat marker BAT26 is shown on the left, and the dinucleotide marker D2S123 is shown on the right. The upper tracking is from germline DNA from blood. The lower tracing is from DNA extracted from a histologic section of a tumor containing more than 50% tumor cells. For marker BAT26, germline DNA shows a single peak, indicating that the patient is homozygous for this marker (arrow). Tumor DNA shows, in addition to the normal allele (single arrow), a new allele (double arrows) that has lost approximately five nucleotides. This constitutes microsatellite stability. For marker D2S123, germline DNA is homozygous, whereas tumor DNA shows two new alleles (triple arrows), one with a loss of approximately 10 nucleotides (left) and one with a gain of two nucleotides (right). Thus, the tumor shows MSI with both markers. All peaks display “stutter”—that is, small amounts of material with a gain or a loss of one or a few nucleotides. This is a normal phenomenon. (Reprinted with permission from Lynch HT, De la Chapelle A. Hereditary colorectal cancer. *N Engl J Med* 2003;348:919–932. Copyright © 2003 Massachusetts Medicine Society. All rights reserved).

If immunohistochemistry reveals that one gene is absent, this is presumptive evidence that the patient probably has HNPCC. Recently, 28 families with a known *MSH2* or *MLH1* mutation were studied. The MSI panel identified all families as being MSI-H, but in five cases a mutant protein was

expressed that could be detected by immunohistochemistry thereby producing a false test.<sup>56</sup>

A cost analysis has been performed on four different gene testing strategies: 1) gene sequencing for Amsterdam-positive individuals (“Amsterdam” strategy); 2) tumor MSI analysis of individuals who meet less stringent modified clinical criteria

FIGURE 38-5. hMLH1 immunohistochemistry. Blue arrow indicates positive nuclear staining for the presence of hMLH1 protein within an inflammatory cell. Black arrow demonstrates the absence of protein within cancer cells,  $\times 400$  magnification. (Courtesy of Robert E. Petras, MD, National Director Gastrointestinal Pathology Services, Ameripath Inc., Oakwood Village, OH and Associate Professor of Pathology, Northeastern Ohio University College of Medicine).

Petras, MD, National Director Gastrointestinal Pathology Services, Ameripath Inc., Oakwood Village, OH and Associate Professor of Pathology, Northeastern Ohio University College of Medicine).

and germline mutation of individuals with MSI-H tumors (“modified” strategy); 3) MSI testing of all colorectal cancers and germline analysis of individuals with MSI-H tumors (“test-all” strategy); and 4) germline mutation analysis of individuals who satisfy the Amsterdam criteria and tumor MSI analysis of the remaining individuals who meet less stringent criteria (“mixed” strategy). The least expensive strategy was the Amsterdam only strategy, but only 10% of mutations were identified. The modified and mixed strategies identified 60% and 75% of the mutations, respectively. These strategies were \$400.00 less expensive than the test-all strategy in the model. Only seven mutations were missed by the mixed strategy per 1000 colorectal cancers. The cost for finding each of these seven extra mutations in the test-all strategy was \$51,000 per mutation.<sup>57</sup> Currently, a mixed strategy seems most appropriate. MSI testing of all colorectal cancers may become standard in the future because of its potential relationship to increased survival and response to chemotherapy. This would make testing all colorectal cancers the best medical practice.

Before genetic testing in HNPCC is done, informed consent must be obtained. Testing should begin with an affected individual (an HNPCC cancer has been diagnosed). It is best to choose a proband with the earliest age of onset of cancer. For a patient who meets the Amsterdam II criteria or the first three Bethesda criteria, it is reasonable to proceed to germline testing. When the clinical risk is lower, MSI testing or immunohistochemistry should be performed first. If the tumor stains positive for MSH2 and MLH1 or is MSS or MSI-L, no further genetic testing is performed. However, if the tumor is MSI-H, or there is absent staining on immunohistochemistry for MLH1 or MSH2, then gene sequencing is performed. Note that only 50% of Amsterdam families have an MMR mutation on gene sequencing, and that HNPCC is a clinical diagnosis, *not* a genetic diagnosis. Further genetic testing can be performed in a research setting when mutations in *MSH2* and *MLH1* are not found. Conversion testing as previously described can be performed as well as testing for *hMSH6* (especially in MSI-L patients or when there are late onset HNPCC pedigrees).

Because of the high number of missense mutations in HNPCC, the gene-sequencing test may be reported as a mutation of unknown variance. This is a non-informative test. When the proband has a negative or a non-informative test, no further gene testing in the at-risk family members is possible. All family members require intensive surveillance. When the proband has a positive mutation, the family members that test positive are carriers of the abnormal gene and need extensive surveillance and/or prophylactic surgery. However, when the proband’s test is positive and the at-risk family members are mutation negative, these family members are not carriers of an MMR gene. Their colon cancer risk is that of the general population. They should be screened accordingly. The cost of screening family members for a known mutation is \$300.

There are also a number of ethical considerations regarding the ordering of genetic testing with respect to insurance

discrimination. Currently, nearly all states have passed legislation prohibiting genetic discrimination in health insurance; however, only “asymptomatic” individuals are protected by such legislation.<sup>58,59</sup>

## Registries

Once a diagnosis of HNPCC is suspected, a referral to a registry for inherited colorectal cancer or to a cancer center with a high-risk clinic is important. A registry has a database or list of families and their members who have a high frequency of colorectal cancer. Personnel at the registry consist of a coordinator, oftentimes a genetic counselor, and a physician director. The whole focus of the registry is patient care, education of patients, families, and referring physicians, and promotion of collaborative research. No single physician has the time to educate high-risk individuals about autosomal dominant inheritance and the cancer risk of inherited colorectal cancers; to gather factual medical data about widely dispersed family members and construct a pedigree; to give counsel about the risks and benefits of gene testing; to perform gene testing and carefully and confidentially explain the results; and finally to coordinate treatment and life-long surveillance. Registry personnel provide further support for myriad problems such as family stress, health insurance difficulties, and job discrimination. A local registry can be found by accessing the Collaborative Group of the Americas on Inherited Colorectal Cancer at <http://www.cgaicc.com>. To emphasize the need for expert counseling and care, a study of 177 patients undergoing genetic testing for FAP was performed. Of those patients, only 18% received pretest counseling, 16% gave a written consent, and a full 30% were given incorrect test interpretation.<sup>60</sup>

## Surveillance

In 1997, a number of medical societies proposed uniform screening criteria for colorectal cancer, proposing separate criteria for average- and high-risk patient groups. Patients with HNPCC or a family history thereof constitute one of these high-risk groups. Because of the 80% lifetime risk of developing colorectal cancer, the American Cancer Society recommends colonoscopy every 2 years beginning at age 21, and annual colonoscopy recommended beginning at age 40.<sup>61</sup> Because cancers in HNPCC can occur at very young ages and develop within 2 years of a negative colonoscopy,<sup>62</sup> it is important to stress to patients that if they have symptoms, they should be checked regardless of their age and even if they have had a recent negative colonoscopy. Colonic neoplasia in individuals with HNPCC seems to develop more rapidly than in average-risk nonaffected individuals.<sup>63</sup> For this reason, many, including the authors, believe that colonoscopy in these individuals should be performed annually rather than every

2 years, even in young individuals. Adenomas in HNPCC patients occur earlier and are more likely to be villous.<sup>64</sup>

The value of screening colonoscopy in HNPCC was demonstrated by Jarvinen and colleagues<sup>65</sup> who studied a group of 252 individuals belonging to 22 HNPCC families. Of these, 137 participated in screening colonoscopy every 3 years, whereas the remainder refused such evaluation. Colorectal cancer developed in 8% of the screened family members, compared with 16% of those who refused screening. In those individuals who were known to have a DNA MMR gene mutation, the rate of colorectal cancer in those who underwent screening was 18% compared with 41% in those who did not undergo screening. All cancers that developed in the screened group were either Dukes' A or B lesions, with no attributable deaths, compared with more advanced lesions in the unscreened group and nine deaths attributed to cancer (8%). Jarvinen and colleagues demonstrated that colonoscopic screening at 3 yearly intervals in HNPCC family members not only reduced the risk of colorectal cancer by half but prevented deaths caused by colorectal cancer and reduced the mortality by two-thirds. Similarly, the study by Rekonen-Sinislao and associates<sup>66</sup> also demonstrated an earlier cancer stage at diagnosis and better 10-year survival in those individuals in whom colorectal cancer was detected during a colonoscopic screening examination compared with those in whom diagnosis was made based on symptoms.

Because of the high risk of endometrial cancer in women, annual transvaginal ultrasound to examine the endometrium, preferably with endometrial aspiration, is recommended beginning between ages 25 and 35 years because the increased risk for gynecologic cancer in these patients begins at age 25.<sup>67,68</sup> There are no data demonstrating the efficacy of this type of screening. One recent study has even shown such screening not to be effective.<sup>69,70</sup> It is important to note that, should a patient from an HNPCC family be diagnosed with endometrial cancer, they should undergo surveillance colonoscopy before hysterectomy in the event that colonic pathology is present and colonic resection is required at the same surgery.

## Treatment

As with other colorectal conditions, there is not one operation that suits all patients. The majority of patients with a diagnosis of HNPCC, based on the finding of an existing colorectal cancer or an advanced adenoma, will be offered colectomy and ileorectal anastomosis (IRA). This is thought to be the operation of choice, which removes the "at risk" organ, reduces cancer risk, preserves anal sphincter function, and retains the reservoir capacity of the rectum. This operation eliminates the need for annual surveillance colonoscopy, because only rigid or fiberoptic examination of the rectum is required. The estimated risk of rectal cancer after colectomy

and IRA is, however, 12% at 12 years.<sup>71</sup> This operation is clearly not suited for those who will not be compliant with follow-up examinations. Colectomy and IRA may not be the ideal operation for the patient with impaired anal sphincter function because of either obstetric injury or age or for patients with decreased mobility. The operation also is not suited for patients with more than three bowel movements per day, because these individuals will frequently have significant diarrhea and poor functional results after colectomy. In some patients, a lesser resection may be in order as a result of any of these reasons. It is however *essential* that both the patient and physician recognize the need for ongoing annual colonoscopy, because the risk for a metachronous colon cancer in HNPCC is 45%.<sup>72</sup> *Conversely*, in the very young patient with a long projected life expectancy or in the patient who is not likely to be compliant with follow-up examinations, total colectomy with stapled ileal pouch anal anastomosis may be the preferred procedure, because it removes nearly all of the at-risk colorectal mucosa.

In cases of rectal cancer not involving the sphincters, either an anterior resection, coloanal anastomosis or colectomy and ileal pouch anal anastomosis can be considered. In the event that the latter option is chosen, preoperative endorectal ultrasound staging is desirable. In cases of a uT2 or uT3 or possible uN1 cancers, preoperative chemoradiation should be given whenever possible, because ileal pouches tolerate radiation poorly.

In women undergoing colectomy, strong consideration should be given to performing a hysterectomy and bilateral salpingo-oophorectomy in the patient who has completed childbearing, because of the increased risk of both endometrial and ovarian carcinoma.

There is controversy as to whether surgical treatment or continued surveillance should be offered to the asymptomatic patient who has a mutation identified by genetic testing, but an as yet "normal" colon. Several studies have examined this question using decision analysis methods; however, factors such as patient compliance must be taken into account.<sup>73,74</sup>

## Prognosis

The survival rate in HNPCC patients with colorectal cancer is better than that of patients with sporadic colorectal cancer when matched for stage and age of onset.<sup>75,76</sup> There is some question of whether or not patients with Stage II or III microsatellite unstable colorectal cancers benefit from 5-fluorouracil-based adjuvant therapy. Whereas some studies report that patients with microsatellite unstable tumors do not benefit from such therapy, other studies suggest a benefit.<sup>77,78</sup> One possible explanation for the differences in such studies could be attributable to different underlying causes of this MSI (e.g., *MLH1* gene-promoter methylation in some patients with sporadic colorectal cancer). Although germline mutations are involved in HNPCC, other mechanisms such as somatic

mutations and the loss of heterozygosity of mismatch-repair genes may be involved in microsatellite unstable tumors.<sup>79</sup>

## Chemoprevention

Currently, there is much interest in chemoprevention. Whereas data exist regarding the efficacy of nonsteroidal antiinflammatory drugs (NSAIDs) in reducing the risk of colorectal cancer in the general population, such data are lacking for HNPCC.<sup>80,81</sup> Currently, NSAIDs and novelose undigested starch are being studied in HNPCC. The CAPP II trial is a controlled, randomized trial of colorectal polyp and cancer prevention using aspirin and resistant starch in carriers of HNPCC. It is a Phase II multicenter study with a multifactorial design, being performed at 33 centers. Patients are randomized to active agent or placebo, the active agents consisting of 600 mg of aspirin and 30 g of resistant starch for 2–4 years.<sup>82</sup> The accrual goal is 1000 HNPCC gene carriers. This study, which began in January 1999 and is projected to end in December 2006, is designed to detect differences in adenoma incidence.<sup>69,82</sup>

Calcium and vitamin D intake have been associated with a decreased risk of sporadic colorectal cancer.<sup>83</sup> Supplemental dietary calcium is thought to inhibit the proliferative effect of bile acids and fatty acids on the colonic mucosa by precipitating these luminal surfactants.<sup>84</sup> A trial of supplemental calcium in HNPCC families did not demonstrate a decrease in epithelial proliferation, although the sample size was small and the study was conducted before genetic testing was available.<sup>69,85</sup>

## Conclusion

Our knowledge about HNPCC continues to grow. This disorder is associated with a germline mutation in one of several MMR genes. Genetic testing is currently available for mutations in genes *hMLH1* and *hMHS2*. Suspicion of this disorder in a given patient is raised by a family history of early age onset cancer, an increased number of first-degree relatives with colorectal cancer, or an HNPCC-related cancer. Endometrial cancer is the most common extracolonic cancer. Although there is debate regarding the frequency and beginning of screening, most clinicians believe that colonic examinations yearly or every 2 years should be performed beginning in patients in their early 20s. Prophylactic colectomy may be offered to known mutation carriers as well as members of at-risk families who develop advanced adenomas. Removal of all of the colon and IRA or colectomy and IPAA are the operations of choice, because they remove most “at-risk” colonic mucosa. In the event of the former, continued surveillance of the rectum is mandatory. With careful surveillance and management, colorectal cancer can be prevented in these patients and the mortality rate decreased. In those who develop colorectal carcinoma, the overall survival rate is more favorable than that of patients with sporadic colorectal cancer.

## Appendix I: Practice Parameters for the Identification and Testing of Patients at Risk for Dominantly Inherited Colorectal Cancer

Prepared by The Standards Task Force, The American Society of Colon and Rectal Surgeons, The Collaborative Group of the Americas on Inherited Colorectal Cancer

–Take a family history. This is the first step in recognizing families possibly affected by inherited colorectal cancer.

–Document a suspicious pedigree; a family tree based on the recollection of family members is not solid enough evidence. Request medical records to confirm diagnosis.

–Identify criteria for genetic testing. FAP is easily recognized clinically when patients present with more than 100 colorectal adenomas. Fewer adenomas are needed for a diagnosis when a patient is part of an established kindred. The Amsterdam criteria are a way of clinically identifying families with hereditary nonpolyposis colorectal cancer, where an MMR gene mutation can be detected.

–Testing for MSI in tumors is a screen for families with hereditary nonpolyposis colorectal cancer where the clinical pattern of the disease is suggestive but not strong enough to fulfill Amsterdam criteria.

–Offer surveillance to families not meeting the above criteria for genetic testing. Families with more than two first-degree relatives affected with colorectal cancer, especially if one is affected at a young age (<45 years), need to be offered endoscopic surveillance even if genetic testing is not indicated.

–Adhere to all protocols for genetic testing. Institutional review board approval, informed consent, and pretest and posttest counseling are the key elements of genetic testing for inherited colorectal cancer.

Summary: It is hoped that these guidelines will assist in the recognition and management of patients affected by syndromes of inherited colorectal cancer.

## Appendix II: Practice Parameters for the Treatment of Patients with Dominantly Inherited Colorectal Cancer (FAP and Hereditary Nonpolyposis Colorectal Cancer)

Prepared by The Standards Task Force, The American Society of Colon and Rectal Surgeons

James Church, MD; Clifford Simmang, MD; on behalf of the Collaborative Group of the Americas on Inherited Colorectal Cancer and the Standards Committee of The American Society of Colon and Rectal Surgeons.

## Section 1. Familial Adenomatous Polyposis

*Guideline 1: Treatment Must Be Preceded by Thorough Counseling about the Nature of the Syndrome, Its Natural History, Its Extracolonic Manifestations, and the Need for Compliance with Recommendations for Management and Surveillance; Level of Evidence: III*

Dominantly inherited colorectal cancer syndromes show a striking pattern of cancer in affected families. This is because of the high penetrance (penetrance = percent of patients with the mutation who have the disease) and often-severe expression (expression = clinical consequences of the mutation) of the mutations involved. FAP has a penetrance of close to 100%, colorectal cancer occurs at an average age of 39 years, and every affected patient is guaranteed at least one major abdominal surgery. Despite these calamitous prospects, families with FAP adapt well to their disease. Most patients are compliant with recommended treatments, take a keen interest in the syndrome, and have an active role in encouraging relatives to undergo screening. However, when a relative has a bad outcome, either because of severe disease or complications of treatment, family psychology may be affected. Noncompliance, denial, or a refusal to accept recommendations may ensue. The best way of avoiding both bad outcomes and an unfortunate response to them is to provide comprehensive, integrated counseling, support, and clinical services. These sorts of services are best provided through a department, registry, or center with personnel who have experience in managing patients and families with these syndromes.

*Guideline 2: Prophylactic Colectomy or Proctocolectomy Is Routine. The Timing and Type of Surgery Depend on the Severity of the Polyposis Phenotype and to a Lesser Extent on the Genotype, Age, and Clinical and Social Circumstances of the Patient; Level of Evidence: III*

The recommendation for prophylactic colectomy or proctocolectomy in FAP is based on the very high rates of colorectal cancer seen in patients who are not screened. In unscreened patients, the incidence of cancer is more than 60%. Appropriate screening and timely surgery can minimize this. The risk of cancer is not uniform, however, and is related to the severity of the colonic polyposis. Debinski and coworkers showed the rate of cancer for patients with >1000 colonic polyps was twice that of patients with <1000 colonic polyps. In its turn, the severity of the colorectal polyposis is often related to the site of the APC mutation in a family. The “hot spot” mutation at codon 1309 is in an area of the gene where mutations always cause severe disease. Mutations in codons 3 and 4 are classically associated with attenuated FAP whereas mutations in the part of codon 15 that is 3′ of codon 1450 are

usually associated with mild colorectal disease. Mutations in exons 5–15E have a variable colorectal phenotype, where some family members have relatively mild disease and others severe. The important aspects of surgery to consider are its timing, its type, and the technical options to be used.

### Timing of Surgery

Even in patients with severe disease, cancer is rare under the age of 20. At-risk family members start screening (either genetic or with flexible sigmoidoscopy) at around puberty. If there is a positive genotype or an adenoma is seen on sigmoidoscopy, colonoscopy is recommended. The risk of cancer of any individual patient can be estimated from the size and number of the adenomas seen on colonoscopy, and surgery planned accordingly. For patients with mild disease and low cancer risk, surgery can be done in mid-teen years (15–18 years). Where there is severe disease, or if the patient is symptomatic, surgery is done as soon as convenient after diagnosis.

### Type of Surgery

There are three main surgical options: colectomy and IRA, proctocolectomy with ileostomy (TPC), and proctocolectomy with ileal pouch–anal anastomosis (IPAA). For any of these options, there are choices of technique. The IPAA can be stapled, leaving 1–2 cm of anal transitional epithelium and low rectal mucosa, or it can be hand-sewn after a complete anal mucosectomy. The operation can be done conventionally (i.e., open), laparoscopically, or laparoscopically assisted. The ileostomy may be a regular end stoma or one of the varieties of continent ileostomy (K or T).

### Choice of Procedure

TPC is almost never done as a first operation except when a proctocolectomy is required and there is a contraindication to a pouch–anal anastomosis (e.g., a mesenteric desmoid tumor prevents the pouch from reaching the pelvic floor, a low rectal cancer invades the pelvic floor, or poor sphincters mean inability to control stool).

There is debate among authorities on which of the other two options should be preferred. Some recommend IPAA for all or almost all FAP patients, basing their recommendation on the risk of rectal cancer after IRA and equivalent quality of life after the two operations. Others have shown better functional outcomes after IRA and recommend it for patients with mild colorectal polyposis. However, the risk estimates of rectal cancer that are an overriding concern for the proponents of universal IPAA are based on data collected before restorative proctocolectomy was an option and may well be overestimates, especially when applied to patients with mild disease. The risk of rectal cancer after IRA is strongly related to the severity of colorectal polyposis at presentation, and IRA is a reasonable option in mildly

affected patients (<20 rectal adenomas, <1000 colonic adenomas). Retrospective data show that such patients have a very low risk of rectal cancer and include all those with attenuated FAP.<sup>30</sup> Bowel function is usually good after IRA, the operation is simple, and complication rates are relatively low. Bowel function after a stapled IPAA is almost as good as with an IRA, and the anastomosis is usually safe enough to allow consideration of the option of avoiding a temporary ileostomy.

There is no argument that patients with severe rectal (>20 adenomas) or colonic (>1000 adenomas), or those with a severely dysplastic rectal adenoma, a cancer anywhere in the large bowel, or a large (>3 cm) rectal adenoma should have a primary IPAA. A stapled IPAA is associated with a risk of anal transitional neoplasia in 30% of patients, although if serious neoplasia occurs (high-grade dysplasia or carpeting of the mucosa), the transitional zone can usually be stripped transanally and the pouch advanced to the dentate line. Even mucosectomy and hand-sewn IPAA is associated with anal neoplasia, although at a lower rate. The disadvantage of anal mucosectomy is worse function and increased complication rates. Both IRA and IPAA require lifelong surveillance of the rectum or pouch, because both are at risk of developing adenomas.

#### Choice of Technique

Mobilization of the colon using minimally invasive techniques such as laparoscopy or a Pfannenstiel incision is ideal for performing colectomy in children, because it minimizes the trauma of the surgery and the pain of the incisions. Its cosmetic result is appealing and it allows an early return to full activities. Whether minimally invasive techniques lower the risk of postoperative intraabdominal desmoid tumors is unknown, but the concept is attractive. A preoperative erect abdominal X-ray will usually show the position of the flexures and indicate whether use of a Pfannenstiel incision for mobilizing the colon is feasible.

*Guideline 3: Lifetime Follow-up of the Rectum (after IRA), Pouch (after IPAA), and Ileostomy (after TPC) Is Required; Increasing Neoplasia in the Rectum Is an Indication for Proctectomy; Level of Evidence: III*

The combination of a germline APC mutation, stasis of stool, and glandular epithelium is potent at producing epithelial neoplasia. Adenomas and carcinomas have been described in the rectum, the ileostomy, and the ileal pouch itself, with the risk and severity of neoplasia increasing with time. The risk of severe neoplasia is mainly determined by the position of the mutation in the gene, as reflected by the severity of the polyposis. Severely affected patients have such a high risk of rectal cancer after IRA that subsequent proctectomy is

almost routine and initial IPAA is to be preferred. Yearly endoscopic surveillance of the bowel after the index surgery for FAP is standard. Two-thirds of patients undergo spontaneous regression of rectal polyps after IRA, an effect that lasts 3–4 years. Subsequent surveillance will give a picture of the stability of the rectal mucosa. Small (<5 mm) adenomas can be watched, although random biopsies are done to exclude severe dysplasia. Increasing number and size of adenomas are indications for more frequent surveillance, and adenomas >5 mm should be removed cleanly with a snare. Repeated fulguration of rectal polyps over many years can cause dense scarring that makes cancers flat and hard to see, and rectal dissection during proctectomy can be very difficult. Chronic rectal scarring makes rectal biopsy difficult, because the forceps tend to “bounce off” the scarred mucosa. Furthermore, scarring leads to reduced rectal compliance, increased stool frequency, and a tendency to seepage and incontinence. Severe dysplasia, or villous adenomas >1 cm, are indications for proctectomy. Proctoscopy is best done with a video endoscope, because comfort is enhanced and the view is better. Excellent preparation and a good view are essential to pick up early cancers that can be flat and subtle.

Sulindac (Clinoril®; Merck & Co., Inc., West Point, PA), either by mouth or by suppository, is effective in making polyps disappear. Celecoxib reduces polyp load, as does the sulindac metabolite exisulind. However, cancers have been reported in cases where sulindac had been effective in minimizing rectal polyps in the rectum of FAP patients who had had IRA, and these anecdotal cases make the long-term use of chemoprevention for rectal polyposis suspect. If it is used in patients who cannot tolerate rectal polypectomy, or who are unwilling or unable to have a proctectomy, close surveillance (every 6 months) with random biopsies to look for severe dysplasia is needed.

There have been at least three recent reports describing adenomas in ileal pouches, with a frequency and severity that depend on time from the initial surgery. Two prospective studies have independently calculated the rate of pouch polyposis as 42% at 7 years. There have been anecdotal reports of large adenomas and more than 100 adenomas in an ileal pouch. In general, these have been treated successfully by oral sulindac, in a dose of 150–200 mg twice daily. The full impact of pouch polyposis will not be obvious until the cadre of FAP patients with ileal reservoirs reaches a mean follow-up of 20 years. This is the time to most ileostomy cancers, and to the highest rates of rectal cancers after IRA.

*Guideline 4: Use of Chemoprevention as Primary Therapy for Colorectal Polyposis Is Not Proven and Is Not Recommended; Level of Evidence: I–II*

Sulindac, celecoxib, and exisulind are nonsteroidal antiinflammatory drugs that have been shown to reduce the num-

ber and size of colorectal adenomas in patients with FAP. Although many studies are short-term, two show effectiveness of sulindac maintained over 4 years. These studies were in patients who had undergone colectomy and IRA. A recent randomized, placebo-controlled, double-blind study of sulindac in genotype-positive, phenotype-negative FAP patients failed to show any effect of sulindac on polyp progression. Furthermore, there have been case reports of cancers occurring in patients with sulindac-mediated ablation of polyps, and the only report of a permanent, complete resolution of rectal polyposis comes from Winde and coworkers who used sulindac suppositories. The effect on polyps is dependent on continued compliance, and there are significant side effects with each medication. These medications should not be used as an alternative to surgery, except in patients with pouch polyposis or in selected patients with rectal polyposis after IRA in whom surgery is risky or unwanted by the patient. In these groups of patients, close surveillance (proctoscopy or pouchoscopy every 6 months) is indicated.

*Guideline 5: Treatment of Duodenal Adenomas Depends on Adenoma Size and the Presence of Severe Dysplasia. Small Tubular Adenomas with Mild Dysplasia Can Be Kept under Surveillance, but Adenomas with Severe Dysplasia Must Be Removed; Level of Evidence: II–III*

The incidence of duodenal adenomas in FAP patients is in the range of 80%–90%. All FAP patients therefore undergo screening esophagogastroduodenoscopy starting at age 20 years. The risk of invasive cancer developing in a duodenal adenoma, or in the duodenal papilla, is considerably higher than that for the average population, but in absolute terms it is still low. The aim of endoscopy is not to eradicate all neoplasia but to make sure that there is no severe dysplasia. Studies of the natural history of duodenal neoplasia in FAP show that rapid progression of dysplasia is uncommon, occurring in only 11% of cases over a mean follow-up of 7 years. Prospective, randomized studies have shown that treatment with nonsteroidal antiinflammatory drugs is ineffective in treating duodenal adenomas, although a recent report indicates that celecoxib may have some effect. If they are not medically treated, low-risk adenomas (small, tubular, low-grade dysplasia) may be biopsied and left alone. High-risk adenomas (>1 cm, villous) are treated. Adenomas with confirmed high-grade dysplasia must be removed. As endoscopic or even transduodenal excision or destruction is ineffective in the long term; duodenectomy has to be considered for duodenal adenomas with high-grade dysplasia after the diagnosis has been confirmed on review by an experienced gastrointestinal pathologist.

*Guideline 6: Duodenectomy or Pancreaticoduodenectomy Is Recommended for Patients with Persistent or Recurrent Severe Dysplasia in the Papilla or Duodenal Adenomas; Level of Evidence: III*

A review of literature reporting treatment of advanced duodenal adenomas shows that recurrence is almost guaranteed unless the duodenum is removed. Transduodenal polypectomy or endoscopic polypectomy may be temporarily effective, but does not offer a permanent cure. The results of pancreas-preserving duodenectomy or pancreaticoduodenectomy for benign or early malignant disease are good, with low recurrence and acceptable morbidity. The outcome of surgery for established cancer is not good, with recurrence and death the usual outcome. Although the risk of duodenal/peripapillary cancer is relatively low in patients with FAP, patients with persistent high-grade dysplasia in the duodenum or papilla are a high-risk group. Careful surveillance is needed, and conservative surgery or endoscopic therapy may be tried. If the severe dysplasia returns or persists, consideration must be given to duodenectomy.

*Guideline 7: Surgery for Intraabdominal Desmoid Tumors Should Be Reserved for Small, Well-defined Tumors with a Clear Margin; Abdominal Wall Desmoid Tumors Should Be Excised Whenever Possible; Level of Evidence: III*

Desmoid tumors are histologically benign overgrowths of fibroaponeurotic tissue occurring rarely in the general population but in 12%–17% of patients with FAP. In the general population, desmoids are usually found in limbs or limb girdles; in FAP, desmoids are usually (80%) intraabdominal and often (80%) present within 2–3 years of an abdominal surgery. Intraabdominal desmoid tumors usually involve the mesentery of the small bowel, where they are intimately involved with the mesenteric vessels. They tend to infiltrate diffusely, kink adjacent bowel loops, and may obstruct the ureters. Attempts at excision are often unsuccessful, involve removal of a variable length of small intestine, and are associated with a high morbidity and a high recurrence.

Intraabdominal desmoid tumors may affect prophylactic colorectal surgery by limiting the length of the small bowel mesentery. This will sometimes prevent an IPAA. The most common scenario in which this occurs is in patients with Gardner's variant of FAP who need proctectomy after a previous ileorectal anastomosis. Patients need to be warned about this possibility and the likelihood of ileostomy before undergoing the surgery. The second most common site for desmoids in FAP is in the abdominal wall. Abdominal wall desmoid tumors are easier to excise than intraabdominal tumors, recurrence rates are lower, and the morbidity associated with

excision is less. They should be excised with a 1-cm margin. It is often necessary to use mesh to cover the defect in the abdominal wall.

*Guideline 8: Intraabdominal Desmoid Tumors Involving the Small Bowel Mesentery Are Treated According to Their Rate of Growth and Their Presentation. Clinically Inert Tumors Should Be Treated with Sulindac or Not Treated at All. Slowly Growing or Mildly Symptomatic Tumors May Be Treated with Less Toxic Regimens Such as Sulindac and Tamoxifen or Vinblastine and Methotrexate. Rapidly Growing Tumors Need Aggressive Therapy with Either Very High-dose Tamoxifen or Antisarcoma-type Chemotherapy. Radiation Is an Option if Collateral Damage Is Not a Big Concern; Level of Evidence: III*

Intraabdominal desmoid tumors vary in their clinical behavior from aggressive, relentless growth to indolent, asymptomatic coexistence. There is no single, predictably effective way of managing intraabdominal desmoids. Evidence suggests that sulindac is partially effective but that a response to this nonsteroidal antiinflammatory agent may not be noticeable for up to 2 years. The role of high-dose antiestrogens is uncertain, with one report describing good results in aggressive desmoids with tamoxifen in a dose of 120 mg/day. Toremifene, a more potent antiestrogen than tamoxifen, has some effect on desmoid tumors but seems to work better in non-FAP desmoids than FAP. A pilot study of the antifibrosis agent pifrenidone resulted in some modest responses. Most aggressive desmoids receive chemotherapy, and there are two regimens reported. The combination of vinblastine and methotrexate has low toxicity and produces some responses. Non-FAP desmoids seem more likely to respond to this combination, although no prospective studies have been done. Antisarcoma therapy such as doxorubicin and dacarbazine is much more toxic but seems to be more effective for rapidly growing intraabdominal desmoid tumors associated with FAP. Radiation is effective in destroying tumors but its effect on the small bowel can be disastrous, causing fistulas and necrosis.

Intraabdominal desmoids that are not growing may be treated by sulindac alone. If they are growing slowly or causing symptoms, it is reasonable to add tamoxifen in a dose range of 80–120 mg/day. The dose should be gradually increased to these levels over a few weeks. If the tumor continues to grow, chemotherapy is appropriate. Really rapid growth is an indication for antisarcoma therapy, whereas a slower growth rate means vinblastine/methotrexate can be tried. A recent report of successful intestinal transplantation after resection of abdominal desmoids reinforces the extent of the surgery needed to remove them, but also offers some hope for tumors that fail to respond to anything else.

## Section II: HNPCC

*Guideline 1: Treatment Must Be Preceded by Thorough Counseling about the Nature of the Syndrome, Its Natural History, Its Extracolonic Manifestations, and the Need for Compliance with All Recommendations for Management and Surveillance; Level of Evidence: III*

Hereditary nonpolyposis colorectal cancer is a dominantly inherited syndrome attributed to an inactivating mutation in one of the human DNA MMR genes. The syndrome is more complex than FAP because more genes are involved, penetrance is less complete, and expression is more varied. Furthermore, the clinical criteria defining HNPCC are arbitrary and not particularly accurate, and the yield of testing for germline mutations is lower than for FAP. HNPCC has a penetrance of at least 80%, and colorectal cancer occurs at a mean age of 46 years. Affected patients usually have at least one surgery and are committed to lifelong surveillance of several organs. Careful counseling is necessary to allow patients and their families to understand the implications of these complexities.

*Guideline 2: When Patients with HNPCC as Defined by Genotype or Compliance with Amsterdam I Criteria Are Diagnosed with More Than One Advanced Adenoma or a Colon Cancer, They Should Be Offered the Options of Prophylactic Total Colectomy and IRA or Hemicolectomy Plus Yearly Colonoscopy. The Choice of IRA Assumes the Anal Sphincter and Rectum Function Normally; Level of Evidence: III*

When patients known to be affected with HNPCC are diagnosed with advanced neoplasia, they can be offered a choice of conventional partial colectomy with surveillance of the remaining large bowel or total colectomy with rectal surveillance. Surveillance involves colonoscopy or proctoscopy (after IRA) every 1–2 years for life. There is evidence that cancers can occur in HNPCC within 2 years of a negative colonoscopy, but that cancers found on screening examinations performed with a 3-year interval can be cured. The risk of metachronous cancer after conventional treatment of an index cancer is 45% in patients with HNPCC, high enough to make prophylactic colectomy a reasonable option. The downside of colectomy and IRA lies in its effect on bowel function and quality of life. In a study of patients having IRA for FAP, quality of life was maintained, although stool frequency increased. These patients were younger than typical HNPCC patients having surgery, but even older patients can do well after IRA provided their anal sphincters and rectums are normal. The outcome of partial colectomy and effective surveillance can be similar to that of colectomy and IRA in terms of minimizing metachronous cancers. Likely patient compliance,

the anticipated quality and frequency of colonoscopy, and the relative costs and reimbursement of the two options therefore influence the choice. Even after IRA, the risk of rectal cancer is 12% in 12 years, so continuing surveillance of the rectum is mandatory.

HNPCC patients diagnosed by genotype with a normal colon are also candidates for prophylactic colectomy. If penetrance of the mutation in the family approaches 100%, this should be strongly considered. There have been two attempts to discern the relative benefits of surgery versus surveillance using decision analysis methods. Syngal and coworkers showed that prophylactic colectomy/proctocolectomy performed at the time of diagnosis led to a greater benefit in years of life expectancy gained than surveillance, but that this benefit decreased the longer surgery was delayed. Furthermore, if prophylactic surgery is performed at the time of diagnosis of a cancer, the gain in life expectancy is only 4 days for colectomy/IRA and 6 days for proctocolectomy. The advantage of surgery is further reduced if the gain in years is discounted. When the outcome of the analysis was quality-adjusted life years (QALYs), surveillance was the most effective strategy, with a gain of 14 QALYs compared with no surveillance, 3.2 QALYs compared with prophylactic proctocolectomy at diagnosis of HNPCC, and 0.3 QALYs compared with colectomy. A similar phenomenon was seen when comparing colectomy with proctocolectomy. Use of QALYs improved the relative value of the lesser operation. In the decision analysis published by Vasen and coworkers prophylactic colectomy at age 40 conferred an increase in life expectancy over surveillance of 8–18 months. In the same scenario, Syngal et al. calculated a benefit for surgery of 9.6 months. These analyses do not take costs into account, however, and they assume a level of compliance and quality of endoscopy that may not be realistic. In the absence of a randomized comparison of surveillance and surgery, both options must be explained to the patient and individual circumstances, such as comorbidity, gastrointestinal physiology, likely compliance, and ease of colonoscopy, taken into account.

*Guideline 3: Patients with HNPCC Who Have a Rectal Cancer Should Be Offered the Options of Total Proctocolectomy and IPAA or Anterior Proctosigmoidectomy, Assuming that the Sphincters Can Be Saved; Level of Evidence: III*

Rectal cancer is an uncommon index cancer in patients with HNPCC. Surgical options, assuming the sphincters can be saved, are restorative proctocolectomy (with IPAA) and anterior resection. There are substantial differences in bowel function after these two procedures, but the risk of metachronous colon cancer after a primary rectal cancer is not known. The decision to preserve the proximal colon and commit to a program of intensive surveillance is therefore based on likely compliance of the patient with surveillance and the likely impact of the surgery on quality of life.

*Guideline 4: Female Patients with HNPCC and Uterine Cancer in Their Family May Be Offered Prophylactic Hysterectomy Once Their Family Is Complete or When Undergoing Surgery for Other Intraabdominal Conditions; Level of Evidence: III*

The lifetime risk of uterine cancer in HNPCC is 42%, and although it is most common in families with hMSH6 mutations, it is also associated with hMSH2 and hMLH1 mutations. Screening for endometrial cancer in females with HNPCC has been shown in at least one study to be ineffective in detecting cancer, and so where uterine cancer is a feature in families, affected females should be offered prophylactic hysterectomy. Oophorectomy should be done at the same time, because the risk for ovarian cancer associated with HNPCC is high and in a multi-institution review of HNPCC-associated ovarian cancer, synchronous endometrial cancer was present in 21.5% of 80 patients.

Brown and coworkers have shown that an increased risk for gynecologic cancer begins by age 25 years. Although the mean age at gynecologic cancer in their series of 67 affected females (43 uterine, 24 ovarian) was 49.3 years, five gynecologic cancers were diagnosed before age 35. The timing of prophylactic hysterectomy and oophorectomy is therefore debatable. It is tempting to offer surveillance during the childbearing years and delay surgery until the patient has had a chance to have her family. Until more data are available, this is the best option. Surgery can be done at the time of another abdominal surgery, or as a separate operation once the patient's family is complete.

#### Levels of evidence

- 
- Level I: Evidence from properly conducted randomized, controlled trials.  
 Level II: Evidence from controlled trials without randomization, or cohort or case-control studies or multiple times series, dramatic uncontrolled experiments.  
 Level III: Descriptive case series or opinions of expert panels.

## Inflammatory Bowel Disease: Diagnosis and Evaluation

Walter A. Koltun

### History

In 1932 Crohn, Ginzburg, and Oppenheimer<sup>1</sup> described 13 patients with “regional ileitis” included in a total of 52 cases of nonspecific granulomatous inflammation of the intestine. Before their publication, numerous others had reported various cases of what were in retrospect, probably Crohn’s disease (CD), as early as 1813,<sup>2</sup> but it was their published description that established the formal classification of the disease syndrome and association with noncaseating granulomas. The surgeon involved in the care of the majority of the patients, Dr. A.A. Berg, did not want his name included in the article. Because of the variable clinical and anatomic manifestations of the illness, “Crohn’s disease” has subsequently become as common a descriptor of this disease entity as the term “regional enteritis.”

The difficulty in distinguishing the colonic form of CD and ulcerative colitis (UC) confused the diagnosis and treatment of these illnesses until their differences were clarified by classic publications by Brooke<sup>3</sup> in 1959 and Lockhart-Mummery and Morson<sup>4</sup> in 1960. These authors pointed out both the segmental and granulomatous features of the colitis in CD. In addition, Brooke contributed significantly to the treatment of these inflammatory illnesses by pioneering surgical techniques in the 1950s that created a more functional ileostomy, which until that time was a miserable and disabling consequence of colectomy.<sup>5</sup> Truelove et al.<sup>6</sup> in 1959 reported on a double-blind, controlled study demonstrating the value of high-dose cortisone as treatment for severe colitis. Other turning points in the management and treatment of CD include the demonstration of the therapeutic value of metronidazole,<sup>7</sup> 6-mercaptopurine,<sup>8</sup> and more recently, the tumor necrosis factor (TNF)- $\alpha$  antagonist, infliximab.<sup>9</sup>

The surgical management of UC has been a continuous evolution starting with colectomy/ileostomy,<sup>10,11</sup> supplanted by the continent Kock ileostomy,<sup>12</sup> and finally the definitive reconstruction procedure known as the ileal pouch–anal anastomosis (IPAA), first described by Parks and Nicholls<sup>13</sup> in 1978 and subsequently refined by Utsunomiya.<sup>14</sup> The IPAA is now the standard of care for the surgical correction of UC.

### Epidemiology

The causes of UC and CD are unknown, and thus epidemiologic data have been collected over many years in the hopes of providing some clues to the etiologies of these illnesses. Much of these data must be viewed with caution, however. Variations in diagnostic criteria, definitions of disease, and biases resulting from surveys done in tertiary care specialty centers, make universal conclusions difficult. However, some general statements can be made using such data that relate to disease prevalence and associated risk factors (Table 39-1).

The prevalence of inflammatory bowel disease (IBD) varies greatly with region of the world studied. Prevalence is the product of incidence and disease duration. Because IBD symptoms tend to wax and wane in severity, prevalence may be underestimated in some studies. IBD is found most frequently in the more temperate climates of North America and Europe. Studies from those regions show prevalence rates much higher than those in Asia, South America, or Africa. Prevalence rates as high as 300–400 per 100,000 population are found in Minnesota (USA), Manitoba (Canada), and the United Kingdom. Conversely, prevalence rates of approximately 23/100,000 are found in Japan, 10/100,000 in Singapore, and 75–120/100,000 in Israel. The relative incidence of Crohn’s versus UC is again, variable, with either being found greater than the other depending on geographic region studied.<sup>15–19</sup>

It is generally recognized that both CD and UC have been increasing in incidence to a remarkable degree over the past 20–30 years with two- to tenfold increases depending on population and region studied.<sup>18,20</sup> These dramatic increases suggest an environmental effect, because a genetic factor would probably not alter disease rates so rapidly.

CD usually occurs in the third decade of life, whereas chronic UC in the fourth decade. There may be a bimodal distribution of disease incidence with a second peak in the sixth or seventh decade, but this is unclear and may simply be attributable to difficulty in differentiating it from other colitides such as diverticulitis or ischemic colitis.<sup>21</sup>

TABLE 39-1. Epidemiologic and associated risk factors for IBD

<b>Epidemiology</b>	
Race/ethnicity	
Whites and blacks > Hispanic, Native American, Asian	
Jews > non-Jews	
Geography	
Northern climates > Southern	
Scandinavia, North America, Europe > Asia, Africa, South America, Japan, Spain	
Sex	
CD: F > M	
UC: M > F	
Age at greatest incidence	
CD: third decade	
UC: fourth decade	
Residence	
Urban > rural	
Indoor > outdoor	
<b>Risk factors</b>	
Diet	
Sugar consumption, ↑ CD	
ETOH, ↓ UC	
Margarine, no association	
Coffee, no association	
Fiber, no association	
Food additives, no association	
Childhood diarrheal illness ↑ IBD	
Higher socioeconomic status ↑ IBD	
Oral contraceptive use ↑ IBD	
Cigarettes ↑ CD	
↓ UC	
Appendectomy ↓ UC	
NSAIDs ↑ symptoms IBD	

Although originally thought to be relatively rare in blacks, more recent case control studies in the United States suggest a similar incidence to whites, although Africa itself has a very low incidence of IBD.<sup>17</sup> There is great variability in the incidence of IBD in Jews around the world, but nonetheless seems to be consistently higher than that found in the non-Jewish population in most countries studied.<sup>22</sup> IBD is more common in urban, “indoor” populations of individuals of middle to upper socioeconomic status, suggesting the “hygiene” hypothesis that relates the lack of early exposure to environmental antigens to the later development of disease.<sup>15,19,23</sup>

There is very little evidence that a specific dietary factor causes IBD although increased sugar consumption is associated with CD and alcohol intake is inversely related to chronic UC.<sup>24,25</sup> Childhood diarrheal illness, oral contraceptive and nonsteroidal antiinflammatory (NSAIDs) use are measurable risk factors for IBD, with NSAIDs reported as precipitating relapse in patients with inactive disease.<sup>26</sup> Smoking has been clearly shown to worsen CD, with increased risk of developing the disease de novo and increased risk of recurrence after surgical resection.<sup>27,28</sup> Conversely, smoking is protective for chronic UC, as is prior appendectomy.<sup>27</sup>

There is clearly a genetic predisposition to IBD. It is probably stronger in CD than UC. If an individual has IBD, there

is a 10%–20% risk of having another family member with IBD. Twin studies have shown that the concordance rate for identical twins is much higher than that for dizygotic or paternal twins (approximately 50% versus 15%), stressing the role genes have in the disease. However, the fact that identical twins do not have a 100% concordance, reinforces the fact that there must also be a nongenetic component to the illness. In families who have multiple affected members, the age of onset is probably earlier and some studies suggest that the anatomic pattern, extent and severity of disease may be similar.<sup>29–31</sup> Genetic techniques of analysis, including linkage and transmission disequilibrium testing using both sporadic and family registries of IBD patients have identified seven areas of the human genome (on chromosomes 1, 5, 6, 12, 14, 16, 19) that are significantly relevant to disease susceptibility,<sup>32</sup> underscoring the complexity of the genetic predisposition to IBD. It seems that no one gene locus is responsible for disease, but that many gene products have a role in the illness. The strongest genetic linkage is with CD and mutations in a locus on chromosome 16 which has now been identified as being in the *NOD2/CARD15* gene.<sup>33,34</sup> This gene is involved in innate host defense against enteric bacteria and mutations in this gene are believed to be responsible for approximately 15%–30% of patients with CD. Its discovery represents a breakthrough in the conceptualization of disease pathogenesis in IBD. Overall, both the epidemiology and now the molecular genetic evidence furthers the concept that IBD is the consequence of environmental exposure to a causative agent in a genetically susceptible individual.

## Signs and Symptoms

### Gastrointestinal Symptoms

#### *Crohn's Disease*

CD can affect any portion of the gastrointestinal (GI) tract from the mouth to the anus. It is usually discontinuous, usually involving several areas of the bowel at once, with sections of normal intestine interposed. The inflammation of CD involves the entire bowel wall, from mucosa to serosa and even into adjacent structures. These features are responsible for its presenting symptomatology.

The most common complaints of any patient with CD are abdominal pain and diarrhea, being found in more than 75% of patients. Weight loss, fever, and bleeding are present in approximately 40%–60% of patients, whereas anal symptoms of abscess and/or fistula occur in 10%–20% of patients. Many classification systems for CD have been suggested but the anatomic one has direct practical relevance in explaining symptoms. CD is most frequently found in the ileocecal region, making up approximately 40% of patients. Abdominal pain usually correlates with disease in this region.<sup>20</sup> Colonic disease is found in approximately 30% of patients and most directly correlates with symptoms of diarrhea and bleeding.

The remaining 30% of patients have disease confined to the small bowel proximal to the terminal ileum and correlates with abdominal pain, bloating, and a sense of postprandial nausea especially if partial obstruction caused by inflammation or strictures occurs. Anal disease is typically associated with patients having the terminal ileal and colonic distributions of disease.

The more recently developed Vienna classification of CD segregates patients into three categories based on behavior: inflammatory (B1), stricturing (B2), and fistulizing (B3).<sup>35</sup> This classification attempts to characterize disease biology but is imperfect. Patients will frequently change categories as disease progresses, because inflammatory disease usually becomes stricturing or fistulizing disease. Louis et al.,<sup>36</sup> over a 10-year period, found that in 125 patients with CD, the B2 and B3 categories (stricturing and fistulizing) each increased from approximately 10% to approximately 30%–40% with a compensatory decrease in the inflammatory, B1 category. Thus duration of disease has a critical role in defining the category in this classification system.

Clinical severity of symptoms is widely variable, because CD typically has a waxing and waning course characterized by periods of disease activity interspersed with periods of remission. At any one time, approximately 50% of CD patients will be in clinical remission. The majority of patients (60%–75%) will have alternating years of quiescence and disease activity. Approximately 10%–20% will have either a chronic, unremitting course or repetitive annual flaring of disease. Prolonged quiescence is found in approximately 10%–15% of patients. The only useful predictor of future disease activity is past clinical behavior.

### *Ulcerative Colitis*

The inflammation of UC characteristically starts in the rectum and extends proximally. So-called backwash ileitis is the only possible area of the small bowel that can be affected in UC, or CD should be suspected. Clinical symptoms relate to the extent and location of disease. Thus, rectal disease results in increased stool frequency, hematochezia, and tenesmus. Diarrhea is a frequent symptom and with tenesmus can result in incontinence, especially at night. Despite severe rectal inflammation, constipation with a sense of incomplete evacuation can be a complaint in 20%–25% of patients, but blood and mucous are nearly always present. With more proximal involvement, abdominal complaints increase including left lower quadrant pain and pain associated with peristalsis or stool evacuation. With increasing severity and extent of disease, nausea, vomiting, and weight loss ensue. Weight loss is attributed both to the loss of serum proteins through the diseased mucosa and the reluctance of the patient to eat in order to avoid exacerbation of symptoms. The development of systemic signs of illness such as tachycardia, fever, and increasing fluid requirement bespeaks severe disease. High-dose steroids may disguise worsening abdominal complaints,

including peritonitis in such circumstances and should not divert the clinician from recognizing the gravity of the development of such symptoms and signs. So-called “toxic megacolon” is a moniker that should be discarded, because severe life-threatening colitis may occur without colonic dilatation and urgent surgical intervention should be based on the triad of toxicity defined by tachycardia, fever, and increased white blood cell count.

## Extraintestinal Manifestations

### *Musculoskeletal*

The most common non-GI complaints in IBD patients relate to the musculoskeletal system. Osteopenia and osteoporosis are very common, in part because of therapeutic steroid use, occurring in as many as 50% and 15% of IBD patients, respectively. Such bone density loss is now recognized as leading to significant comorbidity and complications in IBD patients. One study found a 40% increased risk of bone fractures in IBD patients.<sup>37</sup> The arthropathies associated with IBD are found in up to 30% of patients and are divided into two broad categories. Peripheral arthritis usually affects multiple small joints and has little relation to GI disease activity. Axial arthritis (ankylosing spondylitis) is associated with certain human leukocyte antigen subtypes (B27) and is found in approximately 5% of both CD and UC patients. Its severity usually parallels disease activity. Recently, anti-TNF therapies have been shown to be effective in both CD and the arthropathy of IBD.<sup>38,39</sup>

### *Cutaneous*

Pyoderma gangrenosum and erythema nodosum occur in approximately 0.5%–5% of patients with IBD. These, as well as oral lesions such as aphthous stomatitis and pyostomatitis vegetans, are more frequently associated with CD than UC and usually parallel underlying GI disease activity. The new appearance of pyoderma gangrenosum around the ileostomy of an IBD patient after colectomy is unexplained but is a clear clinical phenomenon.<sup>40</sup> There is a reported increased rate of psoriasis and eczema in IBD patients that does not parallel disease activity. One-third to one-half of patients with pyoderma gangrenosum have IBD.<sup>41</sup>

### *Hepatobiliary*

Primary sclerosing cholangitis (PSC) has a reported incidence of approximately 3% in both CD and UC patients. It may present independently of intestinal disease activity, and colectomy in UC patients does not affect progression of liver disease. The presence of PSC in the UC patient increases the risk for malignant disease in both the colon and hepatobiliary system.<sup>42</sup>

Several studies have suggested an increased incidence of gallstones in IBD, especially CD although this is disputed.

The mechanism is presumed to be attributable to an altered enterohepatic biliary circulation caused by ileal disease.<sup>43</sup>

### Ophthalmologic

Iritis, uveitis, and episcleritis can affect 2%–8% of UC and CD patients and are generally unrelated to disease activity. Iritis and uveitis present as blurred vision, eye pain, and photophobia and require prompt treatment to avoid scarring and even blindness. Episcleritis is typically less threatening and is characterized by scleral injection, burning, and tearing.

### Coagulopathy

There is an identified increased risk of deep venous thrombosis, mesenteric thrombosis, and pulmonary embolism in IBD patients that is not explained simply by increased hospitalization and surgery. Decreased protein S and antithrombin III levels attributed to mucosal loss and increased levels of acute phase reactants including factors V and VIII have been implicated. The mortality of postoperative mesenteric thrombosis in the IBD patient has been reported to be as high as 50%,<sup>44</sup> but probably occurs more frequently than previously recognized with an overall lower mortality and morbidity in its milder forms.<sup>45,46</sup> Anticoagulation and work-up for coagulation disorders are usually recommended.

## Disease Severity Assessment

### Crohn's Disease

The CD activity index (CDAI) is the most frequently used method for quantitating disease severity in CD. It was developed by Best et al.<sup>47</sup> using multiple regression analysis and includes a total of eight items that are measured, multiplied by respective weighting factors, and then summated to yield a score (Table 39-2). It is generally accepted that a total score less than 150 points is quiescent disease, whereas more than 450 is severe, active disease. Relapses are defined

as a score increasing to more than 150 or an increase of 100 points over baseline. The CDAI is most frequently used in longitudinal clinical studies to evaluate the results of experimental interventions. It suffers from many deficiencies including its reliance on subjective complaints and that it is time consuming, requiring the patient to keep a diary for 7-day periods defining symptomatology. Some measured symptoms, such as diarrhea and belly pain, may reflect short gut caused by prior surgery or strictures that do not represent active, inflammatory disease.<sup>47</sup> Other indices have been developed in an attempt to address these criticisms. The Harvey Bradshaw index (or modified CDAI) and the Van Hees index, which relies entirely on nine objective factors such as erythrocyte sedimentation rate (ESR), albumin, temperature, and stool consistency are two such measurement tools, but they are infrequently used, even in protocol settings.<sup>48</sup>

The Vienna classification, discussed above, is an attempt to classify or categorize subsets of CD patients and is not used as a severity assessment tool.<sup>35</sup>

### Ulcerative Colitis

The benchmark study evaluating the effect of cortisone on UC by Truelove et al.<sup>6</sup> in 1955 also described the still most often used clinical assessment tool for severity assessment in UC (Table 39-3). The simplicity and clinical relevancy of the factors in this index allow for its daily use as a clinical tool and also for clinical response in study protocols. Variations on its initial format have included the creation of a “moderate” category for patients displaying features intermediate in value between the mild and severe categories. This index also does not take into account variability in the anatomic extent or observed severity of disease within the colon. Modern clinical studies requiring disease assessment will thus often use a variation on the Truelove and Witts classification which will include additional criteria based on colonoscopic appearance and possibly pathologic severity as well.<sup>49,50</sup>

TABLE 39-2. The CDAI

Item	Data collected	Calculation	Weighing factor
No. of liquid stools	7-day diary	Sum of 7 days	2
Abdominal pain	0–3 scale, 7-day diary	Sum of score for each day	5
General well-being	0–4 scale, 7-day diary	Sum of score for each day	7
Symptoms*	At clinic visit	Sum (6 total possible)	20
Lomotil use	7-day diary	Yes = 1, No = 2	30
Abdominal mass	At clinic visit	None = 0, questionable = 2, definite = 5	10
Hematocrit (HCT)	At clinic visit	M (47 subtract patient's HCT) F (42 subtract patient's HCT)	6
Weight	At clinic visit	% below ideal weight	1

\*Symptoms include presence or absence of each of arthritis/arthritis, iritis/uveitis, erythema nodosum/pyoderma gangrenosum/aphthous stomatitis, anal fissure/fistula/abscess, other fistula, or temperature >100°F.

TABLE 39-3. Truelove and Witts UC activity index

	Mild	Severe
Bowel frequency/24 hours	<4	>6
Blood in stool	+	+++
Fever	Absent	>37.5
Pulse	<90	>90
Hgb	>75% nL	<75% nL
ESR	<30	>30

## Evaluation

### Radiology

The diagnosis of IBD depends on the triad of clinical presentation, radiologic work-up, and histopathology of tissue biopsy. Thus, radiologic studies are critical in the evaluation of the patient with suspected or confirmed IBD.

### Plain X-rays

Conventional radiologic studies have a significant role in the work-up and management of IBD. Plain abdominal radiographs can show signs of obstruction, perforation (free air), and at times thickening of the bowel or loss of haustral markings. The initial presentation of any patient with belly pain and a known or suspected diagnosis of IBD will incorporate a plain and upright film looking for these signs. On the plain film, air can act as a contrast medium and can allow the identification of the more subtle findings of nodularity of the mucosa suggesting ulceration or pseudopolyp formation. Chronic colitis may result in an ahaustral, tube-like colon that can be seen with air contrast (see Figure 39-1). Fulminant or rapidly worsening colitis may result in toxic dilatation (“toxic megacolon”) that mandates surgical intervention and the specific avoidance of colonoscopy or contrast enema studies that may result in perforation. Incidental discoveries of

FIGURE 39-1. Plain radiograph of a patient with worsening symptoms of ulcerative colitis. Note the ahaustral left and transverse colon, signs of small bowel ileus and enlarged (“mega”) transverse colon.

gallstones or renal calculi that occur with increased incidence in patients with IBD may also be made.

### Contrast Radiologic Studies

Contrast studies will more frequently be used in the patient with CD than UC because of its predisposition for small bowel involvement. For the colitic patient, whether caused by CD or UC, colonoscopy is usually the preferred study, frequently obviating the need for barium enema. However, a double-contrast barium enema may still be used to discover or delineate extent of disease in the patient with GI symptoms, especially when caused by CD. Colonic contrast studies in the CD patient can show segmental disease, strictures, and fistulas. Reflux into the terminal ileum occurs in approximately 85% of patients and can reveal ileal disease more effectively than small bowel follow through because of less superposition of intestinal loops. When fistulas or near obstructing strictures are suspected, a water-soluble dye, such as Gastrografin is preferred. This minimizes the complications associated with possible extravasation of the dye if a fistula or intestinal perforation is present or subsequent impaction of barium if passed proximal to a stricture. Not infrequently in the patient with CD, an unsuspected rectal fistula tracking to a diseased terminal ileum is found on rectal contrast study (see Figure 39-3, below). Such a fistula can be easily missed on colonoscopy because it originates with the diseased terminal ileum and the rectum infrequently has other evidence of CD.

The difficulty of reaching the small bowel using fiberoptic instruments results in the common use of small bowel contrast studies to assess the degree of CD involvement of the small bowel. Small bowel series can effectively show areas of stricturing and upstream dilatation but may be difficult to perform or interpret because of slow intestinal transit from strictures, overlying loops of bowel, and pain associated with compression spot views (Figure 39-2). Enteroclysis is preferred over simple small bowel follow through, although its need for the placement of a naso-intestinal tube makes patient cooperation and satisfaction with this study much less. High-density barium must be used as the contrast agent, because water-soluble dyes rapidly dilute out in the small bowel, making detailed assessment of the intestinal mucosa difficult. After placement of the nasal tube beyond the pylorus, relatively small boluses of barium are injected that coat the walls of the intestine and then air is insufflated distending the bowel allowing detailed examination of the mucosa. Repetitive infusions of dye and air, with subsequent spot compression films, can result in remarkable detail being revealed but results are clearly dependent on operator expertise and patient cooperation.

GI contrast studies surpass computed tomography (CT) for detecting enteroenteric and enterocolic fistulas.<sup>51</sup> The discovery of an enteric fistula can be made when orally consumed contrast material is seen in a distal portion of bowel without illuminating intervening intestine, such as can occur with ileal disease fistulizing into the rectum. Sometimes the dye will

FIGURE 39-2. Small bowel follow through contrast study showing terminal ileal stricturing disease, with displacement of adjacent bowel loops caused by ileal thickening.

directly illuminate the fistula or involved organ, such as the bladder, as it tracks from the bowel, whether the contrast is given orally or rectally (Figure 39-3).

Sinography or fistula-gram can be used to delineate the path or origin of fistulous disease in CD patients, whether involving the abdominal wall or perineum. Such studies can

FIGURE 39-3. Colonic contrast study in CD patient showing complex fistulizing disease. Contrast is present in the proximal, diseased ileum and air and contrast in the bladder because of fistulizing disease.

also be done via the drainage catheter after percutaneous drainage of an abscess to document intestinal communication and, again, should be done with water-soluble contrast. Such anatomic localization assists in directing subsequent surgical care (especially when fistulous disease involving the urinary tree is found) and assessing response to therapy.

Retrograde studies through a stoma, especially an ileostomy, can provide very good evaluation for disease. The effectively foreshortened intestine allows better delineation of disease with less overlapping bowel loops and better double-contrast definition.

### Computed Tomography

Abdominal and pelvic CT is probably the most frequently obtained study in the acute work-up of patients with IBD, especially CD. Such studies should be done with orally ingested low-density barium or iodinated contrast material that has been allowed to traverse the entire GI tract. Because of strictures or slow transit time, rectal administration of contrast will sometimes be necessary. CT scanning is especially useful for delineating enterovesical or colovesical fistulas and scans should be obtained before administering intravenous contrast, as contrast originating from the bowel will be seen in the bladder defining the fistula. Air within the bladder without prior instrumentation is also a very sensitive sign defining the presence of a fistula.

The great advantage of CT is its ability to look at the entire thickness of the intestine and its adjacent structures. Thus, thickened intestine, phlegmon, abscess, air in extraintestinal structures, and fistula formation are signs of CD that can be found on CT scan (Figure 39-4). Percutaneous drainage of abscess collections done under CT guidance can also be performed. Although less frequently performed for UC, CT findings that can be seen include increased perirectal and presacral fat, inhomogeneous areas of colonic thickening, target or “double halo” sign of the colon, and changes consistent with cancer development such as strictures or mass lesions.<sup>51</sup>

### Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is playing an increasing role in the evaluation of IBD patients. Intestinal CD can be identified simply by thickened bowel loops on conventional MRI. MRI differs from CT, however, in that the intensity of T2-weighted signals from areas of disease correlate with severity of inflammation, especially after gadolinium administration. Such signal intensity in both the mesentery and bowel decreases with resolution of acute inflammation and may hold promise for monitoring the response of patients to medical therapy.<sup>52,53</sup>

MRI's value in defining perineal disease in the CD patient approaches, and may exceed, that achieved with examination under anesthesia.<sup>52,53</sup> Endorectal coil placement may improve

FIGURE 39-4. CT scan of CD patient with severe terminal ileal thickening and early abscess formation under anterior abdominal wall.

sensitivity but is infrequently necessary and sometimes impossible in the diseased anus. Intravenous injection of gadolinium highlights the fistula tract, and combined with MRI's ability to accurately define soft tissue anatomy, can result in remarkable delineation of disease.<sup>54,55</sup> MRI testing is expensive, however, and is probably unnecessary in the conventional perineal CD patient because an examination under anesthesia performed by a competent surgeon is usually as accurate and can also provide simultaneous treatment.<sup>56</sup> However, MRI is finding a role in reassessing the failed patient for unrecognized pathology and, more recently, in defining whether medical treatment with infliximab has truly healed a patient's fistulous disease. Several studies using gadolinium-enhanced MRI have shown that many fistulas that respond to exclusive medical management are, in fact, still present but quiescent.<sup>57,58</sup>

### Ultrasound

The role of ultrasound in IBD is presently very limited. European centers are more familiar with its use for assessing the GI tract in IBD patients where it is sometimes used to longitudinally follow a patient's response to therapy. In the hands of an experienced operator, so-called transabdominal bowel sonography (TABS) can look for bowel wall thickening, fistula formation, and can even assess functional effects of strictures by observing bowel peristalsis and distention in the vicinity of such pathology.<sup>59</sup> This method of noninvasive intestinal evaluation has not gained wide popularity in the United States.

Intra-rectal ultrasound can be used to document and map perianal fistula formation by injecting a solution of hydrogen peroxide into the external opening. The resulting bubbles are easily seen on ultrasound as they outline the path of the fistula tract. However, such uncomfortable and operator-dependent

techniques of fistula assessment have been largely replaced by MRI scanning (see above).

### Nuclear Medicine

The injection of radionuclide-labeled white cells allows subsequent scintigraphic imaging of the abdominal organs and is increasingly being used as a technique to visualize actively inflamed bowel. Most techniques use indium<sup>111</sup> labeling of autologous leucocytes that are harvested from the patient, labeled, and then reinjected. Indium<sup>111</sup> has the advantage of a long half-life that allows scanning at 6, 12, and 24 hours with any visualized bowel activity as being abnormal. A fixed area of activity suggests an abscess. Newer techniques using technetium-99m-hexamethylpropyleneamine oxime (HMPAO) provide for better image quality because of their relatively selective labeling of granulocytes and also result in a lower radiation dose to the patient. Some studies using this tracer have shown very high sensitivity rates, but specificity is less because of its inability to differentiate between IBD and infectious causes of disease.<sup>60</sup> The advantage of such radionuclide scanning techniques relate mostly to their ability to differentiate between inflamed versus quiescent disease and their use will probably increase as newer labeling agents are devised.

### Endoscopy

Colonoscopy has strongly influenced the diagnosis and evaluation of the patient with IBD. It is the study of choice for the patient with suspected UC because it can directly visualize the entire extent of the disease process. It is similarly relevant for CD when involving the colon, and can also be used to intubate and evaluate the terminal ileum. Most significantly, colonoscopy provides biopsies, which allows a tissue diagnosis to be made by the pathologist. There are numerous indications for colonoscopy in the IBD patient (Table 39-4) and it has a significant role in both medical and surgical treatment. The gross appearance of the colon as seen on colonoscopy can frequently differentiate between CD and UC (Table 39-5). Its use in the patient with severe disease is controversial. Although studies exist suggesting it can be safely done in the

TABLE 39-4. Indications for colonoscopy in IBD

• Diagnosis:	–Gross appearance –Tissue biopsy
• Disease extent	
• Disease complications:	–Fistulas –Stricture –Bleeding
• Preoperative “staging”	
• Monitor response to therapy	
• Stricture management:	–Biopsy –Dilatation

<i>Advanced/late</i>	Ulcerations, transmural disease	Confluent ulcers
	Pseudopolyp formation	Deep "bear claw" ulcerations
	Purulence	Strictures
	Variable thinning/ thickening of colon	Mucosal bridging
	Mucosal bridging	

severely colitic patient, the risk of perforation caused by insufflation, biopsy, or mechanical bending of the scope is generally acknowledged as being high and thus colonoscopy is generally avoided in the acute setting. However, such severely ill patients still need endoscopic evaluation to rule out concurrent diseases such as pseudomembranous or cytomegalovirus-induced colitis. Rigid or flexible proctoscopic evaluation is thus recommended, with biopsies done in the lower rectum below the peritoneal reflection to minimize the risk of free perforation.

The flexible sigmoidoscope is conveniently used for the evaluation of the unsedated office patient, but is limited by its 65-cm length to visualizing the colon up to approximately the splenic flexure. This can often be adequate, however, and in the case of UC, definitive. In the patient with typical presenting symptoms of bloody diarrhea and tenesmus, a flexible sigmoidoscopy with biopsies and stool culture for pathogens and ova/parasites may complete the work-up and make the diagnosis.

There is an increasing experience with through-the-scope (TTS) pneumatic dilatation of colonic or ileocolonic strictures in CD. The technique incorporates repetitive insufflation of the TTS balloon for 15- to 60-second periods, with the larger balloons (25 mm) being associated with more patient pain and complications than the smaller ones (12 mm). In a prospective study of 55 patients, long-term success (mean follow-up of 34 months) with complete relief of obstructive symptoms was achieved in 62% of patients whereas 19 (38%) required operation and six (11%) suffered a perforation.<sup>61</sup>

Upper endoscopy or esophagogastroduodenoscopy (EGD) will infrequently be used in the management of CD because gastroduodenal CD occurs in less than 5% of patients. When CD does affect the stomach or duodenum, however, strictures are common and therapeutic dilatation and biopsies to evaluate for malignancy via EGD are necessary. More frequently,

EGD is useful in the evaluation of the differential diagnosis of upper abdominal pain or dysphagia in the IBD patient. Esophageal candidiasis brought on by immunosuppression, duodenal or gastric ulcerative disease caused by steroids or reflux disease from downstream partial obstruction all occur with increased frequency in the IBD patient and is well evaluated by EGD. So-called push enteroscopy using specially designed flexible scopes has been developed to improve access by the endoscopist to the jejunum, but its use is very limited. The preferred study for evaluation of small bowel CD is still small bowel contrast follow through or enteroclysis.

## Wireless Capsule Endoscopy

Wireless capsule endoscopy (WCE) is a recent unique development for the visualization of the small bowel. An 11 × 26 mm capsule is swallowed that transmits two video images per second to a receiver worn on the belt. Over the 8-hour battery life of the device, more than 50,000 images are transmitted and stored which are subsequently evaluated at 25 frames per second by dedicated software and the human eye. Subtle small bowel lesions, usually out of the reach of the colonoscope or upper endoscope, can be appreciated. Its role in CD is still being clarified, but criteria for its use include the recommendation of prior colonoscopy and intubation of the terminal ileum. Many studies using WCE have found CD in this most common of regions that can be easily reached by a colonoscope obviating the need for the more expensive WCE. In addition, a small bowel contrast series is also necessary because the size of the capsule may cause it to impact at a stricture precipitating acute bowel obstruction requiring surgery. Other problems include its limited battery life in patients with slow transit, the inability to biopsy, and its imperfect localization of identified lesions. Nonetheless, this technology provides an added and potentially more sensitive tool in the diagnosis and management of patients with CD.<sup>53,62,63</sup>

## Pathology

### Ulcerative Colitis

UC begins in the rectum and extends proximally a variable distance with the worst disease being distal and the least disease being proximal. Disease may be limited to the rectum (ulcerative proctitis), extend to only the left colon, or completely to the cecum (pancolitis). The terminal ileum may be inflamed in continuity with the cecum (backwash ileitis). Disease is in continuity and segmental or "skip" disease does not occur, although so-called "rectal sparing" or some degree of patchiness can be seen in the actively treated patient, especially when enema therapy has been given. The gross appearance of the inflammatory process depends on the severity and duration of the disease (Table 39-5). In early disease, inflammation is restricted to the mucosa but in its severest, toxic

form it can become transmural and indistinguishable grossly and histopathologically from CD, with deep ulcerations, pseudopolyp formation, and variable areas of thickened and thinned colonic wall.

The histopathologic features of UC are listed in Table 39-6. There are no pathognomonic features of UC and in its extreme form it can resemble CD. However, typical UC is associated with inflammation limited to the mucosa or lamina propria including relatively uniform crypt distortion and crypt abscesses. Goblet cell mucin depletion is common and the inflammatory infiltrate is usually neutrophilic, two features that distinguish it from CD where mucin depletion is uncommon and the inflammation is usually mononuclear. More severe UC leads to the entire loss of the crypt with deeper submucosal and transmural inflammation and ulceration. In the chronic, more quiescent phase, UC will have mucosal reconstitution but will still have crypt distortion, foreshortening, and branching. Inflammation will be variably reduced, even absent, but when present still relatively uniform in distribution. Dysplasia in longstanding UC is common but can only be interpreted in the setting of noninflamed bowel, because many of its features are common with inflammation, namely, crypt distortion, increased mitotic index, and nuclear atypia.

### Crohn's Disease

The gross features of CD include its ability to affect any portion of the GI tract, its transmural inflammation, and its propensity to create fistulas and strictures, including in the perianal area. Skip lesions are common, resulting in multiple areas of bowel affected simultaneously with intervening segments of normal intestine. Diseased bowel may fistulize into adjacent bowel that is otherwise unaffected, a type of

bystander injury that only requires surgical removal of the offending segment of intestine with primary repair of the fistula in the remaining, healthy bowel. Serositis is common in CD, as is fat wrapping or creeping fat, all nonspecific responses to the transmural inflammation seen. On the mucosal surface, the earliest changes are aphthous ulcers, which are tiny white pinpoint lesions representing mucosal ulcerations in the vicinity of enlarged lymphoid follicles. These are thought to then enlarge and coalesce into the larger, deeper, longitudinal serpiginous ulcers often found in CD. These will have a deep, fissuring appearance and will extend ever deeper into the bowel wall, infrequently perforating freely, but instead recruiting an inflammatory response from adjacent organs that tend to wall off the inflamed bowel and that can then lead to fistulization. Healing is associated with granulation tissue and stricture formation, features not usually found in UC.

Microscopically, the inflammatory infiltrate is frequently mononuclear and there is minimal goblet cell dropout in the mucosa. When crypt abscesses occur, they are nonuniform, affecting some crypts and not others. Vasculitis is sometimes seen (20%) and neuronal hyperplasia is common, both features that are rarely seen in UC. The classic noncaseating granuloma is found in 20%–60% of patient biopsies and is composed of epithelioid and giant cells of the Langhans type. Granulomas probably wax and wane in their presence and can also be found in adjacent tissues affected in continuity, such as bladder, lymph nodes, ovaries, and perianal squamous epithelial skin tags. Their significance is unclear, with some suggesting they indicate a less-aggressive form of CD.

### Indeterminate Colitis

Approximately 10%–15% of colitis patients will have either clinical or pathologic features that do not allow a clear diagnosis of either CD or UC to be definitively made. This is often attributable to rapidly deteriorating, fulminant colitis, where even UC can have transmural or irregular mucosal involvement. Sometimes the gross anatomic appearance is complicated by incomplete response to various medications, especially when delivered transanally as enemas, which can lead to relative “rectal sparing” and therefore suggest CD over UC. Frequently, the correct diagnosis involves the judgment of an experienced clinician who considers not only the histopathology, but also the clinical characteristics of the patient, the history of disease progression, and even more subtle data such as serum antineutrophil cytoplasmic antibody (ANCA) and ASCA testing (see Serum Tests for IBD). More than half of such indeterminate cases can usually be resolved with such consideration of the entire clinical picture. This is especially important in the patient who is a candidate for pelvic pouch reconstruction, where the results of such surgery are significantly worse in the misdiagnosed Crohn's diseased patient.<sup>64</sup>

TABLE 39-6. Histology of IBD

	UC	CD
<i>Early</i>	Crypt distortion, branching Goblet cell mucin depletion Vascular congestion (without inflammation) Mucosal inflammation	Patchy crypt distortion Minimal goblet cell mucin depletion Aphthoid ulcers
<i>Intermediate</i>	Uniform crypt abscesses Loss of mucosa with retention of crypts Lamina propria neutrophils	Focal crypt abscesses Vasculitis (20%) Noncaseating granulomas (20%–60%) Mononuclear cell infiltrate
<i>Advanced/late</i>	Crypt destruction Neuronal hyperplasia uncommon Deeper submucosa inflammation Pseudo polyp, mucosal bridging Dysplasia common	Transmural inflammation Neuronal hyperplasia common Mucosal and submucosal thickening Fibrosis and strictures Dysplasia uncommon

## Serum Tests for IBD

Serum tests for IBD can be divided into several categories: acute phase reactants, nutritional parameters, and inflammatory markers. The prototypic acute phase reactant is the ESR, which is frequently used, especially in CD despite its imperfect correlation with disease activity. It is a necessary component to determine the CDAI (see section above). Some have suggested ESR correlates better with colitis, either CD or UC, than small bowel CD. This may be attributable to the fact that ESR may be normal in CD patients with noninflammatory disease who nonetheless may be very symptomatic because of the presence of “burned-out” fibrotic strictures.<sup>65</sup> Conversely, an acute abscess from a longstanding fistula in ano may increase the ESR without any evidence for flaring of intestinal disease. Similar difficulties have been encountered in correlating disease status with other acute phase reactants, such as C-reactive protein (CRP), orosomucoid ( $\alpha$ -1-acid glycoprotein),  $\alpha$ -1-antitrypsin, and  $\alpha$ -2-globulin.<sup>66</sup> The fecal excretion of  $\alpha$ -1-antitrypsin when measured as a clearance ratio has some correlation to active intestinal disease but difficulty with collection methodology makes this test rarely used. Presently, ESR and CRP are the only two tests frequently used in the clinical arena.

Nutritional parameters are often used to assess the consequence of acute and subacute disease in IBD. Albumin, prealbumin, and iron studies (transferrin, serum iron) are reflective of the combined effects of decreased food intake (to minimize symptoms), compromised absorption (from inflammation or surgical shortening of the bowel), and increased losses (from loss of proteins and blood from mucosal ulceration). B12 is often decreased in CD patients with ileal disease or after surgical resection. Such nutritional tests are nonspecific, but extremely valuable in clinical decision making from either a surgical or medical perspective. Other relevant serum studies include liver function testing that may reveal subclinical PSC.

Research into the immune regulatory pathways that have a role in the inflammation seen in IBD has resulted in the identification of numerous chemokines that are altered in IBD.<sup>48</sup> Many of these, including interleukin (IL)-1, IL-2, IL-6, IL-8, TNF, CD45, soluble IL-2, and interferon-gamma have not been used beyond investigative protocols for a number of reasons. Frequently, serum levels of these cytokines do not correlate with the abnormal levels found in the tissues affected, thus obviating their use as serum tests. A possible exception may be the soluble IL-2 receptor (sIL-2r). Increased serum levels of sIL-2r seem to correlate with mucosal inflammatory activity. Levels decrease with response to therapy in parallel with the CDAI, and high levels have been predictive of clinical relapse.<sup>67</sup>

Perinuclear ANCA (pANCA) is an autoantibody found in the serum of approximately 50%–70% of UC patients but only 20%–30% of CD patients.<sup>68</sup> It does not correlate with disease activity, but is thought to indicate a more aggressive disease type, because of its association with patients who are relatively resistant to medical management and also with

patients who frequently suffer pouchitis after ileal pouch anal anastomosis.<sup>69,70</sup> Another serum antibody, that to a common yeast, *Saccharomyces cerevisiae* (ASCA), has been shown to be present in 50%–70% of CD patients but only 10%–15% of UC patients. Thus, the measurement of both ANCA and ASCA is increasingly being used to try to differentiate between CD and UC when disease is limited to the colon and confusing features, such as rectal sparing, exist.

Although strictly speaking not a serum test, there has been the recent discovery of certain genetic mutations as being associated with CD. The presence of these mutations can be assayed using the DNA of leukocytes harvested by peripheral blood draw. Three mutations affecting the *NOD2/CARD15* gene on the short arm of chromosome 16 have been identified as being associated with CD.<sup>33,34</sup> The *NOD2/CARD15* gene codes for an intracellular protein that has high binding affinity for bacterial peptidoglycan and may have a role in innate immunoresponsiveness to enteric bacteria. Mutations in this gene are found in approximately 10%–30% of CD patients versus 8%–15% of healthy controls. The relative risk of developing CD if mutations are carried in both copies of this gene is 10–40 times that of the general population. The presence of this mutation in a patient with CD is associated with ileal disease, earlier age of onset, and possibly fibrostenosing characteristics.<sup>29,71</sup> Mutations can be easily assayed by polymerase chain reaction techniques, and holds promise for possibly predicting responsiveness to medical or surgical therapies.

## Evaluation of the Acute IBD Patient

The clinical and laboratory evaluation of the presenting IBD patient will depend on many factors. Obviously, a good history and physical examination will focus the clinical caregiver in one or another area that will then direct subsequent testing and care. Many of the testing regimens described previously in this chapter apply to a greater or lesser degree based on clinical circumstances. There is no one good test for IBD, so the clinical judgment, experience, and acumen of the physician is key in patient management. Nonetheless, there are some basic and fundamental testing regimens that should be at least considered, if not repetitively performed, whenever IBD is considered the possible diagnosis. A basic outline of evaluation of the acutely presenting IBD patient is found in Table 39-7. It is important to remember that the patient with a known diagnosis of IBD will frequently still require such a basic work-up whenever their disease flares. This is in part attributable to the recognition that these patients are at significant risk for the development of a superimposed secondary diagnosis not infrequently related to iatrogenic causes. These might include pseudomembranous or cytomegalovirus colitis, stress- or steroid-induced gastric ulceration, fungal sepsis, or neutropenia. In addition, a known IBD patient presenting with worsening symptoms may now have progression of disease or the development of a directly related complication, such as an intraabdominal abscess, bowel obstruction, toxic colitis, or

TABLE 39-7. Evaluation of the IBD Patient

	Test	Purpose
<i>Serum labs</i>	CBC	r/o anemia, leukocytosis
	Electrolytes, renal function	r/o electrolyte disturbance 2° diarrhea, dehydration
	ESR or CRP	↑ in systemic disease
	LFTs, albumin	r/o PSC, nutritional compromise
<i>Stool studies</i>	C. diff.	r/o infectious causes
	O & P	r/o infectious causes
	Pathogens	r/o infectious causes
<i>X-rays</i>	Plain abdominal X-rays	r/o free air, toxic colitis, stones, obstruction
	SBFT / enteroclysis	For small bowel disease
	Barium / Gastrografin enema	For fistulas, strictures, distribution of disease
	CT scan	For abscess, obstruction, fistulas, adjacent organ involvement
<i>Endoscopy</i>	Flexible / rigid scope	For biopsy to r/o CMV, granulomas, pseudomembranes
	Colonoscopy	For biopsy, visualize extent and severity of disease

LFTs: liver function tests

O & P: ova and parasites

C. Diff: Clostridium difficile toxin

SBFT: small bowel follow through

CMV: cytomegalovirus

colovesical fistula. Thus, the studies outlined in Table 39-7 should be regularly considered for the acutely presenting IBD patient, tempered by the good clinical judgment of the caring physician.

# Medical Management of Inflammatory Bowel Disease

Stephen B. Hanauer, Wee-Chian Lim, and Miles Sparrow

Crohn's disease and ulcerative colitis (UC) are chronic inflammatory diseases of the gastrointestinal tract, collectively known as inflammatory bowel disease (IBD). IBD afflicts approximately 1.3 million Americans and seems to be increasing in frequency in many parts of the world,<sup>1</sup> producing chronic relapsing symptoms that are associated with increased morbidity and decreased quality of life. Although its etiopathogenesis is yet to be fully elucidated, it is thought to involve a complex interplay of genetic, environmental, microbial, and immune factors. Since the discovery of sulfasalazine's unanticipated efficacy in UC,<sup>2</sup> numerous agents have been added to the therapeutic "arsenal." Recent advances in our knowledge of the immunopathogenesis of IBD have also opened an exciting new door to biologic therapy. Pharmacotherapy remains the cornerstone of IBD management, with most patients requiring lifelong therapy because of the chronicity of the disease and its typical onset before 30 years of age.<sup>3</sup> Surgery is usually reserved for treating medically refractory disease or specific complications. With the exception of curative proctocolectomy in UC, neither medical nor surgical therapy can offer a cure for IBD. Therefore, the aims of therapy are to control symptoms, improve quality of life, and minimize short- and long-term complications of both the disease and its therapy.

An important principle in the medical therapy of IBD is that there are two phases to treatment: inducing symptomatic remission of active disease and maintaining this remission for the long term. Establishing the anatomic extent and clinical severity of disease is essential to guiding the therapeutic approach. Other important considerations include patient response to previous or current treatment, presence of complications, and side effects of the pharmacologic agents. Tailoring treatment according to the patient's unique needs and preferences has an important role in enhancing treatment adherence, which is crucial to an optimal long-term outcome. Therapeutic strategies continue to evolve with advancing knowledge, and this chapter details the current approach to medical treatment in IBD.

## Medical Management of Crohn's Disease

Crohn's disease, a form of chronic idiopathic IBD, is manifested by focal, asymmetric, transmural, and, occasionally, granulomatous inflammation affecting any part of the gastrointestinal tract, from mouth to anus. The incidence in the United States and other Westernized countries is estimated at 5/100,000 with a prevalence of 50/100,000. Although any age group can be affected, diagnosis is usually made in the second and third decades of life.

This section will cover both the induction and maintenance phases of medical treatments for Crohn's disease, with therapeutic strategies organized according to disease severity. Special mention will be made of the role of infliximab, because this has now become standard therapy for management of moderate-severe and fistulizing Crohn's disease. Areas of particular interest to our surgical colleagues will then be discussed including medical management of perianal fistulae, indications for surgery, and medical strategies to reduce postoperative recurrence of Crohn's disease.

## Induction Therapy for Crohn's Disease

### *Mild-Moderate Crohn's Disease*

Patients with mild-moderate Crohn's disease are generally ambulatory and tolerate liquid and solid intake. These patients typically do not have severe abdominal tenderness, inflammatory masses, bowel obstruction, weight loss of >10%, and are not manifesting signs of systemic toxicity [e.g., fever (>37.5°C), tachycardia (>90/minute), anemia (<75%) of normal value, an increased erythrocyte sedimentation rate (ESR) (>30 mm/hour)].<sup>4</sup> Aminosalicylates and antibiotics are the mainstay of therapy for mild-moderate Crohn's disease, although the topically acting steroid, budesonide, is increasingly being used as a drug of choice for mild-moderate disease, with minimal side effects.

Sulfasalazine (Azulfidine®) was the first aminosalicylate trialed in the 1970s and 1980s. It was proven to be beneficial over placebo in the treatment of ileocolonic and colonic Crohn's disease when given in doses of 3–6 g daily, with 40%–50% of patients achieving clinical remission.<sup>5</sup> Sulfasalazine, is a compound consisting of sulfapyridine and 5-aminosalicylic acid (5-ASA, also known as mesalamine) attached by an azo bond that is cleaved into the active moiety, 5-ASA and its carrier molecule, sulfapyridine, by colonic bacterial azo-reductases and hence has minimal efficacy in Crohn's disease of the small bowel.<sup>2</sup> Its use is also limited by more side effects at higher doses secondary to the systemic absorption of sulfapyridine. Slow acetylators are more apt to develop intolerance, including headache, nausea, vomiting, and dyspepsia, whereas dose-independent hypersensitivity reactions include fever, rash, pneumonitis, hepatitis, pancreatitis, hemolytic anemia, bone marrow suppression, and reversible sperm abnormalities. Sulfasalazine also impairs folate absorption and patients receiving sulfasalazine should receive daily folic acid (1 mg/day) supplements.

Because of these limitations with sulfasalazine, newer formulations of 5-ASA or mesalamine were developed that minimized side effects and utilized varying drug delivery systems to deliver the active drug intact to the mucosa of the small bowel and colon. Delayed-release formulations of mesalamine include Eudragit-S coated mesalamine (Asacol®) that releases 5-ASA in the terminal ileum and cecum at pH 7, and Eudragit-L-coated mesalamine formulations (Salofalk®, Mesasal®, and Claversal®) that releases in the mid-ileum at pH 6. Pentasa® (a sustained-release formulation of mesalamine microgranules enclosed within a semipermeable membrane of ethylcellulose) is designed for controlled release throughout the small and large intestine, beginning in the duodenum. Newer azo-bonded formulations designed for release in the colon include the 5-ASA dimer, olsalazine (Dipentum®), and balsalazide (Colazal®), which is composed of 5-ASA molecules azo-bonded to 4-aminobenzoyl-β alanine. Mesalamine in doses of 3.2–4.0 g daily is well tolerated and has been successful in inducing remission in 40%–50% of patients with mild–moderate Crohn's disease. However, results of clinical trials have produced conflicting results, and there have been no adequately powered trials to date comparing mesalamine with sulfasalazine in Crohn's disease.<sup>6</sup> The use of rectal mesalamine, although frequently used for left-sided Crohn's disease, is not supported by evidence from clinical trials.

Antibiotics are an alternative first-line therapy in mild–moderate Crohn's disease, and seem to work better in patients with colonic rather than small bowel disease. Metronidazole, when compared with sulfasalazine in a crossover trial, had initial similar efficacy, although more patients who failed sulfasalazine therapy responded when “crossed over” to metronidazole than vice versa.<sup>7</sup> Side effects to metronidazole include a metallic taste, and most importantly peripheral neuropathy that can be irreversible, when administered long term in doses of >1 g/day.<sup>8</sup>

A more effective and possibly better-tolerated alternative to metronidazole is ciprofloxacin in doses of 1 g daily. Trials using this dose show it to be equally efficacious to mesalamine, 4 g/day, with approximately 50% of the patients entering clinical remission.<sup>9</sup> In uncontrolled trials, combinations of ciprofloxacin and metronidazole have yielded superior results to using either agent alone.<sup>10,11</sup>

Controlled-release oral budesonide is the only Food and Drug Administration (FDA)-approved agent for treating mild–moderate Crohn's disease involving the ileum or right colon. Budesonide is a more potent glucocorticoid than prednisolone, but has a hepatic first-pass metabolism of 90% such that only 10% reaches the systemic circulation; thus, steroid side effects are greatly minimized.<sup>12</sup> When administered for 8–12 weeks at a dose of 9 mg/day, budesonide led to a higher remission rate than mesalamine, 4 g/day (69% versus 45%), but when compared with conventional corticosteroids the results are conflicting.<sup>13</sup> In a recent metaanalysis of trials comparing budesonide to conventional corticosteroids, budesonide was slightly less effective than prednisone, but was associated with significantly fewer steroid side effects. For a subgroup of patients with ileocecal disease, however, budesonide induced remission in 65%–75% of patients.<sup>12</sup>

Regardless of the treatment strategy chosen, response to therapy should be evaluated after several weeks; 8–16 weeks of therapy may be needed for maximal benefits. Patients achieving remission should be considered for maintenance treatment; treatment failures should be offered an alternative first-line therapy or considered for treatment options offered to patients with moderate–severe Crohn's disease.

### *Moderate–Severe Crohn's Disease*

Patients with moderate–severe Crohn's disease have either failed therapy for mild–moderate disease, or have significant systemic toxicity symptoms including fever, weight loss of >10%, abdominal pain and tenderness, nausea and vomiting without bowel obstruction, or significant anemia.<sup>4</sup> The treatment options for these patients include corticosteroids (prednisone or budesonide), infliximab, and at a relatively early stage, immunomodulator therapy with either thiopurines or methotrexate. Antibiotics may also be used for moderate–severe disease, but only for infectious complications such as abscesses, fistulae, or when used in conjunction with surgical drainage procedures. In patients for whom steroids are either ineffective or contraindicated, infusions of infliximab can provide an alternative therapy.

Corticosteroids are the mainstay of therapy in moderate–severe Crohn's disease and clinical trials with prednisone at doses of 40–60 mg daily for 8–12 weeks have achieved remission in 50%–70% of patients.<sup>5</sup> In clinical practice, prednisone is usually initiated at 40 mg daily and is continued at this dose until remission has been achieved—usually within 7–28 days. Subsequently, prednisone is tapered by 5–10 mg weekly until

patients are on 20 mg, and then by 2.5–5 mg weekly from 20 mg until it is discontinued.<sup>14</sup>

Corticosteroids are neither safe nor effective as maintenance therapy<sup>15</sup> and therefore, once steroids are initiated, maintenance strategies must be simultaneously devised. In patients with moderately severe ileal or ileocolonic Crohn's disease, budesonide 9 mg daily is an effective first-line alternative to prednisone. Treatment failures are usually switched to a conventional corticosteroid.

More than 50% of patients with moderate–severe Crohn's disease who are initially treated with steroids will become steroid dependent or steroid resistant, and may require therapy with an immunomodulator. Patients who smoke and those with colonic disease are particularly at risk; adjunctive treatment strategies usually are needed.<sup>16</sup> No demonstrable benefit has been shown in these patients when combining 5-ASA therapy with steroid therapy.<sup>17</sup>

In recent years, steroid-dependent or refractory patients have been treated with the thiopurines—azathioprine (AZA) (2–2.5 mg/kg daily) or 6-mercaptopurine (6-MP) (1–1.5 mg/kg daily), although dose-response studies for these agents have not been performed.<sup>18</sup> Recently, genetic polymorphisms of thiopurine methyltransferase, the primary enzyme metabolizing 6-MP, have been identified that may allow clinicians to more accurately monitor and dose these medications according to measurements of the metabolites 6-thioguanine and 6-methylmercaptopurine.<sup>19</sup> Prospective studies to assess the value of this therapeutic monitoring have not been performed.<sup>20</sup> The use of thiopurines in moderate–severe active Crohn's disease is limited by their slow onset of action—3–4 months; however, their addition to steroid therapy has been shown to increase remission rates and to allow steroid-sparing.<sup>18</sup> Patients on thiopurines require regular complete blood counts to monitor for leukopenia; these should be performed every 1–2 weeks initially, and then every 3 months once doses are stabilized. Despite previous concerns, there is no increased risk of lymphoproliferative disorders with the thiopurines and they are considered safe during pregnancy.<sup>21</sup>

Parenteral methotrexate, in a dose of 25 mg weekly either subcutaneously or intramuscularly, is an alternative steroid-sparing agent for patients with moderate–severe Crohn's disease. Parenteral methotrexate has been shown to induce remissions and to be steroid sparing.<sup>22</sup> Nausea and asymptomatic mild increases of liver function tests are the most frequently encountered side effects; more serious side effects such as leukopenia and hypersensitivity pneumonitis are seen only rarely. Patients taking methotrexate should be counseled to avoid alcohol, and this drug is absolutely contraindicated in pregnancy.

Infliximab is a chimeric monoclonal antibody to tumor necrosis factor, and is indicated for the induction and maintenance of moderate–severe Crohn's disease patients who are not responding to corticosteroids and immunomodulators.<sup>23</sup> Infliximab is also effective at reducing the number of draining fistulae in patients with fistulizing Crohn's disease.<sup>24</sup>

Emerging indications for infliximab include maintenance therapy for luminal<sup>25</sup> and fistulizing disease,<sup>26</sup> steroid-sparing in steroid-dependent patients, early use in hospitalized patients when rapid amelioration of symptoms is desired, and to curtail some of the extraintestinal manifestations of Crohn's disease.<sup>27</sup>

Generally, infliximab is started at 5 mg/kg for both induction and maintenance therapy of moderate–severe Crohn's disease; some patients in the maintenance phase may require an increased dose of 10 mg/kg. A three-dose induction regimen of infliximab given at 0, 2, and 6 weeks has been found to be the optimal dosing strategy for several reasons.<sup>28</sup> First, a three-dose induction regimen is at least as good as, if not superior to, a single-dose induction regimen. Second, a three-dose induction regimen may be beneficial and allow patients to develop an immunologic tolerance to infliximab. As a result, this regimen may reduce the formation of antibodies to infliximab (previously known as human anti-chimeric antibodies—HACA), and reduce subsequent acute infusion reactions or delayed hypersensitivity reactions, both of which are at least in part related to these antibodies. In the United States, the FDA-approved recommended dose is 5 mg/kg given at 0, 2, and 6 weeks as an induction regimen. Reinfusion every 8 weeks is necessary to maintain response in most patients and is recommended to help reduce the formation of antibodies to infliximab.

Concurrent immunomodulator therapy with AZA, 6-MP, or methotrexate may also improve outcome by reducing the formation of antibodies to infliximab or reducing the incidence of acute infusion reactions or delayed hypersensitivity reactions; most evidence to support this hypothesis is only anecdotal. Given the risk of reactivation of latent tuberculosis, all patients should be screened for tuberculosis with tuberculin skin testing (and chest X-ray if skin testing is positive) before initiating therapy with infliximab.<sup>27</sup>

### *Severe–Fulminant Crohn's Disease*

Patients with severe or fulminant Crohn's disease have ongoing symptoms despite oral steroids or infliximab given as an outpatient and present with high fever, cachexia, persistent vomiting, or may have evidence of an intestinal obstruction or an abscess. These patients almost always require hospital admission and resuscitation with intravenous fluids. Patients with clinical signs of a bowel obstruction or an abscess require an urgent surgical consultation, and intravenous antibiotics should be administered immediately, especially if sepsis is suspected. If sepsis can be excluded, then high-dose intravenous steroids should be started at doses equivalent to 40–60 mg of prednisone by either divided doses or continuous infusion. If patients do not respond to steroids within 5–7 days, alternative therapies such as infliximab, cyclosporine (CSA), or tacrolimus can be considered. Currently, there is no evidence base to support the use of these agents in this setting other than anecdotal experience.

Responders to parenteral steroids or CSA are then transitioned to an equivalent oral dose, whereas those failing medical treatments require surgery.<sup>4</sup>

### *Management of Perianal Crohn's Disease*

Perianal complications of Crohn's disease include ischio-rectal abscesses and perianal fistulae, and often require surgical intervention.<sup>29</sup> Abscesses require surgical drainage with or without the placement of setons, whereas fistulae should be treated at least initially with medical therapy including antibiotics, immunomodulators, or infliximab. Asymptomatic, nondraining fistulae can be safely observed without treatment once coexisting sepsis has been excluded. Initial medical treatment of abscesses should be with the antibiotics metronidazole or ciprofloxacin. Metronidazole in doses of 10–20 mg/kg is effective in reducing or stopping fistula drainage, although it seems that continuous therapy is needed to avoid recurrence, and side effects may be troublesome, especially peripheral neuropathy. In such cases, ciprofloxacin 500 mg per os twice a day is a reasonable alternative, or the two antibiotics can be given as combination therapy.<sup>30,31</sup>

The next line of treatment for perianal disease should be with an immunosuppressant agent such as AZA, 6-MP, CSA, or tacrolimus. Steroids have no role in perianal Crohn's disease. There are no long-term controlled trials assessing the thiopurines for perianal disease, although anecdotal success has been reported in some 40%–50% patients. Intravenous CSA is particularly potent; however, symptoms recur as soon as patients are begun on oral CSA.<sup>32</sup> Similarly, oral tacrolimus is effective, but is also associated with significant nephrotoxicity at effective doses.<sup>33</sup>

The role of infliximab in perianal Crohn's disease deserves special mention. In a placebo-controlled trial, patients who had previously not responded to antibiotics, steroids, or immunomodulators were given 5 mg/kg infliximab at 0, 2, and 6 weeks. Of these patients, 68% had a positive clinical response defined as a reduction by half the number of draining fistulae, and 55% had cessation of draining of all fistulae. The average duration of closure of fistulae was 12 weeks,<sup>24</sup> although maintenance therapy to prevent recurrent drainage or abscess has been demonstrated to be efficacious in the same manner as for luminal disease.<sup>26</sup> Patients receiving infliximab for perianal fistulae may benefit from temporary setons to ensure that recurrent abscess formation is prevented.

### **Maintenance Therapy for Crohn's Disease**

Once remission has been achieved, the aim of therapy must now turn to maintaining this symptomatic improvement. Whereas corticosteroid therapy is successful in inducing remission in the majority of patients, it has no role as maintenance therapy in Crohn's disease, and carries the risk of steroid dependence.<sup>15</sup>

After a medically induced remission with corticosteroids, there is no evidence that aminosalicylates are effective in maintaining remission, unlike in UC.<sup>17</sup> In contrast, the thiopurines—AZA (2–2.5 mg/kg) and 6-MP (1–1.5 mg/kg)—have been proven to be steroid sparing and to maintain medically induced remission.<sup>34</sup> Although the optimal dose and duration of therapy are yet to be defined, maintenance benefits have been proven for up to 4 years of therapy.<sup>35</sup> For patients who have responded to 25 mg/week methotrexate as induction therapy, maintenance benefits using a lower dose of 15 mg/week have been demonstrated, with almost two-thirds of patients maintaining a steroid-free remission at 1 year.<sup>36</sup> Patients on either the thiopurines or methotrexate require regular monitoring of blood counts and liver enzymes<sup>37</sup>; hence, only reliably compliant patients should be chosen for these therapies. The evidence base for maintenance infliximab therapy is rapidly expanding. In a large, multicenter randomized, controlled trial involving 573 patients, those patients receiving 5 or 10 mg/kg infliximab every 8 weeks after a three-dose induction regimen at 0, 2, and 6 weeks were more likely to maintain a steroid-free remission at 30 and 54 weeks than those who did not receive maintenance infliximab therapy.<sup>25</sup>

### **Indications for Surgery in Crohn's Disease**

Unlike UC, surgery for Crohn's disease is not curative, and yet is required in up to two-thirds of patients at some stage of their course to improve symptoms and quality of life. The most common indications for surgery are medically refractory disease, to avoid medication side-effects, or to treat complications of disease such as hemorrhage, perforation, obstruction, or abscess.<sup>4</sup> Although surgical resection is usually done, the disease predictably recurs at the anastomotic site, and stricturoplasty is a reasonable surgical alternative if previous small bowel resections place the patient at risk of short bowel syndrome. Any patient who fails to respond to 7–10 days of intensive inpatient management should be strongly considered for surgery. (See Chapter 42 for surgical management of Crohn's disease).

### **Postoperative Prophylaxis for Crohn's Disease**

Postoperative disease recurrence at 1 year after first resection for Crohn's disease is seen endoscopically in 60%–80% of patients and clinically in 10%–20%, with smoking being the strongest predictive factor for recurrence.<sup>38</sup> Luminal factors also seem to be responsible for disease recurrence, as fecal diversion prevents recurrence, only for it to recur once continuity is reestablished.<sup>39</sup> Hence, there has been increasing interest in medical therapies given postoperatively to delay disease recurrence.<sup>40</sup> Most studies are small and short-term, and have given conflicting results. Aminosalicylates and metronidazole have both been proven to reduce postoperative recurrence in certain subgroups of patients, particularly those with isolated ileal disease. A metaanalysis of six trials

evaluating mesalamine at various doses for this purpose showed that the risk reduction for endoscopic recurrence was 18% and for clinical recurrence was 10%, although no dose response was established.<sup>41</sup> Metronidazole (20 mg/kg) given for just 3 months from the time of ileal resection reduced clinical relapse versus placebo at 1 year from 25% to 4%, although many patients would have difficulty managing such high doses of the drug for longer periods.<sup>2,42</sup> Similarly, ornidazole administered for 12 months can also reduce endoscopic and clinical recurrences but, unfortunately, also is poorly tolerated by many patients. More recently, giving 6-MP 50 mg daily has been shown to be more effective than either mesalamine or placebo at reducing relapse; larger trials are needed to further validate these results.<sup>43</sup>

Thus, at present, there are no consistent recommendations regarding medical therapy after surgical resection for Crohn's disease. Many patients with longstanding strictures have a good postoperative prognosis, whereas patients with rapid progression of perforating complications and smokers have a worse prognosis. All patients should be advised to stop smoking. The choice of a specific postoperative recommendation requires some estimate of the patient's risk of recurrence as well as a thorough discussion with the patient regarding risks and benefits of medical therapy attempting to reduce the risk of clinical disease recurrence.

## Medical Management of UC

In contrast to Crohn's disease, UC is characterized by diffuse mucosal inflammation that is limited to the colon. It invariably affects the rectum, and may extend proximally in a diffuse, continuous, circumferential pattern to involve part or all of the large intestine. The incidence is estimated at 2–14/100,000 person-years, affecting approximately 690,000 individuals in the United States, with a peak incidence in the third decade of life.<sup>1</sup>

This section will discuss the induction and maintenance phases of medical treatments for UC, with therapeutic strategies organized according to disease severity. Similar to Crohn's disease, the clinical goals for UC are to induce and maintain remission. The anatomic extent and clinical severity of disease help guide the therapeutic approach.

### Induction Therapy for UC

Patients with UC typically present with bloody diarrhea, rectal urgency, and tenesmus. The primary goal of therapy is to induce clinical remission and promote mucosal healing.<sup>14</sup> Clinical remission is achieved when the inflammatory symptoms of diarrhea, bleeding, passage of mucopus, tenesmus, and urgency resolve, and with patients' renewed ability to distinguish gas from feces. In endoscopic remission, there is regeneration of an intact mucosa with a visible submucosal vascular pattern, without ulceration, significant friability, or

granularity. Pseudopolyps, mucosal bridging, and areas of "atrophic mucosa" with distorted vasculature represent previous episodes of severe inflammation. Histologically, remission is characterized by the absence of neutrophils in the epithelial crypts, although it is not customary to perform biopsies to confirm histologic remission.<sup>44</sup>

Clinical remission usually precedes endoscopic healing, which usually precedes histologic remission. To successfully begin maintenance therapy, it is imperative to achieve clinical remission; failure to do so virtually guarantees a relapse, with the need to reinstitute intensive and sometimes more aggressive inductive treatment. It has also been demonstrated that failure to achieve endoscopic remission and the presence of residual polymorphonuclear leukocytes in the epithelial crypts are predictors of disease relapse.<sup>45</sup>

Therapies for inducing remission are based on the anatomic extent of disease and clinical severity. Proctitis and distal colitis refer to inflammation limited to below the splenic flexure, and thus amenable to the reach of topical and oral therapy. In extensive disease, the inflammation extends proximal to the splenic flexure and requires systemic medication. Supplementary topical therapy is often beneficial to treat prominent rectal symptoms of urgency or tenesmus. Disease severity is classified as mild, moderate, severe, or fulminant. Patients with mild disease have less than four stools daily, with or without blood, no systemic signs of toxicity, and a normal ESR. Moderate disease is characterized by features of both mild and severe disease. Severe disease is characterized by more than six bloody stools per day, abdominal tenderness with signs of systemic toxicity including fever ( $>37.5^{\circ}\text{C}$ ), tachycardia ( $>90/\text{minute}$ ), anemia ( $<75\%$  of normal value), and an increased ESR ( $>30 \text{ mm/hour}$ ). Fulminant colitis is manifested by more than 10 bloody stools per day, anemia requiring transfusion, signs of systemic toxicity, abdominal distension, and tenderness.<sup>46</sup> For patients with mild–moderate UC, oral and/or topical mesalamine is the mainstay of therapy, whereas topical corticosteroids may be useful in those with distal disease. Oral corticosteroids are reserved for those with moderate–severe disease and for those who did not respond to optimized doses of oral 5-ASA and topical therapies. Patients with severe colitis or those refractory to maximal oral and topical doses of corticosteroids and 5-ASA should be treated with intravenous corticosteroids. Failure to show significant improvement with intravenous corticosteroids is an indication for intravenous CSA, infliximab or a curative colectomy.

### *Mild–Moderate Proctitis*

From a management standpoint, it is best to separate patients with proctitis from those with distal colitis. Although both are amenable to topical therapy, the choice of a topical pharmacologic agent is guided by the proximal extent of disease. Patients with proctitis have disease limited to the rectum, allowing effective topical therapy with suppositories. Mesalamine suppositories 1–1.5 g/day (Canasa®) either

nightly or in divided doses are highly effective for proctitis up to 20 cm, and superior to oral 5-ASA therapy<sup>47</sup> and to topical corticosteroids. The proportion of patients achieving remission increases with the duration of treatment and is not dose dependent. Response is usually seen within 2–3 weeks, with higher response rates (63%–79%) at 4–6 weeks.<sup>48</sup> In patients not responding to rectal mesalamine alone, combination therapy with a topical corticosteroid (foam or enema) is better than either therapy alone.<sup>49</sup> Oral mesalamine may be given to those patients failing topical therapies or as an alternative for those who are unable to tolerate topical therapy, but higher dose regimens are usually required. Systemic corticosteroids are rarely required in patients with ulcerative proctitis and should only be reserved for patients with severe or refractory disease.

### *Mild–Moderate Distal Colitis*

Topical 5-ASA is the treatment of choice for patients with distal colitis and achieves higher response rates than topical corticosteroids or oral 5-ASA therapy. Remission rates increase with the duration of therapy (63%–72% after 4 weeks) and are independent of dose; there are no apparent advantages of giving doses greater than 1 g/day.<sup>48</sup> Treatment is initiated with nightly mesalamine enema 4 g/60 mL (Rowasa®) administered at bedtime. Although topical 5-ASA is the most effective therapy for distal colitis, compliance may be difficult. Generally, mesalamine suppositories are easier to retain because of their smaller volume and more viscous state. Retention of mesalamine enemas is more difficult and may be associated with leakage and occasional abdominal discomfort. Mesalamine gel and foam formulations are easier to retain, but are not available in the United States. If enema retention is problematic for patients, loperamide (Imodium®) may be taken before enema administration to reduce rectal urgency and improve anal sphincter tone. Alternatively, initial therapy with mesalamine suppositories will allow for rapid improvement of rectal inflammation and improve ability to retain enemas. Smaller volume enemas (30 mL), that are easier to retain, may also be used to reach the upper rectum, reserving higher volume suspensions (60 mL) for more proximal spread up to the splenic flexure.

If a response is not seen within 2–4 weeks, an additional mesalamine enema or suppository may be added in the morning. Alternatively, combination therapy of mesalamine enemas at night and morning topical corticosteroids [e.g., hydrocortisone foam: 80 mg per application (Cortifoam®), or enema 100 mg/60 mL (Cortenema®)] may be considered, which is superior to either therapy alone.<sup>50</sup> The systemic bioavailability of rectally administered hydrocortisone approaches 80% because of low first-pass hepatic inactivation, and absorption tends to increase as colonic inflammation is reduced. Therefore, steroid-related side effects may begin to manifest after 2–4 weeks of treatment.

Newer formulations of corticosteroids, such as budesonide, are another therapeutic option to treat mild–moderate distal

colitis. Their high first-pass hepatic metabolism markedly reduces systemic bioavailability, endogenous cortisol suppression,<sup>51</sup> and thus reduces the potential for steroid-induced side effects. A metaanalysis showed that budesonide enemas (2 mg/100 mL, Entocort® enema) are as effective and offer an alternative to conventional topical corticosteroids.<sup>52</sup> 5-ASA enemas have achieved higher clinical remission rates than budesonide enemas although both had similar endoscopic and histologic outcomes.<sup>53</sup> Because the budesonide enema formulation is not available in the United States, our approach is to add budesonide 2 mg tablet into the mesalamine suspensions for night-time administration. Similarly, a compounding pharmacist can produce a combination of 2 mg budesonide/500 mg mesalamine suppository for nightly or twice daily use in proctitis.

A small proportion of patients have mesalamine hypersensitivity. They may demonstrate worsening of rectal bleeding and urgency with rectal mesalamine, usually within 3–5 days of administration. In patients with mesalamine hypersensitivity, rectal mesalamine should be discontinued, which usually provides symptomatic relief within 72 hours. Treatment with topical corticosteroids is usually effective in achieving remission in this group of patients.

For patients with mild–moderate colitis who are not responding to topical mesalamine (with or without topical corticosteroid), oral mesalamine may be added as combination therapy and is superior to either oral or topical therapies alone.<sup>54</sup> For those who are unable to tolerate or refuse topical therapy, oral mesalamine is an effective alternative for inducing remission. However, it is not as efficacious as topical therapy because of “right-sided constipation” in patients with distal colitis, resulting in decreased 5-ASA delivery to the diseased left colon. Oral corticosteroids are reserved for patients failing the aforementioned therapy.

### *Mild–Moderate Extensive UC*

When a patient has mild–moderate extensive UC, inflammation extends beyond the reach of topical therapy and oral pharmacologic therapy is required. Oral sulfasalazine or one of the newer 5-ASA formulations is the treatment of choice. In clinical trials, response rates with oral 5-ASA are similar for patients with distal and extensive colitis. Sulfasalazine achieves remission in 64%–80% of patients, at dosages of 2–6 g/day. There is a dose response for sulfasalazine, with larger doses achieving higher remission rates. Unfortunately, as many as 30%–40% patients are unable to tolerate higher therapeutic doses because of systemic absorption of the sulfapyridine conjugate. Patients on sulfasalazine should also receive daily folic acid (1 mg/day) supplementation because of inhibition of folate absorption.

As mentioned previously, the development of sulfa-free 5-ASA delivery forms have enabled clinicians to deliver larger amounts of the active moiety without the dose-limiting systemic toxicity. Effectiveness of these newer 5-ASA

formulations to induce remission in mild–moderate extensive UC has been confirmed in a recent metaanalysis.<sup>55</sup> Clinical improvement or remission can be achieved in as many as 84% of patients with Asacol® (2.4–4.8 g/day), Salofalk®, Claversal®, Mesasal® (1.5–3 g/day), Pentasa® (2–4 g/day), olsalazine (1–3 g/day), and balsalazide (6.75 g/day). All of the newer 5-ASA formulations have similar pharmacokinetic profiles, are therapeutically equivalent<sup>56</sup> and have similar efficacy to sulfasalazine when equimolar doses are used (1 g sulfasalazine = 400 mg mesalamine = 1.125 g balsalazide) and a dose response is similarly observed. Patients who do not respond to the lower therapeutic dose range within a few weeks should receive doses at the upper end. Adding topical mesalamine or a topical steroid can be a useful adjunct and can help alleviate troublesome rectal symptoms.

The newer 5-ASA formulations are well tolerated and hypersensitivity reactions are rare. Cases of pneumonitis, pericarditis, pancreatitis, and idiosyncratic nephritis have been reported. About 80% of sulfasalazine-intolerant patients will tolerate mesalamine. Up to 30% of patients on olsalazine have worsening of diarrhea resulting from increased ileal secretion, and this dose-related phenomenon usually improves as the colitis heals. However, mesalamine can rarely cause hypersensitivity colitis, which is manifested by worsening diarrhea when 5-ASA therapy is initiated.

Patients with mild–moderate extensive UC not responding to optimal doses of oral mesalamine (with or without topical mesalamine) and those with more severe but nontoxic systemic symptoms will require the addition of oral corticosteroids. Prednisone at doses of 40–60 mg/day is usually initiated and is effective within 1–2 weeks. Oral prednisone demonstrates a dose-response effect between 20–60 mg; 60 mg is only modestly more effective than 40 mg at the expense of greater side effects.<sup>57</sup> Once remission has been achieved, the dose can be tapered by 5–10 mg every week until the patient is on 20 mg, and then tapered by 2.5–5 mg every week thereafter, while maintaining remission with 5-ASA therapy.

### Severe UC

Patients with severe colitis that is refractory to maximal oral treatment with prednisone, 5-ASA, and topical medications should be hospitalized for further management. Initial patient evaluation should include blood tests for hematology, a metabolic panel, and total cholesterol level. An infectious process should be ruled out by stool analysis for ova, parasites, and *Clostridium difficile* toxin, fecal culture and sensitivity, and a rectal biopsy for cytomegalovirus.<sup>58</sup> Indiscriminate use of nonsteroidal antiinflammatory drugs (NSAIDs), anticholinergic agents, and antimotility (e.g., loperamide, diphenoxylate) should be avoided because of the potential of worsening colitis or inducing toxic megacolon.

The mainstay of treatment for severe colitis is parenteral corticosteroids in daily doses equivalent to 300 mg hydrocortisone or 48 mg methylprednisolone. There seems to be no

added benefit to using higher daily doses of steroids. Rectal corticosteroids may be added as adjunctive therapy for those who are able to tolerate and retain enemas, although no controlled studies have confirmed any incremental benefit. There are no data concerning the efficacy of 5-ASA in severe colitis and these may be discontinued, particularly in patients who were recently started on this therapy.

In the original Oxford experience, patients were treated with bowel rest, IV steroids, antibiotics, and rectal steroids for 5–7 days, and then assessed for response. Bowel rest and total parenteral nutrition (TPN) alone have minimal benefit as primary therapy for acute severe UC.<sup>59</sup> Nutritional support should be provided for severely malnourished patients with the recognition that enteral nutrition has the benefit of fewer complications compared with TPN. If patients are nauseated or vomiting, parenteral nutrition may be required. The routine use of antibiotics has been shown to have no primary, therapeutic benefit in the treatment of severe UC; however, most experienced centers administer broad-spectrum antibiotics to patients with fulminant or anticipated transmural disease.<sup>60,61</sup>

Patients with signs of transmural and fulminant colitis (fever, leukocytosis, abdominal tenderness, “thumbprinting” on abdominal radiograph) who are at risk of toxic megacolon and perforation should be placed on bowel rest and started on broad-spectrum antibiotics. Abdominal radiograph should be done to assess for colonic dilation and to look for free air. Narcotics and anticholinergics, which may worsen colonic atony and dilation, must be avoided. Because the failure rate of medical therapy in hospitalized severe UC patients approaches 40%, they should also be followed closely by an experienced surgeon. Patients failing to respond to 7 days of intravenous corticosteroids are unlikely to benefit from prolonging this treatment and should either be considered for intravenous CSA or referred for surgery.<sup>62</sup>

Patients with toxic megacolon are managed as above. In addition, the gastrointestinal tract should be decompressed with the insertion of a nasogastric tube and a rectal tube. Other maneuvers, such as assisting the patient to roll from a supine to prone position every 2 hours and a knee-elbow position, may help redistribute gas to the distal colon and rectum, and aid in the expulsion of bowel gas. These patients should be monitored closely in the intensive care unit for any signs of deterioration. Serial abdominal radiographs are usually reviewed every 12 hours and electrolyte abnormalities, such as hypokalemia that may aggravate colonic dysmotility, are treated aggressively. Medical therapy may avoid the need for surgery in up to two-thirds of patient cases.<sup>63</sup> Failure to improve within 72 hours is an indication for surgery; any clinical, laboratory, or radiologic deterioration on medical therapy mandates an immediate colectomy.

Intravenous CSA is an effective “rescue” therapy for severe steroid-refractory UC and acts as a bridge to maintenance therapy with the slower-acting thiopurines, AZA or 6-MP.<sup>64</sup> Patients who are noncompliant, have a history of inadequately controlled seizures or active infection should not be treated

with CSA. Hypocholesterolemia (serum cholesterol <120 mg/dL) and hypomagnesemia (serum magnesium <1.5 mg/dL) significantly increase the risk of seizures in patients treated with CSA. Whereas hypomagnesemia can be corrected promptly, cholesterol levels are far more difficult to correct, and should be checked early in potential candidates for intravenous CSA.

Before initiating therapy, the risks and benefits of CSA therapy should be reviewed in detail with the patient and an introductory meeting with the surgeons initiated. While continuing intravenous steroids, CSA is started as a continuous infusion of 2–4 mg/kg daily. A recent study confirmed the efficacy of low-dose CSA, which improves its toxicity profile.<sup>65</sup> CSA serum levels are obtained every 48 hours, with a target therapeutic level of 200–400 ng/mL [measured via high-performance liquid chromatography (HPLC)]. Daily inquiries should be made regarding symptoms of CSA toxicity such as paraesthesia, tremors, headache, and nausea. Blood pressure must be monitored and hypertension adequately controlled with a calcium channel blocker. Serum electrolytes are also monitored for CSA-induced nephrotoxicity, hyperkalemia, and hypomagnesemia, and careful attention given to any evidence of infection, especially at central venous catheter sites. Clinical improvement is generally seen within 4–5 days of initiating CSA treatment. Patients who have not demonstrated a significant improvement within 7 days of intravenous CSA therapy, or whose condition deteriorates during CSA therapy, are candidates for surgery.<sup>66</sup>

Most recently, infliximab has been used in patients with refractory<sup>67</sup> or steroid-resistant<sup>68</sup> UC. Two large trials, ACT I and ACT 2, have demonstrated efficacy of infliximab dosed at 5 mg/kg at 0, 2, 6 weeks and then every 8 weeks in moderate–severe UC (Sandborn and Rutgeerts, in press) and as a single dose for severe UC to prevent colectomy (Janerot, in press). The ultimate positioning of infliximab for UC remains to be determined.

## Maintenance Therapy for UC

The second goal of therapy in UC is to sustain the symptomatic improvement of a clinical remission. Clinical remission is achieved when the following inflammatory symptoms resolve: diarrhea, bleeding, passage of mucopus, tenesmus, and urgency. Endoscopic remission implies maintenance of an intact mucosa without ulceration, friability, or granularity and histologic remission presumes the absence of neutrophils in the epithelial crypts. It has been demonstrated that up to 40% of symptom-free patients had an abnormal sigmoidoscopy and 90% had microscopic inflammatory activity.<sup>69</sup>

Aminosalicylates are the primary maintenance therapy to prevent relapse of remitted UC.<sup>70</sup> AZA and 6-MP are useful steroid-sparing agents for steroid-dependent patients and for maintaining remission in those patients not adequately sustained by 5-ASA alone.<sup>57</sup> Corticosteroids, methotrexate, and nicotine are ineffective maintenance agents. Prolonged

administration of CSA at a dosage of more than 5 mg/kg daily is not advisable because of the risk of nephrotoxicity and, hence, has no role as maintenance therapy.<sup>71</sup>

Patients experiencing their first episode of proctitis that has responded promptly to topical treatment may not need maintenance medication as long-term remission may persist. If relapse does occur, there is usually a rapid response to re-treatment. Rarely, patients with a mild first episode of extensive colitis may opt to be followed without maintenance medication although the vast majority of patients will require therapy to prevent relapse.<sup>57,71</sup>

## 5-ASA–induced Remission of UC

Remission can be maintained with oral and/or topical 5-ASA formulations alone after induction therapy for mild–moderate UC. Once remission is attained, topical 5-ASA is the most effective maintenance therapy to prevent relapse of distal disease. Mesalamine suppositories (1–1.5 g/day) and enemas (1–4 g daily) are effective for patients with proctitis and distal colitis, respectively. A dose response is not seen above 1 g/daily in distal disease; however, the frequency of administration is of primary importance.<sup>48</sup> An attempt is usually made to reduce the frequency of topical therapy: initially every night,<sup>36</sup> then every other night, then every third night.<sup>72</sup> Most patients can continue on the lowest frequency of topical therapy that maintains remission and quality of life. The practice of alternate night dosing or every third night dosing does not substantially decrease remission maintenance rates.<sup>48</sup> Patients who flare after a period of quiescence maintained on mesalamine suppositories may have disease extension.<sup>73</sup> These patients will require repeat endoscopy and if extension of colitis is documented, oral therapy will be required.

Oral maintenance therapy for distal colitis is less effective than topical; however, most patients still prefer an oral aminosalicylate for its convenience, and transitioning to an oral maintenance regimen can be attempted. Patients requiring a combination of oral and topical 5-ASA to achieve remission often require combination 5-ASA therapy to maintain remission. An attempt to reduce and taper off rectal mesalamine may be made, but patients who require topical therapy to improve will usually require some regular administration of topical therapy to maintain remission. One study suggested that combination therapy with oral and intermittent rectal mesalamine (twice a week) is better than oral therapy alone.<sup>74</sup>

An oral aminosalicylate is the primary maintenance therapy for extensive colitis. A recent Cochrane review affirmed its efficacy as maintenance therapy in UC.<sup>70</sup> In contrast to topical 5-ASA, there is a dose-dependent efficacy in the maintenance effects of all oral 5-ASA. However, sulfasalazine is often limited by its dose-dependent adverse effects and although the optimal maintenance dose was determined to be 4 g/day, dose reduction to the lower 2 g/day is recommended to best balance sulfasalazine's efficacy and side effects.

There is currently no evidence to suggest that the newer 5-ASA formulations are more effective than sulfasalazine, but they have markedly lower incidence of adverse events, allowing a clinical response with an oral dose of up to 4.8 g/day without increasing toxicity. In the absence of an extensive evidence base for dosing mesalamine maintenance therapy, it has been our experience that the optimal maintenance dose is the same dose required to induce remission. We also administer oral therapy with aminosalicylates on a twice-daily schedule to improve compliance. Adherence to therapy is critical to an optimal long-term outcome, because patients who take less than 80% of the prescribed 5-ASA have a fivefold increase in the risk of relapse.<sup>75</sup> Risk factors for poor adherence include being single, being of the male gender, and use of multiple medications.<sup>76</sup>

### *Steroid-induced Remission in UC*

Corticosteroids (oral or topical) are ineffective maintenance agents and should be tapered and weaned off once remission has been achieved. 5-ASA remains the primary maintenance therapy after a steroid-induced remission, but will usually require higher doses equivalent to 2.4–4.8 g of mesalamine daily. Approximately one-fifth of patients that were treated with corticosteroids are steroid-dependent at 1 year<sup>77</sup>; these patients typically experience a relapse of symptoms when corticosteroids are tapered below a threshold dose of 15–20 mg/day. Because chronic long-term use of corticosteroids is unacceptable, patients should be considered for long-term immunosuppressive drug therapy with the thiopurines or a curative colectomy. AZA at doses of 2–2.5 mg/kg and 6-MP at doses of 1–1.5 mg/kg daily are effective steroid-sparing<sup>78–80</sup> and maintenance agents<sup>81,82</sup> in up to two-thirds of patients. The thiopurines have a slow onset of action and, while allowing time for them to take effect, patients are typically maintained on corticosteroids that are gradually tapered in the subsequent 2–3 months.

### *CSA-induced Remission in UC*

Steroid-refractory patients achieving remission with intravenous CSA are transitioned to oral CSA. The usual prescribed oral dose is twice the daily intravenous dose. In addition to oral prednisone 40–60 mg/day, AZA (2–2.5 mg/kg/day), or 6-MP (1–1.5 mg/kg/day) is initiated before discharge. Long-term outcome studies have demonstrated the importance of maintenance therapy with AZA or 6-MP that will allow more than half of severe, steroid-refractory UC patients to avoid surgery in the long term after a CSA-induced remission.<sup>83,84</sup> Because of the risk of opportunistic infection during the period of triple immunosuppressive therapy, *Pneumocystis carinii* prophylaxis with one double-strength trimethoprim-sulfamethoxazole tablet taken 3 times weekly is now standard therapy. Patients are followed up closely with the goal of maintaining CSA blood trough levels in the range of 150–300 ng/mL (HPLC). Corticosteroids are gradually

tapered within the ensuing 3 months and once adequate time (usually 3 months) has been allowed for the effect of AZA or 6-MP to “kick in,” CSA is tapered by reducing the dose by 50% for 2 weeks followed by complete withdrawal. A patient who relapses while on drug taper will usually be referred for surgery.

### Refractory UC Disease

Some patients continue to have active inflammatory disease despite maximal medical therapy with 5-ASA and steroids, yet are not so acutely ill as to warrant hospitalization for intravenous steroids and/or CSA or surgery. Conditions contributing to refractoriness must be excluded: treatment nonadherence, concurrent use of NSAIDs, infection, and 5-ASA hypersensitivity. Concomitant irritable bowel syndrome (IBS) may masquerade as “refractory” disease; the absence of inflammatory symptoms (urgency, rectal bleeding, fever), the prominence of abdominal bloating and cramping, and a normal flexible sigmoidoscopy aid in the diagnosis of IBS. Uncontrolled series have demonstrated the value of AZA and 6-MP in achieving remission in these steroid refractory, chronically active UC patients.<sup>80,82,85</sup> It is anticipated that infliximab will become an alternative option for this subgroup of patients who do not tolerate or respond to AZA or 6-MP. Colectomy may be the final option in these patients.

### Indications for Surgery in UC

Between 30%–40% of UC patients will eventually require surgery, with the majority of patients requiring surgery within 10 years of initial diagnosis. Emergent surgery is indicated when there is massive hemorrhage, toxic megacolon, perforation, and severe colitis that is unresponsive to medical therapy. Elective surgery is indicated for those with cancer or dysplasia, failure of or suffering from complications of medical therapy, and rarely to correct malnutrition and growth retardation in children, and to control debilitating extraintestinal manifestations. Chapter 41 discusses the surgical management of UC.

### Conclusion

The medical therapy of IBD is a complex and challenging area that requires close collaboration between the patient, gastroenterologist, and surgeon. The concepts or therapeutic goals of first inducing and then maintaining remission are important to understand, and different agents are used to achieve these goals in both Crohn’s disease and UC, albeit with considerable overlap. Corticosteroids are successful at inducing remission in both diseases, but they have no role as maintenance agents, and steroid-sparing agents such as AZA or 6-MP, or methotrexate in the case of Crohn’s disease, should be added at the first sign of steroid-dependence. Infliximab is now well

established in the therapeutic armamentarium for both the induction and maintenance of remission of luminal and fistulous Crohn's disease, although its role in UC is yet to be defined, and awaits the outcome of further clinical trials. CSA may be an effective "bridge" to induce remission in UC until therapeutic serum levels of AZA or 6-MP can be achieved, but is not used for maintaining remission. "Saving the colon at all costs" can no longer be advocated, because surgery provides a viable alternative to patients failing medical therapy or in those experiencing severe complications from either disease and can result in prompt symptomatic improvement in suitably chosen patients.

## Surgical Management of Ulcerative Colitis

Phillip R. Fleshner and David J. Schoetz, Jr.

Ulcerative colitis (UC) is a diffuse inflammatory disease of the mucosal lining of the colon and rectum that manifests clinically as diarrhea, abdominal pain, fever, weight loss, and rectal bleeding. Because removal of the affected organ is curative, surgery has assumed a pivotal position in the management of these patients. Although removal of the entire colorectum and permanent ileostomy had been the standard operation for decades, increased experience with anal sphincter preservation has demonstrated the feasibility of performing surgical procedures that spare sphincter function while still removing all disease. This chapter considers the surgical alternatives, decision making, and techniques surrounding these procedures.

### Indications for Surgery

The overall incidence of colectomy in a UC patient ranges from 23% to 45%.<sup>1-3</sup> This risk is higher in patients with pancolitis than in patients with left-sided disease.<sup>1,2</sup> Indications for colectomy include an acute flare unresponsive to medical measures, development of a life-threatening complication (e.g., toxic colitis, perforation, or hemorrhage), medical intractability, risk of malignancy, disabling extracolonic disease, and growth retardation in children. During an episode of acute colitis, the patient should be aggressively treated with intravenous steroids and bowel rest. The role of parenteral hyperalimentation in this situation is controversial. Encouraging results have been reported with the use of cyclosporine in acute colitis<sup>4</sup> yet long-term effectiveness of this particular treatment modality remains undefined. However, there is no reported increase in the incidence of perioperative complications after subtotal colectomy in patients treated before surgery with cyclosporine.<sup>5,6</sup>

Patients with life-threatening complications are generally easy to recognize and define. Nevertheless, these patients are frequently taking large doses of steroids and may appear deceptively well; consequently, appreciation of the severity of the disease and the timing of operation are of paramount

importance. Medical intractability is the most common indication for operation and may seem difficult to define. In fact, there is probably no strict definition that a physician can uniformly apply. It is important to recognize that medical intractability is a problem the patient identifies in conjunction with the physician. Although a physician may believe that 12 months of steroids or other immunosuppressive management without complete resolution of symptoms is an adequate medical trial, the patient must be convinced that surgery is indicated. Only the patient can decide he or she feels fatigued, has missed much work or school, or is unable to do things he or she would like to do because of the systemic effects of active colitis and its treatment. If the surgeon waits until the patient has arrived at the conclusion that the disease is not satisfactorily controlled medically, the patient will graciously accept alternatives the surgeon has to offer. We believe this is a particularly important strategy for the surgeon to use if the patient is to be satisfied.

Patients with UC are also prone to the development of colorectal cancer. The risk of cancer is relatively low for the first 10 years after disease onset but then begins to increase at a rate of 1%–2% per year.<sup>7</sup> Thus, by the time the patients have had the disease for 20 years, the cumulative risk of colorectal cancer may be as high as 20%. The question of timing of surgery for cancer prophylaxis remains controversial. Certainly, with an established carcinoma, surgical treatment is mandatory. More controversial, however, is the management of patients with dysplasia. Most surgeons contend that during a surveillance biopsy program, identification of high-grade dysplasia by an experienced pathologist is an indication for colectomy. Patients with low-grade dysplasia should also be offered colectomy, although nonoperative management of these patients has been suggested by some because the natural history of low-grade dysplasia has not been well established.<sup>8</sup>

Elective colectomy may be indicated for some categories of severe extraintestinal manifestations of the disease. Persistent or recurrent monoarticular arthritis, uveitis, or iritis all respond favorably to colectomy. However, primary sclerosing cholangitis, ankylosing spondylitis, and sacroiliitis are not

improved by colectomy. The response of pyoderma gangrenosum to colectomy is unpredictable.

Growth retardation is a common feature in children with UC. Contrary to popular belief, steroid therapy cannot be entirely blamed for delayed growth. Inadequate protein intake and excess loss in the colon are also contributory.<sup>9</sup> A rapid growth spurt is often observed after definitive surgery.

## Emergency Versus Elective Procedures

Operative management of UC largely depends on whether the surgery is elective or emergent. Under elective conditions, the four available surgical options are: 1) total proctocolectomy and Brooke ileostomy, 2) total proctocolectomy and continent ileostomy, 3) abdominal colectomy with ileorectal anastomosis (IRA), and 4) ileal pouch–anal anastomosis (IPAA). Total proctocolectomy and Brooke ileostomy has been traditionally regarded as the optimal surgical approach and remains the operation with which alternative procedures should be compared. The technique has been well described and the immediate and late results are very satisfactory. Furthermore, patients avoid any risk for cancer, steroid medications are eliminated, and physician visits and reoperations are kept to a minimum. Although quality-of-life studies<sup>10</sup> have demonstrated excellent results, the loss of fecal continence and its attendant physical and psychologic sequelae continue to be significant drawbacks of the procedure. In addition, problems with nonhealing of the perineal wound, and the high incidence of small bowel obstruction and ileostomy revision, are not to be minimized.

Total proctocolectomy and continent ileostomy couples the benefit of complete large bowel excision with a reduction in some of the untoward aspects of an ileostomy, because no external appliance is needed and the stoma can be placed in a less conspicuous position on the abdominal wall. Continent ileostomy can be performed at anytime in UC patients having previously undergone total proctocolectomy and Brooke ileostomy if they find a standard ileostomy unsatisfactory. Because of increased surgical experience and improved surgical techniques, continent pouch morbidity has decreased since its initial clinical description. Most patients are ultimately happy with the results of the operation. Nonetheless, troublesome complications leading to incontinence continue to plague the postoperative course of a substantial number of patients.<sup>11</sup>

There are many attractive features of colectomy and IRA. The procedure avoids the perineal complications of total proctocolectomy, the risk of sexual dysfunction is minimal, is technically easy to perform, may provide perfect control of feces and flatus, and is well accepted by most patients. However, unlike the three other surgical options, ileorectostomy does not achieve total excision of colorectal mucosa. Many surgeons have not used this operation for UC, arguing that more than 25% of patients will require subsequent rectal

excision for persistent proctitis,<sup>12,13</sup> a small percentage of patients will develop cancer in the rectal remnant, and only half of the patients have satisfactory long-term functional results. Although we concur that this operation should not be advised in most UC patients, IRA does have a role in certain clinical situations. For example, an elderly patient with a long history of UC who develops a transverse colon cancer may be well served with an IRA in lieu of total proctocolectomy. Decisions must be made on an individualized basis, taking into account the compliance of the rectum and the integrity of the sphincter mechanism.

IPAA has the attractive features of complete excision of the colorectal mucosa, avoidance of a permanent intestinal stoma, continence via a normal route of defecation, and no prospect for a troublesome nonhealing perineal wound. Continence is usually preserved and the frequency of defecation is diminished with incorporation of a pelvic pouch into the operative procedure. Although the operation is associated with minimal mortality, the morbidity of this complex procedure is relatively high, and problems such as small bowel obstruction and pouchitis continue to be a cause for concern.

Under emergent conditions, surgical alternatives are limited. If the patient is septic, the diseased or perforated bowel should be removed. If the colon is bleeding, the colon should be removed. Traditionally, it has been taught that the rectum should also be removed. However, with the sphincter-saving alternatives that are currently available, careful preoperative proctoscopic evaluation to exclude a rectal etiology for the bleeding and a subsequent abdominal colectomy with end ileostomy can be safely performed. A subsequent procedure can then restore intestinal continuity. Similarly, with toxic colitis, it is seldom necessary to perform a proctectomy at the time of colectomy. In general, concerns over healing of the perineal wound in these frequently malnourished patients who are taking high-dose steroids should deter surgeons from doing proctectomy in the emergent setting. The authors have not found it necessary to use the blow-hole technique of Turnbull, but this is a philosophically acceptable approach in that it does not preclude subsequent continence-preserving alternatives. This technique is mainly of historical significance because most UC patients currently present for colectomy earlier and are not as nutritionally depleted as when this technique was frequently used.<sup>14</sup>

A few technical issues regarding subtotal colectomy in these patients must be stressed. Mesenteric dissection in the vicinity of the ileocecal valve should be flush with the colon to preserve ileal branches of the ileocolic artery and vein. These branches are necessary to facilitate subsequent construction of an ileal pouch. Distally, it is unnecessary to mobilize the rectum within the pelvis. In fact, dissection of the sigmoid to the sacral promontory, without violation of presacral planes, and a Hartmann procedure are recommended. This has shown to decrease the incidence of pelvic sepsis and facilitate subsequent pelvic surgery. The colon should be

transected at the rectosigmoid junction and an intraperitoneal rectal stump created. Technically, closure of the rectal stump can be hazardous because the bowel is markedly inflamed and does not hold sutures or staples well. Bringing the distal site of transaction out as a mucous fistula, which can be either primarily matured or buried within the abdominal incision<sup>15</sup> or the subcutaneous tissue,<sup>16</sup> are alternative techniques to safely manage the very diseased rectal stump. A transanal rectal drain may prevent leakage from the diseased Hartmann pouch closure site.

There is a trend to avoid subjecting patients to multiple surgical procedures and to perform a definitive procedure at the time of emergent surgery. Although an IPAA can be successfully performed in patients undergoing surgery for emergent complications, the authors believe this generally is not a safe approach. These patients are usually on high doses of steroids and are nutritionally depleted. Patients with UC receiving high-dose steroids (more than 40 mg/day) have a significantly greater risk of developing pouch-related complications after colectomy than patients with UC receiving 1–40 mg/day and patients with UC who are not receiving corticosteroids.<sup>8</sup> From a practical standpoint, surgical options are limited in emergent situations. Salvage of the patient should be the primary concern. Abdominal colectomy is safe in these very ill, nutritionally depleted patients<sup>5,15–18</sup> and the procedure does not preclude any of the other surgical alternatives in the future. Additionally, the patient is able to live with an ileostomy and assess its impact on his or her life, thus allowing for an informed decision regarding subsequent continence-restoring surgery.

## Brooke Ileostomy

The preoperative period should include effective patient education. A patient must be fully informed of the effects of an ileostomy on his or her quality of life. An ileostomy visitor, preferably age and sex matched and who has completely recovered from surgery, is invaluable during this period. Resistance to a permanent ileostomy can be tempered by stressing the beneficial aspects of this operation (e.g., curing the disease). It is also essential, when possible, to select the stoma site preoperatively with the help of an enterostomal therapist. As discussed in Chapter 44, the stoma should be placed in a flat area away from bony prominences, scars, and significant skin creases. Attention to these details will ensure a well-functioning ileostomy.

## Operative Technique

A colectomy is performed in the standard manner with the patient in a modified lithotomy Trendelenburg position. The proctectomy phase of the procedure is remarkable for keeping the dissection close to the rectal wall, especially anteriorly in the area of Denonvilliers' fascia. Meticulous

dissection to minimize the risk of injury to pelvic autonomic nerves is essential. Perineal dissection should be performed in the intersphincteric plane. After the colectomy is removed, a Brooke ileostomy is constructed.<sup>19</sup> An appliance is then placed over the stoma. Bowel function is expected in 3–6 days.

In some situations, the end of the ileum does not reach far enough through the abdominal wall to allow primary maturation. In these situations, the mesentery is usually a limiting factor and selection of a more proximal site in the bowel may allow better mobilization. Alternatively, a loop-end ileostomy rather than an end ileostomy may reach more easily.

## Postoperative Complications

A proctocolectomy with a Brooke ileostomy is a safe procedure with a predictable long-term outcome. It is, however, not entirely free of complications. Delayed healing of the perineal wound is not uncommon and can be quite problematic.<sup>20</sup> Failure of the wound to close should prompt investigation to exclude the presence of retained mucosa, foreign material, or Crohn's disease (CD). Sexual complications of proctocolectomy in men are much less common than in patients having a radical resection for cancer, yet permanent impotence or retrograde ejaculation can occur. Almost 30% of women complain of dyspareunia after this operation, presumably as a result of perineal scarring.<sup>21</sup> Intestinal obstruction is a troublesome complication that can be managed conservatively in most patients. Gentle irrigation of the stoma is an important therapeutic maneuver. Prolonged nonoperative treatment should not be pursued for fear of infarction. Although problems from the ileostomy have diminished markedly with the use of modern appliances and the Brooke modification, skin irritation, stomal stenosis, prolapse, and herniation remain significant causes of postoperative morbidity. Treatment of these problems can be as simple as reeducating a patient about the proper maintenance of the ileostomy. However, up to one-third of these patients ultimately require operative revision.<sup>22</sup> Despite the fact that these patients have undergone major abdominal surgery and have a permanent stoma, their quality of life as measured by validated questionnaires is very good and similar to that of the general population.<sup>10</sup> More than 90% of patients are happy with their current lifestyle. However, significant problems do remain. Almost 25% of patients are restricted in their social and recreation activities, and nearly 15% of patients who are knowledgeable of alternative procedures would consider conversion. In short, the Brooke ileostomy is generally well accepted, although a number of patients experience significant psychosocial and mechanical difficulties.

Current indications for the procedure include elderly patients, individuals with distal rectal cancer, patients with severely compromised anal function, and patients who choose this operation after appropriate education.

## Continent Ileostomy

Physicians involved with patients requiring an ileostomy should be aware of the continent ileostomy. Although this procedure is less often performed today, it remains a viable alternative in patients who have discrete problems with an appliance. A continent ileostomy is usually reserved for patients who have failed Brooke ileostomy or those who are candidates for an IPAA but cannot have a pouch because of rectal cancer, perianal fistulas, poor anal sphincter function, or occupations that may preclude frequent visits to the toilet.

Preoperatively, a search for CD using barium examination of the stomach and small intestine is important. Suspicion of CD contraindicates construction of a continent ileostomy, because the risk of recurrent disease in the pouch is increased; this could necessitate resection of 45 cm of valuable small bowel and render the patient unable to maintain nutrition. Obesity and age over 40 years are associated with an increased risk of pouch dysfunction and represent relative contraindications to the continent ileostomy.<sup>23</sup>

The period before surgery must also include an open discussion with the patient, stressing that although continence is likely, major complications often occur. These setbacks generally must be corrected surgically, sometimes leading to pouch excision and creation of a standard Brooke ileostomy. The patient must comprehend that by learning to care for and intubate the reservoir, he or she has an important role in its functional outcome. Only highly motivated, emotionally stable individuals should consider this procedure.

### Operative Technique

Patients undergoing combined total proctocolectomy/continent ileostomy have a proctocolectomy performed in the usual manner. Excision of a very short segment of terminal ileum and a diligent search for CD during the procedure are essential. In patients with a standard ileostomy undergoing conversion to continent ileostomy, the stoma is mobilized from the abdominal wall. Construction of the reservoir in these two patient groups is then performed in an identical manner.

The technique of constructing a continent ileostomy is conceptually difficult (Figure 41-1). Using the terminal 45–60 cm of the ileum, an aperistaltic reservoir is created by making an S-pouch or a folded two-limb pouch originally described by Kock et al.<sup>23</sup> In the classic technique, two 15-cm limbs of ileum are sutured together with continuous absorbable sutures to form a pouch. The antimesenteric border is incised and then folded over to form a reservoir. The ileum immediately distal to the reservoir is then scarified with electrocautery and 5 cm of adjacent mesentery is removed or thinned of fat and intussusception of this terminal 15 cm of ileum into the pouch is performed. The intussusception is secured with multiple nonabsorbable sutures and staples. The end of the ileum is then brought through the abdominal wall at the preoperatively identified site. Because

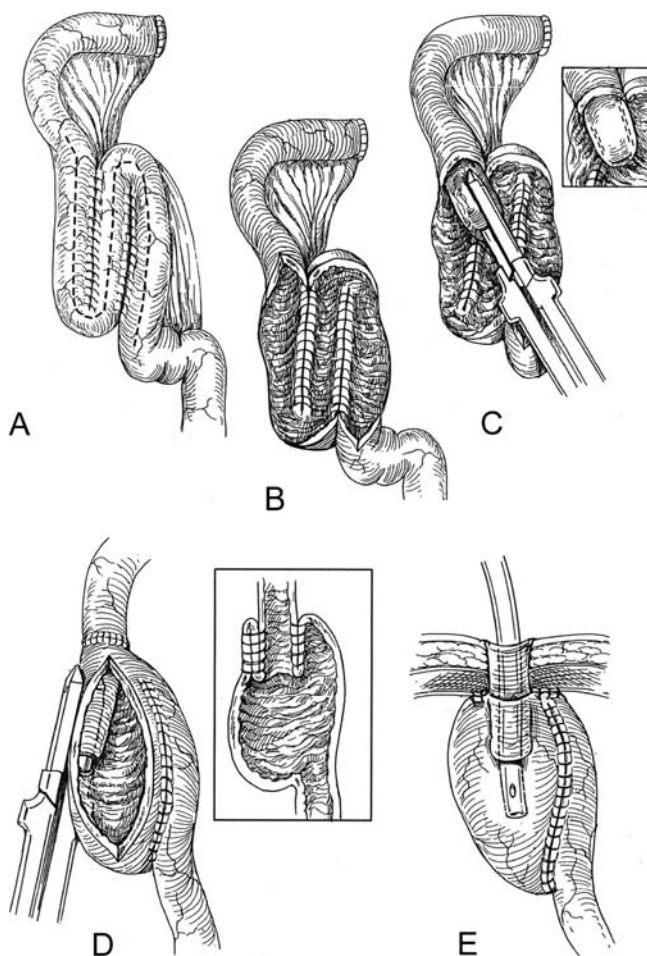

FIGURE 41-1. Continent ileostomy. **A** Three limbs of small bowel are measured and the bowel wall is sutured together. **B** After opening the bowel (see the dotted lines in A), the edges are sewn together to form a two-layered closure. **C** A valve is created by intussuscepting the efferent limb into the pouch and fixing it in place with a linear non-cutting stapler. (Inset: staples in place on valve). **D** The valve is attached to the pouch sidewall with the linear noncutting stapler (a cross-section of the finished pouch is shown). **E** After closure of the last suture line, the pouch is attached to the abdominal wall and a catheter is inserted to keep the pouch decompressed during healing.

no external appliance is required, a continent ileostomy can be located lower on the abdominal wall for cosmetic reasons. The stoma is sutured flush with the skin and the pouch firmly anchored to the posterior rectus sheath. A wide plastic tube with large openings (i.e., Madina catheter; AStra Tech, Molndal, Sweden) is placed into the pouch to allow gravity drainage of the pouch in the early postoperative period. This tube is occluded for progressively longer periods beginning 10 days after surgery until it can be removed for 8 hours without distress. At this point, the pouch is significantly expanded, the tube is removed, and drainage is achieved by intubating the pouch three times a day.

## Postoperative Complications

Postoperative complications that occur with sufficient frequency are nipple valve slippage, pouchitis, intestinal obstruction, and fistula. Nipple valve slippage<sup>24,25</sup> occurs because of the tendency of the intussuscepted segment to slide and extrude on its mesenteric aspect. Difficult pouch catheterization, chronic outflow tract obstruction, and incontinence ensue. Because of the frequency of this problem, many techniques other than simple surgical stapling have been described to stabilize the valve. Wrapping the valve with prosthetic materials does prevent valve slippage but also is accompanied by a potentially unacceptably high incidence of parastomal abscess and fistula formation.<sup>11</sup> Despite these technical modifications, nipple valve slippage remains the most common complication after continent ileostomy, occurring in almost 30% of patients.<sup>11,24,25</sup> Although nonoperative approaches have been attempted to correct this problem, surgical correction is virtually inevitable. Repair of the existing malfunctioning valve or creation of a new valve from the afferent ileal limb is performed.

Pouchitis is recognized in 25% of patients, making this the second most common postoperative complication after continent ileostomy.<sup>11,23,24</sup> Pouchitis refers to nonspecific inflammation that develops in the reservoir, and is thought to result from stasis and overgrowth of anaerobic bacteria. Patients present with a combination of increased ileostomy output, fever, weight loss, and stomal bleeding. The diagnosis is made by history and confirmed by pouch endoscopy. Pouchitis usually responds to a course of antibiotics and continuous pouch drainage.

Other complications include an incidence of intestinal obstruction after continent ileostomy of about 5%. Surgical intervention is mandatory when nonoperative therapy has been unsuccessful. The incidence of fistulas after creation of a continent ileostomy is approximately 10%. Fistulas usually originate in the pouch itself or at the base of the nipple valve. Pouch fistulas result from dehiscence of suture lines or, rarely, ileostomy tube erosion. These tracts may close with bowel rest, parenteral nutrition, and continuous pouch drainage. Fistulas from the base of the valve lead to incontinence, because ileal contents bypass the high-pressure zone of the nipple valve. These fistulas usually arise with tearing of the sutures anchoring the pouch to the anterior abdominal wall. Valve fistulas rarely heal without operation. At laparotomy, the valve is excised, the pouch rotated, and a new continent valve constructed from the afferent tract.

Patient satisfaction with a continent ileostomy is excellent.<sup>26</sup> Most patients note a marked improvement in their lifestyle, and almost all patients work and participate in social and recreational activities without restriction.<sup>24</sup> These observations are understandable in that 90% of patients eventually have total continence after one or more procedures. However, their enthusiasm is surprising considering that complications are quite frequent and often require major surgical intervention.<sup>23,24</sup> The often advertised Barnett modification of the Kock pouch

(Figure 41-2) uses the afferent limb of small bowel to construct the nipple valve and wraps a portion of the residual efferent limb around the nipple valve.<sup>27</sup> This modification was designed to reduce the incidence of valve slippage and fistula formation. Another recently described variation<sup>28</sup> is the "T-pouch" in which a portion of ileum is folded into the side of the pouch rather than being intussuscepted (Figure 41-3). Theoretically, this eliminates valve slippage. Unfortunately, there are no controlled data to suggest that either of these modifications is any better than the standard procedure most centers are using.

## Ileorectal Anastomosis

Before the advent of IPAA, abdominal colectomy with IRA was performed in UC patients who might otherwise have been offered a permanent ileostomy. Currently, IRA is mainly considered in patients with indeterminate colitis (IC), in

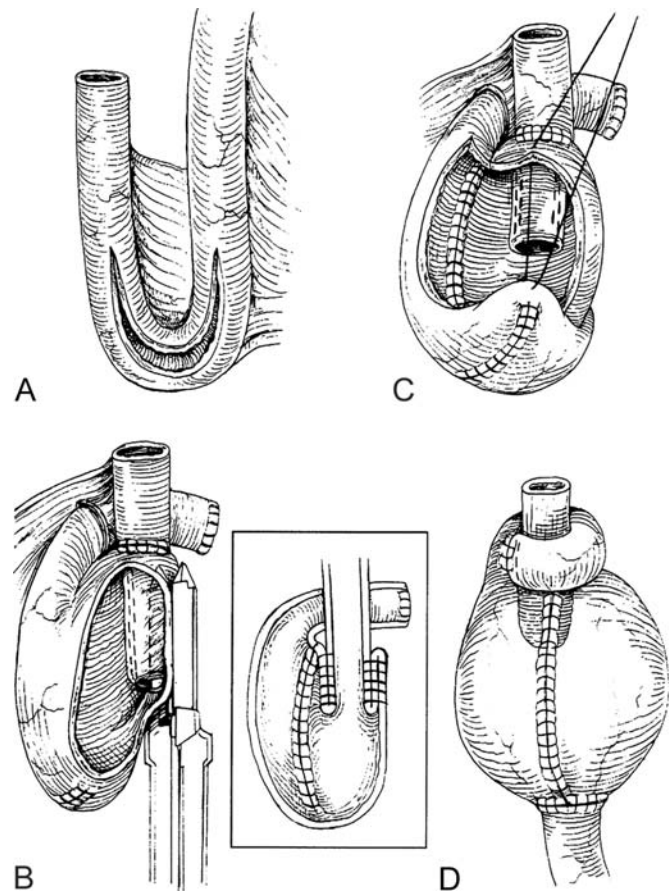

FIGURE 41-2. Barnett continent ileostomy reservoir (BCIR). **A** Two limbs of small intestine are sewn together and opened. **B** The afferent limb is intussuscepted to form a valve and the valve is stapled to the side of the reservoir. **C** The pouch is folded back and sutured closed. Insert shows cross-section of pouch. **D** Completed BCIR. The afferent limb of bowel has been divided and reattached to the apex of the pouch and the efferent limb is wrapped around the valve to form a collar.

FIGURE 41-3. T-pouch. **A** Seromuscular sutures approximate the back wall of the pouch and fix the valve segment to the pouch through mesenteric windows. **B** The bowel is opened. **C** Edges of the bowel are closed over the valve segment. **D** The reservoir is folded in half and closed.

high-risk or older patients who are not good candidates for IPAA, or if there is mild rectal disease in which rectal compliance remains adequate. The use of the operation may also be indicated in the teenager or young adult to rapidly regain good health, avoid a stoma, and return to school or work quickly. Functional results depend on the level of the anastomosis as well as the state of the rectum. Contraindications to IRA include a very diseased and noncompliant rectum, dysplasia or nonmetastatic cancer, perianal disease, and a severely compromised anal sphincter.

### Postoperative Complications

IRA is a safe operation; mortality is low, particularly when it is performed as an elective procedure. The early morbidity of IRA is low, with the incidence of anastomotic leak being less than 10%, and major sepsis is very uncommon. Sexual

function is well preserved. The overall complication rate is much lower than that of an IPAA.<sup>12</sup> Although the frequency of defecation after IRA is variable, most patients pass between two and four semiliquid stools a day. Nocturnal defecation is quite common, but true incontinence is rare.<sup>29</sup>

The main concerns surrounding IRA for UC are the long-term issues regarding cancer risk in the retained rectum and the incidence of persistent rectal inflammation. The overall risk of cancer developing in the rectum after IRA approximates 6%, but this depends on the duration of follow-up.<sup>30</sup> Few of these cancers develop less than 10 years after operation, with most cancers appearing 15–20 years after operation. Cancer in the rectum after IRA produces few symptoms and early lesions are not always easily identified at sigmoidoscopy. Patients being offered IRA must realize the need for semiannual sigmoidoscopy with multiple biopsies to detect dysplasia, polyps, or invasive cancer. This recommendation is particularly important in young adults or children because these patients have the highest risk of developing cancer and are much more likely to be lost to follow-up.

The rectal stump may be the site of recurrent or persistent inflammation in 20%–45% of patients. Clinical features include severe diarrhea, tenesmus, bleeding, and urgency. Rectal excision is needed in those cases that do not respond to topical or systemic therapies. About one-quarter of patients require proctectomy after IRA for severe proctitis.<sup>12,13</sup> The only clinical factor that predicts a successful outcome is the degree of inflammation in the rectum preoperatively, minimal proctitis being associated with an excellent prognosis.<sup>12</sup> A great advantage of the IRA is that should a failure occur, other options remain. Conversion from an IRA to an IPAA may be required when there is a poor functional outcome because of poor rectal compliance, persistent and disabling proctitis, and with development of an upper rectal cancer. If conversion to IPAA is required, it can be performed safely, although poorer bowel function may be expected. However, quality of life is similar before and after conversion in these patients.<sup>30</sup>

## Ileal Pouch–Anal Anastomosis

The most attractive of the continence-preserving alternatives is the IPAA, which consists of near total proctocolectomy, creation of an ileal reservoir, and preservation of the anal sphincter complex. The original operation as described by Sir Alan Parks included a complete stripping of the anal mucosa of the anal canal.<sup>31</sup> In an attempt to improve functional outcome, some surgeons<sup>32,33</sup> preserve the anal transition zone and perform a stapled anastomosis between the ileal pouch and the anal canal immediately cephalad to the dentate line (“double-stapled” technique). Both of these techniques remove the colorectum without creating a perianal wound, preserve innervation to the anus, bladder, and genitals, and retain the usual pathway for defecation. Preoperatively, the rectum should be evaluated sigmoidoscopically. Active rectal

disease requires topical 5-aminosalicylic acid or steroid enemas to minimize rectal inflammation and facilitate mucosectomy. The anorectal sphincter mechanism must be intact to prevent leakage of watery ileal contents. Use of this procedure in patients with poor sphincter function or fecal incontinence must be carefully individualized. Preoperative evaluation also allows the surgeon to be certain that patients undergoing this operation are highly motivated and willing to cope with potential postoperative complications.

### Operative Technique

After appropriate bowel preparation, the patient is brought to the operating room and placed in the modified lithotomy position. A midline incision is made and the abdomen explored to rule out evidence of CD. The colon is mobilized in the usual manner. A few technical points should be stressed. Omentectomy may be inappropriate, because there is a lower incidence of postoperative sepsis when the omentum is preserved.<sup>34</sup> Stapling of the distal ileum flush with the cecum is very important, as is preservation of the ileal branches of the ileocolic artery and vein. These vessels provide perfusion of the pouch after mesenteric division. The pelvic peritoneum is incised and rectal mobilization begun. Dissection is carried ventrally to the level of the prostate in men and the mid-portion of the vagina in women. Posteriorly, the dissection is carried past the end of the coccyx. Mobilization of the rectum should be flush with

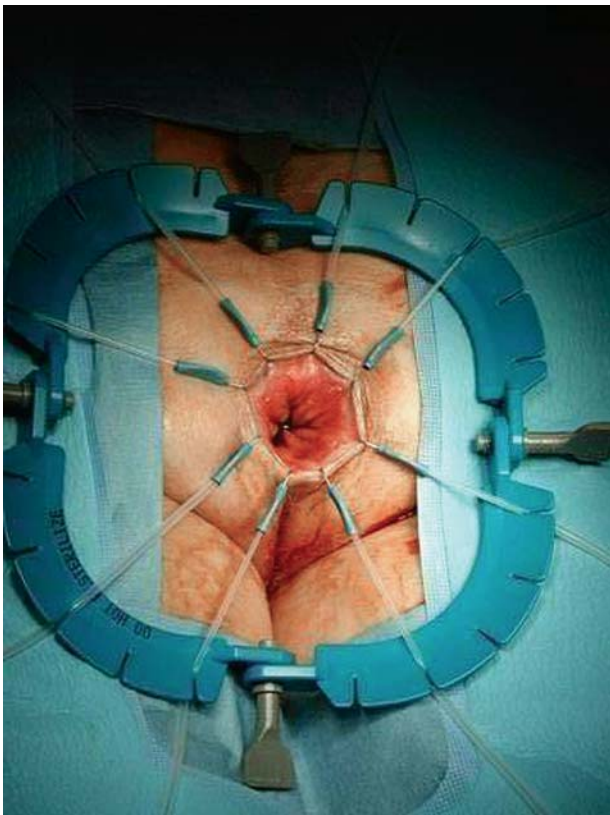

FIGURE 41-4. Lone Star™ retractor.

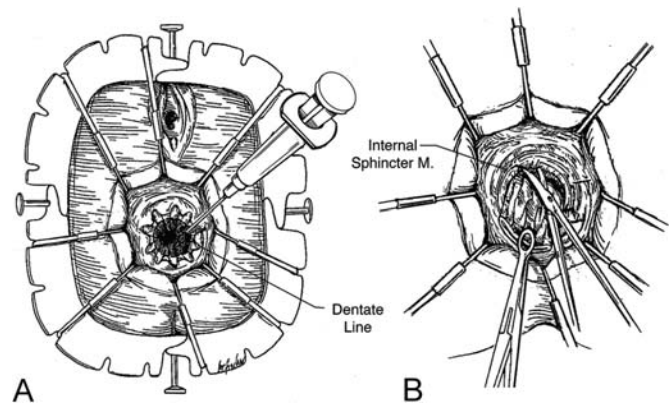

FIGURE 41-5. Mucosectomy. **A** A spinal needle is used to inject saline solution with epinephrine (1:200,000) into the submucosa from the dentate line to the levators. A circumferential incision through the mucosa is made at the dentate line. **B** A sleeve of mucosa is dissected free from the internal sphincter using sharp dissection.

fascia propria to minimize damage to nearby autonomic nerves traveling to urinary bladder and sexual organs.

Mucosal stripping is performed from a perineal approach. The use of a Lone Star™ retractor facilitates exposure and minimizes damage to the sphincter mechanism (Figure 41-4). A solution of dilute epinephrine is injected into the submucosal plane to facilitate mucosectomy and minimize bleeding (Figure 41-5). The excised mucosa and remaining proximal rectum are removed, leaving a short cuff of denuded rectal muscle distally for about 4 cm above the dentate line. Attention is then directed toward creation of the ileal reservoir. The terminal ileum is aligned in a J configuration and the pouch constructed with either a continuous absorbable suture or stapling device (Figures 41-6 to 41-9). Both limbs of the J are approximately 15–25 cm in length, the exact length guided by where the pouch reaches deepest into the pelvis. The prospective apex of the pouch must reach beyond the symphysis pubis to accomplish a tension-free ileoanal anastomosis. Selective division of mesenteric vessels to the apex of a proposed J-pouch will allow for more length (Figure 41-10). Superficial incision on the anterior and posterior aspects of the small bowel mesentery along the course of the superior mesenteric artery, and mobilization of the small bowel mesentery up to and anterior to the duodenum, are two additional important lengthening maneuvers. The pouch is then pulled into the pelvis and the anastomosis performed between the apex of the pouch and the dentate line, approximating full thickness of the pouch wall to the internal sphincter and anal mucosa (Figure 41-11). A proximal defunctioning loop ileostomy is created. One or two suction drains are placed in the presacral space and brought out through the left lower quadrant of the abdomen away from the ileostomy site.

In the double-stapled technique, the anorectum is divided by the abdominal operator approximately 2 cm above the dentate line using a right-angle linear stapler (Figure 41-12). After the pouch is created, the anvil of the mid-sized circular stapler

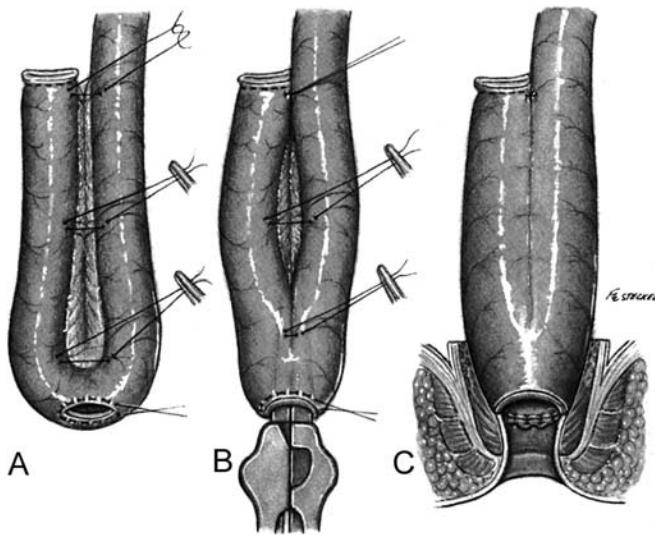

FIGURE 41-6. Ileal J-pouch creation. **A** The limbs of the ileum are oriented using stay sutures. **B** The common wall of the two limbs is then divided using a linear cutting stapler placed through an apical antimesenteric enterotomy. **C** The J-reservoir is then placed within the rectal muscular sleeve and sutured to the dentate line. (Reprinted from Veidenheimer MC. Mucosal proctectomy, ileal J-reservoir, and ileoanal anastomosis. In: Braasch JW, Sedgwick CE, Veidenheimer MC, Ellis FH Jr, eds. Atlas of Abdominal Surgery. Philadelphia: WB Saunders; copyright 1991, with permission from Elsevier).

device is tied in to the apex of the ileal pouch. Before proceeding with the anastomosis, integrity of the rectal staple line is tested using air insufflation. The stapler is placed transanally and the trocar advanced through the transverse staple line. The stapler is then closed as the abdominal surgeon ensures that no extraneous tissues are trapped within the stapling device.

FIGURE 41-7. Ileal J-pouch. Intraoperative photograph showing the two limbs of the ileum properly oriented using stay sutures.

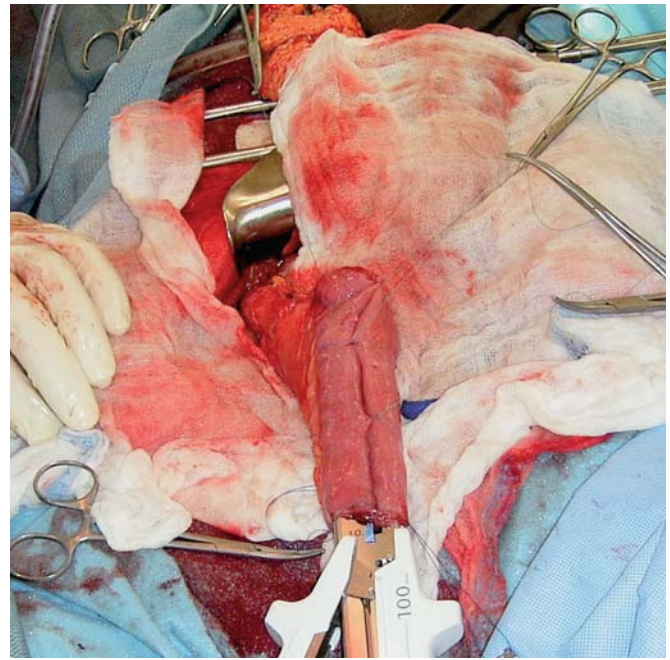

FIGURE 41-8. Ileal J-pouch. Intraoperative photograph showing application of the linear stapler through the apical enterotomy. Note how the stay sutures are helpful in advancing the bowel over the stapler.

Postoperative management is similar to that in patients who have had an ultra-low anterior resection or coloanal procedure protected by a loop ileostomy. Ileostomy output can be quite

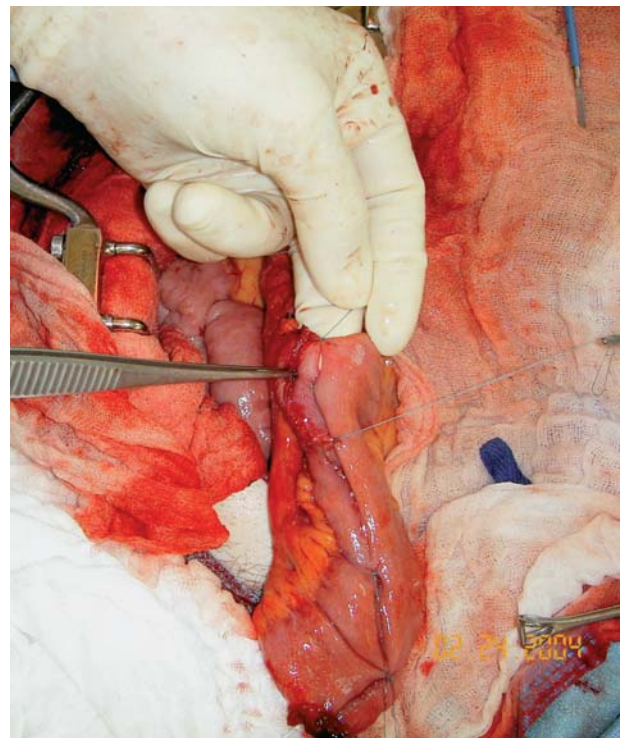

FIGURE 41-9. Ileal J-pouch. Intraoperative photograph showing the completed J-pouch.

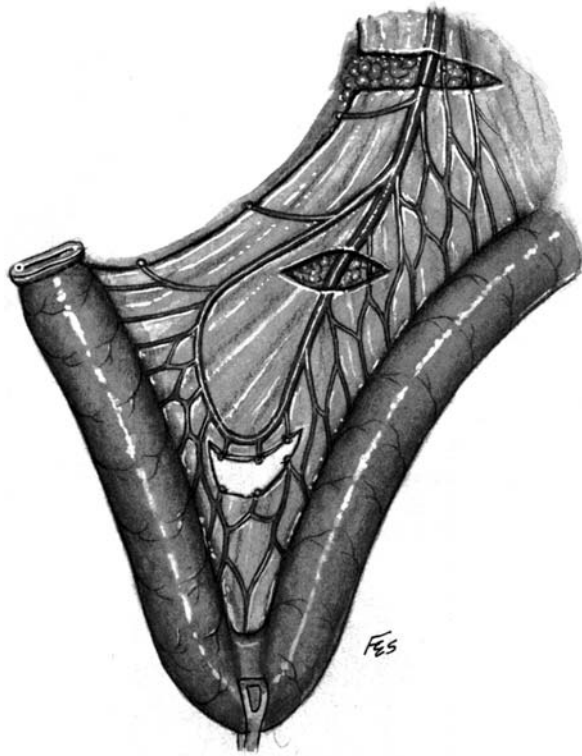

FIGURE 41-10. Ileal J-pouch. The peritoneum is scored to lengthen the mesentery. Selective division of mesenteric arcades is used to produce additional length (Reprinted from Veidenheimer MC. Mucosal proctectomy, ileal J-reservoir, and ileoanal anastomosis. In: Braasch JW, Sedgwick CE, Veidenheimer MC, Ellis FH Jr, eds. Atlas of Abdominal Surgery. Philadelphia: WB Saunders; copyright 1991, with permission from Elsevier).

high, because the stoma is more proximal than a traditional Brooke ileostomy. Patients should be encouraged to keep themselves well hydrated. In some instances, antidiarrheal medication is prescribed.

FIGURE 41-11. Hand-sewn ileoanal anastomosis. **A** After the pouch is gently pulled through the anal canal by the perineal surgeon, four sutures incorporating full thickness of the pouch and a generous bite of the internal sphincter are placed at right angles to anchor the efferent limb within the anal canal. **B** The anastomosis is completed by placing sutures between each anchoring suture. **C** The mucosally intact anastomosis is completed.

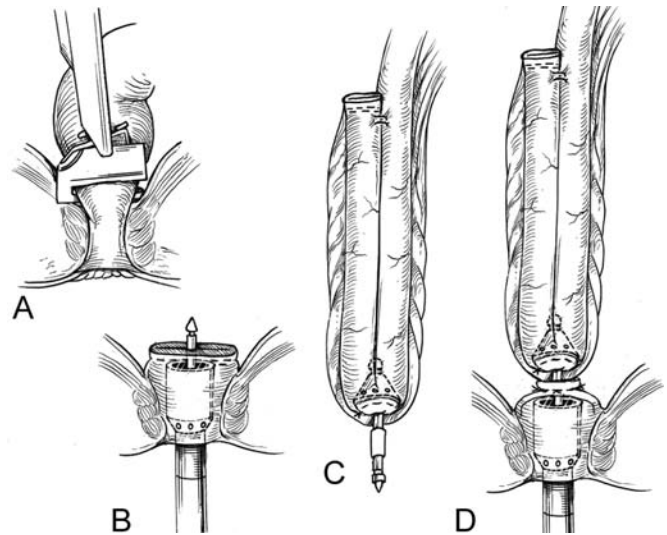

FIGURE 41-12. Double-stapled J-pouch anastomosis. **A** The anvil of a mid-sized circular stapler is tied into the apex of the J-pouch. **B** The anorectum is divided with a stapler within the levator muscles about 1–2 cm above the dentate line. Adjacent tissue such as the bladder or vagina must be excluded from incorporation in the staple line. The integrity of the staple line should be tested with air insufflation through an anoscope. **C** The perineal operator advances the mid-sized circular stapler against the anorectal transaction site and advances the trocar through the transverse staple line. **D** The anvil mechanism is positioned onto the rod of the circular stapler. Before completing the anastomosis, the abdominal operator must prevent extraneous tissue from being trapped into the stapling device.

Patients are usually discharged after 7–10 days in the hospital and return 6–8 weeks later to have the temporary ileostomy closed. Before closure, however, the pouch is thoroughly investigated. Digital rectal examination is used to assess anal sphincter tone and detect anastomotic strictures or defects. The pouch is examined endoscopically to ensure that the suture lines are healed, and a contrast study is performed to detect pouch leaks, fistulas, and sinus tracts. Only after confirmation that pouch abnormalities are not present is the ileostomy closed. Sphincter strengthening exercises should be encouraged in the period leading up to ileostomy closure, because they seem to improve functional results. In more than 90% of patients, the ileostomy can be closed through a peristomal incision. However, in the remainder, the midline abdominal incision must be reopened.

### Postoperative Complications

Performing an ileoanal anastomosis is safe, with reported mortality rates ranging from 0% to 1%.<sup>35</sup> In distinct contrast to mortality, however, morbidity after IPAA remains considerable. Small bowel obstruction occurs in 20% of patients and results from adhesion formation to the large number of raw surfaces after colectomy and from kinking at the ileostomy

site. Most of the obstructive episodes occur in the immediate period after either procedure. The most important factor predictive of small bowel obstruction is rotating the ileostomy 180 degrees (as some authors promote to reduce fecal spillage into the defunctionalized pouch).<sup>36</sup> Although an initial trial of nonoperative therapy is appropriate, surgical intervention may ultimately be required.

Although the incidence has steadily decreased with increasing surgical experience, pelvic sepsis still occurs in 5% of patients after IPAA. Pelvic sepsis may present in the immediate postoperative period or it may be delayed, manifesting as abscess formation (usually presacral) or a perineal fistula. The symptoms suggestive of early pelvic sepsis are fever, anal pain, tenesmus, and discharge of pus or secondary hemorrhage through the anus. Diagnosis is confirmed using computed tomography or magnetic resonance imaging which demonstrates the presence of an abscess or of edematous tissues. Because patients who develop sepsis in the early postoperative period have a higher likelihood of subsequent pouch failure,<sup>37</sup> an aggressive therapeutic approach should be adopted in these patients. Although most patients respond to intravenous antibiotics within 24–36 hours, patients with ongoing sepsis and an organized abscess should undergo early operative endoanal or imaging-guided percutaneous drainage. If drainage of the cavity is unsatisfactory, an attempt should be made to deroof the abscess and curette the cavity through the anus, creating a large communication between the abscess and the reservoir. Sometimes several local procedures are needed to eradicate sepsis. Rarely, an abdominal approach is needed.

The reported incidence of ileoanal anastomotic stricture has varied between 5% and 38%.<sup>38–41</sup> This difference depends in part on the definition of stricture used by different authors. For some, a stricture is a narrowing of the anastomosis that requires at least two dilations<sup>39,40</sup> whereas, for others, a stricture is narrowing associated with pouch-outlet obstruction and poor evacuation that requires repeated dilations. The etiology is usually anastomotic tension that also predisposes to infection from leakage. Full mobilization of the mesentery and avoidance of traction on the reservoir are key technical maneuvers to avoid stricture formation. Anchoring the pouch to surrounding tissues may prevent direct tension on the anastomosis itself. Avoidance of sepsis is paramount to a successful outcome. An apparent stricture may be noted when digital examination is performed for the first time after the operation. These asymptomatic, web-like strictures can be easily disrupted by gentle passage of the finger. More fibrotic strictures can usually be fractured digitally but occasionally the insertion of graded dilators under anesthesia is necessary. Operative management usually requires repeated dilatations yet reasonable function can be expected in more than 50% of patients.<sup>39,40,42</sup> Rarely, a transanal approach involving excision of the stricture and pouch advancement distally is necessary.<sup>43,44</sup>

Anastomotic separation is seen in approximately 10% of patients. If this complication is recognized during

preileostomy closure contrast studies or as a defect on digital examination, ileostomy closure should be delayed until complete clinical and radiographic evidence of healing. Local drainage procedures for an associated abscess or a direct repair of the separation are sometimes necessary.<sup>35</sup> This aggressive approach will almost always be successful, allowing ileostomy closure.

The reported incidence of pouch-vaginal fistula ranges from 3% to 16%.<sup>45–49</sup> The patient complains of a vaginal discharge and clinical examination usually demonstrates the fistula. Occasionally, it is only detected by radiologic contrast enema (pouchogram). It is important to exclude a pouch-vaginal fistula by careful operative examination of the vagina as well as the anal canal before closing the defunctioning ileostomy. The fistula may present before ileostomy closure or after stoma closure.<sup>46</sup> The internal opening is usually located at the ileoanal anastomosis, but less often it may arise at the dentate line, perhaps as a form of cryptoglandular sepsis. Causative factors may include injury to the vagina or rectovaginal septum during the rectal dissection or anastomotic dehiscence with pelvic sepsis. The latter is probably the major predisposing factor because pelvic sepsis rates are significantly higher in patients with pouch-vaginal fistula than in those without.<sup>50</sup> CD has been reported to be more common in patients with pouch-vaginal fistula, yet is difficult to prove in the majority of cases. Management depends on the severity of symptoms. When these are minimal and acceptable to the patient, no action or the placement of a seton may be all that is necessary.<sup>47</sup> In those with a clinically significant degree of incontinence, a diverting ileostomy should be established if not already present. On defunctioning, sepsis is drained with or without placement of a seton suture and, once it has settled, repair is indicated. Simple defunctioning alone does not often lead to fistula closure.<sup>51</sup> Medical therapy is not indicated in managing these fistulas, although one recent series showed efficacy of infliximab.<sup>52</sup> Surgical options are divided into abdominal and local procedures. The former includes abdominal revision with advancement of the ileoanal anastomosis, and the latter fistulectomy with or without sphincter repair, endoanal advancement flap repair, and endovaginal or transvaginal repair. The height of the ileoanal anastomosis is the essential feature that influences the choice of operative approach. Pouch-vaginal fistula from an anastomosis at or above the anorectal junction should be approached abdominally with pouch dissection, repair of the vaginal defect, and creation of a new ileoanal anastomosis. Several authors have reported an approximately 80% success rate using this approach.<sup>51,53,54</sup> A fistula arising from an anastomosis within the anal canal should not be treated with an abdominal procedure because there is not sufficient distal anal canal length to be clear of the fistula. A local procedure is necessary in such circumstances and most surgeons have used either an endoanal ileal advancement flap procedure<sup>45,46,48–50</sup> or a transvaginal technique.<sup>42,50,55</sup> Although both approaches result in fistula closure in 50%–60% of cases, the transvaginal repair

may have an advantage over the endoanal technique because it allows a direct approach to the fistula without the possibility of sphincter damage. Pouch-vaginal fistulas complicating CD are often difficult to treat, recurrence is common, and they frequently lead to pouch excision.<sup>49-51</sup>

The most frequent long-term complication after IPAA for UC is a nonspecific inflammation of the ileal pouch commonly known as pouchitis.<sup>35,56-58</sup> The presence of extraintestinal manifestations of UC before colectomy, especially primary sclerosing cholangitis, has been associated with the development of pouchitis.<sup>56,59</sup> Backwash ileitis does not predict the ultimate development of pouchitis. High-level expression of the serologic factor perinuclear antineutrophil cytoplasmic antibody before colectomy predicts the development of chronic pouchitis after IPAA.<sup>60</sup> The etiology of this nonspecific inflammation is unclear but, as with the continent ileostomy, may be attributable to an overgrowth of anaerobic bacteria. Presenting symptoms include abdominal cramps, fever, pelvic pain, and sudden increase in stool frequency. Treatment of pelvic reservoir pouchitis relies primarily on the use of antibiotics such as metronidazole and ciprofloxacin.<sup>61,62</sup> A mixture of probiotics can also be used in IPAA patients after resolution of the acute symptoms to prevent recurrence of pouchitis.<sup>63</sup> Although these regimens are almost always successful, occasionally steroid enemas or 5-aminosalicylates will be necessary. Patients with chronic pouchitis should be suspected of having CD. Uncommonly, an ileostomy with or without pouch excision is required for severe refractory pouchitis.

The number of bowel movements after successful ileoanal pouch procedures averages six per 24 hours. It should be pointed out that most patients are not particularly concerned with how often they defecate, because most can postpone defecation to accommodate social and recreational activities. Major incontinence is very unusual, although minor incontinence to mucus or stool, particularly at night, is observed in approximately 30% of patients. These patients are managed effectively with good perianal hygiene and the occasional use of a perineal pad. Although continence is clearly altered after pelvic pouch surgery, quality of life is extremely well preserved.<sup>35,64</sup> To obtain these results, however, approximately half of these patients regularly take a bulking agent or antidiarrheal medication to help regulate their bowels. Many patients also tend to eat less in the evening than at midday to minimize bowel movements when they are going out or while sleeping. Total failure, defined as removal of the pouch, occurs in only 5%–8% of cases and is usually caused by pelvic sepsis, undiagnosed CD, or an unacceptable functional outcome. Quality-of-life studies have disclosed that more than 95% of patients are satisfied with their pouch<sup>35,65</sup> and would not go back to an ileostomy.

Issues related to fertility, pregnancy, and the preferred method of delivery are of great importance in the female IPAA patient, many of whom are young and within their reproductive years. The ability of women desiring pregnancy to conceive after IPAA has been evaluated by several

investigators. Most reports are characterized by small numbers of subjects attempting conception after surgery, and therefore do not permit any conclusions about fertility.<sup>66-69</sup> However, two larger studies have shown decreased postoperative fertility.<sup>70-72</sup> The severe decrease in postoperative fertility was attributed to probable tubal occlusion from adhesions, a phenomenon observed in another study.<sup>67</sup> However, physician recommendations against conception and patient concerns about having children affected with UC could not be discounted.<sup>70</sup> A second report from the same group on a different patient cohort found normal fecundity before UC diagnosis and from UC diagnosis to colectomy. However, fecundity decreased 80% after IPAA.<sup>71</sup> Placement of an anti-adhesion membrane around the fallopian tubes and ovaries during surgery may be useful in an attempt to reduce the incidence of these complications.

The optimal method of delivery remains controversial. Cesarean delivery decreases the risk of incontinence resulting from damage to the anal sphincters and yet is associated with complications inherent to abdominal surgery, including injury to the pelvic pouch and adhesion formation. Vaginal delivery may damage the pudendal nerve and the anal sphincter mechanism, but it reduces the problems associated with abdominal surgery and recovery is more rapid. Some short-term studies have shown the safety of vaginal delivery after IPAA.<sup>73</sup> However, vaginal delivery has been shown to cause occult sphincter damage<sup>74</sup> and injury to the innervation of the pelvic floor in normal females.<sup>75</sup> These factors could lead to an increased risk of fecal incontinence with age, which would be particularly devastating in a patient with a pelvic pouch.

## Controversies

In approximately 10% of colitis patients, there are inadequate diagnostic criteria to make a definite distinction between UC and CD, especially in the setting of fulminant colitis.<sup>76,77</sup> These patients are labeled as having IC. Several major clinical concerns remain regarding performance of IPAA for IC, including a higher rate of perineal complications, development of CD, and eventual pouch loss.<sup>78,79</sup> Other investigators, however, have demonstrated acceptable outcomes of this procedure in IC.<sup>80,81</sup> Until the reasons underlying these discrepant data are uncovered, patients with IC should be counseled that undergoing IPAA may predispose them to a higher incidence of pouch-related complications. Although preoperative clinical factors that can predict those IC patients at risk for developing pouch complications or CD after IPAA have yet to be identified, a recent prospective study suggests that IC patients who express specific inflammatory bowel disease serologic markers before surgery have a significantly higher incidence of chronic pouchitis and CD after IPAA than IC patients who have a serologically negative profile.<sup>82</sup>

Another debated issue is whether IPAA should be offered to elderly patients. Two reasons to avoid these procedures in older patients relate to the higher incidence of anal sphincter

dysfunction with increasing age and the morbidity of reoperations in these potentially medically more compromised patients. However, operations for rectal cancer with anastomosis to the anal sphincter are regularly performed in patients in their seventh and eighth decades, and thus many surgeons contend that an IPAA should also be made available. Many groups have demonstrated that IPAA in the elderly patient is safe and feasible.<sup>83,84</sup> It seems that chronologic age should not itself be used as an exclusion criterion. Pouch procedures are feasible in suitably motivated elderly individuals who understand the risks and problems of this procedure. Although bowel frequency remains constant in the first decade after the surgical procedure,<sup>35,85,86</sup> it is unclear what will occur as the patient continues to age. Perhaps the use of a double-stapled technique with preservation of the anal transition zone might improve function over time, but this remains unproven.

Another controversy relates to the use of the IPAA in UC patients who have an established colorectal cancer. The presence of distant metastatic disease is generally a contraindication to IPAA. These unfortunate patients should be managed with segmental colectomy or abdominal colectomy with IRA to facilitate early discharge and allow them to spend the rest of their lives relatively free of complications. Patients with middle and low rectal tumors, in accordance with basic principles of cancer surgery, may not be eligible for this procedure. Radiation therapy, if indicated, should be performed preoperatively; a pelvic pouch should not be subjected to radiation because of a high incidence of pouch loss. UC patients with cecal cancers represent another unique subgroup of patients. The sacrifice of a long segment of adjacent distal ileum with its mesenteric vessels may limit positioning of the reservoir into the pelvis. If a tension-free anastomosis cannot be ensured, a Brooke ileostomy may be necessary. Studies examining the use of the ileoanal pouch in patients with locally invasive cancers of the colon and upper rectum have been conflicting. In one series,<sup>87</sup> UC patients with a carcinoma had postoperative complications and functional results identical to UC patients without cancer. Metastatic disease developed in a small number of patients. In contrast, another study revealed that almost 20% of UC patients with cancer who had an IPAA died of metastatic disease.<sup>88</sup> Because both of these patients had T3 cancers at surgery, it is unclear that their course was adversely influenced by performing IPAA. This conservative management approach is also encouraged by surgeons at the Lahey Clinic,<sup>89</sup> where UC patients with a T3 cancer initially undergo an abdominal colectomy with ileostomy. An observation period of at least 12 months is recommended to ensure that no recurrent disease develops. Another reason to postpone IPAA in these patients is to allow adjuvant chemoradiation therapy to proceed unhindered without any added morbidity from a pouch–anal anastomosis and a relatively proximal ileostomy.

A number of innovations of the IPAA operation spurred by a desire to decrease complications and improve function have led to a series of technical controversies. Some authors

believe that the entire rectal mucosa does not need to be removed. They favor leaving 1–2 cm of distal mucosa behind, transecting the rectum just above the puborectalis muscle and stapling the pouch to the rectal remnant. The potential advantages of the double-stapled approach include technical ease because it avoids a mucosectomy and the perineal phase of the operation, less tension on the anastomotic line, and improved functional results because sphincter injury is minimized and the anal transition zone with its abundant supply of sensory nerve endings is preserved.<sup>90</sup> However, surgeons who oppose this operative approach contend that residual diseased mucosa is at risk of malignancy. There have been nine reports of cancer developing after IPAA, eight in patients who underwent the procedure for dysplasia or colorectal cancer.<sup>91–98</sup> Two of these cases occurred in the preserved mucosa within the anal transition zone.<sup>94,98</sup> Although the origin of adenocarcinoma in these cases is a subject of debate, it is reasonably clear that a double-stapled technique should not be performed in the UC patient who is a high cancer risk (i.e., dysplasia or established cancer) at the time of IPAA. In addition, the potential for continuing colitis in this residual mucosa is another concern. Rauh and coworkers<sup>99</sup> have described a “short-strip pouchitis” that manifests as inflammation at the pouch anal anastomosis thought secondary to residual colitic mucosa. In an effort to resolve these issues, three prospective, randomized trials have demonstrated no significant differences in perioperative complications or functional results in those patients where a mucosectomy was done versus those patients where the distal rectal mucosa was preserved.<sup>100–102</sup> It is important that the surgeon performing an IPAA be familiar with both techniques in the event of failure or inability to use the stapler or when a hand-sewn anastomosis is contemplated but where anastomotic tension is excessive. It must be stressed that if a stapled technique is used, care should be taken to create an ileal pouch to anal anastomosis and not an ileal-to-rectum anastomosis.

Another technical controversial issue is the shape and size of the reservoir. Although the initial ileal reservoir created by Parks in the late 1970s was a triple-loop S pouch,<sup>31</sup> other pouch configurations have been described in an attempt to reduce pouch complications and improve functional outcome (Figure 41-13). Three other configurations that have been described are the double-loop J-pouch, the quadruple-loop W-pouch, and the lateral isoperistaltic H-pouch.<sup>103–105</sup> S-pouches were initially plagued with evacuation problems associated with a long (5-cm or more) exit conduit, frequently requiring pouch catheterization.<sup>31</sup> With shortening of the exit conduit to 2 cm or less, mandatory catheterization has been substantially reduced.<sup>106</sup> The long outlet tract formed in the H-pouch was also associated with pouch distention, stasis, and pouchitis.<sup>107</sup> The W-pouch has been favored by some surgeons<sup>105</sup> because its theoretically greater capacity may lead to fewer daily bowel movements. However, two randomized trials comparing the W- and J-pouch did not confirm this hypothesis.<sup>108,109</sup> In one study,<sup>108</sup> the median number of stools

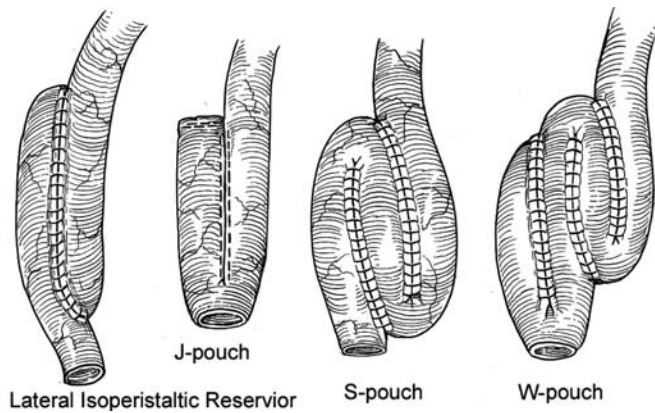

FIGURE 41-13. Different ileal pouch configurations.

per day was the same in patients with a J- or W-pouch, and there was no difference in functional outcome between the two reservoirs in rates of incontinence, urgency, soiling, and the use of antidiarrheal agents. Johnston and coworkers<sup>109</sup> also demonstrated similar functional results between J- and W-pouches 1 year after surgery. At present, most centers perform a J-pouch because it is easier and faster to construct.<sup>108,110</sup> An S-pouch can provide additional length (2–4 cm) compared with the J-pouch and can be useful in minimizing anastomotic tension. However, the 2-cm exit conduit of the S-pouch may lengthen over time and obstructive defecation may develop.

A controversy that merits discussion relates to the routine use of a diverting loop ileostomy. Proponents of routine fecal diversion<sup>111,112</sup> contend that postoperative septic complications are minimized. Loop ileostomy also obviates the problem of immediate severe diarrhea through an edematous ileal pouch and a sphincter that has been damaged surgically by mucosectomy or double-stapling. However, many surgeons believe that the loop ileostomy is counterproductive.<sup>113,114</sup> Notwithstanding the additional operation and increased hospitalization associated with its closure, the morbidity of ileostomy closure is not insignificant, because small bowel obstruction and anastomosis leaks can occur. In addition, these ileostomies may be proximal in the small bowel and thus represent high-output stomas that can cause clinical dehydration. Some surgeons contend that omission of the ileostomy is safe when the anastomosis appears intact and under no tension, the procedure is not complicated by excessive bleeding or other technical difficulties, the terminal ileum is not affected by backwash ileitis, and the patients are not on high steroid doses before surgery. These criteria, however, have not been clearly studied in a prospective, randomized manner. It should be stressed that problems associated with the ileostomy or its closure such as dehydration, anastomotic leak, or bowel obstruction are easily managed with medical or surgical means. The development of a pouch-specific complication in those patients without an ileostomy is a particularly

morbid event requiring repeat laparotomy and fecal diversion in a septic patient. Clearly, more work is needed to further resolve the issue of whether an ileostomy should be routinely used in this procedure. It is clear that although associated with more skin irritation and stoma nursing care, a loop ileostomy is preferred over an end ileostomy for temporary fecal diversion after IPAA because of the ease of loop stoma closure.<sup>115</sup>

Many of the pelvic complications of the ileal pouch can be effectively managed by a perineal procedure. In some cases, however, these local procedures are not successful. The role of abdominal salvage surgery aimed at avoiding pouch excision or indefinite fecal diversion in patients with refractory pelvic sepsis, poor pouch function, or inflammation of retained rectal mucosa remains to be defined. Successful outcomes after salvage surgery have been reported in up to 90% of UC patients.<sup>116–119</sup> Others, however, have reported poorer results.<sup>37,42</sup> This great variability in success rates may be explained by variation in the severity of sepsis and its location in relation to the anastomosis.<sup>37</sup> The duration of follow-up is also an important factor, because failure after salvage continues steadily with time.<sup>37,42</sup> Various factors need to be considered when advising an abdominal salvage procedure, including feasibility of success, magnitude of operation, overall duration of treatment, and the patient's wishes. Counseling is essential and the patient must be given a realistic appraisal of the prospect of a successful outcome. The potential morbidity of removal of the reservoir resulting in a permanent ileostomy should also be discussed, including the possibility of a high-output ileostomy, pelvic nerve damage, and an unhealed perineal wound.

## Conclusion

The approach to the UC patient requiring surgical intervention must begin with an open discussion concerning the pros and cons of each procedure. Surgeons should individualize treatment based on the patients' desires, fears, and expectations. In general, those patients desiring a minimum of complications without regard for continence should undergo total proctocolectomy with Brooke ileostomy. Those patients wishing to preserve fecal continence but also willing to accept a number of potential postoperative complications that in some cases may necessitate a stoma should consider an IPAA. The risk of complications and the unknown long-term effects of continence-preserving surgery require that patients be willing to undergo careful and regular follow-up. Patients not expected to comply with or take care of a continent ileostomy or IPAA should not be offered these procedures.

# Surgery for Crohn's Disease

Scott A. Strong

Crohn's disease is a chronic, unremitting, incurable, inflammatory disorder that can affect the entire intestinal tract. Although the etiology remains uncertain, the distribution and behavior of the disease can be generally characterized. The presenting symptoms and signs, medical and operative options, and outcome likely depend on the disease genotype and phenotype. Specifically, the surgical procedures typically utilized in the operative management of Crohn's disease include nonresectional techniques such as internal bypass, fecal diversion, and stricturoplasty as well as resectional procedures with or without concomitant anastomoses. The morbidity and risk for disease recurrence varies between the different procedures depending on myriad factors such as preoperative variables, site and behavior of disease, and postoperative influences.

## Etiology and Incidence

The cause of Crohn's disease is unclear but recent investigations continue to provide insight into the etiology and pathogenesis of this inflammatory disorder that can affect any portion of the intestinal tract through a complex interplay between conditioning factors and effector mechanisms. The conditioning factors include genetic influences and triggering events that create a permissive host, whereas the effector mechanisms mediate tissue damage through dysregulation of the intestinal immune and nonimmune functions. Patients afflicted with symptomatic disease are likely genetically susceptible because abnormalities in seven loci on chromosomes 16q, 12, 6p, 14q, 5q, 19, and 1p have been identified in selected populations,<sup>1</sup> but there must be other factors at play because these variations have not been replicated in all populations and the proband concordance rate among monozygotic twins is only 50%–60%.<sup>2,3</sup> Initiating or triggering events such as environmental factors and microbial agents also probably contribute to disease susceptibility as evidenced by reports that describe the effects of tobacco usage<sup>4–7</sup> and fecal flora<sup>8</sup> on disease activity. In addition, abnormalities in immune

cellular function, nonimmune cell activity, protein expression, and cellular apoptosis hint as to the role of the dysregulated effector mechanisms in the pathogenesis of Crohn's disease.<sup>9</sup>

The prevalence of Crohn's disease in the United States is approximately seven cases per 100,000 persons, and the incidence has steadily increased over the past 5 decades.<sup>10,11</sup> Internationally, the prevalence is relatively high in northern Europe, significantly lower in southern Europe and Australia, and the lowest in South America, Asia, and upper Africa. This discrepancy in prevalence is likely multifactorial in nature, but it is recognized that the incidence and prevalence of Crohn's disease increases as a region becomes more urbanized.

The male-to-female ratio of the disease is 1.1–1.8:1 and the disease has a bimodal age distribution with the first peak occurring between the ages of 15–30 years and the second between 60–80 years; most persons experience the onset of disease symptoms before 30 years of age. The disorder is more common in whites than in blacks, Hispanics, or Asians, and a two- to fourfold increase in the prevalence has been found among the Jewish population in the United States, Europe, and South Africa compared with other ethnic groups.

## Disease Classification

The original classification of Crohn's disease was described nearly three decades ago,<sup>12</sup> but inaccuracies associated with this and subsequent systems led to the most recent refinement, the Vienna Classification.<sup>13</sup> This scheme was generated by a World Congress of Gastroenterology Working Party that prospectively designed a simple phenotypic classification system based on objective and reproducible clinical variables that include age at diagnosis, anatomic location, and disease behavior. The age at diagnosis is stratified into patients <40 years and those ≥40 years. The anatomic location is classified as terminal ileum, colon, ileocolon, and upper gastrointestinal. Terminal ileal disease is defined as disease limited to the lower third of the small bowel with or without cecal involvement. Colon disease is any colonic involvement between the

cecum and rectum without small bowel or upper gastrointestinal disease. Ileocolon disease is disease of the terminal ileum with colonic involvement noted between the cecum and rectum. And, upper gastrointestinal disease is defined as any disease location proximal to the terminal ileum regardless of involvement in other areas. The disease behavior is grouped as nonstricturing nonpenetrating (inflammatory), stricturing, and penetrating. Subsequent application of the Vienna Classification to clinical practice has demonstrated that the Crohn's disease phenotype markedly changes for a given patient over time<sup>14–17</sup> with 15% of patients experiencing a change in anatomic location and 80% of individuals with inflammatory disease ultimately demonstrating a stricturing or penetrating behavior. Moreover, the ability of experts to independently agree on disease phenotype using the Vienna Classification in controlled trials ranges from poor to fair.<sup>18</sup> It is unclear whether the varied classification systems fail because of the heterogeneity of the disease or inherent shortcomings of the classification schemes. Although these failings limit the utility of the Vienna Classification in clinical trials and disease management, recent advances in determining the genetic linkages associated with Crohn's disease will likely lead to a revised Crohn's disease classification system that combines genotype and phenotype characteristics.

## Operative Indications

The indications for operative management of Crohn's disease include acute disease complications, chronic disease complications, and failed medical therapy. The acute complications are toxic colitis with or without associated megacolon, hemorrhage, and perforation, whereas the chronic disease complications include neoplasia, growth retardation, and extraintestinal manifestations. Failed medical therapy can take several forms including unresponsive disease, incomplete response, medication-related complications, and non-compliance with medication.

### Toxic Colitis

Toxic colitis is a potentially fatal complication of Crohn's disease, particularly if accompanied by megacolon. Although several schemes exist to accurately identify toxic colitis, one reasonably simple system uses a definition that includes a disease flare accompanied by two of the following criteria: hypoalbuminemia ( $<3.0$  g/dL), leukocytosis ( $>10.5 \times 10^9$  cells/L), tachycardia ( $>100$  beats/minute), temperature increase ( $>38.6^\circ\text{C}$ ). Use of this relatively objective definition may aid in the diagnosis and care of these patients whose severe condition can be under-appreciated because of high dosages of steroids, immunomodulators, or biologic agents.

The initial management is directed at reversing physiologic deficits with intravenous hydration, correction of electrolyte imbalances, and blood product transfusions. Free perforation,

increasing colonic dilatation, massive hemorrhage, peritonitis, and septic shock are indications for emergent operation after the patient has been adequately resuscitated. In the absence of these features, medical therapy is initiated with high dosages of intravenous corticosteroids, immunomodulators, and/or biologic agents.<sup>19</sup> Broad-spectrum antibiotics directed against intestinal flora are prescribed to minimize the risk of sepsis secondary to transmural inflammation or microperforation. Anticholinergics, antidiarrheals, and narcotics are avoided because they may worsen already impaired colonic motility or conceal ominous symptoms. Hyperalimentation may be started and the patient is closely observed with serial examinations and abdominal roentgenograms. Any worsening of the clinical course over the ensuing 24–72 hours mandates urgent laparotomy. If the patient improves minimally after 5–7 days of conventional therapy, the medical therapy should be altered or surgery should be advised. Experience with cyclosporine or infliximab in this setting is anecdotal, and should be weighed against operative therapy while understanding that surgery in this setting often relegates the patient to a life-long ileostomy.<sup>20,21</sup>

The principal operative options in patients with toxic colitis complicating Crohn's disease include subtotal colectomy with end ileostomy, total proctocolectomy with end ileostomy, and loop ileostomy with decompressive blowhole colostomy. Of these alternatives, subtotal colectomy with end ileostomy is the most widely practiced procedure. The most difficult aspect of the operation is managing the distal bowel stump. The distal limb may be closed with sutures or staples and then delivered to the anterior abdominal wall where it can lie without tension in the subcutaneous fat of the lower midline wound. Dehiscence of the closure during the postoperative period results in a mucous fistula instead of a pelvic abscess as witnessed when the closed stump is left within the peritoneal cavity. If the bowel wall is too friable to hold sutures or staples, a mucous fistula is primarily created. Rarely, instead of creating the fistula, the rectosigmoid stump must be exteriorized and wrapped in gauze to prevent retraction with a mucous fistula safely fashioned 7–10 days later.

The patient typically improves over the ensuing few days and can be typically discharged within a week of the operation. An ileoproctostomy can be recommended 6 months later in selected persons who demonstrate minimal mucosal inflammation, adequate rectal compliance, absence of significant anoperineal disease, and sufficient sphincter strength. Otherwise, the diseased rectum is left in place and the patient is counseled about the risk of neoplasia and the need for appropriate surveillance endoscopy.<sup>22</sup> In these individuals, proctectomy is usually recommended if disease-related symptoms prove to be too bothersome, neoplasia is identified, surveillance is limited because of stricturing, or laparotomy is warranted for other reasons. Disease-related symptoms are likely to occur in patients with prior anoperineal disease and proctectomy is often required within the first few postoperative years.<sup>21,23</sup>

Proctocolectomy with end ileostomy is rarely performed in the severely ill patient with toxic colitis because of the excessive rates of morbidity and mortality.<sup>24–26</sup> Proctectomy increases the difficulty of the procedure and risks pelvic bleeding as well as autonomic nerve damage. In rare instances of rectal perforation or profuse colorectal hemorrhage, or in the less severely ill patient who would not be a candidate for future ileoproctostomy, proctocolectomy may be a viable option. The surgeon must be cautioned, however, that the macroscopic and microscopic differentiation of ulcerative colitis from Crohn's proctocolitis is especially difficult in severe colitis, and primary proctocolectomy would nullify the future option of a restorative procedure in a patient with ulcerative colitis.

The need for loop ileostomy combined with decompression blowhole colostomy has virtually disappeared with improved medical recognition and more sophisticated management of toxic colitis. The operation is still useful in extremely ill patients or those in whom colectomy would be especially hazardous (e.g., contained perforation, high-lying splenic flexure, pregnancy). Contraindications to the procedure include colorectal hemorrhage, free perforation, and intraabdominal abscess. The operation is considered only a temporizing procedure, and a definitive operation is usually performed approximately 6 months later.

## Hemorrhage

Crohn's disease may be responsible for life-threatening lower gastrointestinal hemorrhage and even exsanguination, but fortunately this is an infrequent complication.<sup>27–30</sup> More frequently, entities unrelated to disease involvement, including peptic ulcer disease and gastritis, may precipitate intestinal bleeding. Accordingly, gastric aspiration and possibly esophagogastroduodenoscopy are required to exclude sources of hemorrhage indirectly associated with Crohn's disease. The principal management of disease-related hemorrhage is determined by the severity and persistence of bleeding as well as the risk for recurrence. Localization of the bleeding site is essential regardless of the planned therapy. In a stable patient with colonic disease, endoscopic evaluation is preferred because this approach allows for disease assessment and therapeutic attempts at control of the identified bleeding site. However, indiscriminate usage of colonoscopy for bleeding colitis should be discouraged because this form of hemorrhage typically accompanies severe colitis, and colectomy with ileostomy is advised in this instance, regardless of the endoscopic findings.

A patient who requires ongoing resuscitation to maintain hemodynamic stability or in whom a small bowel source of active bleeding is suspected should undergo emergent mesenteric angiography to localize the source of hemorrhage and arrest ongoing bleeding through selective angiographic infusion of vasopressin or embolization. If the hemorrhage is localized but cannot be controlled by these interventional

modalities, the catheter is left in position and intraoperative angiography is performed to accurately identify the bleeding site and guide a limited bowel resection.<sup>31</sup> Otherwise, wide resection might be necessary to manage hemorrhage from a small ulcerated area within an extensive segment of affected bowel.

Laparotomy and resection with or without anastomosis are required if the patient's hemodynamic state cannot be sustained, bleeding persists despite 6 units of transfused blood, hemorrhage recurs, or another indication for surgery exists.

## Perforation

Free perforation of the small bowel is also unusual and typically occurs at or just proximal to a strictured site.<sup>32,33</sup> The most appropriate treatment is resection of the involved bowel with immediate or delayed anastomosis. A nondiverted anastomosis should be avoided in the setting of delayed treatment, malnutrition, significant comorbidity, or severe sepsis. Resection with proximal ileostomy has an associated mortality rate of 4% compared with 41% with simple suture closure alone.<sup>34</sup> Perforation of the colon in patients with Crohn's disease is also rare and typically requires subtotal colectomy for optimal management because these cases often occur in the setting of severe colitis or steroid usage.<sup>35</sup>

## Neoplasia

Overall, persons with Crohn's disease are at increased risk for developing cancer compared with the general population. In a population-based study from Canada,<sup>36</sup> these patients had an increased relative risk of developing carcinoma of the small intestine [17.4; 95% confidence interval (CI), 4.16–72.9] as well as malignancies of the liver and biliary tract (5.22; 95% CI, 0.96–28.5), and males were at a particular risk for lymphoma (3.63; 95% CI, 1.53–8.62). Their patients with Crohn's disease were also at increased risk for the development of colon cancer (2.64; 95% CI, 1.69–4.12) and the risk was similar to that seen in persons with ulcerative colitis (2.75; 95% CI, 1.91–3.97); the risk for rectal carcinoma, however, was similar to that demonstrated by a demographically matched cohort without inflammatory bowel disease.<sup>36</sup> Other population-based studies have supported the notion that Crohn's disease of the colon is associated with an increased risk of colorectal cancer,<sup>37–39</sup> whereas reports from some centers<sup>40–42</sup> have not noted the same association.

In a series of 22 patients with colorectal carcinoma complicating their Crohn's disease, 19 (86%) and 9 (41%) had adjacent or distant dysplasia, respectively, supporting a dysplasia-carcinoma sequence in Crohn's disease.<sup>43</sup> When a screening and surveillance program was adopted, dysplasia or cancer was detected in 16% of patients, and the probability of detecting dysplasia or cancer after a negative screening colonoscopy was 22% by the fourth surveillance examination. Accordingly, despite some controversy, many pundits<sup>44,45</sup>

advocate that the endoscopic screening and surveillance protocols used for patients with ulcerative colitis should also be recommended for individuals with Crohn's disease of the large bowel. Specifically, a screening endoscopy should be performed 8–10 years after the onset of disease symptoms and four-quadrant random biopsies should be obtained every 10 cm along the length of the large bowel and directed biopsies should be procured from any strictures, lesions, or masses; subsequent surveillance endoscopy with similar biopsies should then be performed every 1–2 years. The finding of multifocal low-grade dysplasia, high-grade dysplasia, or invasive cancer would likely warrant review by a second experienced pathologist and confirmation would prompt a colectomy.

### Growth Retardation

Abnormal linear growth secondary to delayed skeletal maturation is frequently encountered in children and adolescents with Crohn's disease. Specifically, more than half of children may have a subnormal height velocity and approximately one-quarter will have short stature.<sup>46</sup> Fortunately, surgical resection is often accompanied by growth response and associated psychologic benefit.

### Extraintestinal Manifestations

Extraintestinal manifestations of Crohn's disease occur in nearly one-quarter of patients with Crohn's disease and can involve most organ systems.<sup>47–49</sup> Disorders of the skin, mouth, eye, and joints occur frequently with large bowel disease and their activity typically parallels the degree of intestinal inflammation. Operative management of the intestinal disease can provide beneficial control of the extraintestinal manifestation. Conversely, abnormalities affecting the hepatic, vascular, hematologic, pulmonary, cardiac, or neurologic systems behave independent of the intestinal disease. Other disorders such as nephrolithiasis and cholelithiasis are disease complications that likely arise from altered intestinal absorption.

### Failed Medical Therapy

Antibiotics, probiotics, 5-aminosalicylate compounds, steroids, immunomodulators, and biologic agents all have a potential role in the management of Crohn's disease depending on the clinical presentation. Each medication within these therapeutic groups possesses appropriate dosing parameters, associated side effects, and an optimal time interval during which beneficial effects should appear. Before initiating treatment with any medication, the patient should be counseled about these features and objective criteria for disease response should be discussed and then sought after an established time interval. If the desired response is not achieved, prohibitive side effects arise, or noncompliance is problematic, the medication has failed and another medication should be trialed. When all appropriate

medical therapy has failed, operative intervention is warranted. The continuation of ineffective medical management risks the development of further disease complications that may detrimentally impact surgical outcome.

## Operative Considerations

Some fundamental observations that must be considered when operating for Crohn's disease are as follows:

- Crohn's disease is incurable
- Intestinal complications are the most common operative indication
- Operative options are influenced by myriad factors
- Asymptomatic disease should be ignored
- Nondiseased bowel can be involved by inflammatory adhesions or internal fistulas
- Mesenteric division can be difficult
- Resection margins should be conservative (2 cm)

Crohn's disease is a chronic inflammatory disorder that cannot be cured by medical therapy or operative intervention. Accordingly, treatment focuses on safely alleviating disease symptoms and restoring quality of life while attempting to maintain continuity of the intestinal tract. Of the various operative indications, intestinal complications including stricturing or penetrating disease that are unresponsive to medical therapy constitute the bulk of the indications, and the operative options depend on the multiple variables including patient age, anatomic location, disease behavior, symptoms, prior therapies, nutritional status, comorbid conditions, and associated sepsis. The patient's symptoms are especially important because the disease encountered at the time of surgery is often unanticipated despite preoperative evaluation.<sup>50</sup> In these instances, the findings must be compared with the presenting symptoms and signs, and any extensive disease that does not appear to be contributing to symptoms should be typically ignored. Exceptions to this axiom include the management of out-of-circuit bowel and short, uncomplicated small intestine strictures, which should be addressed in most patients.

Nondiseased bowel can be affected through inflammatory adhesions or internal fistulas. With adhesions, every attempt should be made to conserve the nondiseased bowel, although this can be especially difficult when managing enteroparietal or interloop abscesses. Most internal fistulas are best managed by wedge excision and primary closure of the fistula site in the secondarily affected small bowel. However, a short segmental resection with primary anastomosis may be required for fistulas targeting the rectosigmoid region because these often enter the bowel at the mesenteric margin and simple wedge excision may be vulnerable to breakdown of the suture line.

The mesentery of the diseased bowel is usually thickened because of fat deposition and enlarged mesenteric lymph nodes that straddle the ileocolic and sometimes superior

mesenteric vessels. Attempts at simple division and ligation of the vessels may injure the remaining vascular pedicle leading to a rapidly spreading mesenteric hematoma that risks distal bowel ischemia. Instead, serial overlapping clamps applied to both sides of the intended transection line provide an ample margin or cuff on the mesenteric edge. Heavy, interlocking suture ligatures can then be used to under-run each pedicle caught within the clamps, eliminating concern for a spreading hematoma. Conservative (2 cm), macroscopically normal resection margins are associated with the same rate of operative morbidity and disease recurrence as extensive (12 cm), microscopically normal margins.<sup>51</sup> However, the luminal disease margin can be difficult to judge by inspecting the exterior of the bowel. Whereas inspection of the diseased bowel may reveal lymphadenopathy, creeping mesenteric fat, and cork-screwing of the serosal vessels, the nondiseased bowel may appear dilated with muscular hypertrophy and bowel wall edema. The key to discriminating between diseased and nondiseased bowel lies with palpation of the mesenteric margin of the bowel wall. A mesenteric ulcer will obscure the palpable transition from the mesentery to the bowel wall because of fat deposition between the terminal branches of the marginal vessels. If the surgeon's fingers passing from the mesentery onto the bowel can readily identify the edge of the bowel wall, the luminal mucosa will be macroscopically normal.

## Operative Options

The surgical procedures performed for intestinal Crohn's disease can be divided into groups depending on whether resection of an intestinal segment is performed. The nonresectional procedures include internal bypass, fecal diversion, and strictureplasty, whereas the resectional procedures include resected bowel. Patients often undergo multiple procedures at the time of their single operation and these can be a combination of nonresectional as well as resectional procedures.

### Internal Bypass

Internal bypass was the procedure of choice in the early days of surgery for Crohn's disease when mortality rates associated with resection were high because of lack of transfusion technology, antimicrobial medications, adequate anesthetic agents, and nutritional support services. However, with the advent of these modalities and recognition of complications such as recrudescence, mucocoeles, and malignancy arising in diverted segments, this procedure was largely abandoned. However, bypass operations are still considered reasonable or desirable in specific circumstances. A complicated ileocecal phlegmon with dense attachment to the iliac vessels or retroperitoneum can be aptly managed by an exclusion bypass if the proximal end of the excluded ileal segment is exteriorized as a small mucus fistula and definitive resection is planned to occur in later months. Continuity bypass is

sometimes the preferred method of managing symptomatic gastroduodenal Crohn's disease that is refractory to medical treatment where resection would entail extensive reconstruction of the upper intestinal tract or pancreaticobiliary system.

### Fecal Diversion

Fecal diversion can be permanent or temporary. Many of the stomas created to permanently bypass unresected disease fail to control symptoms secondary to the out-of-circuit bowel, and resection is ultimately warranted. High complex fistulas and deep ulcerations are among the disease characteristics likely to mandate proctectomy with permanent ostomy for persistent disease symptoms despite fecal diversion.<sup>52</sup> Similarly, temporary diversion intended to heal distal disease or its sequelae is usually unsuccessful unless combined with a secondary procedure such as a rectal mucosal advancement flap that directly addresses the problem.<sup>53</sup> Even for free perforation of the small bowel, exteriorization of the proximal bowel alone is rarely the procedure of choice.

### Strictureplasty

The incurable and pan-intestinal nature of Crohn's disease has led to a more conservative operative approach. For patients with multiple strictures of the small bowel, intestinal conservation may be maximally achieved by surgically widening the narrowed segment by performing a strictureplasty. This technique was initially described by Katariya et al.<sup>54</sup> for the successful treatment of tubercular small bowel strictures, and later used in strictures secondary to Crohn's disease.<sup>55</sup> The procedure safely relieves obstructive symptoms<sup>56-58</sup> with the operated patients demonstrating weight gain accompanied by improved food tolerance as well as discontinuation or reduction of steroid usage.<sup>59</sup> Moreover, patients undergoing strictureplasty alone are no more likely to require reoperation than those who undergo a concomitant resection,<sup>60</sup> and reoperation rates after first and second operations are also similar.<sup>61</sup>

The situations for which strictureplasty is considered are as follows:

- Diffuse involvement of the small bowel with multiple strictures
- Stricture(s) in a patient who has undergone previous major resection(s) of small bowel (>100 cm)
- Rapid recurrence of Crohn's disease manifested as obstruction
- Stricture in a patient with short bowel syndrome
- Nonphlegmonous fibrotic stricture

The contraindications to strictureplasty are as follows:

- Free or contained perforation of the small bowel
- Phlegmonous inflammation, internal fistula, or external fistula involving the affected site
- Multiple strictures within a short segment

- Stricture in close proximity to a site chosen for resection
- Hypoalbuminemia ( $<2.0$  g/dL)

Multiple strictures in a patient with an albumin value  $<2.5$  g/dL, preoperative weight loss, or advanced age may be regarded by some as a situation in which strictureplasty should be avoided because of concerns of sepsis, but a proximal diverting stoma with multiple strictureplasties should be considered in this instance.<sup>57</sup> Factors that do not seem to be associated with increased operative risk include perforative or phlegmonous disease remote from the strictureplasty site, steroid dosage, synchronous resection, number of strictureplasties, and length of stricture.

The length of the strictured segment dictates the type of strictureplasty technique used. Short ( $<10$  cm) strictures are best managed by a Heineke-Mikulicz type of strictureplasty, whereas medium length (10–20 cm) strictures can be corrected by a Finney-type strictureplasty. Long ( $>20$  cm) strictures are best managed by a side-to-side isoperistaltic strictureplasty.<sup>62</sup> Regardless the technique, the bowel is incised along its antimesenteric margin extending 1–2 cm beyond the diseased segment, which is identified by the presence of mesenteric ulceration. Biopsy of any suspicious mucosa is performed to exclude carcinoma<sup>63–65</sup> and closure is achieved using an absorbable suture in a one- or two-layer manner. The mesentery at each of the strictureplasty sites is then labeled with metallic clips to allow discrimination between the multiple sites in the unlikely event that postoperative hemorrhage occurs. Selective mesenteric angiography with intraarterial vasopressin infusion will control most bleeding episodes, but the radio-opaque metal clips will help avoid the need to open each of the strictureplasty sites to localize the bleeding site if reoperation is required.<sup>66</sup>

Many centers have used a Finney-type strictureplasty for recurrent terminal ileal disease with the anastomosis created between the terminal ileum and proximal colon.<sup>67–70</sup> Others have extrapolated this experience into patients undergoing their first operation for terminal ileal Crohn's disease.<sup>71</sup> A long ileocolostomy is constructed encompassing the entirety of the diseased bowel. Interestingly, subsequent endoscopic and imaging studies have revealed complete morphologic disease regression.<sup>71</sup>

## Resection

The basic principles of resection should be followed whether an open or laparoscopic approach is used, and include mobilization of both diseased intestine as well as sufficient nondiseased bowel to facilitate the subsequent creation of a tension-free anastomosis or construction of an ostomy. Extensive mobilization may facilitate operations for terminal ileal disease complicated by fused ileal loops or a phlegmonous mass adherent to matted loops of small bowel, omentum, or retroperitoneal structures. Delivery of the ascending colon and terminal ileum into the wound or to the

anterior abdominal wall enables separation of the involved intestinal loops and permits closer inspection to determine which segments require resection. Enteric fistulas often originate from diseased bowel that communicates with nondiseased intestine. Whereas the primary site usually requires resection, the secondarily affected bowel segments are typically treated by conservative wedge excision and simple closure of the resultant defect. The diseased bowel should be resected with conservative margins and the mesentery divided using the previously described methods. Removal of enlarged mesenteric lymph nodes is not a goal of resectional surgery because this practice risks vascular injury without reducing the likelihood of recurrent disease. The specimen should be opened after it has been delivered from the operative field to assure macroscopic disease-free resection margins.

A laparoscopic approach can be used for a variety of resectional procedures and is typically associated with longer procedure times, but shorter lengths of stay and briefer periods of recovery.<sup>72–79</sup> Although disease complicated by fistulas or phlegmons can prove challenging, experienced laparoscopic surgeons have been able to safely complete procedures in these instances without converting to a laparotomy.<sup>80,81</sup>

After the diseased bowel has been resected, the surgeon must decide whether to create an end stoma, an anastomosis, or a diverted anastomosis. In general, an end stoma is desirable in patients who are critically ill, demonstrate fecal peritonitis, or have coagulopathy. An anastomosis can be safely created in most other instances assuming a few general principles are respected that include the following:

- Adequate blood supply must be assured
- Tension or torsion are unacceptable
- Luminal size needs to be equivalent
- The mesenteric defect should be closed

A temporary diverting stoma should be considered to protect the anastomosis in instances of incompletely drained sepsis, excessive blood loss during a long operation, or severe hypoalbuminemia ( $<2.5$  g/dL).

In operations for terminal ileal disease, the neoterminal ileum tends to be the usual site of disease recurrence. Accordingly, the optimal anastomotic configuration and preferred materials are subject to debate.<sup>82–84</sup> Some recent retrospective studies<sup>85–88</sup> and one prospective, randomized trial<sup>89</sup> suggest that larger side-to-side anastomoses are associated with a reduced risk for disease recurrence. Although many investigators have found no association between the materials used to create the anastomosis and morbidity rates,<sup>86,87</sup> at least three studies<sup>85,90,91</sup> have reported that a stapled anastomosis is safer than a hand-sewn anastomosis. Regardless, it is important to use a hand-sewn technique when the bowel wall is abnormally thickened because the stapling instruments are not designed to safely construct an anastomosis under these conditions.

## Specific Anatomic Locations

### Terminal Ileum

Terminal ileal disease is defined as disease limited to the lower third of the small bowel with or without cecal involvement. Approximately 20% of patients with Crohn's disease will express this phenotype, and usually present with symptoms suggestive of inflammation or obstruction. In the majority of cases, resection with construction of an ileal-ascending colon anastomosis is feasible and desirable. All nondiseased ascending colon should be preserved to provide the largest possible surface area for water absorption and to avoid a complex fistula involving retroperitoneal structures associated with recurrent disease involving an anastomosis that overlies the second portion of the duodenum. Alternatively, this is the situation in which some centers avoid bowel resection by creating a large Finney-type ileocolostomy.<sup>71</sup>

Terminal ileal disease with sparing of the ileocecal valve and cecum is ideally treated with resection and enteroenterostomy provided there is sufficient length (5–7 cm) of normal-appearing distal ileum after definitive ileal resection. Preservation of the ileocecal valve helps to minimize the risk of postoperative diarrhea. In many instances, a hand-sewn anastomosis is preferred because the distal segment may be too short to accommodate a stapled anastomosis.

### Colon

Colon disease is any colonic involvement between the cecum and rectum without small bowel or upper gastrointestinal disease. Nearly 40% of patients have this disease distribution, and often complain of inflammatory disease symptoms including abdominal cramping, bloody diarrhea, and urgency.

Persons presenting with segmental disease are best treated with segmental resection to protect against dehydration and electrolyte imbalances associated with loss of the large intestine's physiologic role. In patients with disease limited to the ascending colon, the transverse colon is divided at the level of the middle colic vessels so that the mesenteric root naturally separates the anastomosis from the retroperitoneum, minimizing the risk for recurrent disease complicated by complex fistulas. Alternatively, a more proximal anastomosis may be wrapped with a pedicle of omentum, thereby preventing the anastomosis from lying in direct contact with the retroperitoneum. Disease involving the ascending and transverse colons is treated in a similar manner except an extended right colectomy is recommended because the mesentery of the ileum is more easily approximated to the mesentery of the sigmoid colon than the descending colon. Resection of the additional colonic segment avoids an internal hernia and does not adversely affect the functional outcome. Crohn's disease of the transverse, descending, and sigmoid colons presents a situation in which segmental resection and colocolic or colorectal anastomosis is most frequently used. Segmental

resection is particularly ideal for older individuals (>50 years) and patients with colitis who have previously undergone significant small bowel resection (>30 cm). In both instances, preservation of the ileocecal valve and colonic absorptive surface may protect against diarrhea and dramatically improve the functional outcome. Resection with colectomy is used for these selected patients with left-sided disease, and a cecorectal anastomosis is constructed if the transverse colon is also involved. In younger patients and those without prior small bowel resection, the diseased segment and uninvolved proximal colon are resected and an ileosigmoid or ileorectal anastomosis is constructed.

Colonic strictureplasty has been described for short strictures and seems to be associated with a morbidity rate, risk for surgical recurrence, and postoperative quality of life comparable to that seen with resection.<sup>92</sup> However, given the 7% incidence of malignancy arising in a colonic stricture,<sup>93</sup> some surgeons argue that resection should be exclusively encouraged if all of the outcome measures are comparable.

Patients with extensive colonic involvement, relative rectal sparing, and adequate fecal continence without active anoperineal sepsis or compromised rectal compliance are candidates for colectomy with ileoproctostomy. Rectal compliance can be subjectively judged by distending the rectum during proctoscopy or objectively quantified with anorectal physiology testing; patients whose maximum tolerated rectal volume measures <150 mL will do poorly with an ileoproctostomy.<sup>94</sup> A rare patient presents with pan-colonic disease, significant upper rectal involvement, and sparing of the mid- and distal-rectum. Resection of all disease in this setting leaves an anastomosis only 6–8 cm above the anal verge, and is often associated with impaired function secondary to compromised compliance. Instead, an ileal J-pouch can be configured with 10-cm limbs and joined to the spared mid-rectum after subtotal proctocolectomy. Despite a likely increased disease recurrence compared with that seen with total proctocolectomy and ileostomy, the patient may enjoy several years without a stoma.

Patients with proctocolitis that warrants operative treatment usually require a total proctocolectomy with creation of an end ileostomy, especially those persons with colitis whose proctitis, sphincter dysfunction, or anoperineal sepsis is too severe for rectal preservation and ileoproctostomy. If proctectomy is required, the entirety of the rectum should be excised in a single or staged procedure because of the significant risk of cancer developing in the defunctioned rectal stump despite surveillance proctoscopy.<sup>95</sup> An unhealed perineal wound that persists 6–12 months after endoanal proctectomy should be evaluated to exclude concomitant pyoderma gangrenosum, perineal sinus, enteroperineal fistula, and malignancy. A simple shallow wound will usually respond to repeated wound debridements and diligent wound care with vacuum-assisted closure system and split-thickness skin grafts providing additional benefit. Wounds complicated by a perineal sinus or enteroperineal fistula require more extensive procedures that often include omental, muscle, or myocutaneous flaps.<sup>96–98</sup>

One center has chosen to offer patients with Crohn's disease isolated to the colon and rectum a total proctocolectomy with ileal pouch–anal anastomosis.<sup>99</sup> They have reported that the rates of Crohn's disease–related complications and pouch excision are 35% and 10%, respectively, after 10 years of follow-up. However, other reports suggest that 12%–29% and 45%–52% of patients with Crohn's disease subsequently require pouch excision 5 and 10 years after restorative proctocolectomy, respectively.<sup>100–103</sup> Consequently, a restorative proctocolectomy is usually avoided in the setting of recognized Crohn's disease, and is typically performed only as part of a controlled trial.

## Ileocolon

Ileocolon disease is disease of the terminal ileum with colonic involvement noted distal to the cecum and proximal to the rectum. This disease phenotype occurs as often as terminal ileal disease, and the operative approach to these patients is similar to that already outlined for individuals with terminal ileal or colon disease. Specifically, the surgeon must conserve as much of the nondiseased colon as possible and avoid large mesenteric defects. This often requires the construction of two anastomoses, which does not seem to significantly increase operative morbidity.

## Upper Gastrointestinal

Upper gastrointestinal disease is defined as any disease location proximal to the terminal ileum regardless of involvement in other areas, and represents the phenotype that is often the most difficult to manage because of its predilection for extensive disease and predominantly stricturing or penetrating behavior.

Small bowel disease proximal to the terminal ileum is often typified by several stenotic segments separated from one another by noninvolved bowel. These diseased segments range in length and can measure >50 cm. The prognosis for Crohn's disease diffusely involving the small bowel is significantly worse than that of localized disease.<sup>104</sup> The operative options in a symptomatic patient with diffuse jejunoileitis include internal intestinal bypass, strictureplasty, and resection. Intestinal bypass is preferred by most clinicians because of concerns about bacterial overgrowth and malignant degeneration. Resection risks immediate or future short bowel syndrome and is not generally recommended. An operation that consists of multiple strictureplasties is the procedure of choice using the previously discussed techniques to safely conserve small bowel and relieve symptoms secondary to luminal stenosis. The involved segments can be ignored only in the rare instance in which the diseased intestine appears to be inflamed without evidence of stricture or penetration.

Gastroduodenal Crohn's disease is relatively rare, and the most common presenting complaints are upper abdominal pain and symptoms of duodenal obstruction. Endoscopy will

demonstrate macroscopic abnormalities in the majority of patients with the antrum most frequently involved.<sup>105</sup> Isolated gastric disease is exceedingly rare and any reports of successful treatment are purely anecdotal.<sup>106</sup> For duodenal disease, medical therapy is the mainstay of treatment for inflammatory and penetrating disease, whereas strictures present a different challenge.<sup>107</sup> Ulcer-like lesions are nonspecific, rarely cause stenosis, spontaneously regress, and are usually associated with other diseased sites. Contrarily, stenotic duodenal segments are typically unifocal and often respond poorly to medical management. Endoscopic balloon dilatation has been safely used to treat short duodenal strictures, and the procedure seems to be well tolerated while providing marked symptom relief.<sup>108,109</sup> In the past, the operative management of duodenal strictures was restricted to gastrojejunostomy with or without concomitant vagotomy.<sup>110,111</sup> Protagonists of truncal vagotomy cited the high risk for marginal ulceration whereas antagonists raised concerns about postoperative diarrhea. Recently, success with duodenal strictureplasty has been reported by several centers, and the technique seems to be the procedure of choice if the affected bowel is sufficiently supple and devoid of associated sepsis.<sup>112–115</sup>

## Anoperineum

Crohn's disease will affect the anus or perineum in as many as 61%–80% of patients, and typically occurs with or following the onset of disease in other anatomic locations.<sup>116</sup> Involvement of this area can manifest itself as a fissure, skin tag or hemorrhoid, cavitating ulcer, abscess or fistula, anovaginal fistula, anorectal stricture, or carcinoma. These comprise the basis of the accurately descriptive and comprehensive Cardiff classification of anal Crohn's disease,<sup>117</sup> which has not been widely accepted by clinicians because it is perceived to be of minimal clinical relevance.<sup>118,119</sup> Whereas this classification system is solely based on the anatomic and pathologic features, scoring systems of disease activity have been proposed to complement this scheme. These include the Perianal Crohn's Disease Activity Index<sup>120</sup> and a newer system intended to evaluate and predict the outcome of operative management.<sup>121</sup>

The evaluation of anoperineal Crohn's disease should include a regional examination as well as investigations to determine the extent and activity of disease located elsewhere through varied imaging and endoscopic studies. The regional examination may be significantly enhanced by assessment with fistulography,<sup>122,123</sup> endoanal ultrasonography,<sup>124–126</sup> magnetic resonance imaging,<sup>127–130</sup> or examination under anesthesia. Comparative reports suggest that these modalities are associated with comparable accuracy,<sup>131,132</sup> and overall accuracy might be best enhanced by combining the results of any two modalities.<sup>131</sup>

The first priority of therapy is to drain any associated sepsis through the insertion of drainage catheters with or without placement of noncutting setons. The second priority focuses

on stabilizing the infectious component using antibiotic therapy such as metronidazole or ciprofloxacin. In addition, attempts at medical management of the disease process are initiated with immunomodulators and biologic agents; 5-aminosalicylic acid compounds and steroids provide little benefit. The third priority is optimization of quality of life through continued medical therapy or operative intervention used individually or in combination. Asymptomatic fissures, skin tags, or hemorrhoids are best ignored because surgical treatment may escalate the disease to a point in which proctectomy is eventually required.<sup>52,133,134</sup> Cavitating ulcers may dramatically improve with operative debridement and intraleisional steroid injection in combination with appropriately aggressive medical therapy.

Medical management typically includes antibiotics, immunomodulators, and biologic agents used individually or in combination. Metronidazole (20 mg/kg/day) prescribed for 6–8 weeks is associated with a 50%–56% healing rate, but nearly half of patients will experience disease exacerbation and paresthesias with dosage reduction.<sup>135,136</sup> Azathioprine (2–3 mg/kg/day) or 6-mercaptopurine (1.5 mg/kg/day) used alone heals 54% of fistulas compared with a 21% healing rate with placebo.<sup>137</sup> Three doses of infliximab (5 mg/kg) delivered at 0, 2, and 6 weeks can promote fistula closure in 55% of the patients, as compared with 13% of the patients treated with placebo, and the median length of time during which the fistula remains closed is 3 months.<sup>138</sup> However, ciprofloxacin (1000 mg/day) in combination with infliximab tends to be more effective than infliximab alone,<sup>132,139</sup> and re-treatment with infliximab every 8 weeks is more effective than placebo in maintaining fistula closure.<sup>140,141</sup> Lastly, concomitant immunosuppressive therapy with azathioprine, 6-mercaptopurine, or methotrexate may result in improved outcomes because of a reduction in the frequency of human anti-chimeric antibody formation, acute infusion reactions, and a reduced risk of delayed hypersensitivity-like reactions and formation of antinuclear antibodies.

The operative management of a perineal abscess or anoperineal fistula is predicated upon the patient's baseline continence, complexity of the fistula, amount of sphincter encompassed by the fistula, and severity of rectal involvement. In a review of 21 retrospective studies that focused on fistulotomy for a low-lying fistula, the postoperative incontinence rates ranged from 0% to 50%, and 6% to 60% ultimately required a stoma.<sup>142</sup> The initial healing rates in these studies ranged from 8% to 100%, with rates of 80%–100% in 13 of 21 studies, 60%–79% in five of 13 studies, and <60% in three of 21 studies. The clinical scenario best suited for fistulotomy is the continent patient with a simple, low-lying, posterior fistula without associated rectal disease. Fistulotomy for an anterior fistula in this setting, especially in a woman, may risk incontinence. If fistulotomy is likely to cause a disturbance in fecal continence in a patient with minimal rectal inflammation, a rectal mucosal advancement flap is recommended. The healing rates with this procedure range

from 50% to 80% in series containing at least 20 patients,<sup>143–145</sup> and a history of non-colon Crohn's disease is a predictor of failure.<sup>144</sup> Alternatively, a chronic indwelling noncutting seton can be used in this setting. These setons are more ideally suited for chronic drainage of a fistula complicated by rectal inflammation, with proctectomy required in 0%–33% of patients reported in series composed of at least 20 patients.<sup>146–150</sup> Fibrin sealant has also been used in these situations to obliterate the fistula tract, but success has been limited.<sup>151–153</sup> In some patients, the severity of rectal inflammation or extent of perineal sepsis mandates endoanal proctectomy and permanent fecal diversion.<sup>116,142</sup>

Anovaginal fistulas are more difficult to manage than anoperineal fistulas because they often originate from an anal ulcer and traverse a short distance through sometimes attenuated muscle. Fistulas that are not associated with an anal canal ulcer are usually managed with a rectal mucosal advancement flap if the rectal mucosa is noninflamed,<sup>145,154</sup> or an anocutaneous flap if the rectum is moderately diseased.<sup>155</sup> For women with an anovaginal fistula and anal canal ulceration or severe proctitis, proctectomy is often required.

Many clinicians are beginning to use medical therapy in combination with operative treatment. They are reporting that an examination under anesthesia before infliximab treatment accelerates healing<sup>156</sup> and infliximab treatment followed by definitive surgery has a beneficial additive effect in a multi-step treatment regimen for the management of complex anal fistulas arising in patients with active proctitis.<sup>157</sup>

Strictures, which are typically situated at the top of the anorectal ring, should be ignored if asymptomatic or gently dilated if associated with complaints suggestive of outlet obstruction.<sup>158,159</sup> In selected patients with nondiseased rectums, a rectal sleeve advancement may be attempted.<sup>160</sup> Both squamous cell carcinoma and adenocarcinoma can complicate preexisting anoperineal Crohn's disease and persons with chronic involvement may require examinations under anesthesia with both directed and random biopsies of chronically indurated areas to exclude the possibility of malignant degeneration.<sup>95,161–164</sup> If a cancer is identified, the lymph node drainage basin should be closely examined and an oncologic resection planned with or without perioperative adjuvant therapy depending on the histology and stage of the tumor.

## Special Circumstances

### Enteroparietal Abscess

An enteroparietal abscess is likely best treated by initial external drainage using a computed tomography (CT)-guided catheter if the cavity is accessible or, otherwise, by surgical drainage. Conversely, some surgeons suggest that the abscess is best managed by laparotomy, resection, and occasional anastomosis.<sup>165</sup> Antagonists of this approach cite their concerns about short bowel syndrome after laparotomy because

nondiseased bowel involved by the abscess often requires concomitant resection to manage the abscess.<sup>166</sup> Furthermore, successful CT-guided drainage procedures obviate the need for early as well as late operative intervention in nearly half of patients.<sup>166</sup> Patients with large, recurrent abscesses or fistulas after drainage are more likely to require subsequent laparotomy, but a fistula does not pose much operative difficulty if resection has been deferred for approximately 6 weeks.

### Interloop Abscess

Interloop abscesses, which are considerably smaller than the enteroparietal form, are often occult or subtle in presentation and are usually identified only at the time of resection when separating loops of matted bowel.

### Intramesenteric Abscess

Intramesenteric abscesses arise from penetrating disease eroding into the mesentery of the small bowel, colon, or rectum. In the small bowel, the abscess often dissects between the mesenteric leaves, extending sometimes to the origins of the superior mesenteric vessels. Resection of the bowel with a cuff of mesentery carries a particular risk for vascular injury or secondary hemorrhage. Instead, the abscess is identified by intraoperative needle aspiration, and the purulent fluid is drained back into the small bowel lumen by compression of the mesenteric leaves and needle aspiration. An exclusion bypass of the involved bowel is then performed by creating proximal and distal mucus fistulas, and constructing an enteroenterostomy above and below the diseased segment to restore bowel continuity. The excluded segment is then resected 6 months later. Intramesenteric abscesses of the sigmoid colon or rectum are best managed by external drainage combined with diverting end colostomy proximal to the site of disease. Resection with anastomosis to the normal rectum is performed 6 months later.

### Retroperitoneal and Psoas Abscess

Abscesses arising in this anatomic location may be large and well-circumscribed or poorly localized with the infectious process extending deep to the psoas fascia in both caudad and cephalad directions. CT-guided drainage is usually first used followed by elective resection of the diseased segment. If a CT-guided approach fails, surgical drainage is warranted. A large, multilocular abscess is best treated by incising over the appropriate site, separating the oblique muscles, localizing the abscess by needle aspiration, incising the pyogenic membrane, and digitally disrupting any septations. A drainage catheter is inserted and continued until the cavity has collapsed after 4–6 weeks. If the abscess is initially identified at laparotomy, the diseased segment is mobilized, the involved bowel resected, and an anastomosis is usually constructed. The abscess is then unroofed and extraperitoneally drained,

and omentum is interposed between the bowel and the residual cavity. Sinography is completed immediately before catheter removal to assure collapse of the cavity. If the cavity persists, longer drainage is recommended.

### Enterocutaneous Fistula

Enterocutaneous fistulas can develop before any surgical therapy, during the immediate postoperative period, or several weeks after an operation.<sup>167</sup> Early postoperative fistulas most likely represent breakdown of an anastomosis or an unrecognized enterotomy. Otherwise, they are the result of active penetrating disease. This latter presentation is best evaluated by imaging studies and endoscopy to determine the extent of disease and exclude possible septic foci that would require drainage. Medical therapy is then usually initiated with operative management warranted for significantly symptomatic fistulas that are unlikely to heal or fail to heal with medical treatment. Low-output fistulas that minimally soak a gauze dressing may be managed by nonoperative techniques, especially in patients with significant operative risk. If an operation is required, the fistulizing segment of bowel is typically diseased or situated proximal to an obstructed segment. Regardless, the fistulizing bowel and any other disease sites are addressed. Wedge excision or strictureplasty of the fistula site is not recommended because of the associated risk for postoperative leak and recurrent fistula.<sup>168</sup> However, strictureplasty may be performed in other diseased areas provided the previously mentioned guidelines are followed. In a patient with a complex fistula requiring a prolonged operation with extensive enterolysis, multiple anastomoses, enterotomy closures, or strictureplasties, a diverting stoma proximal to all procedure sites is often prudent to allow healing before restoration of the normal fecal flow. These persons often require home hyperalimentation for 3–6 months followed by stoma closure after preoperative imaging confirms complete healing of all suture lines and no areas of distal obstruction.

The management of a fistula developing during the early postoperative period depends on the timing of the presentation and other variables. If the operation was relatively straightforward and the fistula presents in the first 7–10 postoperative days, re-laparotomy, resection, or fistula repair, and probable proximal fecal diversion is warranted. Beyond that time interval or after a difficult operation, re-laparotomy may be associated with more harm than benefit because of formidable adhesions and the risk of iatrogenic bowel injury. An operation is indicated in these patients if they have evidence of sepsis or hemorrhage that cannot be managed by interventional radiology techniques or potentially life-threatening ischemic bowel. In addition, some individuals with fistulas that are particularly difficult to manage can be aided by a laparotomy whereby the upper abdomen is entered and a segment of jejunum proximal to the fistula site is brought out as a diverting stoma. These patients with postoperative fistulas treated nonoperatively will

usually require home hyperalimentation, somatostatin, and possible gastric decompression until the fistula has healed.<sup>169</sup> If the fistula persists despite 6–12 months of management, operative intervention is planned after extensive evaluation of the fistula and intestinal tract.

## Enteroenteric Fistulas

Enteroenteric fistulas are the most common type of internal fistula arising in people with Crohn's disease, and they have been reported to occur in 33% of patients whereas external fistulas affect 15% of people.<sup>170</sup> Isolated enteroenteric fistulas usually cause few symptoms unless obstructive or septic complications dominate the clinical presentation. However, nearly 40% of patients with internal fistulas initially managed by nonoperative methods will require surgery within 1 year, mainly because of disease intractability.<sup>171</sup> The principles of surgical management include resection of the fistula source, freshening of the defect in the adjacent bowel loop by wedge excision, and transverse closure of the defect. Primary bowel anastomosis can usually be safely performed after resection of the diseased segment is completed. However, certain clinical situations may pose particular difficulties.<sup>172</sup> If a phlegmonous reaction involving the rectosigmoid region is part of an ileosigmoid fistula, suture closure of the sigmoid defect may be vulnerable to breakdown. Instead, a limited sigmoid resection with primary anastomosis should be performed because the likelihood of anastomotic dehiscence is negligible.<sup>173</sup> In these cases, the sigmoid colon is diseased in nearly 40% of patients and the reoperative recurrence rate is significantly increased when preoperative endoscopy is omitted.<sup>174</sup>

## Recurrence

Within a few decades of the first description of regional ileitis, the recurrent nature of the disease was recognized.<sup>175</sup> One year after an initial resection, 60%–80% of patients possess endoscopic recurrence, 10%–20% experience clinical relapse, and 5% demonstrate operative recurrence.<sup>176</sup> Physicians from many centers have tried to elucidate those factors responsible for its recurrent nature, but several of the parameters that initially were thought important in predicting disease recurrence have ultimately proved to be unrelated including age of disease onset,<sup>177–185</sup> gender,<sup>177–185</sup> anatomic location,<sup>177–179,181,182,185</sup> duration of preoperative symptoms,<sup>180,183,186–188</sup> previous resection,<sup>189,190</sup> operative indication,<sup>178,179,185</sup> and blood transfusion.<sup>187,191,192</sup> Although disease behavior may impact the likelihood of recurrence,<sup>182</sup> tobacco usage has been almost uniformly linked to recurrence. Specifically, smoking is an independent risk factor for symptomatic, endoscopic, and operative recurrence.<sup>4–7</sup>

The choice of operation might also impact the likelihood of recurrent disease, and various operative options may potentially affect the recurrence rate. Segmental colonic dis-

ease treated by limited resection with colocolonic or colorectal anastomosis for Crohn's disease of the large bowel has been described by a number of institutions over the past 3 decades<sup>193–201</sup> (Table 42-1). Although the majority of patients will experience symptomatic recurrence, more than 75% will maintain intestinal continuity for more than a decade after their initial resection with anastomosis. Despite the symptomatic recurrence rate, it is important to recall that segmental colonic resection delays the need for permanent ileostomy and partially conserves a portion of the large intestine's functional absorbing surface. Crohn's disease of the colon with relative rectal sparing can be adequately treated by colectomy with ileoproctostomy as described earlier. Longo and colleagues<sup>202</sup> reviewed the Cleveland Clinic's experience using this technique. The procedure was safely performed in 118 patients over a 26-year period. After an average 10 years of follow-up, 61% of patients maintained intestinal continuity with a functioning ileoproctostomy. The success of this operation is independent of patient age and duration of symptoms, but inversely linked, in part, to the presence of concomitant small bowel disease at the time of anastomosis. Many other authors have reported similar favorable findings.<sup>197,199,200,202–207</sup> (Table 42-2) One of the most common components of Crohn's disease that manifests itself after proctocolectomy is recurrence of disease in the ileostomy or remaining small bowel. Scammell and associates reported a 24% and 35% cumulative reoperative rate for recurrence at 5 and 10 years, respectively.<sup>208</sup> The majority of recurrences occurred within 25 cm of the stoma. Although the rates vary, these values largely agree with the experience of others.<sup>199,206</sup>

Various forms of medical therapy have been trialed to prevent the likelihood of recurrent Crohn's disease after operative management, but no clear prophylactic drug regime has emerged. First-line therapy generally consists of the 5-aminosalicylic acid compounds, which are only mildly protective and a recent metaanalysis of studies addressing this indication suggested that they were no better than placebo.<sup>209</sup> Second-line treatment includes immunomodulator medications that are potentially beneficial in postoperative patients with high risk for recurrence, endoscopic lesions noted in the neoterminal ileum, or disease-related symptoms.<sup>210,211</sup>

Third-line therapy would likely include nitroimidazole antibiotics that prevent early endoscopic recurrence and postpone symptomatic relapse, but are not well tolerated.<sup>212</sup> Conventional corticosteroids, budesonide, and probiotics have been shown to ineffectively protect against postoperative disease recurrence, and the biologic agents have not been appropriately trialed.

## Summary

Crohn's disease remains a chronic, incurable disorder that presents unique challenges to the surgeon. The proper care of these patients requires a thorough interview, examination, and evaluation because the presenting symptoms and signs can be quite subtle yet profoundly significant. Multiple factors must be considered to allow development of an appropriate treatment plan. Medical therapy often precedes or complements operative management, and although resection remains the principle operation of choice, the nonresectional techniques are often required to allow bowel conservation. The recurrent nature of the disease mandates that we continue to search for alterations in operative techniques and innovative medical therapies that reduce the need for repeat operations.

# Less-common Benign Disorders of the Colon and Rectum

Walter E. Longo and Gregory C. Oliver

There are a variety of benign disorders of the colon and rectum that are uncommon but may be troublesome to diagnose and manage because of their obscurity and at times chronicity. The etiologies of these less-common disorders include bacterial, viral, parasitic, collagen vascular, ischemic, radiation related, and those involving immunocompromised states. It is often common that when the physician entertains these entities, that they never forget the encounter because of its misleading presentation and uncertain treatment. This chapter will describe the myriad of less-common disorders of the colon and rectum that one may encounter in clinical practice with emphasis on diagnosis, differential diagnosis, treatment, and long-term outcome.

## Ischemic Colitis

Vascular disorders of the midgut and hindgut are extremely morbid conditions. This is because these diseases often afflict elderly individuals with various coexisting morbidities and limited physiologic reserve. This is compounded by the fact that these disorders are often diagnosed late, only after full-thickness intestinal injury has occurred, with perforation or gangrene. Major postoperative complications remain excessive and both early and late mortality rates continue to be significant. Ischemic colitis is the most common form of ischemic injury to the gastrointestinal (GI) tract.

It is paramount that the surgeon involved in the care of ischemia and hemorrhage of the colon and rectum has a thorough understanding of the anatomy of the large bowel. The superior mesenteric artery (SMA) and its branches, the inferior mesenteric artery (IMA) and its branches, as well as contributions of the iliac and pudendal arteries to the rectum contribute to the arterial supply of the large bowel. The ileocolic artery (ICA) arises from the right side of the terminal portion of the SMA and provides blood flow to the terminal ileum, appendix, cecum, and ascending colon. The right colic artery (RCA), which may originate from the ICA or the SMA, provides the predominant blood supply to the ascending

colon. It may be absent in up to 20% of patients. The middle colic artery is the first artery originating from the right side of the SMA, and its branches participate in the blood supply of the ascending colon, transverse colon, and the splenic flexure. The IMA arises from the abdominal aorta and gives rise to left colic and numerous sigmoidal branches, and finally terminates as the superior rectal artery. The superior rectal artery is the principal blood supply to the rectum. The remainder of the blood supply to the rectum comes from the middle and inferior rectal arteries, which are contributions from the internal iliac and internal pudendal arteries. There is variable and often unpredictable collateral blood supply to the colon and rectum. The collaterals between the SMA and IMA are the most important clinically and are the marginal artery of Drummond and the arc of Riolan. The venous drainage of the colon and rectum is more anatomically consistent. The venous blood flow from the colon and upper and middle rectum is via the SMV and inferior mesenteric vein to the portal system, whereas that of the lower rectum and anal canal is via the internal iliac veins.

Ischemic injury to the colon is now recognized to manifest distinct clinical subtypes, ranging in severity from transient segmental colopathy to fulminant gangrenous colitis.<sup>1</sup> The incidence of colonic ischemia in the general population remains unknown. Classically, colonic ischemia is described in elderly patients and those who have significant comorbidities. However, case reports reflect the heterogeneity of this disease. Etiologies including shock, autoimmune disease, coagulopathies, long-distance running, illicit drug use, and medication-induced colonic ischemia have been reported, in patients both young and old. Colonic ischemia remains a disease of variable clinical presentation and outcome.<sup>2</sup>

Ischemic colitis is often recognized as a specific entity characterized by sudden abdominal pain and diarrhea. A spectrum of disease exists, ranging from transient mucosal injury that spontaneously resolves to transmural disease with full-thickness gangrene. An intermediate form also exists in which, after resolution of symptoms, stricture formation occurs. An increased awareness and suspicion that ischemic

colitis is present should initiate prompt diagnostic endoscopy. Unexplained abdominal symptomatology or unexplained clinical deterioration with abdominal symptoms should prompt the clinician to exclude the colon as the source of the problem. Unfortunately, routine laboratory and radiologic investigations often fail to identify colonic ischemia. Colonoscopy is responsible for the increasing awareness of colon ischemia and remains the procedure of choice to document its presence or absence and identify or exclude other colonic pathology.<sup>3</sup>

Two distinct forms of ischemic colitis have been repeatedly described throughout the last 40 years.<sup>4</sup> The spontaneous, usually self-limiting form of ischemic colitis contrasts drastically with the often catastrophic, more fulminant form. Despite the widely divergent outcomes, the initial presentations of the two forms may be identical and are not predictive of the patient's clinical course. Ischemic colitis is generally viewed as a nonocclusive form of intestinal ischemia. Although in some cases a specific anatomic abnormality may be identified, as in ligation of the IMA during repair of abdominal aortic aneurysms, the precipitating episode often resolves by the time of presentation. Diagnosis is dependent on a high index of suspicion for the disease. Correct interpretation of the symptoms, signs, and laboratory values associated with colonic ischemia must be followed by prompt diagnostic imaging, endoscopy, and/or operative exploration, depending on the severity of disease.<sup>5</sup>

Clinical risk factors are important to consider when evaluating a patient for ischemic colitis. Cardiovascular disease and hypertension are common, prevalent, preexisting medical conditions among our group of patients, and many of these patients are taking vasoactive medications, which may have limited the flow to the ischemic segments or have blunted the colon's ability to compensate for low blood flow.<sup>6</sup> Additionally, many have renal failure. The association between morbidity and mortality from ischemic colitis and patients with chronic renal failure has been described.<sup>7</sup> Certainly, one must have a low threshold for complete endoscopic evaluation of the entire colon in these patients when symptoms of an unexplained GI illness are present. Nevertheless, colonoscopy should be avoided in patients with peritoneal signs.

Nongangrenous ischemic colitis should be managed conservatively, because resolution is often self-limiting. Even strictures can be managed without operation because obstruction is rarely complete and endoscopy can differentiate benign from malignant strictures. Adequate hydration initially is important to maintain tissue perfusion. Systemic antibiotic therapy is given with monitoring of white blood cell count and hematocrit. There is no role for systemic anticoagulation. Abdominal pain, acidosis, and clinical deterioration all suggest impending infarction. Conservative therapy has no role once infarction develops and the prognosis is related to the time the diagnosis is made and the colon is resected. At surgery, all ischemic colon needs to be resected. Primary anastomosis should be avoided. Survival is almost uniformly inversely correlated with the

presence of infarction as well as the presence of coexisting morbidities. A recent series demonstrated that pain-associated ischemic colitis has a worse prognosis than melena-associated ischemic colitis.<sup>8</sup> Colonic ischemia affecting younger people is being recognized more frequently where identifiable causes include collagen vascular disease, hematologic disorders, long-distance running, and cocaine abuse.<sup>9</sup>

Total colonic ischemia remains a highly lethal condition. Risk factors for total colonic ischemia seem to be patients who have had profound blood loss after major abdominal surgery or patients with disease entities characterized by fluid shifts such as renal failure on hemodialysis. Regardless, prompt recognition and resection can be lifesaving in severe cases.<sup>10</sup> Ischemic proctosigmoiditis remains a rare entity, thought to be attributable to the abundant collateral blood supply located within the pelvis and perineum.<sup>11</sup> When this entity occurs, often an identifiable precipitating factor is identified. Conservative management is usually effective and proctectomy rarely required.

## Collagen Vascular-associated Colitis

The collagen vascular diseases represent a collection of conditions that are believed to be the result of pathologic alterations in the immune system. They may occur in any organ and may be associated with GI manifestations.<sup>12</sup> Often these entities affect the blood supply to the colon and rectum and may produce ischemic changes and a colitis. Deposition of immune complexes in blood vessel walls resulting in either ischemia or thrombosis is the most widely accepted pathogenic mechanism. These entities include polyarteritis nodosa (PAN), cryoglobulinemia, Henoch-Schönlein purpura, Behçet's syndrome, systemic lupus erythematosus (SLE), scleroderma, and polymyositis.

### Polyarteritis Nodosa

PAN is a systemic necrotizing vasculitis of small- and medium-sized arteries often with visceral involvement. Lesions are segmental and tend to involve bifurcations and branches of arteries. In the United States, the incidence is about 3–5 per 100,000 population per year. Men are affected more frequently than women and the age of onset is 40–60 years. Patients typically present with nonspecific signs and symptoms such as fever, weakness, headache, abdominal pain, weight loss, and malaise. PAN affects multiple systems including renal, musculoskeletal, nervous, GI, integument, cardiac, and genitourinary. The GI tract involvement is similarly nonspecific and presenting signs and symptoms include abdominal pain, nausea, and vomiting, bleeding, bowel infarction, and perforation, as well as cholecystitis, or hepatic/pancreatic infarction. PAN carries a high mortality rate when untreated. Nearly half of patients die within the first 3 months of onset. When immunosuppressive agents are combined with

corticosteroids, the 5-year survival rate may increase to greater than 80%.

GI involvement of PAN is often a poor prognostic factor. Patients often have an abnormal visceral arteriogram with both saccular and fusiform aneurysms of the mesenteric vessels. Abdominal symptoms are often manifested as pain where organ damage caused by ischemia and hemorrhage may occur. GI hemorrhage, bowel perforation, and bowel infarction are often the underlying pathology. Some patients may present with a chronic wasting syndrome in which mesenteric angiography may establish the diagnosis. The Churg-Strauss syndrome (CSS) is a variant of PAN in which GI involvement caused by eosinophilic infiltration causes abdominal pain, bloody stool, and diarrhea. Surgical intervention is required for acute surgical conditions as a consequence of PAN or CSS. Bowel resection with avoidance of an intestinal anastomosis should be performed. A discussion with the family should include the poor prognosis with GI involvement.<sup>13</sup>

### Cryoglobulinemia

Cryoglobulins are immunoglobulins that undergo reversible precipitation at low temperatures. Cryoglobulinemia may be associated with a particular disease such as autoimmune disease, lymphoproliferative disorder, infectious diseases, or it may be idiopathic form termed essential cryoglobulinemia. This disease is thought to be related to immune-complex disease with intravascular cryoglobulin deposits, reduced level of complement and complement fragments that act as chemotactic mediators of inflammation. Cryoglobulinemia may complicate chronic hepatitis infection, and many immune diseases including inflammatory bowel disease. The GI manifestations are rare and may result in ischemia or infarction secondary to a mesenteric vasculitis.<sup>14</sup>

### Henoch-Schönlein Purpura

Henoch-Schönlein purpura is a distinct systemic vasculitis characterized by the tissue deposition of immunoglobulin A containing immune complexes. The clinical symptoms include abdominal manifestations, arthralgias or arthritis, palpable purpura, glomerulonephritis, and colicky abdominal pain. Although the disease is frequently seen in children, adults of any age may be affected. Abdominal symptoms are usually the result of vasculitis in which symptoms include abdominal pain, nausea, and vomiting, and GI bleeding may occur in up to 40% of patients. Intramural hematomas, intussusception, infarction, and perforation of the gut may be a sequelae of this disease.<sup>15,16</sup>

### Behçet's Syndrome

Behçet's syndrome is a chronic relapsing inflammatory, multisystem disorder characterized by widespread vasculitis of large and small arterial and venous vessels. It is most

prevalent around the Mediterranean and Japan. When it appears, it affects young men and runs an aggressive course. In Europe and North America, it mainly affects women. The etiology of the disease is unknown, but most authors believe it arises from a genetic predisposition with a triggering event such as streptococcal infection that leads to alteration in immune function.<sup>17</sup> The GI tract is affected in 15%–65% of cases, and when involved carries a poor prognosis.<sup>18</sup> Mesenteric ischemia and infarction are a result of large vessel disease and ulceration is a sequelae of small vessel disease involving the mucosa. The ileocecal region is the most frequently involved segment. Diarrhea, abdominal pain, colitis, pancreatitis, bleeding, and ulceration from the mouth to the anus are features of GI involvement.<sup>19</sup> It may also present with a mass in the ileocecal region and often mimics inflammatory bowel disease. Behçet's disease and inflammatory bowel disease share many of the extraintestinal manifestations involving the eye, mouth, liver, and joints. Behçet's disease behaves similarly to Crohn's disease with anorectal ulceration and rectovaginal fistula. It is often difficult to distinguish between Behçet's disease and inflammatory bowel disease, because of the similarity in extraintestinal symptoms, such as oral ulceration, erythema nodosum, uveitis, and arthritis. Histologically, the intestinal ulcers of patients with Behçet's disease are indistinguishable from those of patients with ulcerative colitis; however, the finding of the granuloma formation that is characteristic of Crohn's disease can be used to rule out Behçet's disease.

Endoscopic and radiographic evaluation of the small and large bowel will reveal deep ulcers, pseudopolyps, and mucositis. Surgery is often encouraged early in treatment before fatal complications occur. Wide surgical margins are preferred and intestinal anastomoses discouraged because anastomotic leaks, reperforation, and fistulization are common.<sup>20</sup> When these GI manifestations of Behçet's disease occur, the prognosis is poor.

### Systemic Lupus Erythematosus

SLE is a chronic multisystem inflammatory disease that can affect any and every organ system of the body, and follows a relapsing and remitting form. It is an autoimmune disorder involving microvascular inflammation and the generation of autoantibodies. Although the specific cause of SLE is unknown, multiple factors are associated (genetic, hormonal, environmental) with this disease. Disturbances within the immune system result in the formation of immune complexes in the microvasculature leading to complement activation and inflammation. Antinuclear antibodies are present in the serum of virtually all patients with SLE and antibodies to native DNA are highly specific for the diagnosis of SLE.

GI symptoms are common in patients with active SLE. Nausea and dyspepsia are frequent complications. Abdominal pain may be related directly to active lupus. One of the most devastating complications of lupus is GI vasculitis

and carries a 50% mortality rate.<sup>21</sup> Common sequelae include ulceration, hemorrhage, perforation, and infarction.<sup>22,23</sup> The diagnosis of small or large bowel vasculitis is frequently difficult to make because arteriography rarely demonstrates small vessel disease and computed tomography (CT), endoscopy, and small bowel series may also be unrevealing. The diagnosis is often made from surgical specimens after an acute surgical emergency. Medical treatment of abdominal lupus vasculitis often involves corticosteroids and cyclophosphamide.

## Scleroderma

Scleroderma is a multisystem, multistage disorder of small arteries, microvessels, and connective tissue. The disease occurs in all races but affects women three to four times more often than men. Initial symptoms occur in the 20s to 40s. Systemic manifestations may include skin involvement, Raynaud's disease, polyarthritis, and lung, heart, kidney, and thyroid problems. In the GI tract, the disease may affect the esophagus, stomach, or small or large bowel. The GI symptoms may precede the diagnosis by several years, and are often the most difficult to treat. Overproduction of collagen, increased humoral immunity, and abnormal cellular immune function all contribute to the development of scleroderma in other organs. More importantly, the changes seen in the blood vessels in scleroderma have a role in the development of the clinical manifestations of the disease. The esophagus is the GI organ that is most frequently involved and more than 50% of patients diagnosed with scleroderma have esophageal manifestations. In the small bowel and the stomach, chronic intestinal pseudoobstruction, bacterial overgrowth, and malnutrition are the main consequences. These patients often require prokinetic agents which can be used to enhance gut motility. Antibiotic therapy is the treatment for bacterial overgrowth. Somatostatin is used when severe diarrhea develops which occasionally is seen in scleroderma.<sup>24-26</sup>

Scleroderma may also affect the large bowel and colonic motility. Clinically, patients may have severe constipation and may have fecal impaction, rectal prolapse, megacolon, and diverticula. GI bleeding arising from the colon has been reported to result from diverticulosis, stercoral ulcerations, and telangiectasias. Anorectal dysfunction frequently occurs with scleroderma and is similar to that of the esophageal dysmotility. These patients often have decreased internal anal sphincter pressures, a decreased or absent anorectal inhibitory reflex, and reduced rectal compliance. The treatment of constipation may prove difficult, and after conventional treatment fails, daily balanced electrolyte solutions containing polyethylene glycol may be required. Prokinetics are often tried, but results are disappointing. For fecal incontinence, efforts in controlling diarrhea are worthwhile. Antidiarrheals, however, may precipitate pseudoobstruction. Biofeedback may be considered. Finally, malnutrition may be a serious consequence of this disease and appropriate measures should be instituted.<sup>27</sup>

## Polymyositis

Polymyositis is an inflammatory muscle disease of unknown etiology. It is characterized by weakness, high levels of striated muscle enzymes, and electromyographic or biopsy evidence of an inflammatory myopathy. This all is a result of immune-mediated muscle inflammation and vascular damage. The immune system is primed to act against previously unrecognized muscle antigens. It is a disease of adults and common among blacks. Symmetric proximal muscle pain and weakness, dysphagia, arthralgias, joint pain, and, when accompanied by a rash over the face, chest and hands, it is referred to as dermatomyositis. Serum creatine kinase is the most sensitive and specific laboratory study with levels 5-50 times that of normal. The erythrocyte sedimentation rate is usually increased, myoglobinuria may be present, and positive rheumatoid factor and antinuclear antibody may be found. Treatment includes systemic steroids and immunosuppressive agents. GI symptoms include impaired deglutition, impaired gastric emptying, bloating, constipation, and GI hemorrhage. Pneumatosis intestinalis, colonic dilatation, and diverticulosis may be seen. Certain subgroups of polymyositis-dermatomyositis may have an increased prevalence of malignancy. Overall, the 5-year mortality rate is 20%.<sup>28</sup>

## Microscopic Colitis

Microscopic colitis is current terminology encompassing two subtypes: lymphocytic colitis and collagenous colitis. From a clinical perspective, disease manifestations and treatment are alike. These entities are separated by their histologic features. The clinical syndrome of watery diarrhea in the setting of normal radiologic studies of the GI tract and with a normal endoscopic mucosal appearance was problematic to many clinicians. Many patients were lumped into the rubric of irritable bowel syndrome for lack of any better understanding.

In 1976, Lindstrom<sup>29</sup> published the first article describing the association of colonic collagenous deposition and a watery diarrhea syndrome. Four years later, Read and colleagues<sup>30</sup> published the first article referring to microscopic colitis. In 1982, Kingham and associates<sup>31</sup> described six patients who presented with watery diarrhea and normal appearing colons by barium enema study and colonoscopy. However, random colonic biopsies revealed lymphocytic infiltrates in the colonic epithelium. Treating these six patients with antiinflammatory medications resolved their symptoms thus demonstrating the relationship between the infiltrate and the syndrome.

Pardi<sup>32</sup> estimates that microscopic colitis accounts for about 10% of cases of chronic diarrhea referred to major centers for study. Of this 10%, about half represent lymphocytic colitis and half collagenous colitis. Collagenous colitis occurs more often in women (studies exceed 80%) whereas there seems to be no gender differential in lymphocytic colitis.

Both entities principally afflict patients over the age of 60 but cases have been demonstrated in all age groups including pediatrics. Bo-Linn and associates<sup>33</sup> were able to demonstrate that watery diarrhea was secondary to marked depression of colonic absorption. This decreased function led to the associated findings of hypokalemia and, in severe cases, a protein-losing enteropathy. Crampy abdominal pain and weight loss are the major clinical complaints from patients. Stool frequency ranges from 3 to 20 per day. Despite this, dehydration is unusual as are fever, vomiting, and GI bleeding.

Clinical evaluation demands that when the patient comes to endoscopy, biopsies be obtained. Lymphocytic colitis tends to occur uniformly throughout the colon and rectum but collagenous colitis is often patchy, therefore requiring frequent colon biopsies at intervals throughout.<sup>34</sup> The histologic criteria for lymphocytic colitis requires more than 10 lymphocytes per 100 epithelial cells in the colon (Figure 43-1). Normal colons will have less than five lymphocytes per 100 cells. Additionally, a mixed mononuclear infiltrate is present in the lamina propria. The excess deposition of collagen in collagenous colitis occurs in the subepithelial layer of the bowel (Figure 43-2). It is interesting to note that it is not the thickness of the collagen layer that correlates with the severity of the diarrhea, but instead the degree of inflammatory infiltrate.<sup>35</sup> The terminal ileum may be affected by either type of microscopic colitis. Villous atrophy<sup>36</sup> and intraepithelial lymphocytosis<sup>37</sup> may be found on ileal biopsy. Ileal wall changes suggest that perhaps a small bowel luminal constituent is responsible for the inflammatory colonic changes. Studies demonstrating a high prevalence of arthritis (82%) and autoantibodies (50%) suggest the possibility of an autoimmune disorder.<sup>38</sup> Higher than expected prevalence of sprue-like HLA genes in microscopic colitis patients suggests an immunologic basis for the inflammatory changes.<sup>39</sup> Furthermore, diversion of the ileal content via a stoma led to morphologic resolution of colonic inflammatory changes on tissue microscopy. Closing the

FIGURE 43-1. Lymphocytic colitis. Hematoxylin and eosin (H & E) stain; magnification  $\times 540$ . (© 2004 Frederick C. Skvara, MD).

FIGURE 43-2. Collagenous colitis. H & E stain; magnification  $\times 540$ . (© 2004 Frederick C. Skvara, MD).

stoma led to recurrent microscopic colitis.<sup>40</sup> Another factor related to possible pathogenesis of the colonic inflammatory process is bile acid malabsorption (BAM). One report found BAM present in 60% of those studied with lymphocytic colitis versus 27% in collagenous colitis.<sup>41</sup> Of note, 75% of patients with functional diarrhea demonstrated BAM. It therefore suggests that abnormalities of bile metabolism may be concomitant conditions but not causally related to the colonic inflammatory condition.

Recently, a report<sup>42</sup> linked the onset of microscopic colitis to a formulary change in which lansoprazole was substituted for omeprazole. Development of a watery diarrhea syndrome resulted in biopsy proven diagnosis, which resolved on discontinuation of the medication. This finding suggests that medication-induced colonic changes do occur and should be sought after in the evaluation of patients with microscopic colitis.

Treatment options are empiric and are directed at symptom management, management of the inflammatory process, and the potential role of disordered immunoregulation in the pathogenesis of this disease. Because there are multiple medications that impact the above targeted areas, it is recommended that therapy begin with the least toxic regimens. Initially, dietary modifications can be tried, eliminating caffeine, dairy, alcohol, and artificial sweeteners. Nonsteroidal antiinflammatory drugs (NSAIDs) should be discontinued. Loperamide and diphenoxylate/atropine are generally effective at symptom resolution. Bismuth subsalicylate has been demonstrated over an 8-week course to be safe and efficacious in disease management when dosed at 524 mg four times daily.<sup>43</sup> Cholestyramine induced remission in 19 of 22 patients<sup>41</sup> whereas mesalamine produced some response (range of 47%–50%). Steroids were more effective (70%–82% response). Immunomodulator therapy with azathioprine, 6-mercaptopurine, and others has been tried for steroid failures or those requiring chronic steroid maintenance with some success (89%).<sup>44</sup> Surgical options include ileostomy for diversion

or colectomy, with or without restoration of continence. Surgery, as a treatment option, requires failure or intolerance to the medical options available and symptoms severe enough to warrant such aggressive intervention.

## Eosinophilic Colitis

This rare condition is characterized by eosinophilic infiltration of the involved tissues and increased eosinophil counts in peripheral blood.<sup>45</sup> Eosinophilic colitis is usually encountered in the gastric antrum and proximal small bowel. Symptoms include abdominal pain, nausea, vomiting, and weight loss. When the mucosa is involved, bleeding, diarrhea and protein-losing enteropathy may be noted. Differential diagnosis includes tuberculosis, Crohn's disease, parasite infestations, allergic enteropathies, and collagen vascular disorders. Colonoscopic biopsies should differentiate eosinophilic colitis from these other grossly similar appearing conditions.<sup>46</sup> Therapy for symptomatic patients consists of steroids. Spontaneous remissions have been documented. Surgery has a role for management of complications, such as intussusception, obstruction, or hemorrhage and in cases in which diagnostic dilemmas require more tissue.<sup>47</sup>

## Fungal Colitis

Fungal colitides do occur but are thankfully unusual in an immunologically normal patient. Clinical settings in which this diagnosis must be considered include human immunodeficiency virus (HIV) infections, immunocompromised states such as splenectomy, chronic liver disease, and steroid therapy as well as in chronically ill patients being treated with broad-spectrum antibiotics. The major pathogens in this category include *Candida* spp., *Histoplasma capsulatum*, and *Cryptococcus neoformans*. Outside the United States, other fungi may predominate such as is seen with *Penicillium marneffeii* in Southeast Asia.<sup>48</sup>

*Candida* colitis is the more common of these entities found predominantly in patients in the intensive care unit. Usually, the infection is systemic involving septicemia, the pulmonary tract, the urinary tract, and the GI tract. Colonic involvement may be diffuse and thus results in diarrhea, fever, and abdominal pain. Perforation may occur with resultant peritonitis or fistulization. Stool cultures or endoscopic biopsies are diagnostic when typical spores, yeast, or pseudomycelia are demonstrated. Medical treatment is first-line therapy in the absence of peritonitis. This consists of oral nystatin 500,000–1,000,000 units four times daily or in sicker patients, ketoconazole 200–400 mg daily. Alternatively, amphotericin B 0.3–0.6 mg/kg can be administered intravenously.<sup>49</sup> Surgical intervention may be required in the face of free perforation or clinical findings of peritonitis. Despite aggressive surgical intervention, mortality is very high because of the severity of the associated conditions.

## Histoplasmosis

*H. capsulatum* is found endemically throughout the Midwestern United States. Although principally a pathogen of the reticuloendothelial system, it can cause systemic infection in the immunocompromised host. Pulmonic disease is most common but ileocolitis does occur. A granulomatous process causing bleeding, ulceration, stricture formation, and perforation has been described.<sup>50</sup> Endoscopic examination can be confusing because the lesions may appear to resemble adenocarcinoma. Skip areas, pseudopolyps, ulcerations, and plaque-like lesions may be present but biopsies will reveal intracellular budding yeasts within the mucosa when this organism is present. Serologic tests and fungal cultures may also confirm the diagnosis. Although perforation is rare, emergent surgery with resection of the grossly affected tissue and proximal diversion may be necessary. Amphotericin B intravenously administered is indicated in severe cases whereas ketoconazole has been used effectively in patients less severely ill. *Histoplasma* colitis has been reported in otherwise healthy patients but the previously described assessment should demonstrate the responsible pathogen when present.<sup>51</sup>

## Cryptococcus

Cryptococcosis usually affects the central nervous system. *C. neoformans* is acquired via inhalation of soil contaminated with this encapsulated yeast. Isolated GI infection is rare but does occur in immunocompromised patients. Colitis with perforation can occur spontaneously or after endoscopic biopsy and so surgical intervention to manage life-threatening complications may be necessary.<sup>52</sup> A high index of suspicion must be maintained when patients present with symptoms of colitis and a concomitant history of immune suppressive therapy or infection with HIV. Early medical therapy provides the best means of avoiding surgery in these very ill patients. Diagnosis is confirmed by biopsy of infected mucosa demonstrating encapsulated budding yeasts or via culture of stool. Ketoconazole is effective in less severely ill patients but amphotericin B is standard therapy in severely ill or immunocompromised patients.

## Bacterial Colitis

Because bacterial pathogens can produce clinical syndromes, which may mimic other conditions in which surgery is more likely a therapeutic consideration, colorectal surgeons must have a basic understanding of the organisms that cause enterocolitis as well as diagnostic and therapeutic options (see Table 43-1). Bacterial pathogens cause disease within the GI tract in several ways: mucosal adherence leading to secretory diarrhea, toxin production, and mucosal invasion.<sup>52</sup> The very young and the elderly are at greater risk of serious sequelae as are immunocompromised hosts. The majority of infections worldwide occur in developing countries where water

TABLE 43-1. Clinical pathologic characteristics of bacterial colitis

Sign	Organisms capable of producing syndrome
Watery diarrhea	<i>E. coli</i> <i>Salmonella</i> <i>Shigella</i>
Dysentery	<i>E. coli</i> <i>Salmonella</i> <i>Shigella</i> <i>Yersinia</i> <i>Campylobacter</i>
Enteric fever or syndrome	<i>Salmonella</i> spp. <i>Yersinia</i> <i>Campylobacter</i>

contamination, poor food preservation techniques, and fecal contamination of food supplies is more likely. Each of the major bacterial pathogens is reviewed as to the clinical syndromes, complications, diagnosis, and treatment when necessary. For the most part, watery diarrhea syndrome requires supportive measures such as fluid and electrolyte replacement. Dysenteric syndromes characterized by bloody diarrhea, fever, and abdominal pain generally necessitate identification of the organism so that appropriate antibiotic therapy can be initiated (see Table 43-2). The goals of treatment are to decrease the period of bacterial shedding in the stools and to improve the patient's clinical condition, thus lessening the likelihood of invasive complications of infection.<sup>53</sup>

## Escherichia coli

Based on the mechanism by which they cause diarrhea, four classes of *E. coli* are described. Enteropathic *E. coli* is primarily a problem causing outbreaks of severe diarrhea in nurseries. Diarrhea is caused by the bacteria adhering to the mucosa of the enterocytes and the production of a cytotoxin causing mucosal damage. Infection is primarily within the small bowel. The clinical syndrome may consist of watery

diarrhea, vomiting, and fever. The process is generally self-limiting and so therapy is supportive. Trimethoprim-sulfamethoxazole (TMP/SMX) is effective and is recommended in complicated cases.

Enterotoxigenic *E. coli* is ubiquitous in developing nations and is the major organism causing traveler's diarrhea. Thirty to fifty percent of travelers from industrialized nations spending 3 weeks or more in developing nations will experience this infection.<sup>52</sup> The toxin produced does not damage the mucosa but causes a secretory diarrhea. Infection is self-limiting but may cause cramping and low-grade fevers. Treatment is supportive. For travelers wishing to avoid becoming ill with this pathogen, prophylaxis with bismuth subsalicylate, 2 tablets four times daily during periods of exposure is helpful. Unfortunately, salicylate intoxication is a concern in children and thus not recommended in this group.<sup>53</sup>

Enteroinvasive *E. coli* produces a syndrome much like *Shigella*. Mucosal invasion of enterocytes by this strain produces the illness but is usually self-limited. Treatment is supportive unless dysentery develops. Should this occur, TMP/SMX is indicated.

Enterohemorrhagic *E. coli* can cause serious dysenteric problems related to production of a cytotoxin. It has occurred in the United States in outbreaks associated with undercooked hamburger meat. Cramps, low-grade fever, and watery diarrhea progress to a more severe bloody diarrhea. Treatment remains supportive because no effective antimicrobial therapy is known. The clinical presentation may mimic inflammatory bowel disease or ischemic colitis. A hemolytic uremic syndrome or thrombocytopenia may complicate the recovery phase, especially in patients at either age extreme.<sup>54</sup>

## Shigella

Although there are four species of *Shigella* known to cause clinical gastroenteritis, in the United States, *S. sonnei* predominates and *S. flexneri* is second most common. *Shigella* is

TABLE 43-2. Antibiotic therapy for bacterial colitis (adults)

Pathogen	Illness	Treatment
<i>E. coli</i>	Traveler's diarrhea	TMP/SMX 1 double strength tab b.i.d. × 3–5 d or ciprofloxacin 500 mg p.o. b.i.d. × 3–5 d
<i>Salmonella</i>	Bacteremia, sepsis, immunocompromised host, dysentery	Ceftriaxone 1 g IV or IM q 12 h × 2 wk or cefoperazone 30 mg/kg q 12 h × 2 wk or chloramphenicol IV 75 mg/kg/d in 4 divided doses × 2 wk or ciprofloxacin 500 mg IV or p.o. q 12 h × 2 wk or ampicillin 100 mg/kg/d IV or IM q 6 h × 14 d
<i>Shigella</i>	Dysentery	TMP/SMX double-strength tablets (DS), one b.i.d. p.o. × 5 d or norfloxacin 400 mg tablets p.o. b.i.d. × 5 d or ciprofloxacin 500 mg p.o. b.i.d. × 5 d
<i>Yersinia</i>	Sepsis, severe abdominal pain with mesenteric adenitis	Gentamicin 7.5 mg/kg/d administered IV q 8 h for 7–10 d or TMP/SMX DS b.i.d. for 5 d or chloramphenicol IV 75 mg/kg/d given q 6 h for 7–10 d
<i>Campylobacter</i>	Dysentery or sepsis	Ciprofloxacin 500 mg p.o. t.i.d. × 5 d or azithromycin 500 mg q d × 3 d or gentamicin or chloramphenicol as for <i>Yersinia</i> , if severe
<i>Tuberculosis</i>	Enterocolitis	Isoniazid 300 mg p.o. q d and rifampin 600 mg p.o. q d for 4–6 mo
<i>Aeromonas</i>	Dysentery, enteric fever syndrome, immunocompromised patient	TMP/SMX DS p.o. b.i.d. × 7–10 d or doxycycline 100 mg p.o. b.i.d. or chloramphenicol IV 75 mg/kg/d given q 6 h for 7–10 d
<i>Brucellosis</i>	Colitis	Doxycycline 100 mg p.o. b.i.d. for 3–6 wk and streptomycin 1 g IM q 12–24 h for 14 d
<i>Actinomycosis</i>	Abdominal pain, mass, fever	Penicillin G 12–18 million units/d given q 4–6 h for 2–6 wk

b.i.d., twice a day; p.o., per os; q, every; IV, intravenously.

the prototypical pathogen causing a dysenteric syndrome based on the ability of this gram-negative rod to produce toxins permitting epithelial cell penetration and destruction. Malnourished and immunocompromised hosts are most at risk for the debilitating complications of infection.<sup>55,56</sup> Onset of infection follows fecal-oral transmission of a small number of inocula. Sexual transmission does occur but most cases originate from overcrowded housing and daycare facilities.<sup>57</sup> Watery diarrhea, fever, fatigue, and malaise herald the onset of colitis. Gross bleeding and mucous denotes dysentery and requires the more virulent properties usually associated with *S. dysenteriae* and least likely with *S. sonnei* as found in the United States.<sup>58</sup> Bowel obstruction and toxic megacolon are most frequently seen in *S. dysenteriae* infections in underdeveloped nations. Although stool volume is low, making dehydration unusual, the colonic inflammatory process leads to spasm and tenesmus (10–100 bowel movements per day). Diagnosis is best made by stool cultures for enteric pathogens. Endoscopic examination reveals a friable, edematous, erythematous mucosa with focal ulcerations and bleeding. The most often affected area is the rectosigmoid but the more severe the infection, the more proximal the changes progress. As to treatment, because infections with *S. sonnei* in the United States tend not to cause the dysenteric syndrome, supportive care is generally all that is necessary. Avoidance of antimotility agents is critical because their use exacerbates symptoms and predisposes to toxic megacolon. In the immunocompromised host or with the development of dysentery, TMP/SMX, ciprofloxacin, and ampicillin are usually effective at shortening the duration and severity of illness. Emergence of resistance to antibiotics is significant and so local knowledge of susceptibility patterns is important. Treatment should continue until stool cultures convert to no growth of the organism.

## Salmonella

A gram-negative bacilli, *Salmonella* causes predominantly two clinical conditions. The first is typhoid fever caused by *S. typhi* and *S. paratyphi*, endemic in third world countries. The organism is ingested and is susceptible to destruction by normal gastric acidity, pancreatic enzymes, and enteric secretions.<sup>52</sup> Where these barriers to infection are altered either by postsurgical changes or acid-blocking medications, infection is more likely. Incubation periods range from 5 to 21 days with the onset of remitting fevers, headache, abdominal pains, and diarrhea. Hyperplasia of the reticuloendothelial systems can cause marked swelling in the ileocecal area. Hemorrhage, obstruction, and perforation may occur requiring emergent surgical intervention with resection and proximal diversion necessary.<sup>59</sup> The second and by far more common condition in the United States is non-typhoidal salmonellosis. *S. enteritidis* is usually responsible for causing a self-limited gastroenteritis in the warmer months of the year. Contaminated

food products lead to nausea, vomiting, and abdominal pain. Most patients experience watery diarrhea but dysenteric symptoms may develop, especially in the immunocompromised host.<sup>56,58</sup> Infection is primarily small bowel but can progress to a colitis. Stool cultures, rectal swabs, or colonoscopic biopsies will assist in diagnosis. For severe infections in patients who are immune suppressed, have foreign body implants, hemolytic anemia, or pregnant, antibiotic therapy with ampicillin or TMP/SMX should be given as first-line therapy. In the majority of affected patients in the United States, supportive care will suffice.<sup>58</sup>

## Campylobacter

This gram-negative rod is the most frequently identified cause of acute diarrheal illness in United States and industrialized nations. *C. jejuni* is the most common. Outbreaks generally occur during warm weather and are most frequently traced to poor handling or preparation of chicken products.<sup>58</sup> The organism can produce a spectrum of disease from watery diarrhea to dysentery depending on the strain's ability to produce enterotoxin, cytotoxin, or to cause mucosal invasion.<sup>55,56</sup> The terminal ileum and cecum are most frequently involved. Rarely, when the organism elaborates mucosal invasive properties, mesenteric lymphadenopathy may simulate appendicitis or produce an enteric fever-like syndrome. Most cases present with fever, abdominal pain, diarrhea, nausea, and malaise. Symptoms are generally self-limited resolving within 1 week but may linger up to 3 weeks. Immunocompromised patients are at greater risk for severe complications.<sup>58</sup>

Endoscopic findings range from segmental colonic ulcerations to a diffuse colitis. Disease limited to the ileocecal region may mimic Crohn's disease. Diagnosis requires stool cultures because clinically the disease mimics *Salmonella* and *Shigella*. Treatment with erythromycin or ciprofloxacin should be reserved for severely ill patients or any of those affected having an immunocompromised state, i.e., HIV, the very young, or the very old. Otherwise, treatment is supportive. Surgical intervention may be necessary to rule out appendicitis, or less frequently, to treat complications such as megacolon, hemorrhage, or perforation.<sup>59</sup>

## Yersinia

*Yersinia* is a gram-negative coccobacillus capable of producing gastroenteritis commonly in Europe and North America. *Y. enterocolitica* and *Y. pseudotuberculosis* are most frequently associated with clinical disease, the latter being the more severe. Poor food handling and contaminated water are usually associated with outbreaks in the United States.<sup>26</sup> Of significant import to surgeons is that 40% of cases present in a manner very similar to acute appendicitis.<sup>57–59</sup> The organism invades Peyer's patches causing swelling in the terminal

ileum, enlarged mesenteric nodes, localized pain, and watery diarrhea. At surgery, the appendix will appear normal. In severe cases, polyarthritis, erythema nodosum, and Reiter's syndrome may suggest the possibility of Crohn's ileocolitis. Colonoscopic evaluation may demonstrate erythema, aphthous ulcerations, and swelling of lymphoid tissue. Specific fecal culture techniques enhance identification, and serology is available, but both are time consuming.<sup>56</sup> Treatment of uncomplicated cases with antibiotics has not demonstrated clinical improvement except in the immunocompromised host or in the more complicated infection, i.e., enteric-like fever or mesenteric adenitis. In these more serious conditions, tetracycline, ciprofloxacin, TMP/SMX, or aminoglycoside are effective.<sup>56,57,59</sup>

## Tuberculosis

Within the United States, tuberculosis occurs primarily in immunosuppressed populations (especially associated with HIV), among immigrants from underdeveloped nations, among the urban poor, and impoverished Native Americans.<sup>58</sup> Tuberculous enterocolitis is generally contracted via consumption of unpasteurized milk or from swallowing sputum infected from pulmonary tuberculosis. *Mycobacterium tuberculosis* and *M. bovis* predominate in the United States. Distal small bowel and cecal infections are noted and present with abdominal pain, weight loss, and fever. From exposure to illness, clinical illness can be delayed for up to a year.<sup>59</sup> Ulcers of varying depth, fistulas, and stenosis may result from the infectious process. Physical findings include generalized wasting and up to 50% of patients have a palpable mass in the right lower quadrant. Barium enema and/or CT may suggest the diagnosis but features can mimic inflammatory disease or malignancy. Tuberculous pericolic adenitis may produce extrinsic compression and can lead to partial or complete obstruction. Tuberculous peritonitis can present as a surgical emergency mimicking acute appendicitis. Colonoscopic biopsy or fine-needle aspiration have permitted detection of acid-fast bacilli or caseating granulomas without the delay of awaiting culture reports. Diagnostic laparoscopy demonstrated tuberculous peritonitis with 95% accuracy in one series.<sup>59</sup> Stool cultures for viable tuberculosis organisms rarely demonstrate growth but is more likely in active cases of pulmonary tuberculosis. Serology tests have been developed and demonstrate sensitivity for intestinal tuberculosis of more than 80%.<sup>58</sup>

Treatment is usually medical with multi-drug regimens. Isoniazid and rifampin are first-line treatment but pyrazinamide and streptomycin or ethambutol may be added until sensitivity in the immunocompromised host can be established.<sup>58</sup> In more established cases, obstruction of the bowel secondary to sclerosing lesions or fistulous disease may require surgical intervention. It is still recommended that a medical trial be attempted because many patients will

improve and resolve without surgery.<sup>59</sup> Rectal tuberculosis, although rare, can cause stricturing. Most cases improve with anti-tuberculous drugs.

## Neisseria gonorrhoea

As a cause of proctitis, oroanal spread or anal-receptive sexual practices account for the majority of infections in the United States. Although heterosexual transmission is noted, the problem is more widespread in the homosexual population. Sexually transmitted diseases (STDs) are frequently encountered as co-infections with other STDs such as HIV, syphilis, and chlamydia. Gonococcal proctitis generally does not produce many symptoms or signs. Perianal itch, irritation, discharge, or tenesmus may be noted but are not generally troublesome. Physical examination may reveal a brownish purulent discharge, erythema, or fissuring of the mucosa. A mucopurulent discharge is the most common finding (71% in one study).<sup>59</sup> Cultures require a stool-free cotton swab of the rectal discharge which must be promptly plated on Thayer Martin media. A positive smear for gram-negative diplococci should be followed up with appropriate cultures. Treatment is best with a single dose of ceftriaxone intramuscularly. Alternatively, a single dose of oral cefixime, ciprofloxacin, or ofloxacin is effective.<sup>58</sup> Cure rates approach 97%.

## Syphilis

*Treponema pallidum* infection of the anorectum is primarily a disease of anal-receptive males and females. Symptoms are usually minimal and frequently, when present, may be attributed to trauma from the sexual behavior or from mixed co-infections with other STDs. Chancres do occur but may be mistaken for idiopathic anal ulcers, cryptitis, or fissure disease.<sup>58</sup> Mucous, bleeding, and tenesmus may occur. In longstanding infections, a mass may be noted. Endoscopy may demonstrate ulcers but the mass may appear to represent carcinoma. Biopsies, of course, will fail to demonstrate tumor cells.<sup>59</sup> Darkfield examination of the discharge reveals *T. pallidum* organisms that are quite motile. Immunofluorescent stains are highly sensitive to detect this organism. Once diagnosed, parenteral penicillin G provides effective therapy. Missed primary infections may result in secondary- and tertiary-stage disease with the attendant long-term sequelae. Condyloma lata in the perianal area is evidence of secondary syphilis.

## Aeromonas

Colitis caused by *Aeromonas* species seems primarily related to host immunity, i.e., HIV status, immunocompromised adults, children under the age of two, and in generally debilitated

patients. Most infections in the United States are secondary to drinking untreated water. Watery stools, dysentery, vomiting, fever, and cramps are common to most enterocolitises making the diagnosis more obscure. Adults tend to have a more protracted, less severe diarrheal illness whereas children are more prone to an acute, fulminating illness. The latter are more likely to be complicated by hemolytic uremic syndrome, sepsis, and peritonitis.<sup>58</sup> In septic patients, mortality as high as 75% has been reported. *Aeromonas colitis* or severe associated illness should be treated with antibiotics. Quinolones are effective as are TMP/SMX, tetracycline, and chloramphenicol. Some antibiotic resistance has been emerging and so sensitivity testing should be performed. Endoscopic findings are non-specific showing erythema (patchy or continuous), superficial ulcerations, exudates, and friable mucosa. Fortunately, in most patients, infections are mild and self-limited requiring no treatment.

## Brucellosis

*Brucellosis melitensis* is a bacterium that may contaminate unpasteurized goat milk or cheese predominantly in underdeveloped nations. Rare in the United States, it can produce a nonspecific colitis. Cultures of the exudate will reveal the organism. Endoscopic examination reveals inflammatory changes of a protean nature.<sup>58</sup> Serologic tests contribute to early diagnosis and treatment can begin based on this alone. Single-agent therapy has an unacceptably high relapse rate so that currently, doxycycline 100 mg orally twice daily for 3–6 weeks and streptomycin 1 g intramuscularly (IM) every 12–24 hours for 14 days is preferred. Alternatively, TMP/SMX with streptomycin or rifampin is effective.

## Actinomycosis

*Actinomyces israelii* is an anaerobic gram-positive bacterium normally found in the mouth, lungs, and GI tract of humans. Infection can be oro-cervical, pulmonary, or ileocolic. Fever, vomiting, weight loss, and diarrhea occur at the onset of the ileocolic infection. As the infection progresses, abdominal pain associated with palpable masses may develop. The lesions may fistulize to the abdominal wall where the characteristic sulfur granules within the discharge may be noted. Unfortunately, the enterocolic mass often suggests an obstructing neoplasm and so this diagnosis is usually made postoperatively. Obstruction may precipitate the need for surgical intervention. Although the ileocolic area is most often involved, mass lesions and stricturing lesions may occur anywhere else in the colon or rectum. Radiographs are typically nonspecific and seem to support the more common diagnosis of neoplasm. Pus or fistula drainage generally will demonstrate the classic microscopic appearance of *A. israelii* on Gram's stain.<sup>59</sup> Treatment of ileocolic actinomycosis is

resection. Concomitant treatment with high-dose penicillin G, 12–18 million units/day for 2–6 weeks is recommended. Oral penicillin, tetracycline, or erythromycin are usually continued for several weeks after any apparent cure.<sup>59</sup>

## Miscellaneous Colitis

There are a number of unusual and rare causes of colitis that one may encounter. These may be diversion colitis, neutropenic enterocolitis, disinfectant colitis, corrosive colitis, colitis as a result of NSAIDs, and that related to toxic epidermal necrolysis (TEN) (Stevens-Johnson syndrome).

### Diversion Colitis

Diversion colitis is a term used to describe the clinical entity of nonspecific inflammation of excluded colonic and rectal mucosa. Its importance lies in the difficulty to differentiate it from other colorectal inflammatory states when endoscopically evaluating the excluded segment of bowel. The etiology of diversion colitis is thought to be a deficiency of short-chain fatty acids which are the nutrients to the colonic mucosa.<sup>60</sup> This is supported by the fact that daily instillation of short-chain fatty acids results in improved endoscopic appearance of the diverted segment. Often this entity is asymptomatic, but when symptoms occur, rectal bleeding is the prominent symptom. Other symptoms include tenesmus, mucous discharge, and abdominal pain. Endoscopy may reveal mucous plugs, contact irritation, erythema, and ulcerations. Asymptomatic disease requires no pharmacologic treatment. Patients whom diversion is permanent and are symptomatic, twice daily irrigation of short-chain fatty acids is recommended for 2–4 weeks. Other treatments include 5-aminosalicylic acid (5-ASA) enemas and steroid enemas. Periodic examination of the diverted segment for neoplasia is warranted. Diversion colitis completely resolves once intestinal continuity is reestablished.<sup>60–63</sup>

### Neutropenic Enterocolitis

Neutropenic enterocolitis is a potentially fatal condition that is now a commonly recognized complication of chemotherapy for neoplastic disease. However, this disease has been seen in patients who have undergone transplantation, and aplastic anemia. The exact pathogenesis remains challenging because other abdominal diseases mimic its presentation. The process has a predilection for the terminal ileum and cecum, but any segment of the bowel can be involved. Common presenting symptoms are abdominal pain, fever, diarrhea, abdominal distention, nausea, vomiting, and diarrhea with or without blood. A tip-off is coexisting neutropenia in the appropriate patient population. CT seems to be the most accurate method of diagnosis which reveals a thickened and inflamed terminal ileum and cecum. The management of

these patients remains challenging. Bowel rest, intravenous fluids, broad spectrum of antibiotics with parenteral nutrition are the cornerstones of treatment. As the leukopenia resolves, often the patient improves. Surgery is reserved for perforation or peritonitis, or if lack of systematic improvement occurs despite conservative measures after a defined time period. Outcome can be unpredictable; however, coexisting morbidities often overwhelm the septic insult.<sup>64-66</sup>

### Disinfectant Colitis

Commercially available endoscope disinfecting solutions readily cause colonic damage if allowed to contact the mucosa. These endoscopic cleaning solutions, often either hydrogen peroxide or glutaraldehyde, may produce a controversial lesion referred to as pseudolipomatosis. Furthermore, endoscopists may note the appearance of plaque-like lesions that resemble pseudomembranes upon withdrawal of the scope in an area that was previously noted to be normal in appearance. Clinically, in patients suspected of having developed disinfectant colitis, 24–48 hours after the procedure, abdominal cramping, bloody diarrhea, fever, and leukocytosis may develop. This entity remains self-limited although no long-term outcome is currently available. Efforts to prevent this include diligent rinsing and forced air drying. Automatic disinfecting machines should be routinely serviced and volume adjustments in the rinse cycle maintained.<sup>67</sup>

### Corrosive Colitis

Glutaraldehyde and formalin are two potential corrosives used in a wide spectrum of medical care that may be responsible for corrosive colitis. A 2% solution of glutaraldehyde is widely used as a disinfectant because of its broad spectrum of action against acid and alcohol-resistant bacilli, hydrophilic viruses, and spores. Formalin enemas have been shown to improve the endoscopic and clinical features of patients with radiation proctitis. As with disinfectant colitis, these patients develop a self-limiting spectrum of symptoms such as abdominal pain, mucous diarrhea, and rectal bleeding within 48 hours of exposure to the corrosive agent. As always, other mechanisms that may mimic this condition need to be excluded. Treatment remains supportive with intravenous fluids as needed.<sup>68-70</sup>

### NSAID and Salicylate-induced Colitis

The capacity of NSAIDs and salicylates to produce adverse side effects in the gastroduodenal mucosa is well known. In addition, NSAIDs may produce colonic mucosal injury. These drugs are also associated with the reactivation of quiescent inflammatory bowel disease, colonic stricture formation, and perforation and hemorrhage. Presenting symptoms are often diarrhea, rectal bleeding, and abdominal pain, along with a history of NSAID usage. Endoscopic findings range

from patchy erythema and granularity to severe extensive mucosal ulcers. Often the clinical and endoscopic features are indistinguishable from idiopathic colitis. Treatment involves discontinuing NSAID and salicylate use as well as administering 5-ASA and steroid medications. At times, inpatient therapy is required. Relapse is not uncommon and chronic colitis may require surgery.<sup>71</sup>

### Toxic Epidermal Necrolysis

TEN, also known as Stevens-Johnson syndrome, is a severe mucocutaneous exfoliative disease with an uncertain pathogenesis and a high mortality rate. The primary manifestation is the appearance of an erythematous confluent eruption that rapidly evolves into exfoliation of the skin at the dermal-epidermal junction, resulting in large sheets of necrotic dermis. This process seems to be immune-complex mediated and represents an idiosyncratic reaction to a drug or chemical agent. Sepsis, GI hemorrhage, leukopenia, fluid and electrolyte imbalance, and renal insufficiency are the major complications that contribute to the high mortality rate. Diffuse ulceration anywhere within the mucosal surface of the GI tract may occur. The colonoscopic appearance may resemble severe ulcerative or pseudomembranous colitis; however, biopsies show extensive necrosis and lymphocytic infiltration without crypt abscesses or neutrophils. The mucosal sloughing of the bowel may result in melena or intestinal perforation.<sup>72</sup>

### Viral Colitis

Viral colitis is still relatively rare, however it is being seen with increasing frequency in this country. Etiologies include cytomegalovirus (CMV), herpes simplex virus, and viral colitides as a result of HIV or acquired immunodeficiency syndrome (AIDS). Although viral colitis is primarily a disease of immunocompromised patients, CMV colitis has been reported in immunocompetent individuals.

### CMV Colitis

CMV is the most common viral cause of diarrhea and a frequent cause of diarrhea in patients with multiple negative stool test results. It is an affliction that typically occurs late in the course of HIV infection when CD4 counts plummet. Infection is most common in the colon, but concomitant disease may occur in the proximal gut. The clinical manifestations of CMV colitis vary greatly or one may be asymptomatic. Symptoms of these infections include fever, weight loss, abdominal pain, and diarrhea with or without blood. Patients may complain of fever and weight loss without diarrhea. As the disease progresses, frank ulceration, toxic megacolon, and perforation may occur. Anorectal herpes simplex virus infections may be concurrent with colitis; local problems include

lymphadenopathy, tenesmus, severe pain, urinary retention, and lumbosacral dysesthesia. The diagnosis of CMV colitis may be challenging, and one often relies on endoscopic examination. Findings on endoscopy include patchy erythema, with or without ulcerations ranging from small to shallow that may be wide and deep. Because these processes are diffuse, biopsies should be obtained from multiple sites to facilitate diagnosis. Histopathologic examination of biopsy tissue will reveal the characteristic changes of these infections. The inclusions may be very atypical in appearance or few in number. They may also be present in tissue that macroscopically appears normal. Viral cultures can also be obtained on biopsy material. In the end, the diagnosis rests primarily on demonstrating viral cytopathic effect in tissue specimens.<sup>73-75</sup>

Treatment includes supportive care and antiviral agents. Agents of choice for CMV are 9-(1,3 dihydroxy-2-propoxymethyl) guanine (DHPG, ganciclovir) and phosphonoformate (Foscarnet) and for herpes simplex virus, acyclovir. Surgical therapy is required for complications such as bleeding and perforation. Because of the nature of the disease and the immunocompromised state of the patient, subtotal colectomy with ileostomy is advised. Mortality is high and often attributed to sepsis as a result of underlying opportunistic infection.<sup>76,77</sup>

### Herpes Simplex Colitis

Herpes simplex virus, when involved in the GI tract, usually manifests itself as a proctitis. This remains a disease frequently afflicting homosexual males as well as those with AIDS. It usually presents with anorectal pain, discharge, tenesmus, and rectal bleeding as well as difficulty urinating, and sacral paresthesias. The diagnosis is established by history, sigmoidoscopic demonstration of an acute proctitis, and isolation of the virus by culture. A variety of immunoassays currently exist to aid in diagnosis. Oral acyclovir has been demonstrated to be effective in alleviating symptoms. Intestinal perforation associated with intestinal herpes simplex virus infection in an immunocompromised patient has been reported. Relapses are common, especially in sexually active homosexuals.<sup>78-80</sup>

## Parasitic Colitis

### Amebiasis

Amebiasis is the second leading cause of death from human parasitic disease worldwide. The causative protozoan parasite, *Entamoeba histolytica*, is a potent pathogen. Infection usually begins with the ingestion of cysts in food or water that have been contaminated by human species. *E. histolytica* trophozoites invade the intestinal mucosa causing amebic colitis. In some cases, amebas breach the mucosal barrier and travel through the portal circulation causing amebic

abscesses. Many individuals with *E. histolytica* infection have no symptoms and can clear their infection without any signs of disease. Symptomatic patients present with bloody diarrhea and abdominal pain and tenderness. The onset is often gradual with patients reporting several weeks of symptoms. The diarrhea may be profuse without blood; also, rectal bleeding without diarrhea may be an uncommon presentation. Fever is unusual and weight loss and anorexia may be present. Occasionally, individuals develop fulminant amebic colitis with widespread abdominal pain, fever, and peritonitis. Amebomas, which are localized inflammatory annular masses, may develop in the cecum or ascending colon, and can cause obstructive symptoms and mimic carcinoma. The diagnosis rests on the demonstration of *E. histolytica* in the stool or colonic mucosa of patients with diarrhea. Currently there are commercially available enzyme-linked immunosorbent assays (ELISA) that identify *E. histolytica*. The cornerstone of treatment for amebiasis is nitroimidazole derivatives such as metronidazole. Amebic colitis is treated by metronidazole followed by a luminal agent such as paromomycin, iodoquinol, or diloxanide to eradicate colonization. Although fulminant colitis is managed initially conservatively, perforation requires colectomy.<sup>81,82</sup>

### Balantidiasis

*Balantidium coli* is the largest and least common protozoal pathogen of humans and is the only ciliate that produces important human disease. It is most frequently found in tropical and subtropical regions. Communities that are in close association with pigs have an increased prevalence of disease because of the high rate of carriage of this organism by these animals. *B. coli* infection is spread to humans by ingestion of cysts spread by contaminated water and food. The trophozoite invades the distal ileal and colonic mucosa and produces intense mucosal inflammation and ulceration. In the symptomatic patient, diarrhea with blood and mucus is accompanied by nausea, abdominal discomfort, and weight loss. If allowed to progress, it can develop into fatal fulminant colitis with peritonitis and colonic perforation. The diagnosis is made by identification of trophozoites excreted in the stool or from the margin of ulcers seen in the rectum. The most frequently used treatment is tetracycline 500 mg four times daily for 10 days.<sup>83,84</sup>

### Cryptosporidiosis

*Cryptosporidium* colonizes both the small and large intestine and is commonly found in developing countries. It is now closely associated with immunocompromised patients, particularly associated with AIDS. This organism is able to reproduce both sexually and asexually; however, the oocyst is the infective form of the parasite. The organism may be transmitted by a variety of routes, including fecal-oral, hand to mouth, contaminated foods and water, and by pets. A wide range of clinical features exist from totally asymptomatic carriers to

severe life-threatening disease. Clinically, patients develop voluminous watery diarrhea with fever and abdominal discomfort. In immunocompromised individuals, the disease is more severe and can be fatal. The diagnosis is made by identification of oocysts on fecal smears or in large intestinal mucosal biopsies. Treatment remains challenging and spiramycin and paromomycin have been moderately effective.<sup>85</sup>

### Giardiasis

Giardiasis is a disease caused by the protozoan *Giardia lamblia*. It is a worldwide condition with the vast majority of patients being asymptomatic. It is common in hikers and bikers who drink from mountain lakes, adults who care for children who are in diapers, and there is an increased incidence in male homosexuals. Infection results from ingestion of the cyst and produces diarrhea, the most common complaint in the symptomatic patient. Malabsorption may also be manifested. The diagnosis is made by identification of trophozoites in the stool or by a *Giardia* ELISA. A negative stool examination does not exclude the diagnosis. The drug of choice for the treatment of *Giardia* is metronidazole or other nitroimidazole compounds that are better tolerated.<sup>86–88</sup>

### Trypanosomiasis

*Trypanosoma cruzi* is the organism responsible for Chagas' disease or trypanosomiasis. It occurs primarily in Central America and is spread to humans by the bite of the blood-sucking vector Reduviid bug which carries the parasite. The local irritation from the bite results in scratching and subsequent inoculation of the organism into the circulation. Trypomastigotes convert to amastigotes and enter the bloodstream to infect and destroy muscle and nerve cells leading to motility disorders of the intestinal tract and congestive heart failure. Clinically, esophageal and colorectal symptoms develop with the latter manifesting as severe constipation with abdominal pain and distention. The diagnosis is made on linking clinical symptoms with a patient living in an endemic area. Medical treatment with nifurtimox and benznidazole are effective in the acute phase by reducing parasitemia. Once the chronic form develops and tissue damage occurs, surgery is offered. Indications for surgery are megacolon, severe constipation, and chronic fecal impaction. Although various operations have been proposed, either the Duhamel retrorectal abdominotransanal pull through, or if the lower rectum is not involved, extended left hemicolectomy with colorectal anastomosis, may be used. Results have continued to be very favorable for an improved quality of life with low morbidity and mortality.<sup>89–91</sup>

### Ascariasis

Ascariasis is caused by the large round worm *Ascaris lumbricoides*. It is endemic in tropical and subtropical areas and it is

estimated that more than one-fifth of the world's population is affected. Infection occurs from ingestion of the eggs in contaminated food or water. After migrating from the small intestine into the portal venous system, they pass through the liver into the lungs where they are coughed up and swallowed. Intestinal ascariasis produces crampy abdominal pain, but with a large worm load, intestinal obstruction can occur. The diagnosis is made by finding eggs in the stool. Small bowel series may demonstrate worms in the distal ileum. A variety of drugs including pyrantel pamoate, mebendazole, and levamisole have been recommended. Surgery is required for unremitting intestinal obstruction, and if perforation has not occurred, manipulation of the worms through the ileocecal valve will prevent migration of worms through an intestinal anastomosis.<sup>92,93</sup>

### Schistosomiasis

Five species of schistosome are known to produce disease in human intestine. Human infection occurs after penetration of the skin or mucous membranes by cercariae, the infective form of the parasite which is liberated into fresh water by the intermediate snail host. After 1–2 days in the subcutaneous tissue, the cercariae migrate through the venous system and lodge in the liver as mature adult worms. After producing fertilized eggs, miracidia develop within these eggs and eventually migrate into the intestinal lumen and thus the stool. *S. japonicum* preferentially invades the superior mesenteric veins thus involving the small intestine and the ascending colon, *S. mansoni* usually invades the inferior mesenteric veins penetrating the descending colon, and *S. hematobium* invades the bladder, pelvic organs, and rectum. Symptoms are referable either to the skin or the viscus involved with the disease. If migration through the bowel occurs, patients will develop severe lower abdominal pain, rectal bleeding, diarrhea, and passage of mucus. The diagnosis is made by the identification of the ova in fresh stool specimens. Rectal biopsy may also reveal the presence of eggs in the mucosa or submucosa. Treatment depends on which species is involved. Patients with longstanding schistosomal colitis are at risk for carcinoma, but this applies primarily to *S. japonicum*. Cirrhosis with portal hypertension may produce massive hemorrhage from varices requiring portal decompression.<sup>94,95</sup>

### Strongyloidiasis

*Strongyloides stercoralis* is one of the major nematodes that infects humans. It is a soil-dwelling organism endemic to the rural southeastern United States and Appalachia that infects the upper small intestine of humans and rarely the colon. The infective (filariform) larvae in the soil penetrate the human skin, migrate through the circulation to the lungs and break out of the respiratory tree, and are then swallowed. In the upper small intestine, these larvae molt to become adult females which burrow into the submucosa and release eggs

into the intestinal lumen. Sometimes these larvae may penetrate the colonic mucosa producing a colitis. Patients present with diarrhea, weight loss, and a microcytic anemia. The diagnosis can be made by stool aspirates during colonoscopy demonstrating *S. stercoralis* larvae on wet mount examination. Treatment is with oral thiabendazole 25 mg/kg by mouth twice daily for 3 months.<sup>96-98</sup>

### Trichuriasis

*Trichuris trichiura* (whipworm) is found worldwide in both developed and developing countries. Human infection begins after ingestion of ova. Larvae are released into the small intestine and most frequently the cecum and the terminal ileum are colonized. In symptomatic individuals, diarrhea with blood and mucous occurs often associated with abdominal pain and tenesmus. Chronic infection can result in iron deficiency. Stool examination for the barrel-shaped eggs of *T. trichiura* confirms the diagnosis. Mebendazole is the treatment of choice in a dose of 100 mg twice daily for 3 days.<sup>99-101</sup>

### Anisakiasis

Anisakiasis is a disease caused by human infection by the *Anisakis* larvae, a murine nematode found in raw or undercooked fish. With the increased popularity of eating sushi and raw fish in the United States, infection with *Anisakis* is expected to increase. These larvae are usually found in herring, mackerel, salmon, cod, halibut, rockfish, sardine, and squid. Most human infections have been reported from Japan and The Netherlands and involve the stomach. Invasion of the gastric or intestinal wall 1-5 days after eating raw fish may be characterized by the abrupt onset of abdominal pain, nausea and/or vomiting, diarrhea, or an ileus. For transient anisakiasis, supportive measures and reassurance are all that is needed. If the larvae have invaded the intestine or the stomach wall, diagnosis and cure occur with endoscopic or surgical removal if evidence of obstruction or perforation are found.<sup>102-104</sup>

### Tapeworm

A number of adult tapeworms parasitize the intestinal tract of humans. Infection is acquired through the ingestion of the infected flesh of the intermediate host that is raw or inadequately cooked. The diagnosis of tapeworms is made by finding the ova in the feces. *Diphyllobothrium latum* is the fish tapeworm that results from the ingestion of raw fish. The worm produces vitamin B<sub>12</sub> deficiency and fatigue. *Taenia solium* is the pork tapeworm acquired by eating inadequately cooked pork. Cysticercosis occurs when humans ingest the egg of *T. solium* and may present with a variety of neurologic symptoms. *T. saginata* are the organisms responsible for beef tapeworm. This beef tapeworm is found throughout the world and can achieve many meters in length. The clinical symptoms of all tapeworms are variable and include abdominal dis-

comfort, nausea, vomiting, cutaneous sensitivity, headache, and malaise. Many infections are asymptomatic. Treatment of all tapeworms is with either niclosamide or praziquantel.<sup>105,106</sup>

## AIDS Diarrhea

AIDS can result in life-threatening opportunistic infections of the GI tract, of which many present with diarrhea. The etiology of diarrhea in the HIV-positive patient is multifactorial. There are various colitides, distinct ulcerative infections, and a number of malignancies that may occur. HIV infection can affect the entire GI tract and the hepatobiliary system. A number of reviews have emphasized diarrhea, weight loss, swallowing disturbances, and abdominal pain as the major gastroenterologic disorders in AIDS. GI manifestations range in severity from the inconvenience and discomfort of oral and perianal infections through to life-threatening diarrhea caused by intestinal cryptosporidiosis. In the evaluation of the HIV patient with diarrhea, one must be aware that there remains a wide range of infectious pathogens: viral (CMV, herpes simplex), bacterial (*M. avium-intracellulare*) and parasitic (*Cryptosporidium*, *Isospora belli*).<sup>107,108</sup>

The most important goal of evaluating diarrhea in HIV infection is to identify a treatable cause with the minimal amount of diagnostic testing. Evaluation of patients with diarrhea includes three stool samples and colonoscopy with biopsy. Rectal biopsy alone may miss proximal viral disease. Certain opportunistic pathogens such as *Giardia* or *Isospora* may reside in the foregut or midgut and require upper endoscopy for diagnosis. The diagnostic value of radiographic contrast studies in evaluating diarrhea is very low. A comprehensive investigation will reveal an etiologic agent in 90% of patients. If stool evaluation and flexible endoscopy are nondiagnostic, there is some rationale for a limited trial of empiric antibiotics. This approach should be undertaken in the appropriate clinical context. Treatment of pathogen-negative diarrhea consists of volume resuscitation and somatostatin analogs.<sup>109-112</sup>

The differential diagnosis of diarrhea in AIDS includes protozoa, viruses, bacteria, fungi, gut neoplasms, and pancreatic insufficiency. In all patients, at least three stool specimens for fecal leukocytes, ova and parasites, acid fast bacteria, *Clostridium difficile* toxin, bacteria and fat stain should be obtained. Specific therapies depending on the result of diagnostic testing should be implemented. Symptomatic therapy as well as empiric therapy when diagnostic testing is nonrevealing is often undertaken. Surgery is reserved for acute abdominal emergencies and in of itself carries a substantial mortality.

### HIV Colitis

Diarrhea is the most frequent and often most morbid GI manifestations of HIV and AIDS. However, the role of HIV as a diarrheal pathogen remains controversial. Several investigators

have identified HIV within the gut tissue in up to 40% of patients with AIDS. Despite the ability of HIV virus to infect colon cell lines, its ability to produce an HIV colitis remains controversial.

## Radiation-induced Bowel Injury

The advent of radiation as a mainstay of treatment for gynecologic and urologic malignancies has produced an extensive literature on the topic of subsequent complications related to the effects of ionizing radiation on the GI tract. As advances in radiation oncology progressed, our understanding of the long-term aftereffects were slow to develop because of the time lag encountered between administration of treatment and the presentation of the chronic sequela of radiation therapy (RT). Changes in radiation protocols, methods of delivery, and the addition of chemotherapeutic regimens concomitant with administration of radiotherapy continue to evolve. So too will the long-term chronic complications. These developments render older literature on the subject mostly of historic interest. However, several critical principles have been learned and are meaningful in our understanding and treatment of radiation-induced GI complications.

Radiation injury to the bowel is biphasic; there is an acute injury demonstrable during administration of RT and a delayed, chronic injury that may be encountered months to years after completion of treatment.<sup>113,114</sup> Both total radiation dose and rate of administration of that dose are important factors in the incidence of bowel complications. Early work established radiation dose tolerance levels of the various organs. Between 1%–5% of patients receiving 4500 cGy are expected to experience radiation-induced complications over a 5-year period. The complication rate increases to 25%–50% when 6500 cGy are administered. The rectum tolerates 5500 cGy but at 8000 cGy, 25%–50% of patients will experience chronic complications.<sup>115</sup> Higher doses administered over shorter times result in more acute injury.<sup>116</sup> However, the absence of symptomatic acute-phase injury does not correlate with diminished chronic sequela.<sup>117</sup>

Risk factors within the population being treated with RT have been reported and they principally relate to factors that compound the effects of ionizing radiation or increase the likelihood that higher doses of radiation will be delivered to the bowel.<sup>118</sup> Examples of the former include conditions predisposing to intestinal ischemia, i.e., cigarette smoking, hypertension, diabetes mellitus, vasculitides, or arteriosclerotic processes. Examples of the latter include processes that fix the intestine within the field of radiation maximizing exposure, i.e., previous abdominopelvic surgery causing adhesions and inflammatory intraabdominal processes causing immobility of the bowel. For this reason, the terminal ileum is most frequently injured by RT because of fixation within the pelvis secondary to adhesions. In the absence of adhesions, the rectum and rectosigmoid are most frequently

injured because of their normal fixation anatomically within the pelvis. Currently, the most common indications for RT in the United States is cervical cancer, endometrial cancer, prostate cancer, and anorectal malignancies. Techniques to minimize tissue-volume exposure to administered RT include multiplanar delivery systems, patient positioning and blocking to remove other organs from the target area, and filling the bladder to displace other tissues from the pelvis.<sup>118</sup>

The acute effects of radiation on the intestines occurs during the administration of RT. It generally takes several weeks for the injury to become manifest. Concomitant administration of chemotherapy, especially common in the presurgical phase of treatment with rectal cancer, increases the tissue's susceptibility to the therapeutic properties of RT. Likewise, acute-phase radiation toxicity/enteritis is more likely to be noted. The acute injury is primarily mucosal with disruption of the rapidly dividing and growing cells at the base of the crypts. This leads to flattening of the villi and resultant diminution of absorptive and resorptive functions of the affected intestine. Mucositis, cramps, and diarrhea are the typical problems noted. Antimotility agents and, where applicable, antiinflammatory agents generally ameliorate symptoms. Sucralfate, mesalamine, or hydrocortisone enemas have been reported to be efficacious in the acute injury setting.<sup>119</sup> Low-residue or elemental diets together with glutamine supplementation improve the condition. Cessation of radiation or, at least, delaying the ongoing course generally permits most patients to resolve the acute toxicity. For the most part, preoperative radiation permits excision of the targeted tissues, excepting the distal portion of the rectum or anus being used when anastomosis (sphincter preservation) is possible. Nonirradiated proximal bowel is essential in maintaining acceptably low anastomotic leak rates when reconstruction is performed. When coloanal anastomosis is constructed in an irradiated field, many experienced surgeons elect to divert the fecal stream proximally to permit distal healing before restoration of continence, thus minimizing the deleterious effect of pelvic sepsis and anastomotic leakage.<sup>118</sup>

Chronic radiation injury is characterized by progressive, obliterative arteritis, as well as submucosal and transmural fibrosis (Figure 43-3). The endothelial thickening results in arterial and arteriolar thrombosis leading to ischemia. Submucosal collagen deposition leads to impaired tissue oxygenation, especially in the face of obliterative arterial disease (Figures 43-4 and 43-5). These pathologic changes cause the long-term problems associated with radiation such as obstruction, perforation, fistulization, and hemorrhage.<sup>115–117</sup> Evaluation of complications may necessitate GI contrast studies with barium, CT, magnetic resonance imaging, endoscopy, and fistulography. Detailed assessment is mandatory when surgical intervention is considered to optimize operative planning and to have adequate specialized help intraoperatively if the need exists.

Treatments for the complications of chronic radiation enteritis are directed toward symptom relief. Bleeding from

FIGURE 43-3. Radiation colitis demonstrating submucosal fibrosis/telangiectasia. H & E stain; magnification  $\times 215$ . (© 2004 Frederick C. Skvara, MD).

ischemic mucosa with telangiectatic vessels can be managed in one of several ways. Nd:YAG<sup>119</sup> and argon lasers have proven effective in ablating bleeding vascular lesions within reach of an endoscope. Argon is preferred because its energy is specifically absorbed by hemoglobin and so minimizes tissue damage to the already ischemic bowel.

A recent Cochrane Review comparing nonsurgical options for managing chronic radiation proctitis found sucralfate together with metronidazole effective in a small number of patients. The authors call for a multicenter placebo-based trial to reliably evaluate the outcomes of the various treatment regimens.<sup>120</sup>

Some clinical success has occurred with the administration of estrogen-progesterone therapy on a chronic basis. Transfusion needs and frequency of hospitalization have decreased in patients with bleeding secondary to chronic

FIGURE 43-4. Radiation colitis demonstrating submucosal fibrosis/telangiectasia/mucosal atrophy. H & E stain; magnification  $\times 86$ . (© 2004 Frederick C. Skvara, MD).

FIGURE 43-5. Radiation colitis prominence of fibroblasts. H & E stain; magnification  $\times 540$ . (© 2004 Frederick C. Skvara, MD).

radiation enteritis.<sup>121</sup> Where bleeding occurs within the rectum, it is usually associated with radiation treatment of the cervix or prostate. Topical application of 4% formalin to these distal bleeding injuries has proven successful whether done in the office setting or the operating room, depending on the time entailed and amount of tissue needing treatment.<sup>122,123</sup> More recently, GI bleeding secondary to chronic radiation injury has been shown to respond well to hyperbaric oxygen therapy. The protocol frequently used treats the whole body for 60 minutes at 2 atmospheres of 100% O<sub>2</sub> for 30 days. Prostaglandin E<sub>1</sub> can be coadministered for its vasodilatory properties. A small number of patients have been thus treated with complete resolution of bleeding and mucosal healing.<sup>124</sup>

Fistulizing complications are best managed as conservatively as possible. When the severity of symptoms warrants consideration of surgery, the type of surgery will depend on how proximal in the GI tract the problem is and the organ to which the fistula connects. At laparotomy, as little adhesiolysis as possible should be performed because the already ischemic bowel tends to perforate (micro or macro) frequently necessitating more surgery. When possible, fistulizing tissue is best resected back to normal-appearing margins. When the amount of bowel is too excessive to permit resection, proximal diversion or bypass can be considered. Bypass is frequently avoided because diseased tissue is left behind, blind-loops create more symptoms, and bypass anastomosis still leaks at higher than normal rates. Enteric fistulas involving the genitourinary tract can be handled in the same manner with resection generally preferred where feasible. Frequently, within the pelvis, fecal diversion proximally proves safe and effective palliation in an otherwise high-risk situation. In the case of radiation-induced intestinal stenosis or obstruction, the same surgical considerations and options apply. Where feasible, resection and anastomosis of normal-appearing bowel are preferred. In the event of radiation-induced ischemic necrosis of the bowel, resection of necrotic tissue with diversion may be lifesaving. The most important

determinant of operative morbidity and mortality was the location of the radiation injury itself.<sup>125</sup> Small bowel radiation injury in one series had a 38% mortality whereas colonic injury had a 15% mortality rate.

When long segments of small bowel have chronic radiation enteritis, malabsorptive problems arise. Because the malabsorption is secondary to tissue ischemia and subsequent fibrosis, treatment or resection will not restore this function. Patients with this chronic complication therefore require parenteral nutrition to sustain life and are subject to the metabolic complications of long-term parenteral alimentation. When the terminal ileum is affected by radiation, chronic diarrhea and electrolyte imbalance may occur because of failure to resorb bile salts. Symptomatic treatment with cholestyramine may alleviate these problems by binding the bile salts, and should be considered. Likewise, antimitility agents slow transit and so may allow the injured bowel more time to process intestinal contents and minimize the symptoms of chronic radiation enterocolitis.

Unless the clinical presentation of radiation injury to the bowel is emergent, a careful clinical assessment of the patient is vitally important to identify comorbid conditions. Patient nutrition, hydration, and sepsis need to be addressed and corrected wherever possible. Radiologic and endoscopic assessments need to be completed before finalizing a treatment plan. Therapeutic interventions should be considered beginning with the least invasive means first. Chronic radiation injury cannot be reversed because of the secondary ischemic changes. Therefore, goals for treatment should optimize quality of life while minimizing the morbidity and mortality of therapeutic intervention.<sup>126</sup>

## *C. difficile* Colitis

*C. difficile* infection, an important source of colitis particularly in hospitalized patients, presents from either an asymptomatic infection to severe pseudomembranous colitis with bowel perforation and death. The majority of cases are seen after antibiotic usage. The remaining cases include patients receiving chemotherapy, patients with inflammatory bowel disease, and those with a variety of other medical problems. Almost all antibiotics have been associated with *C. difficile* infection. The most frequently implicated classes of drugs are the cephalosporins, ampicillin/amoxicillin, and clindamycin. Neither the antibiotic dosage nor the length of administration has been found to correlate with the development of *C. difficile* infection. The majority of infections occur 5–7 days into the course of antibiotics, but it may present weeks after cessation of the antimicrobials.<sup>127</sup>

Diarrhea is the most common symptom and is found in 90%–95% of cases. Patients with mild disease may present with diarrhea alone, or associated with a low-grade fever and abdominal pain. These patients may also have mild abdominal tenderness and an otherwise unremarkable abdominal

examination. A small percentage of patients develop fulminant colitis with high fever and severe abdominal pain. Diarrhea may be absent in patients with severe disease and progress to toxic megacolon. Hypotension, oliguria, and other manifestations of septic shock may also be found in these severely ill patients.<sup>128</sup>

The laboratory diagnosis of *C. difficile* depends on the detection of the *C. difficile* toxins in the patient's stool. The most reliable laboratory tests for documenting *C. difficile* infection are the stool cytotoxin assay and stool cultures. However, stool cultures do not distinguish between carriers and those with acute infection. ELISA is a most popular test for *C. difficile* toxin in clinical laboratories. The ELISA tests have the advantage of being technically easier to perform and the results are available sooner; however, they are less sensitive than tissue culture. Patients suspected of having *C. difficile* infection can be evaluated endoscopically. The mucosal findings vary with the severity of the disease. In those with mild or moderate disease, endoscopy most often reveals normal mucosa or nonspecific inflammatory changes. In the great majority of those with severe disease, examination demonstrates the classic pseudomembranes which are round, punctate yellow or whitish lesions (Figure 43-6). Although the finding of pseudomembranes suggests the diagnosis of pseudomembranous colitis, biopsy of these lesions is recommended to definitively establish the diagnosis.<sup>129</sup>

When *C. difficile* infection occurs in patients receiving antibiotics, the offending antibiotic should be immediately discontinued if possible. In patients with mild disease, no other specific treatment is necessary. Most physicians will begin empiric antimicrobial therapy if there is a strong clinical evidence of colitis. Three orally administered antimicrobials have been shown to be effective against *C. difficile* infection: vancomycin, metronidazole, and bacitracin. Vancomycin used to be the drug of choice. In most patients, a significant improvement will occur within 2–5 days of

FIGURE 43-6. *C. difficile* colitis with classic pseudomembranes.

treatment. Vancomycin is costly and distasteful. Metronidazole is generally well tolerated and is much less expensive than vancomycin. Metronidazole, unlike vancomycin, is absorbed rapidly from the GI tract and consequently fecal concentrations are low. Despite this, metronidazole has been shown to be highly effective and is given in a dosage of 250 mg orally four times a day for 10 days. Bacitracin, when rarely used, has been shown to be as effective a treatment as vancomycin when 20,000–25,000 units were given four times a day for 7 days.<sup>130</sup>

In patients unable to take antimicrobials orally, intravenous metronidazole seems to be the most effective. Adequate fecal concentrations of metronidazole have been documented in patients with severe colitis after intravenous administration of this antimicrobial. Anion exchange resins have also been used successfully to treat *C. difficile* infection. Cholestyramine and colestipol, each given orally for 10 days, are thought to bind the *C. difficile* toxin in the lumen, thereby limiting the damage caused by the toxins. These agents have not proved to be as reliable as antimicrobials, and therefore it is recommended that they not be used as sole treatment except in cases of mild infection. It is also important that these resins are not given concomitantly with antibiotics because they have been shown to bind to antimicrobials in the intestinal lumen.<sup>131</sup>

Despite adequate medical therapy, surgical intervention may be required. Surgery may be necessary for patients in whom a perforation is suspected or those with toxic megacolon. When surgery is necessary, subtotal colectomy with ileostomy or fecal diversion via end ileostomy and mucous fistula are the most frequently performed procedures. Recurrence of *C. difficile* infection is not uncommon. Most suggest a second and longer course of antimicrobials for patients who have a symptomatic relapse. Some recommend a course of cholestyramine or colestipol after the antimicrobials. Recurrent infection is as responsive to antimicrobial treatment as are primary infections. Unfortunately, up to one-third of patients who relapse once will have further recurrences. Any patient with an unexplained abdominal illness who, in the last 2 weeks, has either been in the hospital or has received antibiotics should be suspected of *C. difficile* infection, even in the absence of diarrhea.<sup>132</sup> A recent review has established evidenced-based guidelines regarding antibiotic treatment for *C. difficile*-associated diarrhea in adults.<sup>133</sup> Surgery for fulminant colitis still commands a poor prognosis.<sup>134</sup>

# Intestinal Stomas

Bruce A. Orkin and Peter A. Cataldo

Surgery involving ostomies is a major component of the general and colorectal surgeon's armamentarium. Proper creation, management, and closure of ostomies is critical both for the treatment of specific disorders as well as for the peace of mind of the patient.

An ostomy is a surgically created opening between a hollow organ and the body surface or between any two hollow organs. The word *ostomy* comes from the Latin word *ostium*, meaning mouth or opening. The suffix *-tomy* implies an intervention, either by surgery or injury. The word *stoma* comes from the Greek word for mouth and is used interchangeably with ostomy. An ostomy is further named by the organ involved. An ileostomy is an opening from the ileum to the skin, a colostomy is from the colon, a gastrostomy is from the stomach, and so forth. When two organs are joined, the descriptive term incorporates both. For instance, an anastomosis between the small bowel and colon might be called an *ileocolostomy*, between colon and the rectum, a *colorectostomy* or *coloproctostomy*. A loop ostomy is formed by bringing an intact loop of bowel through the skin and then dividing the antimesenteric side and maturing it so that there are two open lumens, the proximal and the distal.

Although ostomies used to be performed primarily for the permanent management of fecal output, the majority of ostomies today are created as a temporary measure, either as an end ostomy in the acute setting with later planned take-down and anastomosis, or as a proximal loop diversion to protect a low pelvic or risky anastomosis. It is estimated that 750,000 Americans are living with an ostomy and that 75,000 new stomas are created each year.

In this chapter we will be discussing ostomies brought to the surface of the body, focusing primarily on ileostomies and colostomies.

## Indications for an Ostomy

There are many indications for stoma creation. The details of each will be discussed in the relevant chapters in this book. In general, however, an ostomy is created when an anastomosis is not possible for technical reasons or risk of failure, when

there is nothing distally to attach to such as after an abdominoperineal resection of the rectum, or for proximal diversion (Table 44-1).

Ostomies may be *temporary* or *permanent*. Temporary stomas divert the fecal stream away from an area of concern such as a high-risk anastomosis, located in a radiated field, low in the rectum, or after an injury. Permanent ostomies are required when the anorectum has been removed (abdominoperineal resection) in cancer or Crohn's disease. A permanent ostomy may also be an option in patients with severe fecal incontinence or complications of trauma or radiation such as a rectourethral fistula.

Creation of an ostomy is a traumatic event for most patients, both physically and mentally. Whenever possible, a detailed discussion of the proposed procedure, consequences, and alternatives should be undertaken. A trained enterostomal therapy nurse (ET) or wound ostomy care nurse (WOCN) should meet with the patient both before and after the surgery. When available, a *United Ostomy Association Visitor* should be called to meet with the patient, either before (if the surgery is elective) or after the surgery.

## Stoma Physiology

The physiologic changes that occur in patients with ostomies are primarily related to the loss of continence and reduced colonic absorptive surface area. These affect fluid and electrolyte balance and lifestyle but generally have little effect on nutrition. However, once more than 50 cm of terminal ileum has been removed or taken out of continuity, nutritional consequences are likely.

## Output

Ostomy output is directly related to the location of the opening in the bowel. Distal left or sigmoid colostomies normally produce formed stools that are of similar consistency to that of the anorectum. The more proximal the colostomy, the less surface area is available for water and electrolyte absorption and so the

TABLE 44-1. Indications for an ostomy

more liquid the stools. Right-sided colostomies not only produce a high volume but also have the additional disadvantage of a malodorous output because of the effects of colonic bacteria.

Initially after creation the output from an ileostomy tends to be fairly watery and green or bilious in color. Within a few days to a week of resumption of a regular diet, the material becomes thicker and more yellow-brown, although a greenish tinge often remains. The typical consistency is of watery porridge or applesauce. It is affected by diet, fluid intake, medications, and ongoing problems such as Crohn’s disease or adhesions. If a substantial amount of small bowel has been removed, the output is looser and the patient is more prone to dehydration. It is not uncommon for some food to come through in a recognizable state. Foods notable for this include corn, other vegetables, and nuts. Some pills may also not be broken down in the small bowel, decreasing the bioavailability of these medications. Most ileostomates notice little odor from the output; however, certain foods, such as eggs and fish, may produce an offensive smell.<sup>1</sup>

### Volume

In the healthy control subject, about 1000–2000 mL of fluid passes through the ileocecal valve daily. This is reduced by 80%–90% to 100–200 mL in normal stool as it passes through the colon. Unless the patient has diarrhea, left-sided colostomy output is similar to the feces that would be passed transanally, and there is little loss of total body fluid or sodium.<sup>2</sup>

Although postoperative ileostomy output may be high, it settles down to a regular volume seen. “Ileostomy dysfunction,” although a general sounding term, refers to increased ileostomy output attributed to partial obstruction caused by inflammation and stenosis. This term was coined in the era of secondary maturation (i.e. before eversion of the exposed ileum became widely practiced during ileostomy construction). Historically, high outputs were anticipated for weeks after creation of an ileostomy but this was found to be caused by inflammation of the exposed small bowel serosa (serositis). Once primary maturation was adopted, this problem essentially disappeared.<sup>3,4</sup>

Postoperative colostomy output is also often liquid, but it rapidly becomes formed with the resumption of a normal

diet and the return of ordered motility. The average output of an established ileostomy (in contrast to a newly created ileostomy) is about 200–700 mL with a median of about 500 mL per day. Total bowel rest results in a decrease in output by at least half and may be as low as 50–100 mL per day.<sup>2</sup>

The volume of ileostomy output varies fairly widely among patients but only mildly from day to day in a single individual. Although the average output is about 500 mL per day, a healthy, functioning ileostomy may produce up to 1000–1500 mL in a day especially in the early postoperative period. Outputs above this level usually cause dehydration.<sup>5–9</sup> Large amounts of fluid intake usually do not alter the output volume very much because most of it is absorbed and excreted through the kidneys.<sup>7</sup>

Ileostomates may generally eat a regular diet without restrictions. Decreased fluid intake slows the output and thickens it, whereas fatty food and large amounts of liquid increase transit and the fluidity of the effluent.<sup>1</sup> Prunes and cabbage may also increase the output.<sup>7</sup> Ileostomy effluent is generally weakly acidic at a pH of about 6.3.<sup>2</sup> When the terminal ileum has been resected but colon remains, more of the bile salts will enter the colon, which may result in a secretory diarrhea. This may be ameliorated by the use of oral bile binding agents such as cholestyramine (Questran).

### Transit

An ileostomy discharges frequently and output is not eliminated by the timing of meals or rest. Yet, in most patients, the output increases with meals and certain foods. Surgical resection of the anus and rectum and/or colon effects the function of the proximal gastrointestinal tract and the integration of hormonal and neuroenteric activity. These interactions are complex and not well understood in health, much less in postoperative patients. Although the data are limited, it seems that small bowel transit times decrease after ileostomy, possibly related to mucosal hypertrophy and adaptation. The specific mechanisms are not known. Gastric emptying has been a subject of several studies but the results are conflicting. Soper et al.<sup>10</sup> found that gastric emptying is not altered in ileostomy patients. Yet, small bowel transit is longer than in control subjects (348 versus 243 minutes). In a more recent study, Robertson and Mathers<sup>11</sup> found that gastric emptying of liquids is not altered but emptying of solids is slowed.

Ileostomy output and dehydration may be decreased by prolonging the transit time to allow for more absorption. Codeine, loperimide, and Lomotil have all been shown to have this effect.<sup>12,13</sup>

### Fluid and Electrolyte Balance

The average ileostomy puts out about 500 mL of water and 60 mmoles of sodium per day. This is 2–3 times higher than found in normal fecal output.<sup>2</sup> Consequently, the ileostomate must compensate by increasing intake or conserving other losses.

Urinary volume is relatively decreased in patients with ileostomies by as much as 40%, whereas renal sodium losses may be decreased by 55%.<sup>14,15</sup> Yet, despite the efforts of the kidneys to maintain balance, total body water and sodium reductions may be a chronic condition in ileostomy patients.<sup>16-18</sup>

The chronic dehydration and loss of fluid and electrolytes make ileostomy patients prone to dehydration. Rehydration is best accomplished with fairly large amounts of normal saline.<sup>2</sup> There is an inverse relationship between absorption of nutrients and electrolytes and transit time.<sup>19</sup>

## Flora

The normal terminal ileum harbors few organisms in the healthy individual. After creation of an ileostomy, the distal ileum is rapidly colonized with a variety of bacteria. The microflora of an individual is fairly stable over time whereas there is great variability among individuals.<sup>20</sup> Staphylococci, streptococci, and fungi are increased whereas *Bacteroides fragilis* is rarely found in ileostomy effluent. The major variations in the flora of effluent from ileostomies, transverse colostomies, and feces per anum are in the relative numbers of anaerobes with log differences increasing from proximal to distal.<sup>21,22</sup>

## Nutrition

The colon has little role in the maintenance of normal nutrition, working primarily to absorb fluid and to store feces so that the frequency of bowel evacuation may be limited. Thus, removal of the colon alone has little effect on nutrition. Patients who require a total proctocolectomy for disease such as ulcerative colitis or Crohn's disease are often malnourished because of their underlying problem. Postoperatively, they are able to gain weight and return to a much better level of nitrogen balance and general nutrition.

Loss of more than a few feet of the terminal ileum may result in loss of bile acids and poor absorption of fat and fat-soluble vitamins.<sup>7,23</sup> Specifically, vitamin B<sub>12</sub>, necessary for normal hemoglobin synthesis, may not be adequately absorbed in patients with terminal ileal loss or significant Crohn's disease. This results in pernicious or macrocytic anemia, and these patients may require monthly administration of vitamin B<sub>12</sub> (intramuscular or nasal). Absorption may also be impeded by distal ileal bacterial overgrowth.<sup>24-26</sup> Kidney stones may be a consequence of chronic dehydration and acid urine. Adding sodium bicarbonate to the diet as well as increasing fluid intake may help to prevent uric acid stone formation.<sup>27-29</sup>

## Preoperative Considerations

### Access, Adherence, Activity, Attire

Preoperative patient preparation is essential and patients should be counseled and marked. In many institutions this is done by an enterostomal therapist.

Factors to consider in relation to stoma placement include: occupation, clothing styles (including belt line), flexibility and range of motion, abdominal wall contour when sitting and standing, and physical limitations or disabilities.<sup>30</sup> Other factors include prior abdominal incisions, bony prominences, and abdominal girth. Although in most elective settings, the stoma therapist will provide preoperative marking, it is imperative for any abdominal surgeon to have this skill as well because at times a stoma therapist may not be available.

Siting through the umbilicus is a reasonable alternative when there is no other good location. Raza et al.<sup>31</sup> believed that this was a good option based on their series of 101 patients; only four needed revision and there were no parastomal hernias or prolapse. Fitzgerald et al.<sup>32</sup> noted that after closure in infants and children, the scar resembles a normal umbilicus and is cosmetically superior to that of an ostomy placed elsewhere.

Nevertheless, standard ostomy sites lie to either side of the midline overlying the rectus muscle and are the preferred location for stoma placement (Figure 44-1). In the supine position, a site is marked 5 cm away from prior incisions, bony prominences, the umbilicus, and the patient's belt line. This is usually located just lateral and inferior or in some cases superior to the umbilicus.

With the patient sitting and standing, the site is checked to ensure skin folds or crevices do not interfere with appliance fitting. In obese individuals, the stoma must not be hidden below a large abdominal pannus or stoma care will be very difficult. In this circumstance, a supraumbilical stoma is often more functional. Once proper placement is ascertained, the spot is marked with indelible ink. In complex cases, a stoma appliance can be fixed to the proposed site and worn for 24 hours to test placement.

## End Ostomies

Most left colon colostomies are placed in the left lower quadrant of the abdominal wall, exiting through the rectus sheath. Most distal ileostomies are placed in the right lower quadrant. Occasionally, a higher or more lateral site may be chosen depending on body habitus, other scars, clothing, mesentery and bowel length, and surgical considerations. As noted, preoperative marking is essential, whenever possible, to select the best place for a stoma. The site is marked with indelible ink or scratched with a needle before preparation so the mark is not lost.

After the abdominal portion of the procedure is completed, the bowel and mesentery are again assessed for stoma construction with attention to length and viability. An adequate length of bowel should be mobilized to allow the intestine to come through the abdominal wall so it may protrude appropriately without undue tension. The blood supply to the end of the ostomy should be maintained to avoid ischemia. Similarly, the fascial and skin openings need to be large enough to avoid occluding the mesenteric vessels and the

FIGURE 44-1. Stomal placement. The site is selected to bring the stoma through the rectus abdominis muscle. (From Beck DE. Intestinal stomas. In: Beck D, ed. Handbook of Colorectal Surgery. 2nd ed. lumen. It is usually fairly easy to bring out enough small intestine. Occasionally, if there is extensive inflammation, bowel wall thickening, or a very wide abdominal wall in the obese, it may be difficult. It may be more difficult to obtain a good length of colon, especially if the mesentery is thick or short. Mobilization of the proximal colon, especially around the splenic flexure, is often necessary. Ligation of some of the distal vascular arcades may also be necessary but should be done with great care to assure good distal perfusion. Although usually not necessary, the very end of the bowel may be stripped of mesentery for 1–3 cm and it will generally survive on submucosal perfusion. The surgeon should not hesitate to make a large fascial incision because a late hernia is preferable to early ischemic necrosis or retraction.

Although there are many variations in the details of ostomy creation, the principles are universal. The following describes the authors' technique. A Kocher clamp is applied to the fascial edge of the incision and a second is placed on the subcuticular layer. The surgeon holds a folded, wet gauze pad in the left hand beneath the abdominal wall through the incision, using the Kocher clamps to line up the abdominal wall layers. The abdominal wall is tented up with the left hand by pushing firmly on the abdominal wall from within. A 3- to 4-cm-diameter circular skin incision is made at the marked site using a #15 blade (Figure 44-2). With electrocautery, the skin disk is excised, leaving all of the subcutaneous fat. This allows the stoma to sit up rather than pull down as is more likely if the fat is removed. The assistant retracts the incision and the fat laterally and medially with a pair of Richardson or Army-Navy retractors. The subcutaneous fat is divided with the electrocautery vertically, progressively replacing the retractors deeper until the anterior fascia is encountered (Figure 44-2B). The fascia is divided vertically. Although some surgeons use a cruciate or plus-sign fascial incision (“+”), a vertical fascial incision is recommended because more fascia will remain intact between the ostomy site and the midline wound. The rectus muscle is split in the direction of its fibers and held apart with a large Kelly clamp. The retractors are

repositioned to separate the muscles, exposing the posterior fascia. The posterior fascia and peritoneum are then incised with the electrocautery onto the wet lap pad. A large Kelly clamp is passed through the aperture and the pad is removed. The internal orifice may be viewed by lifting up on the Kocher clamps and levering the Kelly clamp up through the wound. The posterior opening may be enlarged as needed by incising the peritoneum and posterior fascia vertically, avoiding bringing the incision toward the midline wound. The opening is assessed and dilated by passing a finger, a thumb, and then two fingers. Any additional fascial widening needed is performed to allow easy passage of the bowel. A finger or clamp is kept in the opening at all times to avoid losing the tract, especially through the muscle plane. The end of the bowel to be used as the stoma is grasped with one or two large Babcock clamps placed through the aperture. This limb is then gently fed through the channel from within, rather than dragging it through with the Babcock clamps (Figure 44-2). This must be done carefully to avoid tearing the mesentery. If the fascial opening is too tight it should be further opened. The ileum should protrude 3–5 cm whereas the colon may protrude 1–2 cm. A bowel clamp such as a Glassman is placed across the protruding bowel to keep it at the correct level while the abdominal procedure is completed and the abdominal incision is closed. This clamp should not occlude the mesentery. It has been the authors' practice to place four interrupted 3-0 absorbable sutures from bowel seromuscular layer to the peritoneum and posterior fascia. We do not attempt to close the lateral gutter between the limb and abdominal wall.

### Maturation

The maturation technique of an ileostomy or a colostomy differs because of the nature of the effluent and the size of the lumen. A matured ileostomy should protrude 1–3 cm after eversion to create a spigot or faucet effect. This directs the liquid output into the appliance and decreases the problem of ileal contents irritating the skin and getting underneath the faceplate. Because of the more formed nature of the stool, colostomies may be flatter, although a small amount of protrusion is beneficial for appliance placement and adherence. In general, the stoma is *matured primarily* by everting the end and sewing it to the skin edge as the last phase of the operation. An appliance is placed along with the dressings so that the effluent will be collected and the stoma will function normally as soon as the ileus resolves. The abdominal incision is closed and a wet towel is placed over the wound. After a long operation, there is a tendency to rush through this phase; however, it is critical to the success of the operation and the rehabilitation of the patient to spend the necessary time to create a well-formed stoma. The end of the bowel limb is excised removing the staple line or the straight clamp. The lumen is cleansed with Betadine-soaked gauze as needed.

### End Ileostomy Maturation

Four sutures of a 3-0 absorbable material are placed to evert the ileum. These sutures are placed equidistant around the protruding bowel at the top, bottom, left, and right. The suture is first placed through the seromuscular and mucosa edge. A small but solid bite of the subcuticular edge of the skin opening is taken. The suture should not go through the surface of the skin because of the possibility of implantation of mucosa cells into the skin and resultant weeping patches and severe peristomal irritation. The third bite is taken through the seromuscular layer of the ileal wall at the level of the skin (Figure 44-3C2). Each of the four sutures is placed and tagged. The four tags are then grasped and the stoma is everted by gently pulling on the sutures while simultaneously pushing up on the seromuscular layer in between, half way down from the cut edge of the bowel to the skin with the back end of a forceps. This maneuver allows the ileum to evert and intussuscept. The four sutures are then tied down. One to two additional simple buried sutures are placed in between the everting ones to further approximately the mucosal-cutaneous junction. The midline wound is covered by a thin strip of nonadherent gauze and then the stoma appliance is placed. The opening in the faceplate should be cut to 5 mm

FIGURE 44-3. Ileostomy maturation. **A** Ligation. **B** Trimming of the ileal mesentery. **C.1** Serosa is attached to Scarpa's fascia and the mucosal edge sutured to dermis. **C.2** Triangular stitch from ileal end to serosa to dermis; tying sutures inverts the ileum to the skin. (From Beck DE. Intestinal stomas. In: Beck D, ed. Handbook of Colorectal Surgery. 2nd ed. Copyright 2003 by Taylor & Francis Group LLC (B). Reproduced with permission of Taylor & Francis Group LLC (B) in the format Textbook via Copyright Clearance Center).

larger than the diameter of the stoma to allow for swelling. The collection bag is oriented so that it hangs to the patient's side for the first few days while recumbent. Once the patient is ambulating well, it is rotated so that it hangs down toward the feet. Additional dressings are applied.

### End Colostomy Maturation

Although a left-sided colostomy may be flush to the skin, slight eversion is preferred to improve appliance adherence and because weight gain may result in retraction. The procedure is similar to ileostomy maturation as outlined above. However, the stoma is trimmed so that only 1–2 cm protrudes. The four quadrant sutures do not need to include the third bite through the seromuscular layer at skin level unless this is needed to hold the stoma up. Because the stoma diameter is larger, two to three buried sutures may be placed in between each of the quadrant sutures.

### Controversies

Several controversies exist about the creation of a stoma. Traditionally, absorbable sutures have been placed transabdominally from the seromuscular layer of the bowel to the posterior fascia and peritoneum to help fix the limb in place and reduce the incidence of parastomal hernias and prolapse or retraction. This has been questioned recently. It is still the authors' practice to place four interrupted 3-0 absorbable sutures from seromuscular layer of the bowel limb to the peritoneum and posterior fascia.

Other issues under discussion include whether an adhesion barrier should be placed around the limb as it exits the abdominal cavity because this may decrease the formation of adhesions and the incidence of small bowel obstruction. Some surgeons have adopted this practice. Perhaps even more controversial is whether a mesh patch should be placed prophylactically around the stoma to decrease the high incidence of parastomal hernias. Use of mesh around a stoma has always been viewed with skepticism because of the risk of infection and the subsequent need to remove the mesh. Yet, there are no data on the incidence of this problem.

Most stomas are primarily matured, however secondary maturation may be preferred when the bowel is too thickened and inflamed to evert, when it is too friable or weak to hold sutures, or when the patient is unstable and the additional time is not warranted. In cases of toxic colitis, megacolon, or distal obstruction, the bowel may be so distended and friable that it will not hold sutures. When operating for peritonitis, the colon or small bowel may be markedly thickened and inflamed. In these situations, the bowel may simply be exteriorized as a straight end and, in the manner of Jones, wrapped in a long length of moist gauze to hold it on the abdominal wall. The stoma may then be secondarily matured with the time interval determined by the appearance of the bowel and the condition of the patient. Usually, this is in the range of 2–7 days.

Hebert<sup>33</sup> described the *loop-end ostomy* for difficult-to-mature stomas in obese patients with a thick abdominal wall and a thickened or shortened mesentery. The bowel to be used as the stoma is divided with a linear stapler. The proximal end is brought through the abdominal wall aperture. The antimesenteric side is opened as the ostomy and the staple line is left along the side of the tract. A portion of the staple line may be excised as part of the maturation as needed (Figure 44-4).

### Lateral Mesenteric Closure

A number of authors have advocated closing the lateral sulcus when constructing a colostomy or fixing the ileal mesentery to the falciform ligament when creating an ileostomy. This is done in an attempt to reduce the incidence of volvulus around the stomal limb and obstruction. Theoretically, a form of volvulus may occur because the bowel is fixed anteriorly at the abdominal wall and posteriorly by the mesentery. Yet, in clinical practice, this problem rarely occurs. In this author's experience with several hundred stomas, stomal volvulus has been a problem in only one patient. Yet, some surgeons cling to this religiously whereas others doubt its usefulness.

John Goligher of Leeds, England took this notion to its extreme by advocating creation of an *extraperitoneal colostomy* (Figure 44-5).<sup>34</sup> C.P. Sames described a similar technique.<sup>35</sup> The colon was extensively mobilized and tunneled

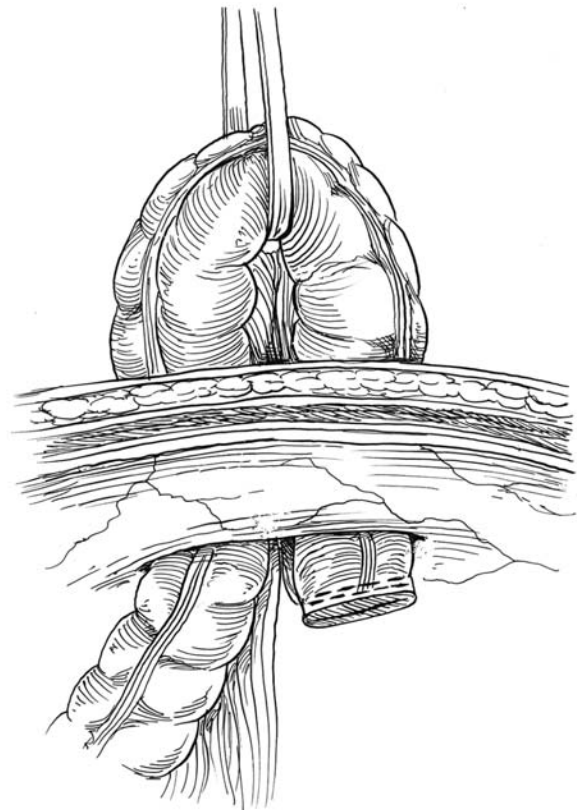

FIGURE 44-4. Loop-end colostomy.

FIGURE 44-5. Extraperitoneal colostomy. **A** Peritoneum is opened, and an extraperitoneal tunnel is created with blunt dissection. **B** Colon is brought through the tunnel, and mesenteric defect is closed. (From Beck DE. End sigmoid colostomy. In: MacKeigan JM, Cataldo PA, eds. *Intestinal Stomas. Principles, Techniques, and Management*. Copyright 1993 by Taylor & Francis Group LLC (B). Reproduced with permission of Taylor & Francis Group LLC (B) in the format Textbook via Copyright Clearance Center).

from posterior to anterior beneath the peritoneum and then through the abdominal wall.

### Mucous Fistula

The term mucous fistula refers to the distal end of the divided bowel that has been brought through the skin and matured as a stoma. Typically, when the bowel is completely transected, with or without resection of a segment, the proximal end may be made into an end stoma, e.g., ileostomy or colostomy. This is the functioning stoma through which the bowel contents empty. The other, or distal, end may be closed as in a Hartmann's procedure or may be brought to the surface and matured. This is referred to as a mucous fistula because it is an opening that occasionally produces mucous. A mucous fistula may be placed in a number of locations. Classically, this end of the bowel was brought out through the lower end of the vertical abdominal incision, but it may also be placed in its own site away from the wound and the primary ostomy, or it may even be brought up adjacent to the end ostomy and only opened a small amount as in the end-loop colostomy of Prasad et al.<sup>36</sup> (Figure 44-6).

The advantage of a mucous fistula is primarily that the distal portion of the bowel may be decompressed through this opening. This is important when an obstruction remains in the distal bowel such as an unresectable tumor. Closure of the distal end might result in a closed loop which, when filled with mucous, secretions, and bacteria, could rupture and result in peritonitis. A mucous fistula may also be used to access the distal bowel for purposes of observation, irrigation for wash-out, or for therapy. It is also a simple matter to find the distal limb when operating to close the ostomy. The obvious disadvantage of a mucous fistula is the second stoma site on

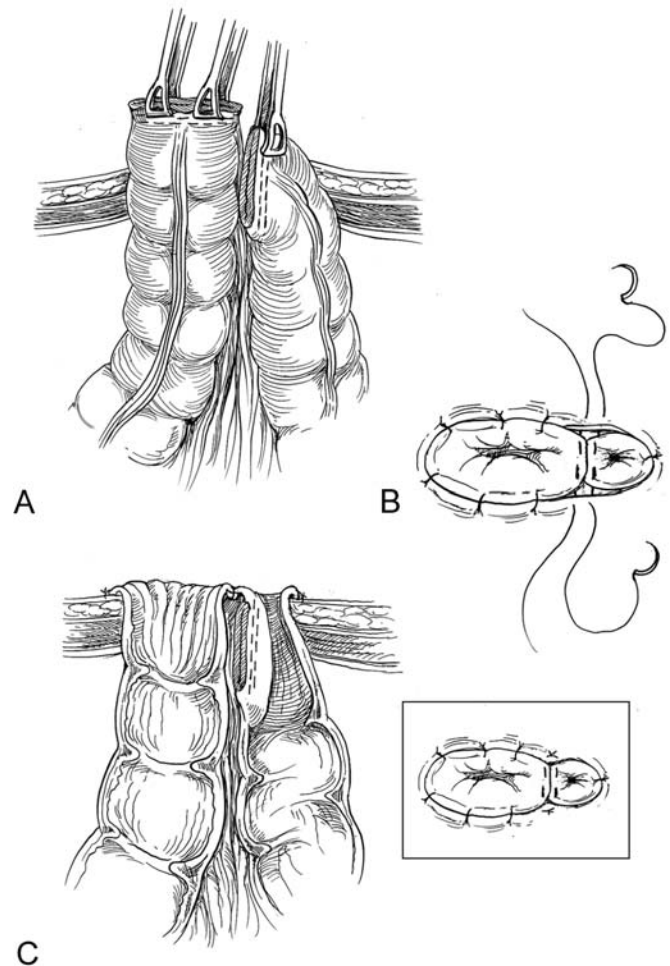

FIGURE 44-6. End-loop colostomy (Prasad). **A** The entire divided edge of the proximal limb and the antimesenteric corner of the distal limb are gently drawn through the opening in the abdominal wall. After the abdomen has been closed, the staple line of the proximal limb is excised completely and only the antimesenteric corner of the distal staple line is removed. **B** The proximal limb is matured flush with the skin by suturing the deep dermal skin to full-thickness colon with absorbable sutures. Transition sutures may be placed to help mature the mucous fistula, which has the appearance of a "mini-stoma." **C** Sagittal view of the completed end-loop colostomy. Note the portion of the distal staple line in the subcutaneous tissue.

the patient's abdominal wall. Although a mucous fistula does not produce a large amount of material, small amounts of mucous do emanate from time to time.

### Diverting Stomas

#### Indications

Whether a colostomy or ileostomy, diverting stomas are nearly always created for a single purpose: to prevent fecal content from reaching a distal segment of the large bowel,

either because of fear of leak (distal or difficult anastomosis) or to treat a leak (trauma, perforation, or anastomotic disruption). Once this principle is understood, the indications for and selection of an appropriate diverting stoma becomes straightforward.

Table 44-2 lists the common current indications for diverting ileostomies, colostomies, and end-loop stomas. These include protection of distal anastomoses, predominately ileal pouch-anal or coloanal anastomoses, complicated diverticulitis, treatment of anastomotic leaks and pelvic sepsis, large bowel obstruction, trauma, and fecal incontinence.

The end-loop stoma (including end-loop ileostomy, end-loop colostomy, end-loop ileocolostomy) as described by Prasad et al.<sup>36</sup> has created another option for fecal diversion which now allows the creation of a diverting stoma with remote intestinal segments (in association with colonic resection).

These three options exist for diverting stomas and the choice between these options will affect not only short-term complications, but the complexity of subsequent surgery and the quality of life (QOL) of the ostomate as well.

When deciding which stoma to create, the surgeon must thoughtfully consider the following principles:

1. Will the stoma achieve its primary purpose? Will it protect the anastomosis or treat the anastomotic leak?
2. Can a stoma be safely created? Can that segment of bowel reach an appropriate site on the abdominal wall and be matured successfully?
3. How will life with this stoma be, particularly if subsequent stoma takedown does not take place?
4. Will stoma choice affect subsequent stoma takedown? Loop stomas and end-loop stomas avoid the necessity of laparotomy for takedown versus the Hartmann procedure.
5. Will stoma choice limit future reconstructive options? Sigmoid colostomy may make a subsequent coloanal anastomosis more difficult versus loop ileostomy.

In both urgent and elective situations, these factors should be considered before initiating the surgical procedure. The patient can then be marked for potential stoma sites and counseled appropriately before surgery begins.

Although loop ostomies are usually meant to be temporary, a significant number are never closed. Because the patient

must live with the loop stoma for at least several months, and sometimes for the remainder of his or her life, careful attention to ostomy construction remains very important.<sup>37,38</sup>

Another controversy exists regarding the distance between the diverting stoma and the distal area “to be protected.” This pertains particularly to urgent operations without bowel preparation when treating an anastomotic leak or colonic perforation. Concerns exist that the column of stool between the stoma and the leak will continue to contaminate the peritoneal cavity preventing adequate treatment of intraabdominal sepsis. These concerns began in the early days of stoma creation when transverse loop colostomy and drainage were the preferred treatment for perforated diverticulitis. They continue today when a loop ileostomy is used in conjunction with drainage to treat an anastomotic leak or to protect a left-sided colonic anastomosis in emergency surgery without preoperative bowel preparation.

### *Loop Ileostomy Versus Transverse Loop Colostomy*

When treating pelvic infection from a colonic source or particularly when choosing elective diversion for protection of low pelvic anastomosis, transverse loop colostomy and loop ileostomy are the major options. In nearly all situations, loop ileostomy is the superior choice. Transverse loop colostomy, except in rare circumstances, should be a procedure of historic significance only.<sup>39</sup>

Loop ileostomies are easy to construct, allow for better stoma placement, and are tolerated much better by ostomates. The effluent from both stomas is similar in volume and consistency. Therefore, colostomies offer no protection from fluid and electrolyte disturbances or skin irritation. In addition, loop ileostomies are easier and safer to “takedown” when restoring intestinal continuity.

In addition, loop transverse colostomies have a much larger lumen, rarely stay everted, often prolapse or retract, are usually placed in the epigastrium (a very inconvenient location), and are quite malodorous.

In a randomized, prospective trial by Williams et al.,<sup>40</sup> transverse loop colostomy was compared with loop ileostomy for elective protection of distal anastomoses. All ileostomies and colostomies objectively completely diverted the fecal stream. Nearly all complications were twice as common with transverse colostomies when compared with ileostomies (Table 44-3). Infection at the time of creation and at takedown, odor, leakage, and skin problems were all significantly higher in patients with transverse colostomies. In addition, multiple visits to the stoma therapist were needed in 58% of colostomy patients versus 18% of ileostomy patients. Others have expressed similar opinions and noted similar results.<sup>41,42</sup> Hernia formation at the ostomy closure site was much more common with transverse colostomies.<sup>43,44</sup>

Considering the available data, loop ileostomy should be the procedure of choice for proximal diversion of left-sided

TABLE 44-2. Indications for diverting stomas

- 
- Protection of distal anastomosis

Leakage	31	18
Odor	53	6
Infection at takedown	30	0

anastomoses. The ileostomy is smaller, may be located in the right lower quadrant rather than the right upper quadrant as for a loop transverse colostomy, is less odorous, and easier to pouch and manage. Closure of the ileostomy is also an easier operation with fewer complications.<sup>45</sup>

### Loop Colostomy

A loop colostomy can be created with any segment of the colon that can be mobilized to reach the abdominal wall. Only two sites, however, are generally used, the transverse colon and the left colon (sigmoid or descending). Because the transverse loop colostomy is rarely used today, construction of the left-sided loop colostomy will be described (Figure 44-7). If necessary, a transverse loop can be created in a similar manner using an appropriate segment of colon and matured in the right or left upper quadrant.

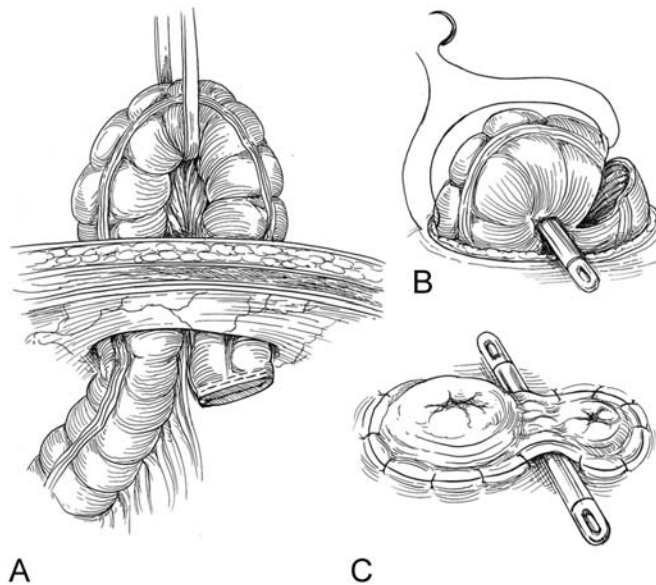

FIGURE 44-7. Loop-end colostomy. **A** A tape or rubber drain is passed through a small hole in the mesentery of the segment of colon to be exteriorized. **B** A plastic rod is placed through the mesenteric opening to support the loop on the skin and is sutured in place. The loop is opened transversely for about two-thirds of its circumference toward the distal end. The longer portion of the colon is everted with interrupted absorbable sutures. **C** Completed loop colostomy.

### Loop Sigmoid Colostomy—Technique

The sigmoid and left colon are mobilized along the white line of Toldt as for a standard left colon resection, and an appropriate segment of colon is selected for stoma creation. In general, the most distal colonic segment available should be chosen. The bowel should be mobilized until the selected segment easily reaches the abdominal wall.

The peritoneum covering the mesentery adjacent to the bowel wall medially and laterally is then scored with electrocautery. A hemostat is passed immediately adjacent to the colon wall. Palpating the junction of the bowel wall and the mesentery with the index finger and thumb on the nondominant hand to guide the hemostat helps identify the correct site and avoids injury to the bowel wall. A Penrose drain or an umbilical tape is pulled through to encircle the bowel and identify the stoma site. A colored seromuscular suture is then used to mark the distal limb to prevent maturation of the incorrect end. The premarked stoma site, usually in the left lower quadrant, is excised. A disk approximately the size of a quarter is usually sufficient, but may need to be enlarged depending on the size of the colon. Smaller is better because it is easier to enlarge than decrease the size of the trephine. Small Richardson retractors expose the anterior rectus sheath. Counter pressure, applied from under the abdominal wall with the nondominant hand of the surgeon holding a wet gauze, facilitates this dissection.

The anterior rectus sheath is opened vertically for 3–4 cm. A small transverse extension may be made laterally in the midpoint. Medial extension should be avoided because this minimizes the fascial distance between the stoma site and the midline incision and may increase the risk of hernia. A curved instrument is used to bluntly spread the rectus abdominus in the direction of its fibers. The retractors are repositioned to spread the muscle, exposing the posterior rectus sheath. This is divided with the cautery onto the nondominant hand in the peritoneal cavity. The opening is enlarged to accept two fingers to the proximal interphalangeal joint.

The colon is passed, more by pushing than pulling, from the abdomen through the stoma site. Care is taken to avoid twisting the loop. The distal segment is oriented inferiorly and confirmed by the location of the colored suture. At times, a bar is placed beneath the loop to lie on the skin on either side of the opening for support. This is generally removed after 5–6 days. Once the colonic loop has traversed the abdominal wall without tension or evidence of ischemia, the abdomen is closed in standard manner and the incision is covered with a wet, sterile towel. There is no need to fix the colonic mesentery to the lateral peritoneal gutter because this maneuver has not been shown to decrease small bowel obstruction. Similarly, there is no need to fix the colonic wall to the fascia opening at the stomal site because this has not decreased the risks of parastomal hernia or stomal prolapse.

The colon is opened transversely just above the site where the distal-most portion meets the abdominal wall. Eighty

percent of the colonic wall is transected. The distal end is matured primarily without eversion to the inferior one-third of the stoma trephine. The proximal end can be matured with or without slight eversion. If eversion is desired, classic tripartite sutures are passed from the dermis to the seromuscular layer 2–3 cm from the terminal end, and then full thickness to the terminal portion of the proximal stoma. After three everting sutures are placed, they are all tied, effectively everting the proximal or functional end of the stoma. Maturation is completed by adding sutures between the dermis and the cut end of the bowel as necessary to ensure mucocutaneous approximation. With this technique, the functional limb should occupy 75% of the circumference of the stoma trephine, with distal limb occupying the remainder. A support rod is generally unnecessary, but can be used if there is some tension on the stoma and retraction is a concern.

After surgery, a two-piece appliance with a clear collection bag is fit into place, and left undisturbed for 3–4 days. This allows for easy inspection of, and access to, the new stoma. Diet is advanced as intestinal activity resumes. Vascularity and patency of the stoma can be inspected by removing the stoma bag and, if necessary, peristomal evaluation can be performed by removing the appliance faceplate.

### Loop Ileostomy

A loop ileostomy is created using the most distal ileal segment available that reaches the abdominal stoma site without creating tension on the stoma or distal anastomosis (especially when diverting an ileal pouch–anal anastomosis). Usually, this is 10–15 cm proximal to the ileocecal valve. Mobilization of the cecum and attachments of the terminal ileum to the retroperitoneum is occasionally required.

After selecting the appropriate ileal segment, a hemostat is passed under the bowel using the fingers of the nondominant hand to identify the mesenteric edge of the bowel and to protect it from injury. A Penrose drain or umbilical tape is pulled through this defect and clamped with a hemostat. A colored seromuscular suture is used to mark the distal portion to prevent maturation of the wrong stomal limb.

After identification and preparation of the ileal segment, the abdominal wall opening is created. A disk of skin, at the premarked stoma site, slightly smaller than a quarter, is excised. A defect through the abdominal musculature is created similar to that for a loop colostomy. The ileal segment is passed through the abdominal wall without twisting, ensuring that the previously placed suture, marking the distal end, is oriented caudally. The limb may be supported by a plastic rod, if the surgeon chooses.

After closing the abdominal incision in standard manner and protecting the wound with a sterile towel, the ileum is prepared for stoma creation. Two Allis clamps grasp the bowel at the junction between its distal-most portion and the abdominal skin. Electrocautery is then used to transect 80% of circumference of the bowel wall. The distal, or nonfunctional, end is

matured without eversion with three sutures between dermis and the full thickness of the terminal bowel. One suture is placed on the antimesenteric border of the distal end, whereas the other two are placed at the junction between the distal and proximal limbs. When passing sutures through the skin, only the inferior 25% of the stoma site circumference is used, leaving the remainder for the functional end. The proximal limb must be matured with eversion to prevent complications associated with caustic ileal effluent. *Tripartite bites* containing dermis, seromuscular layer of the bowel wall 2–3 cm proximal to the transected end, and full-thickness bowel wall at the transected end are then taken. Three sutures are placed on the antimesenteric border, and at the junction of the proximal and distal limbs of the stoma. After all three everting sutures are placed, they are tied sequentially and the proximal or functional end is everted. A single suture is placed between each of the prior sutures (only containing terminal bowel and dermis) to complete stoma maturation. A clear two-piece appliance is fixed to the stoma site in the operating room. This allows for visual inspection of the stoma in the postoperative period.

### End-loop Stomas

End-loop stomas, as originally described by Unti et al.<sup>46</sup> consist of end-loop ileostomy, end-loop colostomy, and end-loop ileocolostomy. They offer the advantages of providing a well-everted, easily managed stoma in which laparotomy is not required for takedown and providing complete diversion of stool and decompression of the distal end. In addition, end-loop stomas may be created with remote intestinal segments (in association with bowel resection).

The technique for creation of all three is similar with the exception that two bowel segments must be approximated when creating an ileocolostomy. Creation of an ileocolostomy will be used to illustrate the technique. After right colon resection, the mesenteric defect is closed approximating the terminal ileum and the proximal transverse colon. A standard stoma trephine is created at the preselected stoma site (usually in the right upper or lower quadrant) as illustrated in the previous sections. The entire circumference of the terminal ileum and only the antimesenteric border of the previously stapled transverse colon are brought through the stoma site.

The abdominal incision is then closed. The antimesenteric corner of the transverse colon staple line is cut off with Mayo scissors. It is then matured to the stoma site dermis with three sutures without eversion. After this, the terminal ileal staple line is cut off completely. The ileum is everted as for standard end ileostomy. A single, full-thickness suture between the everted terminal ileum and the antimesenteric corner of the transverse colon completes the maturation.

As previously mentioned, this technique with minimal modification can be used to create an end-loop ileostomy or an end-loop colostomy. This technique produces upright stomas that are nearly indistinguishable from traditional end

stomas to the ostomate. They are easy to pouch, requiring no support rod, and therefore are rarely associated with skin problems. Most importantly, laparotomy is not required for subsequent takedown. Because both the proximal and distal segments are located at one stoma site, a peristomal approach can nearly always be used to restore intestinal continuity. Complications will be discussed in the next chapter, but there are no complications unique to end-loop stomas, not seen in traditional loop stomas.

### Turnbull Blowhole Procedure

As early as 1953, decompressive transverse colostomy was recommended for patients with toxic colitis.<sup>47</sup> Turnbull and Weakley<sup>48,49</sup> described a technique of intestinal decompression to be used in patients with toxic megacolon whose colon was so dilated and tissue-paper thin that any attempt to perform an acute resection was likely to result in massive peritoneal contamination and possible death. This procedure was used as a bridge to a more definitive resection after the patient had recovered from their acute illness.

#### *Turnbull Blowhole Technique*

A short, left paramedian incision is made to find a loop of distal ileum proximal to any terminal ileal disease. A small, lower midline incision can be substituted which may be incorporated into an incision used for a subsequent operation. The terminal ileum is exteriorized via a right lower quadrant incision and suspended over a bar. A 5-cm epigastric or right upper quadrant incision is made over the area of maximal transverse colon dilation for the “blowhole.” The operative incision is closed. The ileostomy is primarily matured as a loop. The “blowhole” colostomy is matured in two layers (Figure 44-8). The seromuscular layer of the bowel wall is fixed to the fascia with several running sutures, leaving several centimeters of serosa exposed in the middle. The lumen is entered and the full thickness of the bowel wall is gently sutured to the skin with simple interrupted sutures. No attempt is made to evert this stoma because the tissue is likely to tear. Appliances are placed over both stomas.

Over the years, remarkable results have been reported in patients who are critically ill with a high expected mortality.<sup>50,51</sup> Remzi et al.<sup>52</sup> from the Cleveland Clinic reported their recent results, noting that even in Turnbull’s own institution the procedure was now rarely performed. They described 17 patients over 18 years of age who underwent this procedure for inflammatory bowel disease, *Clostridium difficile* colitis, adult Hirschsprung’s disease, and palliation for malignant bowel obstruction with metastases. Two of the patients with inflammatory bowel disease were pregnant. All four patients with metastatic carcinoma died of their disease. Twelve of the remaining 13 patients have been reconstructed, all with good results.

Obviously, the indications for this procedure have decreased over the past few decades because of better medical

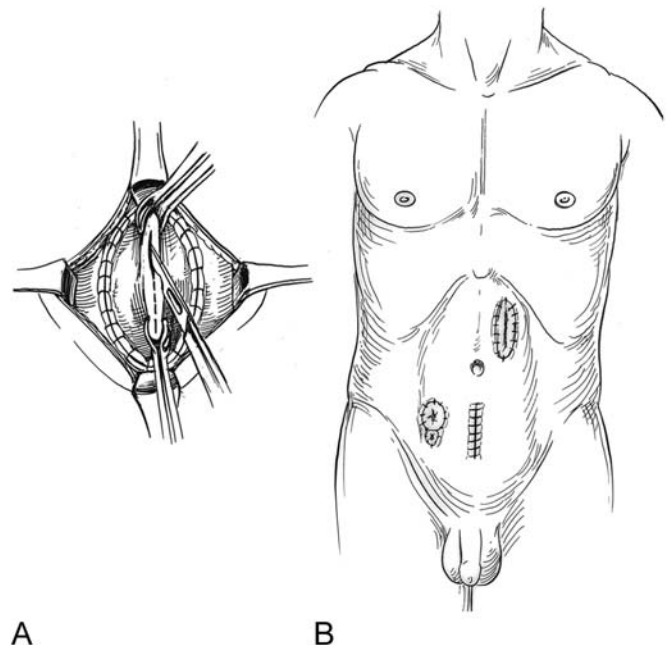

FIGURE 44-8. Blowhole colostomy and loop ileostomy “Turnbull procedure.” **A** Through an incision made over the dilated transverse colon, the colon wall is sutured to the peritoneum to prevent intraabdominal contamination. The colon is opened and the edges of the opened bowel are sutured to the skin. **B** A loop ileostomy is created in the right lower quadrant usually through a lower midline incision.

management of inflammatory bowel disease, earlier referral for definitive surgery, and better critical care. Yet, the blowhole procedure is still a reasonable alternative in critically ill patients with toxic megacolon and large bowel obstruction and should remain a part of the colorectal surgeon’s armamentarium.

### Loop Ostomy Closure

Closure of a loop ostomy is generally a fairly straightforward procedure. Greater than 95% may be performed locally at the site of the stoma without having to reopen the midline or main abdominal incision. Occasionally, additional procedures may be necessary at the time of stomal closure such as repair of a parastomal hernia or even lysis of adhesions for an acute or chronic small bowel obstruction.

Closure of an end stoma is a much more extensive procedure than loop closure because the ends are separated and an intraabdominal approach is usually necessary. Closure of a Hartmann’s procedure, especially if the distal end is in the pelvis, can be just as difficult as any resective procedure. Thus, this procedure should be performed with the same precautions, preparation, and concern as any colon resection.

The time interval between creation of the ostomy and closure will vary depending on the initiating disorder and the condition of the patient. It is best to wait until any inflammatory

process has had adequate time to settle and for adhesions to soften. The patient should also be in as good condition as possible. Most temporary ostomies are closed in 2–3 months. A 6-week interval is the usual minimal period because adhesions tend to be severe before this. Periods of only 1–2 weeks or up to many years are occasionally used. Long time periods may be associated with disuse colitis or proctitis because the bowel normally obtains some of its nutrients such as glutamine from the passing contents. Irrigation with a solution of short-chain fatty acids may ameliorate this problem when symptomatic until continuity is reestablished. Atrophy and stenosis of the distal segment may rarely occur.

### *Loop Ileostomy Closure Technique*

The only preparation necessary is a liquid diet the day before surgery and nothing after bedtime. Intravenous antibiotics are administered with the induction of anesthesia. A proctoscopic examination of the rectal anastomosis or the ileal pouch may be performed first with the patient in the lithotomy position. The patient is placed in the supine position. Some surgeons place a pursestring suture to close the ostomy lumen. The abdomen is prepped with Betadine solution and the patient is draped. A circumferential incision is made around the stoma at the mucocutaneous junction. If the skin is to be closed primarily, then the incision is extended as an ellipse laterally and medially for 1–2 cm. The edge of the stoma is grasped with straight hemostats at each of the four quadrants. These are used to hold the stoma up and retract it. Initially, Senn retractors are used to provide countertraction on the edges of the wound. These are replaced by small Richardson retractors as the wound becomes deeper. Using fine scissors and cautery, the dissection is carried down onto the antimesenteric surface of each limb, usually superior and inferior. Because the small bowel does not have fat appendages, the antimesenteric surface is smooth and unencumbered. It may be readily followed down to the anterior fascia on each side. The dissection is continued around, identifying the mesentery as it bulges out from under the loop, usually medially and laterally. The circumferential dissection of the subcutaneous portion of the loop is completed, exposing the anterior fascia all around. The serosa is freed from the fascia and rectus muscle using sharp dissection. There may be areas of tenacious adhesions and so care must be taken to avoid serosal tears and enterotomies. A finger may be inserted through a freed area and swept around the limb within the peritoneum to loose filmy adhesions and to identify areas of adherence. Additional intraabdominal adhesions may be released as needed to allow the loop to be exteriorized and to free 1–2 cm of the posterior fascia all around for later closure. If the fascial opening is very tight, it may be released by incising the rectus fascia superiorly or inferiorly for several centimeters and splitting the rectus muscle. This adds little risk but may provide significant visibility and may ease the dissection. The limb is carefully examined for serosal tears or enterotomies and these are repaired.

Continuity may be reestablished by either a sewn end-to-end anastomosis or by a stapled side-to-side anastomosis. If a sewn anastomosis is to be made, the opening in the loop must be cleared of adhesions and the mucocutaneous junction must be excised. Adhesions between the two limbs are divided so that the loop may be laid out in a straight line. The everted stoma is released and the eversion reduced. The attached skin and mucocutaneous junction are excised, leaving healthy, clean bowel edges. The opening usually encompasses about two-thirds of the cross-section of the bowel. The anastomosis is made with a single layer of inverting 3-0 suture using either absorbable material such as polyethylene glycol (Vicryl) or permanent material such as silk. The anastomosis is performed in two halves that are suspended between seromuscular, inverting stay sutures. These are placed just outside of the opening on either end and bridge the middle of the defect. The interrupted sutures are then placed sequentially from one side to the middle and then from the other side, inverting the mucosal edge. If the stoma must be excised, a standard end-to-end anastomosis may be made.

Currently, the anastomosis is usually made with a stapler in a side-to-side manner. This has proved to be reliable and faster, and bowel function may return sooner because it is typically a larger diameter anastomosis. After the limb has been mobilized, the skin is excised. The open end of the loop is held up with Babcock clamps. Throughout the procedure, the limbs are held vertically to reduce the risk of soilage. The two arms of the GIA stapler are placed into each of the two limbs of the loop. They are brought together with locking of the staples so that the mesentery is as lateral as possible and the staple line goes through the mid portion of the antimesenteric surface of the bowel. When locking the stapler, it is helpful to place two fingers between the bowel wall and the mesentery and to spread them, separating the mesenteric sides. The GIA stapler is fired and removed. The corners of the staple line are grasped with Allis clamps and pulled apart. Several Allis or Babcock clamps are placed in between to approximate the open edges of the bowel. This end is then stapled shut with a 60-mm linear stapler (TA-60). This creates a triangulated anastomosis that is wide and large. A crotch stitch is placed to complete the anastomosis. The limb is placed back into the abdominal cavity. The fascia is closed in a single layer with large, absorbable sutures. The skin may be closed with staples or subcuticular sutures or left open to heal secondarily.

### *Loop Colostomy Closure Technique*

A loop colostomy may be closed in essentially the same manner as that of a loop ileostomy. Preparation usually includes both a mechanical washout and antibiotics. The dissection creates a larger wound and care must be taken to avoid cutting across fat epiploicae and diverticula. Because the lumen of the loop colostomy is larger than an ileostomy, a two-layered closure is often used. The mucosa is run with an absorbable

suture and inverting, seromuscular (Lembert) sutures are placed using silk. A side-to-side stapled anastomosis is also safe and frequently used.

### *Closure of the Hartmann's Procedure*

A Hartmann's procedure is used when a primary anastomosis is not feasible or safe as in the case of significant trauma, colonic obstruction, acute diverticulitis and toxic colitis, or megacolon. Typically, a variable amount of colon has been excised, a colostomy has been created, and the upper rectum has been closed. The entire colon may have been removed as in the case of toxic colitis, leaving an ileostomy and the closed rectum. In any case, the goal is to take down the stoma and reestablish continuity with either a colorectal or ileorectal anastomosis. Although this may be performed using hand-sewn techniques, the double-stapled method is now most often used. The advantages of an end-to-end stapled anastomosis are nowhere more clear than with this procedure.<sup>53</sup> At times, the procedure may be performed using a laparoscopic approach if adhesions are not too extensive.

A bowel preparation including both a mechanical washout and antibiotics is performed to cleanse the proximal colon. Enemas may be used to clear the rectum of mucous plugs and debris. If the proximal end is an ileostomy, then a clear liquid diet the day before surgery with nothing after bedtime is all that is necessary. The distal remaining bowel is cleansed at the beginning of the procedure using a sigmoidoscope and irrigating solution such as Betadine diluted 50% with saline. Some prefer to use a balloon catheter and enema procedure. The abdomen is prepped and draped. The abdominal cavity is entered through the old incision or laparoscopically. Adhesions are lysed as necessary and the rectal pouch is identified. Usually, little mobilization is needed if a stapled anastomosis is planned. The uterus or vagina or other tissues may need to be freed from the closed end. The ostomy is taken down from the abdominal wall. The end is trimmed, removing the skin and mucocutaneous junction. A standard double-stapled colorectal or ileorectal anastomosis is made with an appropriately sized stapler. A 29- or 33-mm stapler is usually used for a colorectal anastomosis, whereas a 25- or 29-mm stapler will usually fit into an ileorectal anastomosis. The anastomosis is tested with air or fluid and the donuts are examined for defects.

### Results of Stoma Closure

Loop ostomy closure is still a significant operation with associated mortality and morbidity. There are actually quite a few studies that address these issues.<sup>54-59</sup> Fortunately, the risk of perioperative death is quite low at 0%–2%. Most of these deaths are attributable to nonsurgical conditions such as cardiac disease or pulmonary embolism. The rare, related death is attributable to sepsis from an anastomotic leak.

Overall complication rates of 15%–30% are consistently reported, although there are a few studies that report a wide range from 2.4% to 57%. These differences are probably related to the nature of the complications (attributed to the stoma closure or not) and the type of follow-up. There are no consistent differences between patients who had an elective or emergent ostomy.<sup>54-65</sup> In individual series, complication rates seem to decrease when subsequent time periods are analyzed, yet many reports from major institutions show similar rates from the 1970s through today.<sup>66</sup>

The most common complications of loop ostomy closure are wound infection (9%–34%), bowel obstruction (0%–10%), fecal fistula (0%–5%), and leak (0%–3%). Anastomotic strictures (0%–1%) and intraperitoneal abscess (0%–1%) after closure are fairly rare. Long-term consequences such as incisional hernias and small bowel obstructions are not uncommon with rates increasing over time from 2% to 10% or more for both.<sup>54-56,60,61,67-69</sup>

Risk factors that increase the complication rates of ostomy closure include diabetes, advanced age, type of ostomy being closed (end loop), increased operative time, and higher blood loss.<sup>61</sup> The most significant factors in several studies were steroid dependence and hypoalbuminemia.<sup>64</sup> A combination of factors, such as a high score, diabetes, and renal, cardiac, or pulmonary disease also portend a more difficult course.<sup>59</sup>

The surgical technique used for loop closure has been examined. Simple sutured closure of the anterior wall of the loop colostomy may have a lower complication rate than resection and anastomosis but there is no consensus on this.<sup>62,70,71</sup> Stapled and sewn anastomosis methods are of equal efficacy for colostomy closure.<sup>63,72</sup> The technique of loop ileostomy closure has been studied in several recent reports. Phang et al.<sup>73</sup> from the University of Minnesota reviewed a large series of ileostomy closures in which three techniques were used: simple sutured closure of the enterotomy, resection with hand-sewn anastomosis, and stapled anastomosis. Their overall complication rate was 24% which included wound infections (14%), small bowel obstructions (5%), and anastomotic leaks (3%). There was one death (0.3%) attributed to a cardiac event. The only difference was in the obstruction rate which was highest in patients who underwent resection with sutured anastomosis (12%) and lowest with simple enterotomy suture (2.3%). In a randomized trial, Hull et al.<sup>74</sup> from the Cleveland Clinic found that stapled and hand-sewn closures were equivalent in terms of complications, resumption of intestinal function, and length of stay. The only difference was that the stapled procedure was slightly faster. Others have also found these two techniques to be equivalent.<sup>70</sup>

The timing of ostomy closure has been a hotly debated topic for years. Some believe that early closure, even during the original hospital stay, will reduce costs and speed recovery. Others believe that early closure will abrogate the benefits of the diversion and result in higher complication

rates. A careful review of the literature found 11 studies with specific data supporting delayed closure, usually for 3 months, and only two that found no difference between early and late closure.<sup>55,60,63,71,75,76</sup> Most surgeons recommend a 2- to 3-month interval.

It is generally believed today that loop ileostomies have a lower complication rate than loop colostomies. Closure of these stomas may also differ in morbidity although the support for this is limited.<sup>40,70,77</sup>

Closure of a Hartmann's procedure is a major operation with all of the risks of any resection and anastomosis in a reoperative setting. In this setting, most authors have also found that delaying the closure for 3 months is beneficial.<sup>76,78-80</sup> Recently, several small reports of successful laparoscopic closures of Hartmann's procedures have appeared.<sup>81-84</sup> This seems to be a reasonable approach; however, there should be a low threshold for conversion to an open procedure.

## Minimally Invasive Stomas

Minimally invasive stomas can be created through three different approaches: 1) trephine stomas (those created with all exposure through the stoma site itself), 2) endoscopically assisted stoma creation, and 3) laparoscopically assisted stoma creation. Each offers its specific advantages and disadvantages as do traditional techniques for stoma creation. None of these techniques change the indications for, or proper siting of, a stoma. These less-invasive techniques should be used only when stoma creation is indicated and a properly sited stoma can be safely created.

### Trephine Stomas

Trephine stomas originated with the very beginnings of stoma surgery.<sup>85</sup> Before the advent of general anesthesia, aseptic technique, and transabdominal surgery, stomas were created through either flank or iliac incisions which doubled as the stoma site after completion of the procedure.<sup>86</sup>

Currently, trephine stomas are rarely performed because of advances in surgical technique. Difficulty with exposure leads to two significant problems: 1) identifying the proper intestinal segment, and 2) discerning the proximal limb from the distal limb of the stoma. This can lead to a stoma that is distal to a site of a large bowel obstruction or maturation of the distal stomal segment resulting in iatrogenic bowel obstruction.<sup>92</sup> For these reasons, endoscopic and laparoscopic assistance have been added to trephine stoma creation.

### Endoscopically Assisted Colostomy

Trephine stoma creation with endoscopic assistance is reserved for left-sided colostomies. Proximal to the left colon, its utility is severely limited by colonic distention secondary

to passage of the endoscope. Endoscopic assistance is frequently used for sigmoid colostomy creation without bowel resection. Common indications include fecal incontinence, perianal sepsis, sacral decubiti in spinal cord-injured patients, and creation of covering stomas in association with complex anal surgery. Patients who have multiple abdominal operations, have had prior left-sided colon resection, or who are obese are poor candidates for this approach.

### *Endoscopically Assisted Colostomy Technique*

Patients are prepared as for standard left-sided colostomy creation. An effective mechanical bowel preparation is essential to allow passage of the endoscope. A preselected stoma site is marked preoperatively by the enterostomal therapist, preferably in the left lower quadrant. The patient is placed in modified lithotomy position with legs in low stirrups, but the "foot" position of the operating table is left in its customary up position. The abdomen is prepped and draped in routine manner. The flexible sigmoidoscope (or colonoscope) is passed transanally into the sigmoid colon by the surgeon. The assistant identifies the endoscopic light transilluminating the left lower quadrant. The endoscope is then manipulated until the light approaches the premarked stoma site (Figure 44-9). The endoscope is left in place, resting on the "foot portion" of the operating room table. The surgeon then scrubs in. A circular disk of skin is removed from the premarked stoma site. The abdominal wall is traversed in standard manner and the colon identified by palpating the endoscope. The endoscope is

FIGURE 44-9. Sigmoidoscopic manipulation of sigmoid colon to pre-marked stoma site on abdominal wall.

withdrawn several centimeters and the sigmoid colon delivered through the stoma site, with care taken not to lose orientation of the proximal and distal ends. The sigmoid colon is then transected with a linear stapler as for standard end-loop stoma. To confirm orientation, the antimesenteric border of the distal staple line is transected. Air is insufflated via the endoscope and saline is drizzled over the distal stomal limb. Correct orientation is confirmed by air bubbles emanating from the distal colotomy. The distal antimesenteric border is matured without eversion and the proximal, functional end is matured in the standard manner. Insufflated air is once again confirmed to be originating from the distal limb to ensure correct orientation. The endoscope is withdrawn and the procedure terminated. Patients generally may resume a regular diet on the following day.

The limiting factors for the use of this technique include sigmoid length and fixation, abdominal wall obesity, prior surgery and adhesions, and the ability to pass the endoscopy through any strictures. As for all minimally invasive operations, the patient should be prepared for conversion to a laparoscopic or open approach.

### Laparoscopic-assisted Stomas

End and loop colostomies as well as end-loop ileostomies can be created with laparoscopic assistance. Laparoscopy does not change the indications for stoma construction. Additionally, the techniques for stoma maturation are identical to those for open stomas. Initial reports of successful laparoscopic ostomy creation began to appear in 1991 through 1994.<sup>87-89</sup> Many more have been published since.

### Laparoscopic Ileostomy

In many cases of laparoscopic-assisted ileostomy, laparoscopy is only necessary to facilitate the proper selection and identification of an appropriate ileal segment as well as ensure maturation of the proximal limb.

#### *Laparoscopic Ileostomy Technique*

A laparoscope is inserted through an umbilical port. A second port is inserted through the preoperatively marked stoma site. The terminal ileum is identified and its mobility assessed (Figure 44-10). If the ileum is free from attachments, a segment 10–15 cm proximal to the ileocecal valve is located and held with an atraumatic locking grasper through the stoma site port. Correct orientation of the proximal and distal limbs is confirmed, and the grasper is held firmly by the assistant. The ostomy site is enlarged to a standard stoma size by excising a disk of skin and dividing the fat and fascia vertically. The rectus muscle is split vertically and the posterior fascia and peritoneum are opened. The ileum is gently pulled through the opening, making sure that the site is wide enough to avoid injury to the bowel. This may be facilitated by using

FIGURE 44-10. Laparoscopic ileostomy. Bowel is manipulated to the stomal opening using the laparoscopic Babcock grasper. (From Beck DE. Minimally invasive surgery. In: Beck D, ed. Handbook of Colorectal Surgery. 2nd ed. Copyright 2003 by Taylor & Francis Group LLC (B). Reproduced with permission of Taylor & Francis Group LLC (B) in the format Textbook via Copyright Clearance Center).

a large Babcock clamp and rocking the loop back and forth to see which side is most mobile. Pneumoperitoneum is reestablished with the ileum preventing release of carbon dioxide through the stoma site. Proper orientation is ensured, and then the pneumoperitoneum is released and the stoma is primarily matured.

If the terminal ileum is fixed to the right gutter or the right iliac fossa, mobilization will be required. In this situation, an additional trocar is placed in the left lower quadrant and retroperitoneal attachments and adhesions to the terminal ileum and cecum are freed as necessary to ensure construction of a tension-free stoma. During this dissection, the right-sided grasper is used to reflect the terminal end and cecum toward the upper abdomen to improve visualization, create traction, and facilitate safe dissection. The use of laparoscopy facilitates terminal ileal identification and allows for mobilization of ileal attachments. Numerous articles have attested to its safety and efficiency.<sup>89,90</sup>

### Laparoscopic Sigmoid Colostomy

As in laparoscopic-assisted ileostomy, if the sigmoid colon is redundant and has minimal retroperitoneal attachments, then proper identification and orientation of the sigmoid colon are all that are required. This technique mirrors that described for laparoscopic-assisted ileostomy. If, however, the sigmoid colon is short and relatively fixed, then additional laparoscopic dissection will be required.

### Laparoscopic Sigmoid Colostomy Technique

The patient is placed in the supine position. A rolled towel may be placed underneath the left hip. Both arms are carefully secured at the side and tucked. After prepping and draping, the patient is rotated to the right and placed in moderately steep Trendelenburg position. This facilitates exposure by allowing the small bowel to “fall out” of the left lower quadrant. The abdominal is entered through an umbilical or right rectus port and another port is placed through the premarked stoma site in the left lower quadrant. A 5-mm port is placed in the right lower quadrant and, if necessary, an additional port may be placed in the suprapubic region to facilitate retraction and dissection. The sigmoid colon is identified, grasped, and retracted medially. The sigmoid colon is mobilized from lateral to medial and from the rectosigmoid junction to the mid descending colon. Great care must be taken to protect the retroperitoneal structures including the ureter and gonadal bundle. While the assistant retracts the sigmoid colon medially, the surgeon gently separates the mesentery from the retroperitoneum by pushing the retroperitoneal structures posteriorly and laterally. Once the correct plane is entered, this dissection proceeds fairly easily. If the correct plane is not found, then tearing of the small gonadal and periureteric vessels often occurs. The extent of mobilization necessary varies and so the laxity of the sigmoid mesentery is assessed at regular intervals during the dissection to determine when there is adequate length to complete the exteriorization of the loop. Once the colon is mobilized, an appropriate segment is grasped and pulled up to the abdominal wall at the premarked stoma site. Proper orientation is ensured by carefully noting the proximal and distal limbs and the absence of twists.

The loop is held in place with correct orientation by the assistant with an atraumatic locking grasper placed through the stoma site trocar. The left lower quadrant trocar site is enlarged to a standard stoma size by excising a disk of skin and dividing the fat and fascia vertically. The rectus muscle is split vertically and the posterior fascia and peritoneum are opened. The colon is gently pulled through the opening, making sure that the site is wide enough to avoid injury to the bowel. This may be facilitated by using a large Babcock clamp and rocking the loop back and forth to see which side is most mobile. Pneumoperitoneum is reestablished and proper orientation is ensured. The pneumoperitoneum is released and the stoma is matured as a loop, end loop, or end stoma in routine manner as desired.

Patients resume intestinal activity and diet very quickly, often eating the evening of, or the day after, surgery. Discharge from the hospital is possible as soon as stoma teaching is complete. Multiple studies have attested to the safety and advantages of laparoscopic-assisted colostomy creation.<sup>87,88,90,91,93–105</sup>

### Conclusion

Minimally invasively created ileostomies and colostomies are generally safe and well tolerated. They avoid the need for a major laparotomy and patients resume regular diet and

activities fairly quickly in most cases. They have been shown to be safe and are now often the procedure of choice when a diverting ostomy is needed and no other abdominal procedure is necessary.

### Technical Tips for Difficult Stomas

The creation of a stoma is, in reality, the creation of an anastomosis between the intestine and skin. All principles that apply to formation of anastomoses equally apply to stoma construction. Stomas should be well vascularized, approximated without tension, formed from healthy bowel, and constructed with attention to technical detail. In addition, the stoma should be placed properly, through a trephine of correct size, and created from an intestinal segment appropriate to accomplish the stoma's purpose whether temporary or permanent.

Often this is a simple, straightforward task. However, in emergency situations or in individuals with multiple prior abdominal incisions and operations, an obese abdominal wall, or short thick mesentery creation of a well-perfused, tension-free, properly placed stoma can present a significant challenge. As mentioned, preoperative planning is essential. In a patient with a challenging abdominal wall as a result of obesity or multiple incisions, preoperative marking (often with two alternative sites) may significantly ease stoma creation. For example, a supraumbilical site in the obese abdomen will decrease the thickness of the abdominal wall that must be traversed, therefore improving perfusion and decreasing tension (Table 44-4). A left-sided colostomy is often more difficult to construct than an ileostomy. However, in very obese individuals with significant mesenteric shortening, even an ileostomy can be challenging.

Generally, a supraumbilical stoma site is best for a colostomy because there is less of an abdominal wall pannus and greater colonic mobility. The peritoneal attachments of the left colon are mobilized completely, leaving the colon connected only by its midline blood supply. If this standard mobilization fails to create a tension-free stoma then the following steps, generally in ascending order, will nearly always lead to an acceptable left-sided colostomy (Figure 44-11): 1) the splenic flexure should be completely mobilized; 2) medial peritoneal attachments at the base of the colon mesentery should be transected; 3) the inferior

TABLE 44-4. Technical points for creation of an emergent ostomy

- Gentle handling of the friable bowel and mesentery
- Mobilize as much as necessary to reduce the risk of tension, tearing, and ischemia
- Large fascial opening to accommodate thick bowel and mesentery
- Site the stoma more superiorly than usual to avoid postoperative management problems
- Consider secondary maturation if eversion might be difficult or too time consuming

FIGURE 44-11. Operative measures to obtain left colon length. 1) Division of lateral colonic attachments; 2) division of the splenic flexure; 3) division of the inferior mesenteric artery at its aortic take-off and the inferior mesenteric vein; 4) second division of the inferior mesenteric vein at the inferior border of the pancreas; 5) incision of the splenic flexure mesentery. (From Rafferty JF. Obtaining adequate bowel length for colorectal anastomosis. *Clin Colon Rectal Surg* 2001;14:25–31, permission pending).

mesenteric artery can be transected proximal to the left colonic arterial takeoff to decrease tethering by the colonic blood supply; 4) “windows” should be created in the peritoneum overlying the colonic mesentery just below the stoma to create mesenteric lengthening.

Thickened mesentery associated with the terminal portion of the left colon can be trimmed, leaving only 1 cm (containing the marginal artery) attached to the colon wall. An oversized stoma trephine will decrease tension and venous compression, therefore improving vascularity to the stoma. These maneuvers will usually lead to a well-perfused, left-sided colostomy without tension. In the rare circumstance that, despite these maneuvers, this is not possible, a loop-end or “pseudo-loop” colostomy can be created. Following all previously prescribed maneuvers, the distal or terminal end of the left colon is stapled closed and left in the peritoneal cavity. Through an oversized stoma trephine, the antimesenteric border of the colon several

centimeters proximal to its closed end is brought through the abdominal wall guided by a Penrose drain. The antimesenteric border only is matured primarily to the abdominal wall without eversion (Figure 44-12). This is similar to the “blowhole” colostomy as described by Turnbull many years ago. This leads to a less than ideal, but functional stoma, which will allow recovery in an emergency setting. The stoma can be revised or reversed at a later date at an appropriate period.

Rarely, the bowel to be exteriorized is so edematous, rigid, and friable that sutures will not hold and will only tear and further compromise the bowel. At these times, the Jones technique is of particular usefulness. This is primarily used for end stomas and mucous fistulas. The stoma is brought out through a general fascia opening to avoid tearing and ischemia. At least 5 cm of bowel should sit above the skin. This spout is simply wrapped in a long roll of cotton gauze (Kerlix) which is kept moist. The stoma may be matured in 5–7 days or more at which time the edema will have decreased and the limb will have adhered to the fascia.

Finally, when creating a difficult stoma or if perfusion is a concern, it is occasionally best to create and mature the stoma before closure of the abdominal wall. This will facilitate any maneuvers necessary to create a functional, well-perfused stoma. At times, the barrier of a closed abdominal incision will lead the surgeon to accept a less than adequate result wanting to avoid reopening the abdomen. Technical points are summarized in Table 44-4.

## Appliances Systems

In recent years, the quality and variety of ostomy appliances have increased markedly, and so there is now an appliance for almost every situation. Appliances are available for colostomies, ileostomies and urostomies. Most are disposable and available in one- or two-piece systems (Figure 44-13). The basic appliance has an adhesive faceplate with a central

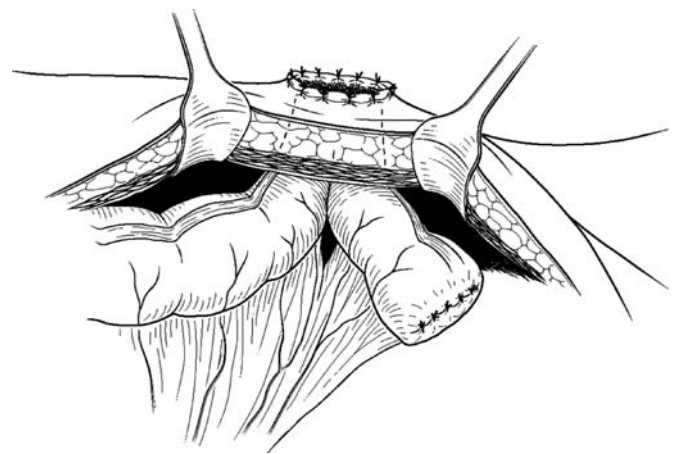

FIGURE 44-12. Trephine loop-end ostomy in patient with obese abdominal wall. (From Cataldo PA. Technique tips for the difficult stoma. *Clin Colon Rectal Surg* 2002;15:183–190, permission pending).

FIGURE 44-13. Ostomy appliances (picture).

opening and a collection piece or “bag.” Most of the two-piece systems are connected by a Tupperware-style plastic ring. The central opening is sized to fit the stoma with a small 2- to 3-mm margin so that it is not too tight and does not erode into the mucosa. The ET/WOCN can assist patients and physicians in product selection.

There are many accessories that may be used with different pouching systems. Belts are available to lend additional support and security, especially during vigorous physical activity. Stoma Protectors may be used to minimize risk of stoma trauma at work or with contact sports. There are many pastes and creams and barrier inserts that may be used in patients with irregular peristomal surfaces or other local problems. Deodorant tablets may be taken orally or placed in the pouch. This is usually not necessary because current pouches are impervious to odor. Spray deodorants may be used in the room in which the appliance is changed. There are also a large variety of undergarments available, ranging from girdles and panties with built-in support panels to underwear with layered pockets to keep the plastic pouch from irritating the skin to sexy lingerie.

### Ostomy Management

The most common problems encountered in the care of ostomy patients are attributed to stoma location and construction. Ostomy appliances should be changed when the stoma is least likely to function, usually before meals in the morning.

Left-sided colostomy patients are candidates to learn the process of colostomy irrigation. Colostomy irrigation is essentially a method of performing an enema through the colostomy to stimulate evacuation and avoid further drainage for a time. The goal of irrigation is not to actually wash the colon out but to stimulate motility and evacuation. This allows more freedom of activity for the patient with little worry of bowel action. Many ostomates may be trained to irrigation once every 1–3 days and a significant number are fairly dry in between.

### Outcome and QOL

Long-term survival is primarily related to the underlying disease process, and many patients with a permanent ostomy live a long life. The overall well being of a patient is difficult to describe. Several measures of *Quality of Life* (QOL) have been developed that attempt to quantify specific areas or *domains* including physical well being and functional status, psychologic function, social interaction, somatic sensation, and sexual function.<sup>106,107</sup>

Recent studies have shown that patients with a well-constructed and managed ostomy often enjoy a very good QOL, and that a stoma may actually be preferable to a poorly functioning anorectum with incontinence, pruritus, odor. In addition, colostomy patients seem to function better than ileostomy patients. This is probably attributable to the less-frequent and more-formed output of the colostomy.<sup>108</sup> Of all ostomy patients, those with a colostomy who irrigate regularly have the best results in terms of confidence and participation in activities.<sup>109</sup> QOL improves markedly after surgery in all patients with inflammatory bowel disease and seems to improve over time in most patients.<sup>110</sup> Patients undergoing colostomy for cancer continue to worry about the risk of cancer recurrence and are less concerned about the consequences of the stoma.<sup>108,111–113</sup> “Lifestyle” is altered in between 40% and 80% of patients, especially those with ileostomies. Severe restrictions may be present in up to 10% of patients and mild to moderate restrictions in 30%–50%.<sup>109,114</sup>

Several studies have highlighted the importance of preoperative and postoperative counseling by an ET/WOCN. All patients improved their QOL after stomatherapy and this intervention seems to be most important during the first 3–6 months after surgery.<sup>109,110</sup>

Although most patients with major spinal cord injuries develop regular bowel habits with the standard management programs, some develop chronic bowel dysfunction with constipation, impaction, and incontinence. Colostomy has been performed in some of these patients as a last resort. Evaluation of these patients reveals that the large majority have a significant improvement in their QOL scores, that hospitalizations for bowel dysfunction may be reduced by 70%, and most wished they had undergone the procedure sooner. The colostomy resulted in simplified bowel care routine, less time spent on bowel management, and increased independence.<sup>115,116</sup>

## Conclusions

Although permanent ostomies are becoming less common, they are still occasionally necessary. Temporary ostomies including loop ileostomies and colostomies, divided ostomies, and Hartmann procedures are still used quite often. The construction, care, and closure of stomas are major areas of concern for the general and colorectal surgeon. Patients are more aware of this aspect of their surgery than almost anything else. Thus, attention to this aspect of surgical care is critical. Appropriate preoperative preparation and postoperative support are necessary for all patients undergoing ostomy surgery. Early referrals to an ET/WOCN and the United Ostomy Association are very helpful.

## Stoma Complications

Neil Hyman and Richard Nelson

Despite substantial advances in surgical technique and enterostomal therapy, complications after stoma creation remain extremely common. The rate of stoma-specific complications in the literature varies quite widely, ranging from 10% to 70% depending on the methodology of the study, the length of follow-up, and the definition of a “complication.” For example, virtually all ostomates will have at least transient episodes of minor peristomal irritation and skin irritation is the most frequently reported stoma complication. Studies only reporting problems that require revisional surgery will obviously report a much lower rate of complication. As such, the relative incidence and frequency of the specific complications will tend to be quite variable from series to series.

Stoma-related complications may be classified as those that are metabolic or best managed by medical intervention and those that have a purely structural etiology and are best managed by surgical intervention. Among the medical complications, the most common early complications are peristomal skin irritation, leakage, high output, and ischemia. The most frequently reported late complications include dehydration and nephrolithiasis, cholelithiasis in ileostomy patients, bleeding in patients with liver disease, and of course also in those with recurrence of the disease for which a stoma was created, such as Crohn’s disease. In this chapter, we will make some general comments about the incidence and nature of stoma complications. We will then review the specific problems of a high-output stoma, parastomal dermatitis, bowel obstruction, and later complications such as stoma stenosis, peristomal hernia, and stomal prolapse.

### Incidence

The prevalence of intestinal stoma complication has been assessed in a number of publications. From Cook County Hospital, the incidence of stoma complications was recorded in 1616 patients.<sup>1</sup> A total of 34.2% of these individuals experienced a complication related to their stoma, 27.7% of

those individuals having an early complication, and only 6.5% a late complication. This publication also assessed the location of various stomas and their risks of complication. The location with the highest risk was loop ileostomy with a rate of almost 75%. The only other stoma location to have a complication rate exceeding 50% was descending end colostomy with 65%. The location of an intestinal stoma with the lowest risk was an end colostomy of the transverse colon, in which 69 individuals had an overall complication rate of only 5.8%.

In a publication from Hong Kong, the specific type of complication associated with each stoma location was described.<sup>2</sup> Parastomal hernia was most often seen with an end sigmoid colostomy in that series, although it was prevalent with all stoma types except ileostomy. Stomal stenosis was seen more often with a loop sigmoid stoma, prolapse with a transverse colostomy, and skin excoriation with an ileostomy. This series included 322 stomas in 316 individuals. Risk factors leading to these complications have been assessed in several publications, including a case series from Holland, in which emergency stoma construction was significantly associated with both stomal necrosis and high stoma output.<sup>3</sup> Obesity was associated with an increase in stoma necrosis. Among the leading diseases needing stoma formation, Crohn’s disease and colonic ischemia were both associated with increased risk for ostomy-related complications. Crohn’s disease was more prevalently associated with retraction and ischemia causing stoma necrosis. The series included 345 stomas in 266 patients.

In reports from Louisiana State University in New Orleans<sup>4</sup> and Swansea in the United Kingdom,<sup>5</sup> logistic regression was done to assess which risk factors were independently associated with complications. In the former study, inflammatory bowel disease and obesity both were associated with higher risk. A preoperative visit by an enterostomal nurse was associated with a significantly lowered risk of complications. In the latter publication, emergency surgery was usually associated as an independent risk factor for finding a stoma in a skin crease and early skin excoriation. Diabetes was associated with later skin problems.

## Skin Problems

### Skin Irritation/Leakage

Skin irritation (Figure 45-1) is very common among patients with a stoma. The problem is far more often seen in patients with an ileostomy because of the liquid, high alkaline, active enzymatic caustic effluent<sup>6</sup>; this highlights the need for proper technique when an ileostomy is created. Nugent et al.<sup>7</sup> describe the results of a study using quality of life questionnaires in 391 ostomates. Fifty-one percent reported problems with a “rash” and 36% had experienced leakage, both of which were much more frequently seen with ileostomies than colostomies. Thirty percent of patients with a colostomy and 55% with an ileostomy had experienced a reaction to the adhesive. However, only 8% of ostomates reported a substantial degree of difficulty associated with skin irritation.

Although a minor degree of skin irritation on occasion is probably inevitable, most significant cases of skin irritation are potentially preventable. Preoperative marking by an enterostomal therapist can help assure proper siting and a secure fit. Appropriate location and careful appliance fitting minimizes the noxious, irritating effect that can be associated with leakage on unprotected peristomal skin. Patients also need to be monitored for allergic reactions to the components of the appliance. An adequate spigot with a close-fitting faceplate prevents exposure of the peristomal skin to the ileostomy effluent. However, even the best-fitting appliances around the best-made stoma will leak if frequent emptying of the appliance is not practiced and pooling of effluent around the base of the stoma occurs.

Particular attention must be given to older patients who may have limitations in eyesight or dexterity. Patients with a high-output stoma are at particular risk for skin irritation and ulceration if they do not have an appropriately fitted

appliance. Obesity has been frequently reported to be associated with an increased risk of skin irritation, which is likely attributable to technical problems with stoma construction.<sup>8</sup> Strong consideration should be given to placing the stoma in the upper abdomen where there is typically much less creasing of the abdominal wall, subcutaneous fat, and the patient can see it much more readily.

The patient should be instructed to avoid creams or ointments that may interfere with the adherence of their appliance. In the postoperative period, a stoma will tend to become less edematous and the abdomen becomes less distended. As such, it is quite common to need to “downsize” the appliance at the first postoperative visit to minimize exposed skin. Changing a stoma too frequently may lead to excessive “wear and tear” on the parastomal skin; however, too long an interval between changing the appliance may be associated with erosion of the protective barrier.

Even with the help of an excellent enterostomal therapist, specific skin infections may occur. Fungal overgrowth is evident when there is a bright red rash around the stoma with associated satellite lesions. This is typically easily treated by dusting the peristomal skin with an appropriate antifungal powder. If the dermatitis conforms precisely to the outline of the stoma appliance, then an allergic reaction to the wafer or other component of the appliance is likely the culprit (Figure 45-2). Peristomal skin irritation may also be associated with reactivation of inflammatory bowel disease, or the development of pyoderma gangrenosa. Antibiotics, steroids, release of appliance pressure, and local applications of epidermal growth factor have all been tried to resolve the pyoderma. There is no correlation with Crohn’s disease activity in remote portion of the bowel and the occurrence of pyoderma around the stoma.

FIGURE 45-1. Stomal skin irritation.

FIGURE 45-2. Allergic skin reaction.

## High-output Stomas

A high-output state is typically described in association with an ileostomy, rather than a colostomy. Marked diarrhea and dehydration occur in 5%–20% of ileostomy patients, with the greatest risk occurring in the early postoperative period. An ileostomy usually functions by the third or fourth postoperative day.<sup>6</sup> The output typically peaks on the fourth postoperative day, with outputs of 3.2 L or more reported. Because the ostomy effluent is rich in sodium, hyponatremia can be a problem. The particular window of vulnerability for dehydration seems to be between the third and eighth postoperative day. However, in time, the small bowel typically adapts and there is a steady decrease in ostomy output. However, patients with an ileostomy, particularly those who have had concomitant small bowel resection, remain at risk to become dehydrated. Most often, this is easily managed by oral rehydration with one of the commonly available sports drinks. However, patients who have lost considerable absorptive surface because of previous bowel resection and/or those with recurrent/residual active Crohn's disease are at particular risk. In addition to the loss of absorptive surface area, ileal resection also removes the fat or complex carbohydrate stimulation of the so-called "ileal brake" which slows gastric emptying and small bowel transit.<sup>9</sup> Fluid and electrolyte maintenance in these patients may require a period of parenteral hydration and nutrition. Elements of the diet can augment output and should be avoided in marginal cases. These might include foods high in sugar, salt, or fat.

Ileostomy diarrhea may be treated in its milder forms with fiber supplements or cholestyramine which can thicken secretions, but not change water content. Often opiates may be required to slow intestinal transit. In refractory cases, somatostatin analog has been used with some success. Somatostatin reduces salt and water excretion and slows gastrointestinal tract motility. However, its clinical usage has met with variable results.<sup>10,11</sup> Special mention is made of patients with a proximal ostomy required to treat complications of an anastomotic leak. Good results have been reported with exteriorizing the leak and reinfusing the ostomy effluent into the downstream limb until gastrointestinal continuity can be restored. This has led to weaning parenteral nutrition in a substantial number of patients.<sup>12</sup>

## Nephrolithiasis

A related problem in patients with an ileostomy is the development of urinary stones. The obligatory loss of fecal water, sodium, and bicarbonate reduces urinary pH and volume.<sup>13</sup> Whereas approximately 4% of the general population develops urinary stones, the incidence in patients with an ileostomy is approximately twice that. Whereas uric acid stones comprise less than 10% of the calculi in the general population, they comprise 60% of stones in ileostomy patients. There is also an increase in the incidence of calcium oxalate stones,<sup>14</sup>

and as a result, foods high in oxalate, such as spinach, should be avoided by ileostomates.

## Bowel Obstruction

Life table analyses suggest that bowel obstruction is a rather common complication of ostomy creation. As many as 23% of patients with an ileostomy have been reported to develop bowel obstruction. Adhesions are probably the most common cause, but small bowel volvulus or internal hernia may also be the cause. Although it is frequently mentioned that suture of the mesentery to the lateral abdominal wall may prevent volvulus or obstruction, retrospective analyses have not shown any benefit to this maneuver. Treatment is not dissimilar to other patients presenting with a mechanical small bowel obstruction.

However, special note must be made of food bolus obstruction. Many patients with an ileostomy will develop signs and symptoms of bowel obstruction because of the accumulation of poorly masticated or digested food (e.g., popcorn, peanuts, fresh fruits, meat, and vegetables). A careful history may reveal dietary indiscretions. Furthermore, the possibility of a food bolus obstruction should be considered in any patient with an ileostomy who has radiologic evidence of a distal obstruction. A well-lubricated finger can be gently inserted into the stoma to feel for impacted material. A red rubber catheter is inserted gently into the ostomy and saline irrigation initiated. If suspicious concretions begin to pass into the stoma, the irrigations may be carefully repeated until the obstruction is relieved. A water-soluble contrast enema through the obstructed stoma may also be both diagnostic and therapeutic by dislodging the bolus.

## Ischemia

Edema and venous congestion are very common after stoma creation because of mechanical trauma and compression of the small mesenteric venules as they traverse the abdominal wall. This is typically self-limiting and requires no treatment. However, stomal ischemia (Figure 45-3) is more serious and often related to tension on the mesentery or excessive mesenteric division, particularly in obese patients. A stoma of questionable viability may be examined by insertion of a glass test tube or flexible endoscope into the stoma. If the stoma is viable at fascial level, then the patient may be carefully observed. However, if there is question about the viability of the stoma at fascial level, immediate laparotomy and stoma revision is required. Early ischemia is seen in 1%–10% of colostomies and 1%–5% of ileostomies.<sup>15</sup> Stomas do not get better once the patient is awake, but generally only get worse in the early postoperative period. Every effort must be made at construction of the original stoma to make one of perfect-appearing viability, assuring good blood flow in and out to the skin. It never takes as long to do this as it does to manage an ischemic or necrotic stoma.

FIGURE 45-3. Stomal ischemia.

### Late Hemorrhage

Late stomal bleeding may be caused by direct trauma, but heavy bleeding is, especially from an ileostomy, caused by portal hypertension and the development of stoma varices. Many therapies have been described for this, but none subjected to rigorous clinical trials. Correction of coagulopathy and direct pressure are important first steps. Whether direct treatment by injection sclerotherapy or systemic treatment by some form of porto-systemic shunt provides better short- and long-term outcome is undecided. The placement of a trans-hepatic intrahepatic portal shunt (TIPS) is a nonoperative alternative that should be considered. Ostomy revision does not provide a lasting solution.

### Surgical Complications

Surgical complications of intestinal stoma formation can broadly be divided into those that occur early, those that occur long (late) after their construction, and those that occur at stoma closure. Early complications of stoma construction include necrosis, retraction (Figure 45-4), skin irritation, small bowel obstruction, surgical wound infection, and sepsis. Late complications are dominated by prolapse (Figure 45-5), peristomal hernia, skin irritation, and fecal fistula. Closure-related complications include surgical wound infection, fecal fistula, anastomotic dehiscence, small bowel obstruction, and incisional (peristomal) hernia (Figure 45-6).

The prevention and management of each of these complications are best assessed in randomized, controlled clinical trials. A total of 18 randomized trials have been performed in some way related to stoma construction<sup>16-32</sup> (Table 45-1). The most common study design has been randomization of patients to receive either temporary loop colostomy or loop ileostomy, then following these patients for various complications.<sup>16-20</sup> The operations for which these stomas were

FIGURE 45-4. Stomal retraction.

done were either low anterior resection for carcinoma or a mixture of colonic procedures related to both cancer and diverticular disease. Table 45-2 shows a metaanalysis of each of the complications that have been assessed in some or all of these publications. These analyses show that the only significant difference between the two stoma locations was an increased risk of stoma prolapse associated with loop colostomy. In the other cases, there was no significant difference in the risk of complications listed in Table 45-1. Statistical heterogeneity did not exist for any of these calculations, validating the metaanalysis. The risk of overall complication is perhaps less in all these studies because these were temporary stomas. A much more thorough metaanalysis has recently been published.<sup>33</sup>

FIGURE 45-5. Stomal prolapse.

FIGURE 45-6. Peristomal hernia.

## Stoma Closure

Looking at the other end of a stoma's history, there are two randomized trials that compared stapled anastomosis to hand-sewn anastomosis during stoma closure, the first in patients who had an ileostomy closure after ileo pouch anal reconstruction<sup>21</sup> and the second in a more mixed group of surgical patients.<sup>22</sup> The only complication cataloged in both trials was the risk of small bowel obstruction subsequent to closure. The risk of obstruction was significantly less in the metaanalysis in patients having stapled closures as opposed to hand-sewn (Table 45-2). There was also no statistical heterogeneity in this analysis. Time to flatus was reported to be less among the stapled closure patients in the first trial, although length of hospital stay was equivalent in both studies. In the second trial, the risk of fecal fistula and surgical wound infection was slightly lower among those patients having a stapled closure.

It is common practice to wait a minimum of 1.5–3 months before closing an intestinal stoma after its construction. This practice was assessed in a randomized trial related to trauma laparotomy patients having temporary colostomies. Patients were randomized to either early or late stoma closure. The average length of time for closure in the early group was 11.8 days and in the late group 104.8 days.<sup>23</sup> There was no overall difference in complications between these two groups, nor individually for fecal fistula, small bowel obstruction, or surgical wound infection. The last six trials listed in Table 45-1 compared either patients getting a stoma with patients not getting a stoma or various types of stoma construction and resection in complicated large bowel obstruction. Unfortunately, stoma-related complications were not reported in any of these trials.

## Parastomal Hernia

Regarding surgical management of each of the complications listed in Table 45-1, there are regrettably no informative randomized trials. There are many case reports and case series, but these are seldom presented with the comparison group that allowed quantitative assessment of the efficacy of the procedures being described. Therefore, opinion concerning

the treatment of prolapse, hernia, retraction, or necrosis is anecdotal and not evidence based.

The difficulty in choosing the right therapeutic approach is best described in a thorough review by Carne et al.<sup>34</sup> of parastomal hernia, a condition that is a useful surrogate for all the other stoma-related complications. In that review, incidence of hernia is described to occur in anywhere from 0% to 48.1% of individuals. Much of this variation is clearly attributable to definition, because some herniation (similar to some degree of hemorrhoids) can be seen in many patients, whereas more conservative observers would only describe a hernia that prevents the patient either from maintaining the appliance over their stoma or one that causes obstructive symptoms. The risk of recurrence is also well discussed in this review. It is found to be so prohibitively high that it seems best to be conservative in undertaking operative repair, limiting surgery only to those most symptomatic patients.

Prevention of parastomal hernia includes discussion of the following parameters: the site of the stoma related to the rectus muscle, the size of the abdominal aperture, the use of prophylactic mesh implantation at various levels in the abdominal wall, transperitoneal versus extraperitoneal tunneling of the stoma, and fixation of the stoma to the abdominal fascia. Of interest in this review is that there are six cited studies that have examined whether or not a stoma should be placed lateral to the rectus border to prevent hernia. Most authors found that it made no difference.

The prophylactic use of mesh wrapped around the stoma has in fact been subjected to one randomized trial in patients getting permanent intestinal stomas.<sup>25</sup> Among 54 patients, none with the mesh developed hernia, whereas 8 of 27 without mesh did. There was no small bowel obstruction in any of these patients. Other case series of prophylactic mesh use have described both stomal stenosis and erosion and infections related to mesh placement, which have tended to make this not a very popular technique.

The options available for repair of parastomal hernia include direct local tissue repair, resiting of the intestinal stoma with closure of the primary aperture, and the application of mesh around the stoma at various levels within the abdominal wall. Once again there are no randomized trials comparing any of these techniques. Three techniques, colon fascia repair, mesh, and relocation in a small series were assessed in a nonrandomized trial. Surgical wound infection was more common when mesh repair was used and recurrent hernia much more common when there was just direct fascial repair around the stoma.<sup>35</sup>

All of the operations that have been described to repair parastomal hernia can be applied to patients with prolapse, retraction, and skin irritation associated with flush ileostomy. In addition, for patients with prolapse, local amputation and reanastomosis can be used, often with low morbidity. The best operation to perform in individuals having significant complications is closure of the stoma and restoration of intestinal continuity. This should be done whenever possible.

## Conclusions

In conclusion, none of the risk factors listed for stoma complications at the beginning of this chapter (obesity, emergent construction, diabetes, Crohn's disease, ischemic colitis) are actually within the control of the operating surgeon except for the role that an enterostomal nurse has in preoperative assessment of stoma patients. Second, in choosing the type of intestinal stoma to perform, the retrospective studies and randomized study often conflict. Ileostomy would seem to be more at risk for complication than the case series,<sup>1</sup> yet loop colostomy clearly is associated at least with increased risk of prolapse in the randomized trials.<sup>6-10</sup>

Randomized clinical trials are difficult to perform. They are expensive, they take a great deal of time and effort, and recruitment of participants is often painfully difficult. But this study design is the most valid means of determining the efficacy of any therapeutic intervention. Table 45-1 demonstrates the feasibility of doing randomized trials in a number of clinical settings related to intestinal stomas. Yet relating to the treatment of complications of intestinal stomas (not their initial construction) there are none. There are enough individuals that have intestinal stomas and enough surgeons who need to know how to prevent these very prevalent complications to answer all of the unanswered questions related to stoma complications.

## Incontinence

Cornelius G. Baeten and Han C. Kuijpers

Fecal incontinence is the inability to control feces and to expel it at a proper place and at a proper time. To understand incontinence it is good to know how humans are able to be continent. Many factors contribute to the ability to control feces.<sup>1</sup> The consistency of the feces is important. Firm stool can be controlled much easier than liquid stool. The peristalsis in rectosigmoid has a role in keeping the rectum empty, for most of the time. This special antiperistaltic movement in the original rectosigmoid explains why patients with low anterior resection often have urgency and difficulties controlling their stool because they miss this part of the bowel. The rectal capacity is important to store feces for some time. A nondistending rectum gives frequent urgency and leads to loss of stool when there is no toilet available. The pelvic floor muscles are of help to form a barrier when they are contracted and help during defecation to open the anus. The internal anal sphincter is consistently contracted and gives a watertight closure of the anal canal with the help of the hemorrhoidal tissue that fills the opening of the anal canal. The sensibility of rectum and anus gives awareness of stool in the distal rectum and activates the contraction of the external sphincter as additional help for the internal sphincter. The central nervous system has to be intact to govern the sensoric input and the motoric output. Malfunction is obvious in small babies whose brain is not developed enough, or in demented people despite a normally functioning anorectal unit. All these factors form a delicate system to keep the human continent. When something goes wrong in one of these factors, it is dependent on the quality of the other factors whether this leads to incontinence. Next to these factors there is also the cultural background that determines whether or not it is embarrassing to lose stool. In Western society it is normal to defecate in a private secluded location. In China, community toilets are very common. In other societies, defecation on demand is very well accepted, for example, in the court of the Roy Soleil in 18th century France. So culture determines whether loss is accepted as normal or not.

Fecal incontinence forms an enormous economic problem for society. In younger people it often means loss of jobs and

dependency on social welfare. For older people the costs of admission in a nursing home are high. When patients stay at home and ultimately want to be treated for this condition, the costs are still high. Also, protection with diapers and pads, medication for skin protection, treatment for psychologic depression, and the use of constipating agents may consume a considerable part of medical resources.<sup>2</sup>

### Symptoms

Fecal incontinence is a frequent problem but very much underreported because of embarrassment. It is not a diagnosis but a symptom of different causes. It is a socially devastating disorder, which affects at least 2.2% of community-dwelling adults and 45% of nursing home residents.<sup>3</sup> Fecal incontinence forms the most important reason to place patients in a nursing home.

Because of the social stigma surrounding the loss of bowel control, the complaint is often not directly voiced. The patients become so embarrassed that they do not seek medical advice but rather become confined to their homes and are afraid to visit family and friends. Perineal pads are often inefficient and unacceptable. Many suffer from social isolation and loss of self-esteem. The psychologic impact is devastating. They often conceal their problems by complaining of chronic diarrhea, defecation problems, or rectal urgency. Most incontinent patients can be helped, but physicians are poorly informed about treatment options. A thorough history is therefore essential in assessing patients with fecal incontinence.

At first, a precise characterization of what is meant by incontinence should be evaluated. Flatus, involuntary passage of gas, is often the first, sometimes the only, symptom. Increasing degrees of severity involve loss of liquid stools followed by loss of solid feces. Partial incontinence may be defined as uncontrolled passage of gas and/or liquids and complete incontinence as the uncontrolled passage of solid feces.

Soiling is a bothersome disorder characterized by continuous or intermittent liquid anal discharge. It should be

differentiated from discharge due to fistulae, proctitis, and prolapse. Patients complain about stains in their underwear. They often wear sanitary napkins or tissues. The discharge causes inflammation of the perineal skin with excoriation, perianal discomfort, burning sensation, and itching. It usually indicates the presence of an impaired internal sphincter function or a solid fecal mass in the rectum.

Pseudoincontinence and encopresis are the involuntary loss of formed, semiformed, or liquid stool associated with functional constipation in a child. Pseudoincontinence is caused by anatomic disorders such as a mega sigmoid or anal stenosis whereas no anatomic abnormalities are found in encopresis. The most common cause of encopresis is functional fecal retention defined by a history of more than 12 weeks of passage of less than two large-diameter bowel movements per week, retentive posturing, and accompanying symptoms such as fecal soiling. Sometimes it is associated with enuresis and urinary tract infection. The persistent fecal incontinence frequently brings ridicule and shame to the affected child.

An assessment of bowel habit is essential. Is there diarrhea, and how often? Irritable bowel syndrome should be excluded. It is a common functional bowel disorder characterized by intermittent abdominal pain and changes in defecation pattern in the absence of other medical conditions with similar presentations. Physical findings and currently available diagnostic tests lack sufficient specificity for clinical use. The diagnosis is based on characteristic clinical findings and the exclusion of other disorders. Episodes of diarrhea and constipation alternate. Incontinence often occurs as a consequence of diarrhea.

Urgency refers to patients with a need to defecate immediately at the risk of incontinence when facilities are absent. It is seen in patients with impaired rectal compliance as in proctitis or after low anterior resection, or with impaired sphincter function. Assessment of the severity of incontinence is important. Details of frequency, stool consistency, and frequency of defecation should be evaluated. An incontinence score may be helpful in this. The severity of incontinence can be described in scores of the many incontinence-scoring lists. The most used scoring lists at the moment are the Vaisey and the Wexner index.<sup>4</sup> They give not only a value for the loss of gas, liquid, and solid stool, but also for the impact on daily life. Almost all severity indexes score on the frequency of loss of gas liquid and solids. Many patients change their lifestyle and stay at home, close to the toilet. This means an underestimation of the frequency of loss of feces. It is possible, in the extreme, that they do not lose anything and are considered continent despite their complaints.

The best way to get information is a combination of severity index, special quality of life questionnaires (FIQOL) developed by the American Society of Colon and Rectal Surgeons and anamnesis. Is there passage of stool without the patient being aware of it or is he aware but unable to control it? Is there a regular use of laxatives or other medications that

promote diarrhea or constipation (fecal impaction)? A sexual history should be obtained. Regular anal sex leads to internal sphincter dilatation and soiling. A careful obstetric history should be taken noting multiparity, forceps assistance, difficult childbirth and perineal tears. Specific inquiry should be made concerning perineal trauma and anorectal surgery. Previous prolapse surgery, urinary incontinence, and the presence of prolapses should be noted because they often occur in pelvic floor denervation. A history of neurologic disorders is essential. The presence of central nervous system disorders, peripheral neuropathy, low back injury, and diabetes mellitus should be established. Is the patient immobilized or bedridden? A history of large or small bowel resection, pelvic irradiation, or inflammatory bowel disease should be recorded.

## Causes of Incontinence

### Congenital

Anorectal anomalies represent a spectrum of defects. The anal canal is often absent. Most patients have different degrees of development of the pelvic muscle structures and consequently different degrees of rectal proprioception. There may be rectal communication with the urinary tract or vagina. A significant number of these children suffer from fecal and urinary incontinence, and sexual inadequacy. Patients with low forms of anorectal agenesis have little impairment in continence after early surgery whereas patients with high defects affecting the pelvic floor, the rectum, and urogenital tract, are usually incontinent. The various operative procedures depend on the type of deformity. The ultimate goal is to create a perineal opening with adequate sensory and motor control. They are a continuing challenge for the pediatric surgeon. Control of defecation after surgical correction of high and intermediate types of congenital anorectal malformations is difficult. Most adults with high anorectal malformations who have undergone abdominoperineal or direct perineal repair have severely defective fecal continence and poor quality of life.<sup>5</sup> Major advances in the management of these children have occurred during the last 10 years. The posterior sagittal approach has led to a better understanding of the internal anatomy of these defects, and a more rational way to manage the patients. Voluntary bowel movements are achieved in 75% with occasional soiling in 40%. Common sequelae are constipation and urinary incontinence after the repair of cloacas. Fecal incontinence occurs in 25% but can adequately be managed by bowel management programs.<sup>6</sup> These results are not generally accepted; some state that the posterior sagittal approach for high and intermediate anorectal malformations does not give better functional results than the pullthrough operation. The presence or absence of sacral defects has a role in the prognosis.<sup>7</sup> A detailed explanation of the operative technique is beyond the scope of this chapter.

Fecal incontinence is common in patients with spinal cord lesions such as spina bifida and meningocele. Constipation is another major stigma. The congenital defects in the lumbosacral spine disturb the sensory and motor nerves supplying the skin and pelvic floor muscle. The sensory and motoric functions are impaired or absent, compromising the dynamics of continence. Frequently, colonic motility is delayed and pudendal neuropathy is always present. Rectal sensation is reduced and anal squeeze pressure impaired or absent.

### Pelvic Floor Denervation

The pelvic floor muscle is innervated by the pudendal nerves and by the S3 and S4 branches of the pelvic plexus. Intense and recurrent straining, as in difficult childbirth and constipation may lead to stretch-induced injury of the pelvic floor innervation, especially the pudendal nerves. Irreversible injury occurs when nerves are stretched as little as 12%. Histologic studies of the pelvic floor muscles in these cases reveal changes consistent with denervation and reinnervation, in the most abnormal showing only a few remaining fibers with myopathic features scattered in a matrix of fibrous tissue.<sup>8</sup> This muscle fiber loss is associated with weakness of the pelvic floor and with incontinence.

Similar manometric and electromyographic features have been found in normal elderly women and men suggesting a normal age-related denervation with a compensatory reinnervation of the pelvic floor muscle. Although increased pudendal nerve terminal motor latency may indicate that neuropathy is present, normal pudendal nerve terminal motor latency does not exclude weakness of the pelvic floor.<sup>9</sup>

### Obstetric

There are two ways by which vaginal delivery may damage the pelvic floor and anal sphincters. The first one is direct mechanical tear of the anal sphincters, a serious complication of childbirth. The incidence of obstetric tears varies from 0.6% to 9%.<sup>10,11</sup> Occult injuries, visualized by endoanal ultrasonography, have been reported in 20%–35%.<sup>12,13</sup> Defects of the external anal sphincter have traditionally been diagnosed by palpation and electromyography but anal endosonography enables clear imaging of both the internal and external sphincter muscles. Factors that affect the risk for developing obstetric tears are use of forceps, mediolateral episiotomy, and primiparity.<sup>14,15</sup> Sixty percent of patients with an obstetric tear also have evidence of pudendal nerve damage.<sup>16,17</sup> The other mechanism is pelvic floor denervation resulting from compression or traction injury to the pudendal nerves during vaginal delivery, particularly when it is prolonged or requires forceps assistance. Birth weight also correlates. Assessment of pudendal nerve function is important in women with post-

partum fecal incontinence because it can influence treatment options.<sup>18</sup>

### Iatrogenic

Fecal incontinence is a frequently neglected but rather common complication of anorectal surgery. The incidence increases to 30%–50% after partial internal sphincterotomy<sup>19,20</sup> and fistulotomy<sup>21–24</sup> with soiling being the most common complaint occurring in 35%–45%. Local sphincter lesions and intraanal scarring (keyhole deformity) are not the sole explanation for the high incidence of incontinence because it also occurs after non-muscle-cutting anorectal surgery such as anal stretch,<sup>25</sup> hemorrhoidectomy,<sup>26</sup> and transanal advancement flaps.<sup>27–30</sup> The internal anal sphincter is easily damaged with an anal retractor used to gain access to the anal canal and lower rectum. This excessive dilatation of the anal canal results in a serious damage of the internal sphincter resulting in a decrease of resting pressure. The Park's anal retractor is especially, notorious for this.<sup>31,32</sup>

Low anterior resection compromises anorectal function. Postoperative continence is even poorer after radiochemotherapy.<sup>33</sup> Anal sphincter function is preserved but neorectal capacity, maximum tolerable volume, and rectal compliance are reduced resulting in an increased stool frequency, and episodes of incontinence and soiling.<sup>34,35</sup> Colonic pouch construction has gained increasing popularity in reconstruction after low anterior resection because it offers superior long-term function compared with low straight or side-to-end colorectal anastomosis.<sup>36,37</sup>

### Traumatic

Fecal incontinence caused by trauma is uncommon. Causes include military or traffic accidents complicated by pelvic fractures, spine injuries or perineal lacerations, insertion of foreign bodies in the rectum, and sexual abuse. There is often extended destruction of the sphincter complex and pelvic floor complicated by pelvic nerve injury. Immediate recognition is vital to a successful outcome and may obviate the need for a diverting stoma. Evaluation must include a search for involvement of other structures and an evaluation of the anal sphincters. Foreign bodies most often do not cause significant anorectal injuries. Extraction of these diverse objects requires ingenuity. Superficial injuries may be left open or sutured closed.<sup>38</sup> Anal intercourse is associated with reduced resting pressure in the anal canal and an increased risk of anal incontinence.<sup>39</sup>

### Radiation

More than three-quarters of patients receiving pelvic radiotherapy experience acute anorectal symptoms and up to one-fifth experience late-phase radiation proctitis. Many of these

symptoms are self-limiting, and mucosal complications may often be treated by nonsurgical methods such as topical formalin application, endoscopic argon plasma coagulation, and hyperbaric oxygen therapy. Approximately 5% develop other chronic complications, such as fistula, stricture, and disabling fecal incontinence.<sup>40</sup> Structural abnormalities and septic complications are likely to require surgery. Varying degrees of destruction of the muscular components of the rectum and anal canal occur leading to muscle damage and radiation enteritis. Causes of radiation-induced incontinence are proctosigmoiditis, small bowel injury, fistula formation, reduced rectal capacity, diminished internal and external sphincter function, and rectal mucosal sensitivity.<sup>41–43</sup> These are the results of progressive changes in the connective tissues and vasculature resulting in fibrosis, ulceration, stricture, and fistula formation. Conservative treatment options are of limited value. Surgery may be considered if symptoms are severe, provided sphincter function is adequate and recurrent disease is excluded. When the condition becomes intolerable, colostomy is the last resource. Symptoms progress over time. Large prospective studies with accurate dosimetric data and long-term follow-up are needed to provide meaningful information on which to base new strategies to minimize the side effects from radiotherapy. Modern techniques in the delivery of radiotherapy will help minimize the likelihood of rectal complications.

## Physical Examination

Clinical examination is of paramount importance in the evaluation and management of incontinent patients. It should enable the physician to derive an appropriate strategy of treatment. Routine abdominal examination should be performed. The presence of scars should be noted. Neurologic assessment should be done when there is suspicion of neurologic disorders. At first, the physician should explain to the patient what to expect during the examination in an effort to allay embarrassment and anxieties. Observation should be made of whether the patient wears a pad or whether there are signs of fecal soiling on the underwear. Several positions may be used for anorectal examination. For patient comfort, the left-lateral position may be preferred above the knee-chest position. The kneeling prone-jackknife position gives the best exposure. Inspection of the perineum may reveal perineal soiling, excoriation, a patulous anus, an ectropion, a keyhole deformity, or other anal deformities. The physician should inspect for evidence of scars from previous operations or trauma, fistulas, hemorrhoids, or prolapse. The perineum should also be inspected while the patient is bearing down to observe for mucosal or complete rectal prolapse. Perineal descent is present when the perineum balloons during straining. It is a physical sign of weakness of the pelvic floor and is often seen in the descending perineum syndrome and pelvic floor denervation. The most prevalent abnormality of descending

perineum syndrome on testing is perineal descent  $>4$  cm.<sup>44</sup> Digital rectal examination should assess the degree of anal resting tone, a function of the internal sphincter. Anal scars should be palpated to determine if it is soft or whether there is induration suggestive of residual inflammation. Normally the anal canal is closed snugly around the examining finger. Decreased tone may be noted if there is a rectal prolapse, a history of previous anorectal surgery, fecal incontinence, or repeated anal intercourse.

The increase of anal tone during squeezing, a function of the external sphincter, should also be noted. Digital estimation by an experienced examiner is equally as good as assessment of anal sphincter function with anal manometry.<sup>45</sup> It is a poor predictor of exact canal pressure but a patulous anus can easily be discriminated from an actively contracting sphincter. Anal manometry provides more objective data. Simple lateral retraction of the buttocks or downward pulling of the puborectalis are other methods to reveal a patulous anus. Digital examination of the vagina should be performed to check for vaginal prolapse, rectoceles, cystoceles, or enteroceles. An impaired sphincter tone during bearing down is found in incontinence and descending perineum syndrome. The sphincter complex and perineal body can be assessed by bidigital anovaginal examination (the thumb in the vagina and the index finger in the anorectum). An empty and destroyed anterior perineal body is suggestive for an obstetric sphincter lesion. The puborectalis muscle can be palpated bilaterally and posteriorly as a prominent sling passing around the rectum thus creating the anorectal angle that is normally  $90^\circ$ . During bearing down, the dorsal transverse bar should flatten out as a sign of pelvic floor relaxation. Paradoxical contraction suggests anismus. Inserting the index finger into the rectum and pushing the anterior wall forward and downward into the vagina can demonstrate a rectocele. Impacted feces can be felt in the lower rectum. When the gloved finger is withdrawn it should be inspected for blood and color of stool. Description of findings should be recorded adequately. The "o'clock" position requires a known patient position; recording in an anatomic manner (anterior, posterior, right, left) is a better alternative.

## Anal Manometry

Anorectal manometry includes a number of specific tests that are helpful in the diagnostic assessment of patients with fecal incontinence. It includes resting anal pressure, anal squeeze pressure, the recto anal inhibitory reflex, compliance of the rectum in response to balloon distension, and sensory thresholds in response to balloon distension.<sup>46</sup> The interpretation of these diagnostic tests is complicated by the fact that patients are able to compensate for deficits in specific physiologic mechanisms maintaining continence and defecation by using other biologic and behavioral mechanisms. It gives a reliable, reproducible, and objective assessment of anal sphincter function. Resting

pressure represents internal sphincter function whereas squeeze pressure reflects external sphincter function. Many different techniques have been advocated such as water-perfused catheters, closed water- or air-filled balloons, and microtransducers. Each system has its own normal values. Anal pressures in normal individuals have a large range and vary with sex and age: patients with low values may be continent whereas high pressures do not guarantee continence. Squeeze pressures are higher in men than in women. Older patients exhibit lower pressures but a significant age-related difference cannot be demonstrated. Resting and squeeze pressures are lower in incontinent patients than in normals. It does not correlate with the severity of incontinence and neither does it predict postoperative results. Some patients with fecal incontinence are found to have manometric values within the normal range. In these patients, a decrease in rectal adaptation could be causative.<sup>47</sup> Patients with soiling often have normal squeeze pressures but lowered resting pressures.<sup>48,49</sup> Anal manometry is indicated in fecal incontinence to exclude impaired sphincter function as the cause of incontinence and to assess the effects of operative procedures on sphincter functions.

## Defecography

Defecography is the radiologic visualization of the act of defecation. It provides a picture of the successive phases of defecation and gives an impression of pelvic floor activity during these actions. Changes in the rectal configuration and the anorectal angle become visible and the degree of evacuation can be studied. It has become evident that it can demonstrate abnormalities that were unsuspected on clinical examination. It has been demonstrated that the anorectal angle is increased in pelvic floor denervation as a sign of pelvic floor weakness. But there is a wide interobserver variation in the measurement of the anorectal angle making quantification an exercise of limited clinical value. The value of defecography in fecal incontinence is to demonstrate the presence of internal rectal intussusception in patients with perineal symptoms or the solitary rectal ulcer syndrome.

## Endosonography

Endosonography is a diagnostic tool to investigate the anal sphincters. The most frequently used instruments have a 360° rotating head and work with 7 or 10 MHz. It is possible to see both anal sphincters and to determine their length and width. Atrophy, scar tissue, and also defects in the sphincters can be seen. These endosonograms make it possible to find old ruptures even when there is no marking in the anal skin. Sometimes it is difficult to visualize defects in the perineum of a woman. In these cases, additional vaginal endosonography can be helpful.

Three-dimensional endosonography improves the understanding of the nonexperienced investigators but does not add anything to the diagnostic work-up.

## Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) of the pelvic region is an excellent way to visualize the anal canal, lower rectum, and the surrounding tissue of prostate, bladder, and uterus. The MRI can be performed with an endo-coil in the anus and with surface phased array coil.<sup>50-52</sup> The endo-coil has the advantage that the sphincters are better visualized but in an unnatural way. The endo-coil has a diameter of 2 cm and the sphincters are stretched during the investigation. This causes the same problem as with endosonography in which visualization is obtained with an opened sphincter. An MRI without an endo-coil but with a phased array coil gives a view of the natural contracted sphincter. Both methods reveal lesions as well as atrophy of parts of the sphincters.

## Pudendal Nerve Latency Time

Pudendal nerve latency time offers the opportunity to evaluate nerve damage to the pelvic floor. It measures the time from an electrical stimulus of the pudendal nerve to the onset of the electrical response in the muscles of the pelvic floor. An easy, painless way of performing this test is with the use of the finger electrode. This electrode is mounted on a glove and contains an electrode at the end of the finger that can be placed intrarectally on the pudendal nerve. A second electrode is located at the base of the finger and registers the anal response. A prolonged latency is taken as evidence of neuropathy.

## Sensation Test

The sensation of anus and rectum can be tested with two methods: the anus is extremely sensitive caudal of the dentate line and insensitive proximal of this line. Electrical stimulation of the distal anus and determination of the sensory threshold give an impression of this sensation. The sensitivity of the rectum is studied with inflation of an intrarectal balloon. The minimal volume that is sensed, the first urge sensation, and the maximal tolerable volume are determined. A high threshold of the minimal volume sensed in the rectum is abnormal (usually >20 mL).

## Endoscopy

Endoscopy has a limited value for investigation of fecal incontinence. It can exclude some diseases that give diarrhea and mucus production (proctitis, colitis, solitary rectal ulcer, villous adenoma, etc).

## Treatment

### Conservative Treatment

Nonsurgical treatment is the initial approach to the incontinent patient. It aims at improving continence, quality of life, psychologic well-being, and anal sphincter function. In functional incontinence, the underlying disorder should be treated. Diarrhea is the most common aggravating factor for fecal incontinence. Its cause should be evaluated. Perineal pads are efficient and acceptable for minor incontinence only. The aim of pharmacologic treatment of fecal incontinence is to try to achieve passage of one or two well-formed stools a day. It can be tried with simple constipating agents such as loperamide diphenoxylate, codeine phosphate, or bile acid binders. Many of these suppress the propulsive activity of the small bowel and colon. Bulking agents may improve the consistency of a liquid stool.

Laxative abuse should be stopped. Successful treatment of encopresis, overflow incontinence, or pseudoincontinence requires a combination of parent and child education, behavioral intervention, medical therapy, and long-term compliance with the treatment regimen. After complete evacuation of the impacted rectum, reaccumulation of stool should be prevented by appropriate use of laxatives and well-balanced diets including fibers and fluids followed by gradual weaning of the laxative regimen and instituting toilet training such as regular attempts to defecate and habit training. Surgical treatment can be considered for an anatomic defect in pseudoincontinence such as resection of a megacigmoid.

Dietary advice may help some patients. Patients with the pattern of soiling may be successfully treated with stool bulking agents (e.g., psyllium or bran).<sup>48</sup> An empty rectum is the best prevention of involuntary loss of stool. Glycerine or bisacodyl suppositories and phosphate enemas may be helpful. Daily colonic irrigation is a suitable alternative. Retrograde colonic irrigation can be performed by influx of lukewarm water from a water bag or from a pump. The antegrade continence enema (Malone) procedure has improved the lives of many patients who struggle with intractable forms of constipation or incontinence. The non-refluxing, catheterizable appendicocostomy provides the opportunity to treat

previously therapy-resistant patients to administer large-volume enemas through a right lower quadrant stoma to flush the colon every other day.<sup>53</sup> It works well in patients with incontinence secondary to spinal cord disorders. The technique induces highly effective emptying as demonstrated by scintigraphic techniques whereas the effect of retrograde irrigation is correlated with the extent to which the irrigation fluid has entered the colorectum (normally 1 to 2 L).<sup>54</sup> Dangerous electrolyte abnormalities such as low sodium or hypochloremia are rare but the potential morbidity warrants periodic evaluation.<sup>55</sup> Even patients with soiling seem to benefit from colonic irrigation.<sup>56</sup> It reduces or eliminates soiling in approximately 78% of children with myelomeningocele.<sup>3</sup> When, after several trials of conservative and surgical treatment, a patient remains symptomatic, the anal plug may be offered. It is effective in controlling fecal incontinence and well tolerated in a minority of patients. Evaluation quickly reveals whether the patient will find it an effective and acceptable option.<sup>57</sup>

### Biofeedback Treatment

Biofeedback is the use of technology to give the patient better information about specific physiologic activities that are under the control of the nervous system but not clearly or accurately perceived by the patient. The rationale underlying biofeedback assumes that the physiologic activity that is monitored is causally related to a clinical problem and that alteration of that activity can lead to resolution of the problem. Biofeedback is a time-consuming and labor-intensive, but harmless and inexpensive, treatment for fecal incontinence, which benefits approximately 75% of patients but cures only about 50%. It may be most appropriate when there is neurologic injury (i.e., partial denervation), but it has been reported to also benefit incontinent patients with minor structural defects.<sup>3</sup> Fecal incontinence is one of the few indications for which biofeedback is considered to be clinically effective. The technique is designed to improve the threshold of rectal sensation and to coordinate pelvic floor contraction with rectal distension. Rectal sensation seems to be a critically important determinant in achieving success with biofeedback. Appropriate candidates should be motivated and able to understand the procedure, sense the rectal stimulus, and

TABLE 46-1. Algorithm for treatment of fecal incontinence

Consistency	Cause	First choice	Second choice	Third choice
Diarrhea	Inflammatory	Antiinflammatory drugs	Constipating drugs	Colostomy
Pseudodiarrhea	Encopresis	Laxatives	Lavage	Colostomy
Solid	Pelvic floor	Biofeedback	SNS	Colostomy
	Sphincter intact	SNS	Lavage	Colostomy

Soiling	Keyhole defect	Lavage	PTQ implant	

SNS, sacral nerve stimulation; DGP, dynamic graciloplasty; ABS, artificial bowel sphincter; PTQ, implant silicone particles.

contract the pelvic floor. It is not helpful in patients with profound denervation of the pelvic floor or absence of innervation. Patients with decreased rectal capacity as in proctectomy or proctitis do not respond.<sup>58</sup> Despite the many reports of success with biofeedback, the mechanisms of action remain uncertain. Improvement of external sphincter function is not achieved. It remains uncertain whether biofeedback is more effective than placebo treatment or behavioral treatment.<sup>59</sup> The technique of external sphincter contraction exercises under direct electromyographic vision does not lead to an improvement of external sphincter function either.<sup>60</sup>

### Balloon Training

Increasing volumes of water in a rectal balloon can be of help to bring down the threshold of first urge. It is a tool to improve the sensibility of the rectum.

### Electrostimulation

Electrostimulation as a treatment for fecal incontinence is widely used among physicians and physiotherapists. It is claimed to improve muscle function and to decrease the susceptibility of the muscle to fatigue. Data to support this claim, however, are lacking. Indications in the literature are widespread or poorly defined and objective manometric data not presented. It can be done by direct implantation of electrodes on the external sphincter or by anal plug stimulation. Some report a decrease of incontinence score, but an improvement in continence and external sphincter function does not occur.<sup>61–63</sup> Electrostimulation is not a clinically effective treatment of anal incontinence.

### Operative Treatment

#### *Anal Encirclement Procedures*

The anal encirclement procedure, originally described by Thiersch in 1891 for the treatment of complete rectal prolapse, has later been adopted for treatment of fecal incontinence. Different materials have been advised for this procedure including nylon, silk, fascia strips, silver wire, and silastic bands. A static barrier to the passage of feces is thus constructed offering nothing in the way of voluntary control and maintenance of continence. The complication rate is high and a variety of complications have been described such as fecal impaction, infection, wire migration, and perineal discomfort. An indication for this procedure does not exist anymore. Instead, a colostomy should be considered.

#### *Anterior Sphincteroplasty*

Patients with incontinence secondary to an obstetric or iatrogenic anterior defect are best suited for surgical correction of fecal incontinence. Fecal diversion is unnecessary because it

gives no benefit in terms of wound healing or functional outcome, and it is a source of morbidity.<sup>64</sup> The presence of a rectovaginal fistula is no contraindication. A temporary diverting enterostomy may be constructed when there is a high risk of sepsis or in reoperations. Poor result after adequate sphincter repair is attributed to coexistent pelvic floor denervation.<sup>16,17</sup> Primary sphincter repair is inadequate in most women with obstetric ruptures after vaginal delivery because most have residual sphincter defects and about 50% still experience incontinence.<sup>65–67</sup> A full mechanical bowel preparation is given preoperatively combined with parenteral antibiotics. After insertion of an indwelling bladder catheter, the patient is placed in the prone jackknife position and the buttocks taped apart. A transverse incision is made over the destroyed and empty anterior perineum. Injection of an adrenaline solution may be used to diminish bleeding. The scar tissue is dissected up to the level of the anorectal ring. The anal mucosa is dissected off the internal sphincter and scar tissue after which the fibrous remnant of the sphincter is divided. The scar at the sphincter ends is preserved to anchor the sutures because sutures are less likely to tear out from fibrous tissue than healthy muscle. The ends of the mobilized external sphincter are snugly overlapped and sutured together with absorbable mattress sutures. Dissection should not go further laterally than half the circumference of the anal canal allowing an overlap of 1.5 cm, in order to avoid damaging the nerve supply to the external sphincter entering posterolaterally. Outcome after end-to-end repair is somewhat inferior to overlapping repair whereas overlapping repair might be associated with more evacuation difficulties.<sup>68</sup> The advantage of dissection and separate repair of the internal and external anal sphincter is not clear. When the perineal body is absent, an anterior levatorplasty may be performed by approximating the inner fibers of the puborectalis limbs with 3–4 interrupted sutures at the deepest portion of the perineal dissection. The mucosa is sutured to the skin edge to avoid retraction. Wound closure should be performed in a V-Y manner to increase the anovaginal distance. The central portion of the wound is left open for drainage or closed and a suction drain left in the perineum. Packing should not be used. Sitz baths are recommended to optimize perianal hygiene. A normal diet is permitted from the first day. Laxatives are prescribed for 2–3 weeks to avoid hard stool. Defecation is earlier and less painful whereas functional outcome is not different compared with bowel confinement regime.<sup>69</sup> The perineal wound is usually closed in 4–6 weeks. Good functional results are usually obtained in 50%–80% but seem to deteriorate with time. Continence is rarely perfect and many have residual symptoms. Some may develop new evacuation problems.<sup>70</sup> The most important factor in the return to normal sphincter function is an increase in squeeze pressure.<sup>71</sup> Poor outcome is usually associated with pelvic floor denervation or a residual sphincter defect.<sup>65</sup> Repeat anterior repair is advocated for symptomatic residual defects.<sup>72,73</sup> Repair of laterally and posteriorly placed injuries is less successful. Results of internal

sphincter repair are poor. The defects usually persist as shown by ultrasonography, and functional and clinical findings are disappointing.<sup>74,75</sup> Transsphincteric injection of silicone biomaterial can provide a marked improvement in fecal incontinence related to a weak or disrupted internal anal sphincter. This is associated with improved sphincter function and quality of life.<sup>76</sup>

### *Postanal Repair*

Postanal repair was originally described by Parks as a method to improve fecal incontinence by restoring the anorectal angle and lengthen the anal canal. The procedure is simple to perform, safe, and requires minimum technology. The principal indication is denervation damage of the pelvic floor. Adequate muscle mass must be present for this operation to be successful. There is no relation between preoperative physiologic assessment and postoperative results; the currently available preoperative testing has not altered the success rate.<sup>77</sup> A full mechanical preoperative bowel preparation or rectal washout should be done combined with parenteral antibiotics. The prone-jackknife position should be preferred. A curved incision is made behind the anus and an anterior skin flap is dissected. The intersphincteric space, an avascular plane between internal and external sphincter, is identified and dissected free up to the upper part of the anal canal where Waldeyer's fascia, a dense fibrous structure, is encountered. Division gives access to the pelvis. The rectum can be dissected free from the levator ani by blunt dissection. A lattice is constructed by plicating the pubococcygeus and, in a second layer, the puborectalis. Additional sutures are placed in the deep and superficial part of the external sphincter. Some prefer nonabsorbable sutures. Part of the skin is left open to prevent sepsis. Laxatives are prescribed and patients are instructed not to strain in the early postoperative period. Complete wound healing usually occurs in 3–4 weeks. The initial results are good; continence for solid stool is restored in 40%–50%. Long-term benefits, however, are only reported by 30%–40% of patients; 30% are not improved at all. The mechanism of restoration of continence is unclear, the anorectal angle is not restored, and external sphincter functions remain far below normal values.<sup>77–80</sup> Despite the low success rate, the absence of any mortality, and the low morbidity, it has a place in the management of fecal incontinence because there are few alternatives. Total pelvic floor repair, a combination of postanal and anterior repair, does not produce consistent changes in anatomy or physiology either. It rarely renders patients completely continent but substantially improves continence and lifestyle in approximately half of them.<sup>81,82</sup> It is likely that improvement after these procedures is caused by creation of a local stenosis or a placebo effect rather than by improvement of muscle function.<sup>81–83</sup> The main indication is incontinence in conjunction with severe pelvic floor descent syndrome. Posterior reconstruction may be replaced by sacral nerve stimulation.

### *Sacral Nerve Stimulation*

Based on the good results of urologists in treating patients with urinary incontinence, colorectal surgeons became interested in this treatment. The first observation was that patients with double incontinence, treated for their urinary incontinence, developed improved fecal control. Matzel began sacral nerve stimulation for fecal incontinence in 1995.<sup>84</sup> This method is now gaining popularity in Europe and is being studied in the United States. The method is very attractive because it offers the opportunity to test the stimulation before the decision for a permanent implant is made. For the test, the patient is placed in the prone position and a needle is brought in the foramen of S3. High-voltage stimulation on the needle gives a contraction of the anus and pelvic floor. It also gives a tingling sensation in the anovaginal region in women and in the anoscrotal region in men. This indicates that the tip of the needle is positioned in the proximity of the third sacral nerve. A test wire is brought through this needle and the needle is withdrawn. The test wire is glued to the skin of the buttock and connected to an external screener. The stimulation starts with a low voltage just above the threshold for sensation and the patient is sent home for a 3-week period. In these 3 weeks the patient keeps a diary with all defecations, urgencies, and incontinence episodes. This can be compared with a similar diary that was written during 3 weeks in the period before the test stimulation. When there is an improvement in continence, an implant may follow in which a permanent electrode is fixed to the sacrum and connected to an implantable stimulator. The average longevity of such a stimulator is 8 years. The stimulator is implanted in the lower abdominal wall or in the buttock. So far it remains unclear how this stimulation works. Probably the proprioceptive fibers are triggered and reflexes suppressed or enhanced. In the literature, an average success rate of approximately 80% is given. The long-term results of the urologists are very good and one may expect a similar result in fecal incontinence. Complications are minimal and mostly related to infection. The best indication for sacral nerve stimulation is fecal incontinence in patients with intact anal sphincters or for patients who had an unsuccessful anal repair in the past.<sup>1,85–88</sup> It seems to work well in patients with neurogenic incontinence. It is currently available only as part of a trial or when placed for urinary incontinence also.

### *Dynamic Graciloplasty*

Patients with a completely destroyed anal sphincter or a large gap between both ends of the sphincters cannot be helped anymore with anal repair. For these patients, dynamic graciloplasty may be a good solution. The gracilis muscle is a long muscle at the medial side of the upper leg. It is an auxiliary muscle for the adductor muscles and can be detached from its insertion without the risk of hampering the adductor function. This muscle can be freed from its insertion up to the neurovascular bundle, folded in the upper leg, and subcutaneously tunneled to the perineum. It is long enough to

encircle the anal canal and to be attached to the periosteum of the inferior ramus of the pubic bone. Anatomically, this muscle is probably the best replacement of the destroyed sphincter, but it is intrinsically the worst muscle for sphincter function because of its composition of a minority of type one fibers (long acting, slow twitch) and a majority of type two fibers (short acting, fast twitch). This makes the gracilis a fatigable muscle that only conscientiously contracts by will. With chronic low-frequency stimulation, the gracilis can change its fiber composition and become a nonfatigable muscle that contracts on demand of the stimulator. This is what is necessary for continence: an automatic long-term nonfatigable contraction of the sphincter. The electrical stimulation is given by an implanted stimulator through an intramuscular electrode that is placed very close to the gracilis nerve. The muscle is closed permanently but can be opened by switching off the stimulator with the help of a handheld programmer.<sup>89</sup> Defecation is possible at that moment and with the same programmer the stimulator is switched on and the anus is closed again after the defecation. The results are dependent on the experience of the surgeon and the success rate varies between 40% and 80%. The complication rate of this intervention is high but most problems are treatable without influence on the final result.<sup>90-95</sup> Unfortunately, this has not been approved for use in the United States.

### *Artificial Bowel Sphincter*

An alternative for dynamic graciloplasty is in some cases the artificial bowel sphincter. Instead of autologous muscle, the anus is now encircled with an implantable fluid-filled, silicone elastomer cuff. This cuff is connected by tubings with a control pump and a pressure-regulating balloon. The inflated cuff compresses the anus all the time. By using the control pump situated in the labia or scrotum, the fluid is manually pumped from the cuff toward the balloon. The empty cuff allows passage of stool. The pressure in the balloon presses the fluid back into the cuff through a flow regulator at the pump. The pump is a one-way pump and the fluid can pass the pump passively because of pressure. The operation is easier to perform than graciloplasty, but a disadvantage is the foreign material that has to be placed around the anus. Erosion from the cuff through the anus and the vagina is a common complication.<sup>89,96,97</sup> Operator experience is very important to the successful outcome of the procedure. Continence is excellent when the procedure works.

### *Colostomy*

When conservative and operative treatment has failed to create an acceptable level of continence, the patient is in fact left with a perineal colostomy. An abdominal colostomy may then be offered to the patient as a last alternative but it should be performed only after thorough counseling. The option of a colostomy should be mentioned during the first consultation. It subsequently should be the patient's initiative to start the

discussion on colostomy construction after which an appointment is made with the stoma therapist for further counseling. A colostomy is usually well accepted by the patient because it reliably simplifies bowel care and prevents incontinence, and thus clearly improves quality of life. Because mucus production in the excluded rectosigmoid will persist and mucus retention is impossible because of the impaired sphincter function, a continuous drainage of brown-grayish, foul-smelling mucus will occur, wetting and staining the underwear and eroding the perineal skin. It is not acceptable for the fastidious patient who finds that his symptoms persist despite this, reluctantly accepted, stoma. Rectosigmoid resection leaving a rectal stump of 3–4 cm should therefore be added to the procedure. Resection does not completely eliminate mucus secretion but normally reduces it to an acceptable level. However, when perineal symptoms persist, an intersphincteric rectal excision should be considered. When intractable constipation coexists, creation of a double-loop ileostomy should be considered.

### *Perioperative Management*

Perioperative antibiotic prophylaxis is advisable for all interventions for incontinence and mandatory in the operations with implant of foreign material. Preoperative bowel preparation is not necessary. A solid bolus high in the colon is preferable to the contamination by Lumen fluid during the intervention. Postoperative administration of laxatives is of help in the prevention of passage of firm stool in the first postoperative days. Perioperative protection with a deviating colostomy is usually not necessary.

## Conclusion

Fecal incontinence is no longer an untreatable disease. In almost all cases, it is possible to help patients with conservative management, operations, or with combinations (Table 46-1). It is important to evaluate all factors that contribute to incontinence and to direct therapy to the restoration of most of these factors. Diapers should no longer be the gold standard.

# Rectal Prolapse

Anthony M. Vernava, III and David E. Beck

Prolapse, in general, is defined as: “A falling down of an organ or part . . . from its normal position.” Rectal prolapse is a “falling down” of the rectum so that it is outside the body. Its appearance is that of an erythematous, proboscis-like object and is a true intussusception of the rectum through the sphincters. The condition is embarrassing and can be socially debilitating although it is rarely a medical emergency. It is associated with fecal incontinence, and in women, is associated with other pelvic floor abnormalities. The precise cause of rectal prolapse is unknown although two theories of etiology have been proposed. At the beginning of the nineteenth century, Moschowitz<sup>1</sup> suggested that prolapse is a sliding hernia through a defect in the pelvic fascia. More recently, and with the benefit of cindefecography, Broden and Snellman<sup>2</sup> proposed that prolapse is actually a circumferential intussusception of the rectum. It is this latter theory that most investigators subscribe to. The majority of patients afflicted with rectal prolapse have a long history of constipation and straining.

The disorder is more common in women, especially in older age groups. Affected men tend to be younger (20–40 years of age) and usually have a predisposing disorder (e.g., congenital anal atresia). Women are at increased risk of developing prolapse by virtue of their anatomy (i.e., wide pelvis) and because of childbearing. Vaginal delivery is known to stretch the pudendal nerves and long-term neurologic damage can occur at this time resulting in perineal descent, prolapse, and incontinence. A vast number of different procedures have been described to manage the disorder serving as testimony to the uncertain etiology of the disease and the resultant disagreement about optimal surgical therapy (Table 47-1).

Patient factors that influence the choice of operation are: age, sex, medical condition, extent of prolapse, bowel function, and status of fecal continence. Procedure-related factors that influence the choice of operation include: extent of procedure, potential morbidity, recurrence rate, impact on fecal continence and bowel habit, familiarity and ease of technique.

## Patient Evaluation

Constipation and straining, fecal incontinence, and erratic bowel habits typify the symptoms associated with prolapse. These symptoms are nonspecific and are associated with both mucosal pathology and functional bowel disease therefore, a complete evaluation before operation is necessary.

Spontaneous prolapse is obvious on inspection (Figure 47-1).<sup>3</sup> Some patients may require straining to produce the prolapse, and the straining patient is best examined in the squatting or sitting position. The patient can be examined while he or she is on the toilet by having the patient lean forward or using a long rod to which a mirror is attached placed between the patient's legs to view the prolapse. Another option is to place a flexible endoscope into the toilet with the viewing end pointed toward the perineum.

Full-thickness prolapse is distinguished by its concentric rings and grooves as opposed to the radially oriented grooves associated with mucosal prolapse (Figure 47-2). Inspection should also include examining the perianal skin for any maceration or excoriations. A digital rectal examination is important to detect concomitant anal pathology and to assess resting tone and squeeze pressure of the anal sphincters and function of the puborectalis muscle.

Colonoscopy or flexible sigmoidoscopy with barium enema should be performed to rule out associated mucosal abnormalities. Defecography is usually not necessary in the evaluation of full-thickness prolapse but it is an essential part of the evaluation of internal procidentia (rectoanal intussusception). Anal manometry can help assess sphincter function; longstanding prolapse typically damages the internal anal sphincter and may cause poor resting pressures.<sup>4</sup> In such patients, synchronous levatorplasty should be considered at the time of prolapse repair and may further improve continence.<sup>5</sup> In a manometric study evaluating patients with rectal prolapse, Spencer<sup>4</sup> reported that the anorectal inhibitory reflex was frequently absent or abnormal, that resting anal pressures were abnormally low, and squeeze pressures were normal. Anal electromyography and pudendal nerve terminal

motor latency are generally not clinically helpful unless there is a history of severe straining. In such cases, anal electromyography presence of inappropriate puborectalis contraction. When discovered, biofeedback can be used for therapy. Colonic transit times should be done in patients with a coexisting history of severe constipation so that the correct operation can be chosen. Individuals with slow-transit constipation and site markers concentrated in the left and sigmoid colon typically benefit from a synchronous sigmoid colectomy and rectopexy versus rectopexy alone or even perineal rectosigmoidectomy.

## Surgical Procedures

The surgeon must decide between a perineal operation and an abdominal procedure. Men are at risk for sexual dysfunction with an abdominal approach, therefore this option is chosen cautiously. The risk of impotence for abdominal rectopexy should approach 1%–2% in skilled hands.

The most common abdominal operations are resection with or without rectopexy or rectopexy alone. The perineal procedures are perineal rectosigmoidectomy (Altemeier) or mucosal sleeve resector (Delorme). Elderly, high-risk patients are best treated by perineal procedures which can be performed under a regional anesthetic, or even a local anesthetic with intravenous sedation. Healthy adults with normal bowel habits may undergo either rectopexy ± sigmoidectomy or perineal rectosigmoidectomy ± levatorplasty. Bowel function has a role in determining specific therapy. Constipated patients should undergo resection and rectopexy. Incontinent patients should undergo either abdominal rectopexy or perineal rectosigmoidectomy + levatorplasty. Recurrent prolapse mandates knowledge of the prior repair because that information will dictate future options; the prior dissection may limit the available alternatives because of blood supply divided.

## Perineal Procedures

### Perineal Rectosigmoidectomy

Perineal rectosigmoidectomy was popularized by Altemeier and his name is the eponym attached to the procedure.<sup>6</sup> The operation can be performed under a general or spinal anesthetic or even a local anesthetic with intravenous sedation. Typically, patients receive a mechanical and antibiotic bowel preparation. The prone position is preferred; however, the left lateral (Sim's) or lithotomy position can also be effectively used. The rectal wall is injected with an epinephrine containing compound for hemostasis. A circumferential incision is made in the rectal wall approximately 1–2 cm above the dentate line (Figure 47-3). The incision is deepened until the full thickness of the rectal wall has been divided. Once a full-

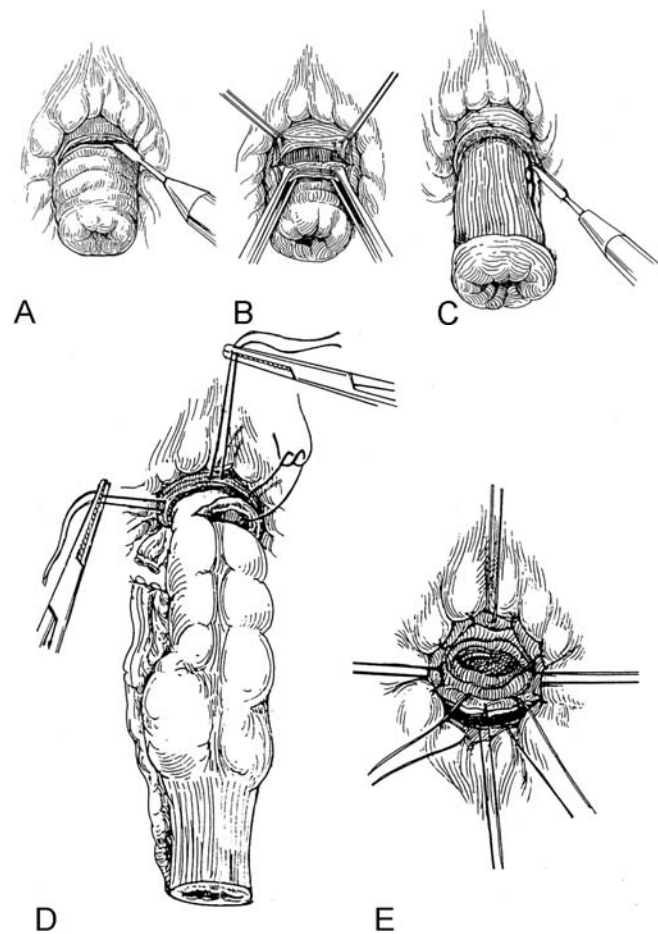

FIGURE 47-3. Perineal rectosigmoidectomy. **A, B** Incision of rectal wall. **C** Division of vessel adjacent to bowel wall. **D** The prolapsed segment is amputated. Stay sutures previously placed in distal edge of outer cylinder are placed in cut edge of inner cylinder. **E** Anastomosis of distal aspect of remaining colon to the short rectal stump. Reproduced with permission of Taylor & Francis Group LLC (B) in the format Textbook via Copyright Clearance Center).

thickness incision has been made, the cut edge of the rectum is pulled down and the mesorectum is divided and ligated, progressively advancing more cephalad. Anteriorly, a peritoneal reflection (hernia sac) is encountered. The dissection continues until there is no further redundancy remaining in the rectum/sigmoid colon, this requires judgment and experience. After the redundant rectum has been adequately mobilized, it is divided and a hand-sutured coloanal anastomosis is performed. An EEA stapler can also be used to perform the anastomosis. In cases of severe fecal incontinence, a levator plication can be performed before the coloanal anastomosis improves continence in two-thirds of patients.<sup>5,7</sup> After the procedure, patients are allowed to ambulate and eat on postoperative day 1.

Reported results of the perineal rectosigmoidectomy are summarized in Table 47-2. Mortality has been low and morbidity ranges from 5% to 24%. Most morbidity is from the preexisting medical problems; however, most series report anastomotic complications in a small number of patients. Recurrence rates range from 0% to 10% in series with a follow-up of 6 months to 5 years. Recurrence rates are higher for series with longer follow-up. Improvement in incontinence has been reported in the majority of patients in whom levatorplasty is performed.<sup>16</sup>

### Delorme Procedure

Another perineal option is mucosal proctectomy first discussed by Delorme in 1900.<sup>17</sup> It is ideally suited to those patients with full-thickness prolapse limited to partial circumference (e.g., anterior wall) or less-extensive prolapse.

The Delorme's procedure for treating rectal prolapse differs from the perineal rectosigmoidectomy (Altemeier) in that only the mucosa and submucosa are excised from the prolapsed segment (Figure 47-4). Delorme's procedure can be performed under general, spinal, or local anesthesia. The bowel is prolapsed and the submucosa infiltrated with epinephrine solution. One centimeter cranial (proximal) to the dentate line, the outer cylinder is incised through the mucosa only. The mucosa and submucosa are dissected off the

underlying muscle. The mucosectomy may be more difficult in patients with prior anal surgery or a history of diverticulitis. The plane of dissection may be facilitated by continued submucosal injection of epinephrine solution as the dissection continues toward the apex of the prolapse. Four polyglycolic acid sutures (2-0) are placed sequentially in the rectal muscle at the anterior, posterior, and lateral positions as the dissection continues. These sutures plicate the muscle and provide traction. The dissection is carried into the apex and the mucosa which has been dissected free is transected. The polyglycolic acid sutures (2-0) are used to reconnect the edges of the bowel. Four additional sutures are used to approximate the bowel between the placating sutures. Additional 3-0 sutures are placed in an interrupted or running manner to complete the circumferential approximation of the mucosal edges.

Results of Delorme's procedure are summarized in Table 47-3. Reported operative mortality rates from a series of patients treated by Delorme's procedure range from 0% to 2.5%.<sup>18-23</sup> Morbidity reported at 0% to 32% includes hemorrhage, anastomotic dehiscence, stricture, diarrhea, and urinary retention. Recurrence rates (7%–22% at 1–13 years

postoperatively) are higher than with a perineal rectosigmoidectomy. Incontinence is improved in 40%–50% of patients.<sup>16</sup> Constipation was not a problem in most series.

### Thiersch Procedure

Anal encirclement was first described by Thiersch in 1891.<sup>24</sup> He placed a silver wire subcutaneously around the anus with the patient under local anesthesia. The mechanism of this procedure was to mechanically supplement or replace the anal sphincter and stimulate a foreign body reaction in the perianal area. There were several reports of the use of this procedure in the early part of this century, especially in Europe.<sup>25</sup>

William Gabriel is credited with reviving interest in Thiersch's operation in the 1950s.<sup>25</sup> He reported on 25 cases of incontinence or minor rectal prolapse. He did not recommend this operation for major degrees of prolapse.

For this operation, the patient is placed in the prone jack-knife, lithotomy, or left lateral position (Figure 47-5). A local anesthetic is administered and a radial incision made on both

sides of the anus about 2 cm from the anal verge. A curved hemostat or special circular needle is used to tunnel from one incision to the other above the anoperineal ligament anterior to the anus, keeping external to the external anal sphincter. The material for encirclement is brought through the tunnel. Tunneling is continued posterior to the anus above the anococcygeal ligament and the encircling material brought through so that the two ends meet.<sup>26</sup> The encircling material is then secured by tying snugly over an index finger in the anus. A variety of materials used for encirclement include nylon, silk, silastic rods, silicone, Marlex mesh, Mersilene mesh, fascia, tendon, and Dacron.<sup>10</sup> Complications of this procedure include breakage of the suture or wire, fecal impaction, sepsis, and erosion into the skin or anal canal. The Thiersch operation does not correct the prolapse but narrows the anus enough that the prolapse is confined to the rectum, accomplishing this goal in 54%–100% of cases.<sup>27</sup> Because of its failure to correct prolapse and the morbidity of this procedure, it is reserved for the most seriously ill patients who are unable to undergo one of the previously described perineal procedures. Results of the Thiersch procedure are summarized in Table 47-4.

## Abdominal Procedures

### Abdominal Rectopexy and Sigmoid Colectomy

Abdominal rectopexy and sigmoidectomy was initially described in 1955 by Frykman<sup>35</sup> for management of full-thickness rectal prolapse and it remains an essential treatment option. The operation consists of four essential components: 1) complete mobilization of the rectum down to the levator musculature, leaving the lateral stalks intact; 2) elevation of the rectum cephalad with suture fixation of the lateral rectal stalks to the presacral fascia just below the sacral promontory; 3) suture of the endopelvic fascia anteriorly to obliterate the cul-de-sac; and 4) sigmoid colectomy with anastomosis. The modern components of the operation are essentially the same with the exception that most surgeons no longer obliterate the cul-de-sac (Figure 47-6). Results with abdominal rectopexy and sigmoidectomy are summarized in Table 47-5.

### *Abdominal Rectopexy*

Simple suture rectopexy without sigmoid colectomy has been reported as an effective surgical treatment for rectal prolapse.<sup>43,44</sup> Typically, this operation has been used in patients

who do not have associated constipation with prolapse. The rectum is mobilized down to the levator floor preserving the lateral ligaments. The lateral rectal stalks are then sutured to the presacral fascia just below the sacral promontory, using

a nonabsorbable suture, such as Prolene. Results are summarized in Table 47-6.

### Ripstein Procedure

Described in 1963 by Ripstein and Lanter,<sup>45</sup> the Ripstein operation had been one of the most popular procedures for management of rectal prolapse. It is currently seldom used, probably because of the success of alternate therapies and because this particular operation requires the use of prosthetic material, placed around the rectum.

The rectum is mobilized posteriorly down to the coccyx. A 5-cm piece of prosthetic mesh (Marlex or Prolene) is sutured to the presacral fascia, 5 cm below the sacral promontory in the midline. The rectum is retracted cephalad and the lateral edges of the sling are wrapped around the rectum and sutured to it (Figure 47-7). Care must be taken to avoid making the wrap too tight and causing an obstruction. Results are summarized in Table 47-7.

### Ivalon Sponge

The Ivalon (polyvinyl alcohol) sponge wrap operation, first described in 1959 by Wells,<sup>50</sup> is currently the most popular operation for rectal prolapse in the United Kingdom. The operation is performed with the patient in the lithotomy position and the rectum is mobilized posteriorly down to the levator ani. Anterior mobilization of the rectum is also performed. A piece of Ivalon is then placed in the pelvis, sutured to the presacral fascia with nonabsorbable sutures, and then wrapped around the rectum which has been retracted cephalad. The sponge is then sutured to the rectum such that only three-fourths of the rectum is wrapped (the anterior rectum is left free of the sponge). The peritoneum is then closed over the sponge excluding it from the peritoneal cavity (Figure 47-8). In the United States, surgeons have used praline or Marlex mesh instead of a polyvinyl alcohol sponge

TABLE 47-6. Results of abdominal rectopexy

to perform a posterior wrap. Results of posterior wraps are summarized in Table 47-8.

### Laparoscopic Rectopexy

Laparoscopic approaches to the management of full-thickness rectal prolapse, including rectopexy alone, or in combination with sigmoid colectomy have been reported to have comparable success rates and morbidity to open surgery, with the added benefit of shorter hospital stays. These laparoscopic approaches likely represent the future direction of definitive operative management.<sup>52-55</sup> Heah et al.<sup>53</sup> reported on 25 patients, with a mean age of 72 years, who underwent laparoscopic rectopexy without resection for management of full-thickness prolapse. Four of 25 patients (16%) required conversion to open operation. Morbidity occurred in 3 of 25 patients (12%). There were no cases of recurrent prolapse or mortality.

Ashari et al.<sup>54</sup> reported a 10-year, single-center experience with laparoscopically assisted resection rectopexy for management of full-thickness rectal prolapse in 117 patients. Mortality occurred in 1 of 117 patients (0.8%) and morbidity in 9%. Seventy-seven of the 117 patients (66%) were followed a median period of 62 months. Recurrent full-thickness rectal prolapse occurred in 2 of 77 patients (2.5%) and mucosal prolapse occurred in 14 (18%). Operative times decreased by 39% (from 180 to 110 minutes) over 10 years.

Kairaluoma et al.<sup>55</sup> reported a case-controlled comparison between open and laparoscopic surgery for rectal prolapse involving 106 patients (53 in each group) and included both rectopexy alone and rectopexy combined with resection. Morbidity and mortality were statistically no different between the laparoscopic group and the open surgery controls. Recurrent full-thickness rectal prolapse occurred in 6% of the laparoscopic group and 13% of the open surgery group but this was not statistically significant ( $P = .186$ ). Hospital stay was significantly shorter in the laparoscopic group than in the open surgery controls for both rectopexy alone and for rectopexy combined with sigmoid colectomy.

### Recurrent Prolapse

As discussed previously, recurrence is not uncommon after surgical treatment of prolapse. Depending on the specific initial therapy selected, recurrent full-thickness rectal prolapse can occur in more than 50% of patients, although most recent reports place recurrent prolapse after resection with rectopexy to be less than 10%. Typically, perineal operations for prolapse have a higher risk of recurrence compared with abdominal approaches. Over a 30-year period, Hool et al.<sup>56</sup> reported recurrent rectal prolapse in 24 of 234 patients (10%). Nine of the 24 recurrences occurred after an initial perineal operation and 15 of 24 recurrences occurred after an initial abdominal approach.

When full-thickness rectal prolapse recurs, it is important to reevaluate the patient for both constipation and other

pelvic floor abnormalities in order to tailor the management to address those issues. Therefore, patients with recurrent prolapse will require evaluation in the anorectal physiology laboratory with manometry and defecography. Patient comorbid conditions will also have an important role in treatment selection, as was likely the case in selecting the initial operation.

A major consideration in determining the best surgical option to treat the recurrent prolapse is the residual blood supply of the remaining large bowel. Any patient who has undergone a prior rectal or sigmoid resection with anastomosis requires very careful evaluation before undergoing a secondary procedure. The initial operative procedure performed for prolapse has a dominant role in determining the selection

of the next operation. In such patients, the obvious risk to a secondary resection is ischemia to the segment of large intestine between two anastomoses.

Recurrent full-thickness rectal prolapse can be successfully managed using the same operative options applied to initial disease. Reports in the literature place successful treatment of recurrence at between 85%–100%.<sup>57,58</sup> Unfortunately, although

TABLE 47-8. Results of Ivalon sponge operation

Authors	No. of patients	Recurrence (%)	Mortality (%)	Morbidity (%)
Sayfan et al. <sup>38</sup>	16	00	00	12.5

Novell et al. <sup>51</sup>	31	3	00	19

most authors indicate the initial operative technique, the recurrence, and the secondary operative technique, they fail to adequately describe their rationale for selection of the secondary procedure. For that reason, there is very little data upon which to base an intelligent treatment decision for management of recurrent prolapse. There is no specific algorithm available that can be applied to select the best operation for treating recurrence, except that many reports suggest treating young patients using an abdominal approach and elderly patients using a perineal approach. The treating surgeon is left to make an individualized recommendation from the options that are summarized in Table 47-9. Also, the bowel dysfunction associated with prolapse, including constipation and diarrhea, is largely unimproved after correction of the recurrence.<sup>56-58</sup>

Fengler et al.<sup>57</sup> reported the results of managing recurrent full-thickness rectal prolapse in 14 patients who had initially undergone perineal rectosigmoidectomy (10), anal encirclement (2), Delorme procedure (1), and anterior resection (1). The average length of time to recurrence was 14 months. Salvage operations performed to manage the recurrence included: redo perineal rectosigmoidectomy (7), abdominal rectopexy (1), resection + rectopexy (2), Delorme procedure (1), anal encirclement (1). Patients were followed for 50 months after treatment for their recurrence. One patient died from an unrelated problem. Among the 13 remaining patients, no patient experienced a re-recurrence of the prolapse. Successful management of the recurrent prolapse failed to resolve fecal incontinence in three patients.

Pikarsky et al.<sup>58</sup> reported on 27 patients with recurrent full-thickness rectal prolapse. Initial operations included: abdominal rectopexy (7), Delorme procedure (7), perineal rectosigmoidectomy (7), anal encirclement (4), and resection rectopexy (2). Operations performed for recurrence included: perineal rectosigmoidectomy (14), resection rectopexy (8), rectopexy (2), pelvic floor repair (2), and Delorme procedure (1). Re-recurrence of prolapse occurred in 4 of 27 (15%) after a median follow-up period of 24 months.

TABLE 47-9. Management options for recurrent rectal prolapse

Initial operation	Options for management of recurrence
Perineal rectosigmoidectomy	Redo perineal rectosigmoidectomy Abdominal rectopexy (avoid resection)
Abdominal rectopexy	Redo abdominal rectopexy (± sigmoid colectomy) Perineal rectosigmoidectomy
Abdominal rectopexy + resection	Redo abdominal rectopexy (± re-resection) Avoid perineal rectosigmoidectomy

If the patient has undergone an initial perineal rectosigmoidectomy, then a repeat perineal rectosigmoidectomy or abdominal rectopexy can be safely performed. However, in such cases, abdominal rectopexy with sigmoid colectomy should be avoided because of the risk of ischemia to the retained rectal segment. For those patients who have undergone prior abdominal rectopexy but who now have recurrent prolapse, a redo abdominal rectopexy is an acceptable approach.

### *Solitary Rectal Ulcer Syndrome and Colitis Cystica Profunda*

Solitary rectal ulcer syndrome (SRUS) and colitis cystica profunda (CCF) are uncommon conditions frequently associated with rectal prolapse.<sup>59</sup> SRUS is a clinical condition characterized by rectal bleeding, copious mucous discharge, anorectal pain, and difficult evacuation. Despite its name, patients with this condition can have single, multiple, or no rectal ulcers. When present, the ulcers usually occur on the anterior rectal wall just above the anorectal ring. Less frequently, they may occur from just above to 15 cm above the dentate line. Ulcers usually appear as shallow with a "punched out" gray-white base surrounded by hyperemia.

Cystica profunda is a benign condition characterized by mucin-filled cysts located deep to the muscularis mucosae. Although cysts can occur in any segment of the digestive tract submucosa, they are most frequent in the colon and rectum. When these lesions are found in the colon or rectum they are called CCF and appear as nodules or masses on the anterior rectal wall. Patients can be asymptomatic (with the lesions identified on screening endoscopy) or complain of rectal bleeding, mucous discharge, or anorectal discomfort. Most will admit to difficulty with bowel movements. CCF is a pathologic diagnosis whose most important aspect is to differentiate it from colorectal adenocarcinoma. This prevents unnecessary radical operations.

CCP and SRUS are closely related diagnoses and some authors consider them interchangeable. The etiology of these conditions remains unclear, but a common feature is chronic inflammation and/or trauma. The inflammation may result from inflammatory bowel disease, resolving ischemia, or trauma associated with internal intussusception or prolapse of the rectum, direct digital trauma, or the forces associated with evacuating a hard stool.

In symptomatic patients, an endoscopic evaluation of the distal colon and rectum will reveal the lesions described above. Defecography documents intussusception in 45%–80% of patients. The differential diagnosis of both CCF and SRUS includes: polyps, endometriosis, inflammatory granulomas, infectious disorders, drug-induced colitides, and mucus-producing adenocarcinoma. Differentiation among these entities is possible with an adequate biopsy. Biopsies obtained via a rigid proctoscope, or an endoscopic snare excision, may be necessary to obtain enough tissue for an accurate

diagnosis. CCF is characterized pathologically by mucous cysts lined by normal columnar epithelium located deep to the muscularis mucosae. The overlying mucosa may be normal or ulcerated and the submucosa surrounding the cysts is fibrotic and contains a mixed inflammatory infiltrate. In adenocarcinoma, the epithelium is dysplastic and the surrounding stroma is reactive.

Treatment is directed at reducing symptoms or preventing some of the proposed etiologic mechanisms. Conservative therapy (high fiber diet and modifying bowel movements to avoid straining) will reduce symptoms in most patients and should be tried first. Patients without rectal intussusception should be offered biofeedback to retrain their bowel function.<sup>60</sup> Pharmacologic therapy has had limited success, but is reasonable to try before embarking on surgery. If symptoms persist, a localized resection may be considered in selected patients.<sup>61</sup> Those suitable for localized resection should be significantly symptomatic, be good surgical risks, and have localized, accessible areas of disease. Patients with prolapse are considered for surgical treatment [abdominal rectopexy, segmental resection and rectal fixation, perineal proctectomy (Altmeier), or a mucosal proctectomy (Delorme)]. Those without prolapse may be offered excision which varies from a transanal excision to a major resection with coloanal pullthrough.

## Conclusion

Optimum management of patients with rectal prolapse requires careful patient evaluation for synchronous functional bowel disorders. Although the precise etiology of rectal prolapse remains unclear, the condition is frequently associated with constipation and straining and, intuitively these coexisting symptoms seem to have a role in the development of prolapse in many patients. Management of any associated constipation, either medically or by the addition of sigmoid colectomy, seems important to the ultimate outcome of treatment, although it remains unclear as to whether successful management of constipation results in a lower risk of recurrent prolapse. Fecal incontinence is a frequent complication of full-thickness rectal prolapse; unfortunately, successful treatment of the prolapse results in only a 50% chance of improvement in preexisting fecal incontinence.

Operative management can be divided into abdominal approaches and perineal approaches. Generally, abdominal rectopexy, with or without resection, has a higher morbidity but a much lower risk of recurrence than perineal rectosigmoidectomy. Selection of the best specific procedure for a given patient remains highly individualized, at the physician's discretion, and depends on variables such as the patient's general medical condition, comorbid disorders, the presence of incontinence or constipation, and any prior surgery for prolapse. Typically, the clinician balances the risk of recurrent prolapse against the operative morbidity (e.g., abdominal

rectopexy versus perineal rectosigmoidectomy). Therapeutic options such as anal encirclement and placement of mesh are not routinely performed in the United States given the reasonably good results achieved with either abdominal rectopexy ( $\pm$ sigmoid colectomy) or perineal rectosigmoidectomy. Laparoscopic rectopexy with or without sigmoid colectomy seems to be both safe and effective and will likely replace open abdominal surgery in the management of rectal prolapse. At this time, it is unclear whether laparoscopic rectopexy is more effective and is as safe as perineal rectosigmoidectomy for elderly, high-risk patients.

SRUS and CCF are uncommon colorectal conditions associated with prolapse. As benign conditions, efforts are directed to establishing the diagnosis, excluding malignancy, and treating symptoms. A directed history, physical examination, and endoscopic biopsy will confirm the diagnosis. Therapy to modify bowel movements and habits has had the most success. If these measures fail, surgical therapy to correct rectal prolapse or locally excise the lesions may be considered.

## Constipation

Amanda Metcalf and Howard Michael Ross

One of the most common complaints voiced to internists, gastroenterologists, and colon and rectal surgeons alike is that of constipation. Patient definitions of constipation are so variable that the term itself is meaningless and focused questioning regarding the patient's actual bowel habits is mandatory. To facilitate research into and treatment of constipation and other functional bowel disorders, a multinational panel of experts was convened in Rome, Italy. The Rome criteria for the diagnosis of constipation requires two or more of the following for at least 3 months:

- Straining more than 25% of the time
- Hard stools more than 25% of the time
- Incomplete evacuation more than 25% of the time
- Two or fewer bowel movements per week

Sonnenberg and Koch<sup>1</sup> described the enormity of the problem in the United States in 1989. These authors estimated that four million people in the United States complain of frequent constipation, a prevalence rate of 2%. Complaints of constipation are two to three times more common in women than men and complaints increase with increasing age. The incidence of constipation is also higher in nonwhites than whites, in people from a lower socioeconomic and educational status, and in the southern United States. A more recent study in elderly residents of Olmstead County in Minnesota further underscored the enormity of the problem.<sup>2</sup> Talley et al. found that nearly one in two women and one in three men over the age of 65 either had complaints of constipation or took laxatives. The magnitude of the problem requires the colon and rectal surgeon to understand the causation of constipation, be facile with the tests used in the evaluation of the constipated patient, and be able to recommend both medical and surgical therapies when appropriate.

### Etiology

Constipation can be secondary to a long list of conditions and medications (see Table 48-1). Physiologically, a number of complex interactions are necessary for the development of

formed stool, the passage of stool through the colon, and the elimination of the stool bolus. Evaluation of the constipated patient must include investigation into all of the factors potentially responsible for constipation.

Diet affects the size, consistency, and frequency of bowel movements. Dietary intake of fiber is highly correlated with stool bulk. Inhabitants of countries with higher fiber intake pass more voluminous stool than those in countries with a lower intake of dietary fiber. Inhabitants of Western countries typically ingest inadequate amounts of fiber, secondary to reliance on processed grains. Because colonic distension triggers peristalsis, bulkier stools are a stronger and more efficient stimulus for colonic propulsion than smaller stools.

As noted, female gender is associated with a higher prevalence of constipation. Knowles et al.<sup>3</sup> reported that of 2004 patients evaluated by transit study at three European tertiary referral centers for intractable constipation, 92% were women. No definitive explanations exist for the gender difference seen, although hormonal influences and pelvic anatomy have been suggested.

Many medical conditions are recognized to affect bowel function. Hypothyroidism and diabetes, lupus and scleroderma, neurologic illness, immobilization, and psychiatric disease are but a few of a long list of medical maladies associated with increased rates of constipation and should be considered as a source of constipation during evaluation. Mechanisms of dysfunction include alteration in motor function of the gut and autonomic neuropathy as seen in hypothyroidism and diabetes mellitus, respectively. Hirschsprung's disease and Chagas' disease alter the function of the colon through damage to the enteric nervous system. Connective tissue disorders alter the functionality of intestinal smooth muscle. Colonic stricture secondary to carcinoma, inflammatory bowel disease, radiation, or endometriosis can cause colonic obstruction. Medications for the management of common disorders such as hypertension promote the development of constipation. Opiate and anticholinergic use, as well as laxative abuse, is associated with constipation. Opiates decrease the propulsive activity of the colon through

Chagas' disease
Pelvic floor abnormality
Nonrelaxing puborectalis
Anal stenosis
Rectocele/enterocele

activation of mu-opiate receptors found on neurons of the enteric nervous system.

## Evaluation

The evaluation of the patient complaining of constipation begins with a detailed history. Specific details of the patient's complaints—stool size, frequency, consistency, ease and efficacy of evacuation—should be noted. Also important to note are the age at onset of symptoms, diet and exercise details, medical history, surgical history, and medication. Query into psychiatric illness and sexual and physical abuse must be performed, because they are associated with defecation difficulties. Symptoms of pelvic floor dysfunction involving the urinary tract should be ascertained. A patient diary of dietary intake, defecation frequency, stool consistency, and any associated symptoms can be very helpful to both the patient and the medical provider.

Physical examination will likely be unremarkable. Abdominal distension or the presence of a mass may be noted. Rectal examination should involve a clinical evaluation of resting tone and the ability to voluntarily contract and relax the anal sphincter. Evaluation for pelvic floor dysfunction such as perineal descent with straining, the presence of a rectocele or cystocele, and the volume and consistency of stool in the rectal vault should be noted.

The evaluation of the patient with symptoms of constipation that do not respond to a trial of diet and medical therapy begins with the elimination of a structural bowel obstruction via colonoscopy or barium enema. Once obstruction has been eliminated as the cause of constipation symptoms, colonic transit time should then be assessed.

The purpose of the radiographic evaluation of the patient with constipation complaints is to identify conditions that may require treatment paradigms other than diet and medication therapy. Specifically, slow-transit constipation (colonic inertia) and pelvic floor outlet obstruction are entities that may be better treated with surgery and biofeedback, respectively. Evaluation of upper gastrointestinal motility, colon motility, and the mechanism of defecation is currently possible. When combined with anal manometry, a picture of a patient's ability to propel and eliminate stool can be generated.

Colonic transit time can be estimated via marker studies or through scintigraphy. The precise technique chosen depends on availability and whether one desires a global or more precise measurement of transit. The most widely available technique for determining colonic transit uses radiopaque markers and radiographs of the abdomen. The concept of assessing transit using markers was first developed by Hinton et al.,<sup>4</sup> modified by Martelli et al.,<sup>5</sup> and further simplified by Metcalf et al.<sup>6</sup>

To obtain a global assessment of whether or not patients have slow-transit constipation, the technique requires the patient to refrain from all enemas, laxatives, and most medications for 2 days before the ingestion of 24 radiopaque markers. The patient is required to ingest 30 g of fiber daily during the test and must continue to refrain from taking medication and laxatives. An abdominal radiograph is obtained on the fifth day. The distribution and the number of markers present in the colon are noted. Eighty percent of normal patients will have passed all the markers by 5 days. If the markers are found to have accumulated in the rectum, outlet obstruction is suggested. If the markers remain scattered throughout the colon and more than 20% of the markers remain in the colon after the fifth day after ingestion, colonic inertia can be diagnosed.

A more precise assessment of transit delay can be obtained by having the patient ingest radiopaque markers on three sequential days while following the same instructions and obtaining a radiograph on the fourth and seventh day (see Figure 48-1). The number and distribution of the markers are tabulated and totaled. The resultant numeric values can then be compared with the established value for normal controls.

FIGURE 48-1. Marker study revealing colonic inertia.

The mean colon transit time through the entire colon in men has been shown to be 31 hours in males and 39 hours in women. Patients with normal transit constipation will have a colon transit time that is in the normal range (<65 hours in 95% of men, <75 hours in 95% of women).

Scintigraphic evaluation of colonic transit has been described, and although not as widely available, is useful in the assessment of transit in the colon and proximal gut.<sup>7</sup> Transit times obtained through scintigraphy are generated by following the passage of a radiolabeled meal. Small bowel and gastric emptying rates can also be estimated with this one examination. Normal small bowel transit is between 90 and 120 minutes.

Outlet obstruction suggested on a marker study can be further characterized through defecography. Defecography facilitates visualization of the mechanism of defecation. Nonrelaxing puborectalis or a large rectocele can both be identified on a defecogram.<sup>8</sup>

Anal manometry reveals the absence of the rectoanal inhibitory reflex and therefore suggests the presence of Hirschsprung's disease. Balloon expulsion testing performed during manometry can add to the reliability of the diagnosis of pelvic floor outlet obstruction caused by nonrelaxation of the puborectalis muscle.<sup>9</sup> Anal electromyography is performed

in conjunction with manometry. The recruitment of puborectalis muscle fibers during defecation simulation indicates the entity of nonrelaxing puborectalis outlet obstruction.

Assessment of upper gastrointestinal motility is appropriate in patients who are demonstrated to have slow-transit constipation. Patients with generalized motility disturbances and colonic inertia have less favorable results after surgical intervention than patients with colonic inertia alone.<sup>10</sup> Small bowel transit time may be measured scintigraphically as mentioned above or with a lactulose hydrogen breath test. The principle of this examination is that hydrogen produced through lactulose fermentation only occurs in the colon. If one records the time from ingestion of lactulose to hydrogen production, small bowel transit time can be inferred.

## Medical Treatment of Constipation

Therapy of the constipated patient should begin with patient counsel. It is sage advice to help the patient understand that a daily bowel movement is not requisite to good health. All providers should strive to decrease patient anxiety over the act of defecation. The elimination of malignancy and mechanical causes of symptomatology, performed for the evaluation of constipation, often goes far in this regard.

Simple measures that can influence the passage of colonic content are increasing physical activity and fluid intake. Exercise, even gentle walking, can facilitate the elimination of stool. Fluid intake can cause the stool to be softer and easier to pass. Medications that promote constipation should be eliminated or substituted with alternatives that are less constipating.

Lack of dietary fiber intake is a major factor in the development of constipation symptoms. Bulk-forming agents are a first-line therapy in the prevention and treatment of constipation. Bulk-forming agents facilitate an increase in the size of the stool bolus as well as make the stool softer. Bulking agents facilitate these changes by delivering a mass of nondigestible substrate to the colon and, because of their hydrophilic nature, facilitate the absorption and retention of fluid. Bulk laxatives are derived from the nondigestible components of plants or are synthetic methylcellulose derivatives. Common bulk agents are psyllium (Metamucil, Konsyl), methylcellulose (Citrucel), and calcium polycarbophil (FiberCon). Side effects of fiber therapy include bloating and flatulence. A dietary intake of 20–30 g of nonstarch polysaccharide is generally recommended to minimize symptoms of constipation.

Osmotic laxatives are a class of medications that promote the accumulation of large volumes of fluid in the colon lumen through the delivery of osmotically active molecules into the small and large bowel. The osmotically active particles can be derived from sugars or salts. Sorbitol and lactulose are examples of sugar-based osmotic agents. Lactulose is broken down in the colon yielding the production of fatty acids, hydrogen, and carbon dioxide. Caution in the presence of these gases can cause an explosion.

Osmotic laxatives can also be based on nonabsorbable ions, frequently derived from magnesium or phosphate. Examples are magnesium hydroxide (milk of magnesia) or sodium phosphate (Fleets Phospho-soda). Caution must be exercised in patients with renal insufficiency because hypermagnesemia can result. Polyethylene glycol-based products are used in many bowel-cleansing regimens. Chronic use can lead to electrolyte disturbances and dehydration.

Colonic irritants are a class of agents that diminish constipation through stimulation of colonic motility. Anthracene derivatives include senna and cascara and are found in Senokot and Peri-Colace. Long-term anthracene intake can generate a characteristic brown discoloration of the mucosa called pseudomelanosis coli. There is some debate whether long-term intake of anthracene laxatives increases the risk of colon cancer. Bisacodyl is another irritant and can be found in the agent Dulcolax. Long-term use of anthracene irritants may lead to poor colon function and such use is therefore discouraged. However, there is little objective evidence to support this belief.

Mineral oil and docusate sodium (Colace) are laxatives that act through the manipulation of the composition of stool. Mineral oil coats the stool bolus, preventing fluid absorption from it. Docusate sodium lowers the surface tension at the stool water interface, allowing greater penetration of the stool with fluid.

Enemas and suppositories are used to stimulate a bowel movement. Strategies include promotion of defecation through distension (saline enema), rectal irritation (soapsuds, bisacodyl), or physical softening of the stool (glycerine).

## Colonic Inertia

Colonic inertia, also called slow-transit constipation, represents a severe functional disturbance of colonic motility, which results in significant disability to the patient. Patients with colonic inertia, similar to patients with normal transit constipation and patients with outlet obstruction, exhibit infrequent defecation and may experience abdominal pain, bloating, nausea, difficulty with and incomplete evacuation of stool. Only a very small percentage of patients with constipation actually have colonic inertia. The diagnosis of colonic inertia requires the documentation of abnormal colonic transit (>20% of ingested markers present and scattered throughout the colon on day 5 of colonic transit time testing). Patients with constipation are often highly motivated to relieve their symptoms. Many are very willing to undergo surgery. Total abdominal colectomy (TAC) for colonic inertia is only appropriate for patients with documented abnormalities in colonic transit. TAC entails the risk of abdominal operation and intestinal anastomosis. Persistent or recurrent constipation, progression to small bowel inertia, and fecal incontinence may occur after TAC with ileorectal anastomosis and must be explained to the patient. Precise evaluation of colonic motility and pelvic floor

function is critical in the identification of patients that truly exhibit colonic inertia and have the highest probability to benefit from surgical intervention. A review of the outcomes of surgical intervention for colonic inertia follows.

Lane<sup>11</sup> reported the results of surgical intervention for the elimination of constipation in 1908, and described the resolution of constipation symptoms through the removal of the abdominal colon in two-thirds of patients. Lane performed his series of operations without the benefit of manometry, transit studies, or defecography. Remarkably, he was able to state that if the abdominal colon was not removed, symptoms could recur.

Dr. Lane's words speak volumes. "In the earliest cases in which I removed the greater part of the large bowel the symptom demanding it was pain, usually in the caecum, splenic flexure, or sigmoid. Though I was aware of the associated symptoms of autointoxication I did not operate for their removal, nor was I aware that the excision of the large bowel would result in their complete disappearance. I only became conscious of this result after the removal of the large bowel. And the comparatively abrupt change which ensued during the few days following the operation was almost startling. The recognition of the immense advantages which these miserable people obtained from the removal of the large bowel then induced me to operate also in cases where pain was not necessarily such a marked feature, but where life was becoming a burden through the misery and distress induced by the autointoxication and its result. . . . At first I was satisfied in most cases to remove the large bowel as far as the splenic flexure, as I believed that the risk of the operation was reduced by leaving the descending colon and sigmoid, for these structures being vertically placed I did not expect that material would accumulate in them above the junction of the ileum and rectum. I found, however, that many of those in whom I left them complained, after a lapse of time, of symptoms which I was able to attribute to distension of the descending colon and sigmoid with gas. Therefore I excised the residual bowel in many such cases of incomplete resection and took away the entire large bowel with the exception of the rectum in all primary operations."

Multiple trials have recently reported the long-term results of TAC for colonic inertia. Pikarsky et al.<sup>12</sup> from the Cleveland Clinic Florida identified 50 patients that had undergone TAC for colonic inertia between 1988 and 1993. Thirty were available for telephone interview designed to assess bowel function, concomitant use of any antidiarrheal medications, postoperative complications, persistence or development of preoperative symptoms such as pain or bloating, and overall satisfaction. The mean follow-up was 106 months (range, 61–122 months). Remarkably, all 30 patients reported the outcome of surgery as "excellent." The average number of bowel movements per day was 2.5 (1–6). Twenty percent of patients required admission for small bowel obstruction and half of these patients required laparotomy for obstruction (10%). Two patients (6%) required assistance with bowel

movements despite operation. Two patients (6%) needed antidiarrheal medication to reduce bowel frequency.

Long-term follow-up has also recently been reported by Webster and Dayton<sup>13</sup> from the University of Utah. Their retrospective review identified 55 patients who underwent TAC for colonic inertia. Eighty-seven percent were female and the average age was 40. Postoperatively, 8% experienced a bowel obstruction. "Good" or "excellent" results were reported by 89% of patients. "Poor" results were reported by 11% of patients. The mean stool frequency per day was three at 12 months from surgery. Verne et al.<sup>14</sup> from the University of Florida identified 13 patients who underwent TAC for colonic inertia between 1983 and 1987. Seven patients had an ileosigmoid anastomosis and six an ileorectal anastomosis. The overall number of bowel movements per week increased from 0.5 to  $15 \pm 4.5$  postoperatively.

The Mayo Clinic reported their long-term results of TAC for colonic inertia in 1997.<sup>15</sup> Seventy-four patients were identified as having had a TAC. Fifty-two had slow-transit constipation alone and twenty-two had colonic inertia and pelvic floor dysfunction. These twenty-two underwent pelvic floor retraining followed by surgery. Similar to most other studies, 90% of patients had a "good" or improved quality of life. All patients could pass stool spontaneously. Nine percent of patients developed a small bowel obstruction. There was no difference in the surgical outcome of patients who required pelvic floor retraining and surgery when compared with the group that required surgery alone.

FitzHarris et al.<sup>16</sup> from the University of Minnesota addressed the question of whether the increase in bowel movements experienced by patients with colonic inertia that undergo TAC resulted in an improved quality of life. Patients were sent a survey that inquired about bowel function and included a gastrointestinal quality-of-life index. Gastrointestinal quality-of-life index scores were correlated with specific functional outcomes. Eighty-one percent of patients were at least "somewhat" pleased with their bowel movement frequency, but 41% cited abdominal pain, 21% incontinence, and 46% had diarrhea at least some of the time. Five percent of patients had recurrent or persistent constipation and 17% underwent lysis of adhesions for small bowel obstruction. No correlation was found between frequency of bowel movements and quality-of-life scores. If offered subtotal colectomy again, 93% of patients stated they would accept. These authors concluded that although the vast majority of patients were no longer constipated, a significant number had persistent or new adverse symptoms.

Knowles et al.<sup>17</sup> in 1999 published a thorough review of the outcome of colectomy for slow-transit constipation. All series published in the English language through 1999 including 10 or more patients treated with colectomy for colonic inertia were included in the review. Thirty-two studies between 1981 and 1998 met entry criteria. The authors noted that the median rate of success in these studies was 86% with a range between 39%–100%. The authors of the review revealed that no study

was controlled with respect to the outcome from other surgical or medical interventions. Although not every study in the review commented on each potential functional outcome variable, many patterns of postoperative problems were identified. Fecal incontinence was reported in 16 series with a median incidence of 14% (range, 0%–52%). Persistent abdominal pain was reported in 14 series. A 41% median incidence of abdominal pain was identified, with a range between 0%–90%. Recurrent constipation was reported in 15 series with a median incidence of 9% (range, 0%–33%). A permanent ileostomy was created in 5% of patients because of poor functional outcome (0%–28%).

Despite consistently increasing stool frequency, TAC to treat colonic inertia does not guarantee a successful functional outcome. Furthermore, even extensive preoperative work-up does not ensure patient satisfaction. In their study of 21 patients diagnosed with slow-transit constipation via colon transit studies, anal manometry, defecography, pelvic floor electromyography, and determination of small bowel transit time, Mollen et al.<sup>18</sup> found a satisfaction rate of 52% after 1 year. They appropriately caution against the promiscuous use of colectomy to treat functional constipation. Operations other than TAC with ileorectal anastomosis have been proposed in the treatment of colonic inertia. Segmental resection has the theoretic advantage of reducing diarrhea and fecal incontinence. In a consecutive series of 28 patients with slow-transit constipation as determined by scintigraphic transit study that were subsequently treated with segmental colectomy, 23 patients were pleased with the outcome.<sup>19</sup> The median follow-up in this study was 50 months. The median stool frequency increased from one to seven per week. Incontinence was unchanged. Similarly in a study from China using right or left colectomy to treat transit abnormalities of either the right or left colon, 37 of 40 patients followed for 2 years had improvement of their symptoms without diarrhea or incontinence.<sup>20</sup> Three of the 40 patients experienced recurrent constipation that ultimately required TAC with ileorectal anastomosis. Because the follow-up time of these studies is short and the ability to define segmental colonic transit inexact, TAC remains the most widely accepted surgical treatment option in the treatment of colonic inertia. Historically, patients having segmental colectomy have had poor results.<sup>21</sup>

Proctocolectomy with ileoanal pouch reconstruction has been described as a salvage operation for patients with recurrent constipation after subtotal colectomy with ileorectal anastomosis for slow-transit constipation. The number of patients that have had pouch reconstruction for salvage after subtotal colectomy has been quite small. Keighley et al.<sup>22</sup> reported the results of eight patients who underwent such radical surgery. Four of these eight ultimately required pouch excision for recurrent constipation. Proctocolectomy as initial treatment for slow-transit constipation and rectal inertia has recently been explored.<sup>23</sup> Two of 15 patients required pouch excision within 18 months because of intractable pelvic pain. Significant improvement in lifestyle scores were recorded in

the categories of physical function, social function, pain, and general health for the group during the follow-up period.

A difficult subgroup of patients with slow-transit constipation to treat is those with concomitant pelvic floor dysfunction. Bernini et al.<sup>24</sup> from the University of Minnesota evaluated 16 patients who had a combination of colonic inertia and non-relaxing pelvic floor as diagnosed by transit marker study, electromyography, and defecography. All patients completed preoperative biofeedback training and could demonstrate relaxation of the pelvic floor musculature. Despite biofeedback training, difficult evacuation persisted. Postoperatively, 43% of patients had complete resolution of symptoms of constipation or difficult evacuation. Eighteen percent complained of diarrhea and incontinence of liquid stools. Six of the 16 patients complained of incomplete evacuation. The authors concluded that subtotal colectomy could improve some symptoms in patients with colonic inertia and nonrelaxing pelvic floor, however, incomplete evacuation persisted in a significant number of patients. Almost half were dissatisfied with their surgery.

## Irritable Bowel Syndrome

Irritable bowel syndrome (IBS) is a disorder in which patients have abdominal discomfort and altered bowel habits that defy explanation by identifiable organic pathology. Although there is overlap between patients in this category and those described in the previous section, this diagnosis is more inclusive because patients can have constipation or diarrhea. There are no specific tests to identify this disorder. Rather, it is a diagnosis of exclusion, and remains a clinical diagnosis. The most recent consensus of the clinical features of IBS is known as the Rome criteria and was reached at the conference described earlier. These criteria were reached to standardize the diagnosis of this disorder for both research purposes and clinical practice.<sup>25</sup> The Rome criteria for a clinical diagnosis of IBS are listed in Table 48-2. In essence, patients must have chronic symptoms that include abdominal pain relieved by defecation and or associated with a change in the consistency or frequency of stools. These symptoms are variably associated with mucorrhea and/or abdominal bloating.

TABLE 48-2. Rome criteria for IBS

---

**Abdominal pain or discomfort characterized by the following:**

Relieved by defecation

Associated with a change in stool frequency

Associated with a change in stool consistency

**Two or more of the following characteristics at least 25% of the time:**

Altered stool frequency

Altered stool form

Altered stool passage

Mucorrhea

Abdominal bloating or subjective distension

---

Population-based studies in Western countries report an overall prevalence of IBS of 10%–20%.<sup>26</sup> With the exception of Hispanics in Texas and Asians in California, who may have a lower rate, the prevalence is similar in Western minority populations.<sup>27,28</sup> Some studies suggest that the incidence may be lower in Asian countries and Africa. In Western countries, women are 2–3 times more likely to develop IBS than men; in India, this phenomenon is reversed.<sup>29</sup> The prevalence seems to be lower in the elderly. Retrospectively, many patients report childhood symptoms, and 50% of patients have symptoms before age 35.<sup>30</sup> The incidence in Western countries is 1%–2% per year.

It has been recognized for many years that there are a variety of disorders associated with a clinical diagnosis of IBS. These include nonulcer dyspepsia, fibromyalgia, chronic fatigue syndrome, dysmenorrhea, urinary tract symptoms, and psychiatric disorders. Patients who undergo physician evaluation for IBS tend to have increased scores for depression, anxiety, somatization, and neuroticism on standardized tests, although no specific pattern of personality traits in patients has been identified. Patients with IBS who present for evaluation are at least twice as likely to meet criteria for psychiatric disorders as patients with organic disease. The most frequent of these disorders are depression and generalized anxiety. Interestingly, individuals with clinical symptoms of IBS who do not seek medical care have a similar prevalence of psychiatric disorders as the general population.<sup>31</sup> This suggests that the psychiatric disorder may be more important in healthcare-seeking behavior than as an etiologic agent of the syndrome.

It has been estimated that only 10% of patients with IBS symptoms consult a physician for evaluation or treatment of their symptoms. With the exception of Indians, women are more likely than men to present for physician evaluation. The socioeconomic impact of this disorder is significant. There are estimated to be 3.5 million physician visits in the United States, and IBS is the most common diagnosis in gastroenterologist practice. Patients with IBS have more work absenteeism, more physician visits, and report a lower quality of life.<sup>32</sup>

The current theories regarding the pathophysiology of IBS are of a complex interaction between altered gut motility and or visceral hyperalgesia and neuropsychopathology. Many studies measuring myoelectric activity in the colon have demonstrated abnormalities in patients with IBS. Normal colonic myoelectric activity consists of background slow waves with superimposed spike potentials. Bueno et al.<sup>33</sup> demonstrated increased long spike bursts in patients with constipation and irregular short spike bursts in patients with diarrhea. Myoelectric studies in the small bowel have demonstrated shorter intervals between the migrating motor complex, which is, of course, the predominant interdigestive small bowel motor pattern.<sup>34</sup> Patients with IBS have variations in the colonic slow wave frequency and a blunted late peaking postprandial response of spike potentials in the colon. Transit

studies in the small bowel have demonstrated delayed meal transit in patients with constipation-predominant IBS and accelerated meal transit in patients with diarrhea-predominant IBS.<sup>35,36</sup> These studies and others suggest an underlying generalized hyperresponsiveness of smooth muscle in patients with IBS.

Visceral hyperalgesia seems to be another component of this disorder. Studies measuring the perception of gut distension using various techniques have demonstrated abnormally low sensitivity in both the small and large bowel.<sup>37,38</sup> It seems that patients with a diagnosis of IBS have both an increased awareness of gut distension, and experience such distension as painful at lower volumes and pressures as normal subjects. This is especially in response to rapid distension.<sup>39</sup> Although there has been some argument regarding a reporting bias in patients with IBS (i.e., routinely reporting pain at lower subjective intensities than normal controls), such differences do not account for all of the sensory abnormalities seen.<sup>40</sup> Furthermore, patients with IBS have widened dermatomal referral pain patterns than normal controls from gut distension.<sup>41</sup> This visceral hypersensitivity is not associated with a somatic hypersensitivity.<sup>42</sup> It is thought that patients with IBS may have sensitization of the intestinal afferent nociceptive pathways in the spinal cord.

The central nervous system modulates gut function for optimal digestive function. The limbic system, medial prefrontal cortex, amygdala, and hypothalamus communicate emotional changes to the gut via the autonomic nervous system. In turn, signals from the gut to the brain can effect reflex regulation and mood states.<sup>43</sup> Recent studies have suggested that patients with IBS may process visceral afferent input in the central nervous system in an abnormal way and this response may be modified by attentional factors such that stress, anxiety, and prior unpleasant life events increase the perception of painful events.<sup>44-46</sup> On a biochemical level, patients with IBS have been demonstrated to have increased hypothalamic corticotropin-releasing factor in response to stress, as well as an exaggerated colonic motility response.<sup>47</sup>

The relationship between psychopathology and IBS is not clear. As noted previously, patients with IBS have a higher incidence of panic disorder, major depression, anxiety disorder, and hypochondriasis than normal populations.<sup>48</sup> In addition, they report a higher prevalence of physical or sexual abuse.<sup>49</sup> Two-thirds of patients with IBS report the onset of gastrointestinal complaints with an axis I disorder.<sup>50</sup>

In summary, patients with IBS have been demonstrated to have abnormal gut motility, visceral hyperalgesia, and neuropsychologic abnormalities. In a particular patient, any of these factors may predominate, but all may be involved and they are not mutually exclusive. An understanding of these abnormalities has led to the emergence of new possibilities in the pharmaceutical treatment of this syndrome.

The altered stool habits reported by patients with IBS can be constipation, diarrhea, or alternating constipation and diarrhea. Constipation can be described as hard and/or infrequent

stools, or painful defecation requiring laxative use. Diarrhea is usually described as small volume, frequent, urgent, and watery stool. Diarrhea when present is often postprandial in nature. Usually patients have either constipation or diarrhea alone, however, alternation between each can be present. Abdominal pain is usually perceived as diffuse, and is most common in the lower abdomen, especially on the left. Sharp pain may be superimposed on a more chronic duller component. Pain may be precipitated by meals and is often relieved by defecation. Patients often report increasing bloating and gas through the daytime hours, which may or may not be associated with objective evidence. Mucorrhea, either white or clear, is often reported. Patients with IBS are more likely to report upper gastrointestinal symptoms of nausea, vomiting, and heartburn. Overall symptoms may be worse in times of stress. Symptoms that are not typical of IBS that should alert the clinician to organic disease include: onset in middle age or older, progressive or nocturnal symptoms, anorexia, weight loss, fever, hematochezia, painless diarrhea, or steatorrhea.

Although there are emerging novel medications for IBS that may prove useful, much current medical therapy depends heavily on reassurance. Explanation and patient education have an important role in the management of this chronic disorder. Treatment strategies depend not only on the type of symptoms present but their severity and chronicity.

Fiber supplementation may improve symptoms of either constipation or diarrhea, although studies are inconclusive because of a strong placebo effect. Many physicians believe that polycarbophil-based bulking agents may be tolerated better than psyllium-based compounds because of an exacerbation of bloating symptoms in some patients with the latter. Similarly, ingesting more water, avoiding caffeine and legumes are all reasonable patient advice.

As noted above, treatment strategies are symptom directed. Currently available and widely used pharmacologic agents for patients with diarrhea-predominant IBS include anticholinergic medications, nonabsorbable synthetic opioids, and tricyclic antidepressants.

Anticholinergics inhibit intestinal smooth muscle depolarization at the muscarinic receptor. These include dicyclomine hydrochloride (Bentyl) and hyoscyamine sulfate (Levsin). Either has been shown to decrease fecal urgency and pain. Nonabsorbable synthetic opioids, which are frequently used as antidiarrheals act via peripheral mu-opiate receptors. Diphenoxylate hydrochloride with atropine (Lomotil) or loperamide (Imodium) inhibit intestinal motility and prolong transit through the gut. They also reduce visceral nociception via afferent pathway inhibition. They improve stool frequency, urgency, and consistency. Tricyclic antidepressants such as amitriptyline (Elavil) and imipramine (Tofranil) have also been evaluated in off-label use in very low doses for a visceral analgesic effect. Either medication increases orocecal transit time, reduces abdominal pain, mucorrhea, and stool frequency. These results are at subtherapeutic doses for the treatment of depression.

Novel treatments that have been introduced more recently for patients with diarrhea-predominant IBS include the serotonin (5-HT<sub>3</sub>) agonist Alosetron (Lotronex). This drug inhibits activation of nonselective cation channels that modulate the enteric nervous system. It has been approved only for women with severe diarrhea-predominant symptoms of IBS who have not responded to conventional medication. It has been demonstrated to improve abdominal pain and decrease diarrhea in such patients.<sup>51</sup> Alosetron was temporarily removed from the market by the Food and Drug Administration because of serious and unpredictable side effects including colonic ischemia and toxic megacolon. Cilansetron is another 5-HT<sub>3</sub> antagonist currently undergoing testing. This medication shows promise for relief of symptoms in both male and female patients with diarrhea-predominant IBS.<sup>52</sup>

For patients with constipation-predominant IBS who do not respond to fiber supplementation (20 g/day) or do not tolerate it, osmotic laxatives such as milk of magnesia, sorbitol, or polyethylene glycol may be tried.

A novel pharmacologic agent that is currently available is the serotonin (5-HT<sub>4</sub>) agonist, Tegaserod. Tegaserod is a partial 5-HT<sub>4</sub> agonist and accelerates transit in the small bowel and colon. It has been demonstrated to be useful in improving constipation and improving global IBS symptoms in women with constipation-predominant IBS.<sup>53</sup>

Other novel agents undergoing evaluation primarily for symptoms of pain include clonidine (alpha-adrenergic agonist), fedotozine (kappa opioid agonist), and ammonium derivatives (antimuscarinic and neurokinin-receptor antagonist). Of these, fedotozine is clinically available for this indication and has shown to be helpful in reducing symptoms of pain in patients with IBS.<sup>54</sup>

An adjunctive therapy to medication is psychological treatment. This is appropriate when there is evidence that stress or psychologic factors are contributing to an exacerbation of symptoms, or patients have failed to respond to medical treatment. A clear explanation of the rationale for such treatment is important in patient acceptance of such therapy.

## Pelvic Floor Disorders

Frank J. Harford and Linda Brubaker

Pelvic floor disorders are relatively common entities in clinical practice. These disorders can include abnormalities of bowel storage, bowel emptying, regional pain, and anatomic abnormalities. This chapter will review the anatomic abnormality of rectocele and the group of regional anorectal pain disorders.

### Rectoceles

Rectoceles are a nonpainful, poorly understood disorder without a gold standard for diagnosis. Rectoceles occur almost exclusively in women, particularly women who are vaginally parous. The relationship between anatomy and function in the distal rectovaginal region has not been studied adequately and there are significant gaps in medical and surgical knowledge.

A common clinical definition of rectocele is abnormal rectovaginal anatomy that allows the rectum to be in direct contact with the vaginal serosa without an intervening layer. Usually, rectoceles are diagnosed when rectovaginal support abnormalities are observed during physical examination. There may be protrusion of the posterior vaginal wall beyond the hymen with or without strain effort. Using the internationally validated staging system for pelvic organ prolapse,<sup>1</sup> the distal-most posterior vaginal wall is 3 cm from the hymen. In rectocele formation, this normal anatomy is lost and the distal posterior vaginal wall moves closer toward the hymen or may protrude outside the hymen.

The differential diagnosis for this physical finding includes other abnormalities of vaginal attachment, usually the vaginal apex (with or without the uterus). Differences in physical examination techniques affect the degree of prolapse that is detected. The side-lying or prone jackknife examination that is favored by many colon and rectal surgeons is sufficient to detect some forms of prolapse; however, the standing straining vaginal examination provides the best opportunity to determine the full extent of anatomic abnormalities. Gynecologic surgeons have placed more focus on repair of the vaginal apex, which then provides secondary resolution of

the distal vaginal support defect for many women. Another important differential diagnosis includes abnormalities in perineal support, including severe atrophy or denervation of the levator muscles. Abnormalities in these muscles allow the genital hiatus to widen significantly, causing the vaginal opening to appear larger. This is often referred to as a pseudo-rectocele.

Some specialists use fluoroscopy as an aid to physical diagnosis (Figure 49-1). There is little literature regarding these techniques, the lack of a “gold standard” diagnosis has limited progress in this field. It is clear, however, that the finding of “rectocele” in asymptomatic women during fluoroscopic examination should not prompt surgical repair. Moreover, review of fluoroscopically recorded defecation has demonstrated significant variability in the movement of the distal rectovaginal wall in normal women. The promptness and completeness of defecation are probably more important than the maximum excursion of the anterior rectal wall.

Isolated rectoceles are distinctly uncommon and virtually always occur in the presence of a significant defecation disorder. The decision to surgically readdress rectocele must be carefully considered after a full evaluation of the symptoms that are being attributed to the abnormal anatomy.

The symptoms of rectocele are believed to be stool trapping, difficult defecation, and vaginal protrusion of the posterior vaginal wall. Rectoceles are not painful and reports of pain should prompt the physician to seek other diagnoses. It is widely appreciated that many women with relatively large “rectoceles” have no symptoms attributable to this finding. They are able to conduct all pelvic functions without difficulty, including sexual function, and bowel storage and emptying. Other women with minimal abnormalities on physical examination may report great bother from difficult defecation and stool trapping. In the absence of severe symptoms or findings, the recommended primary intervention is generally attention to optimize stool consistency. For many affected women, this requires appropriate amounts of fiber, adequate hydration, and improved toileting habits. In certain centers, allied health professionals such as nurses and/or occupational

FIGURE 49-1. This is a typical fluoroscopic appearance for a rectocele (R). The protrusion is distal with a normal anal opening and proximal rectum. Other support abnormalities are also seen in the bladder (B).

or physical therapists can assist the surgeon with these important behavioral changes. Biofeedback to establish pelvic floor outlet relaxation during defecation may be helpful.

When symptoms are persistent despite appropriate attention to stool consistency, surgical treatment may be considered. The goal of the surgery should be clearly stated by the surgeon and clearly understood by the patient. Mismatch of goals in this area of poorly understood physiology are common. For example, a patient may not mind the bulge at all, but she is greatly bothered by the need to manually assist her defecation with her hand. Although surgery may be quite effective at relieving her abnormal anatomy, the symptom resolution for hand-assisted defecation is much lower. The planned surgery will not be considered successful by the patient (and therefore by the surgeon) unless the bothersome symptom that prompted the surgery is finally relieved. Honest surgeons will recognize that surgery has significant limitations in relief of certain forms of defecation disorders, but is reasonably effective at normalizing anatomy.

Preoperative testing should include age and risk-appropriate cancer screening (e.g. colonoscopy). Pudendal terminal motor latency testing has no role in selection of patients for rectocele surgery. Defecography may be helpful in documenting failure of the puborectalis muscle to relax during attempted defecation and to establish the presence or absence of internal intussusception as a cause of outlet obstruction of the rectum.

A variety of surgical options are available. The surgeon's belief about the etiology of the rectocele typically determines the technique selected. Gynecologists favor an approach aimed at reinforcement and perineal reattachment of the normal intervening layer of rectovaginal tissue. There are only two randomized surgical trials.<sup>2,3</sup> Both of these studies report that the transvaginal approach is superior to the transanal route. Whereas some have argued that there is a distinct fascia,<sup>4</sup> others refute this. More recently, gynecologists have begun supplementing this tissue with a wide variety of graft materials, although no materials have been proven superior to repair without graft.

Colon and rectal surgeons may approach rectocele from a transanal approach, focusing attention on the capacious rectal vault, and reducing it with pursestring or placating sutures. Sehpayak<sup>5</sup> reported a case series of 355 patients who had a transanal rectocele repair treated with a technique similar to mucosal prolapse. Symptoms attributable to the rectocele were recorded pre- and postoperatively. This technique focuses on abnormalities within the bowel wall itself. A similar technique, described by Khubchandani et al.,<sup>6</sup> also includes excision of the mucosa. Validated outcome assessment of this technique is pending. Block<sup>7</sup> has described a frequently used approach, restricted to midlevel or midvaginal rectocele. The technique in this case series has not yet been tested in a randomized surgical trial. Transanal stapled reduction of the anterior rectocele has recently been evaluated for safety and feasibility but efficacy in a randomized trial is pending.

There is a paucity of literature addressing the symptoms that are appropriately attributed to rectocele, indications for rectocele surgery, the optimal outcome measures after surgery, and the durability of optimal surgical outcomes. This is regrettable given the frequency with which this surgery is performed in American women.<sup>8</sup>

Unsuccessful rectocele repair can occur when either anatomy or symptoms are not corrected. Additional problems may occur when new symptoms arise. One very troubling postoperative complication can be dyspareunia, which in some women can completely preclude sexual activity and destroy intimacy. All operations in the distal posterior vagina and perineum may cause new-onset dyspareunia, and this risk should be disclosed to patients during the negotiation of the informed consent. Recurrent anatomic problems that do not seem to be triggered by abnormal bowel function may be attributable to a widespread abnormality of pelvic support, such as vaginal apical prolapse (with or without a uterus). Physical examination of vaginal supports in the standing straining position is essential and strongly recommended even before a first surgery. A combined gynecologic-colorectal-urologic approach is sometimes needed to address the combination of issues.

Patients who experience initial resolution of anatomy and symptoms may experience relapse if the behavioral program to optimize stool consistency and toileting is not followed. Severe constipation is not a distal rectovaginal problem and it is not reasonable to expect rectocele repair to resolve this symptom. Continued attention to underlying disorders, such as severe constipation, is necessary to preserve optimal rectocele repair.

## Pelvic Pain Syndromes

### Epidemiology

Chronic pelvic pain is not an infrequent cause for medical consultation. The prevalence of chronic pelvic pain in the female population is estimated to be 3.8%. This is similar to

the prevalence of back pain or asthma. It accounts for about 10% of all visits to gynecologists.<sup>9</sup> A North Carolina survey of primary care practices found that 39% of women complain of pelvic pain.<sup>10</sup> In a telephone toll of about 18,000 United States households, the Gallop Organization reported that 16% of women surveyed complained of chronic pelvic pain.<sup>11</sup>

Although pelvic pain is more common in women, it is certainly not confined to the female gender. In a United States survey of functional gastrointestinal disorders, the prevalence of functional anorectal pain was 11.1% of the male and 12.1% of the female respondents to the survey.<sup>12</sup> In a United States survey of physician visits between 1990 and 1994, there were two million healthcare visits per year associated with the diagnosis of prostatitis.<sup>13</sup> Ninety percent of patients with the diagnosis of prostatitis do not have bacterial prostatitis. In 1998, a National Institutes of Health consensus conference designated a new term to encompass these patients—Type III chronic prostatitis/chronic pelvic pain syndrome.<sup>14</sup> In a study of patients with CPPSIII, they were found to have significant differences in muscle spasm, increased tone, and pain on palpation of the muscles of the pelvic diaphragm.<sup>15</sup>

The role of the specialist in the care of these patients is to eliminate intrinsic disorders of the genitourinary and gastrointestinal organs in the pelvis and, if none are found, to

treat the pain. The more common pain syndromes are described below. An algorithm for the management of these patients is depicted in Figure 49-2.

### Levator Syndrome

Levator syndrome is but one of the symptom complexes in the broader category of chronic pelvic pain or chronic idiopathic rectal pain. It is a pattern that was recognized and described in the 1930s and will be discussed as a separate entity. The rigor with which the syndrome is defined varies greatly and thus leads to some confusion. Simpson<sup>16</sup> reported the symptom complex first in 1859, but Thiele,<sup>17</sup> in 1936, described it in more detail and attributed the symptoms to spasm of the pelvic floor musculature.

The term coccygodynia has been applied to this symptom complex in the early descriptions. It has also been referred to as piriformis syndrome, puborectalis syndrome, diaphragma pelvis spastica, and pelvic tension myalgia. Grant et al.,<sup>18</sup> in one of the largest modern series of cases, described it as pain, pressure, or discomfort in the region of the rectum, sacrum, and coccyx that may be associated with pain in the gluteal region and thighs. They made the observation that pressure on the coccyx was rarely painful and regarded the label of

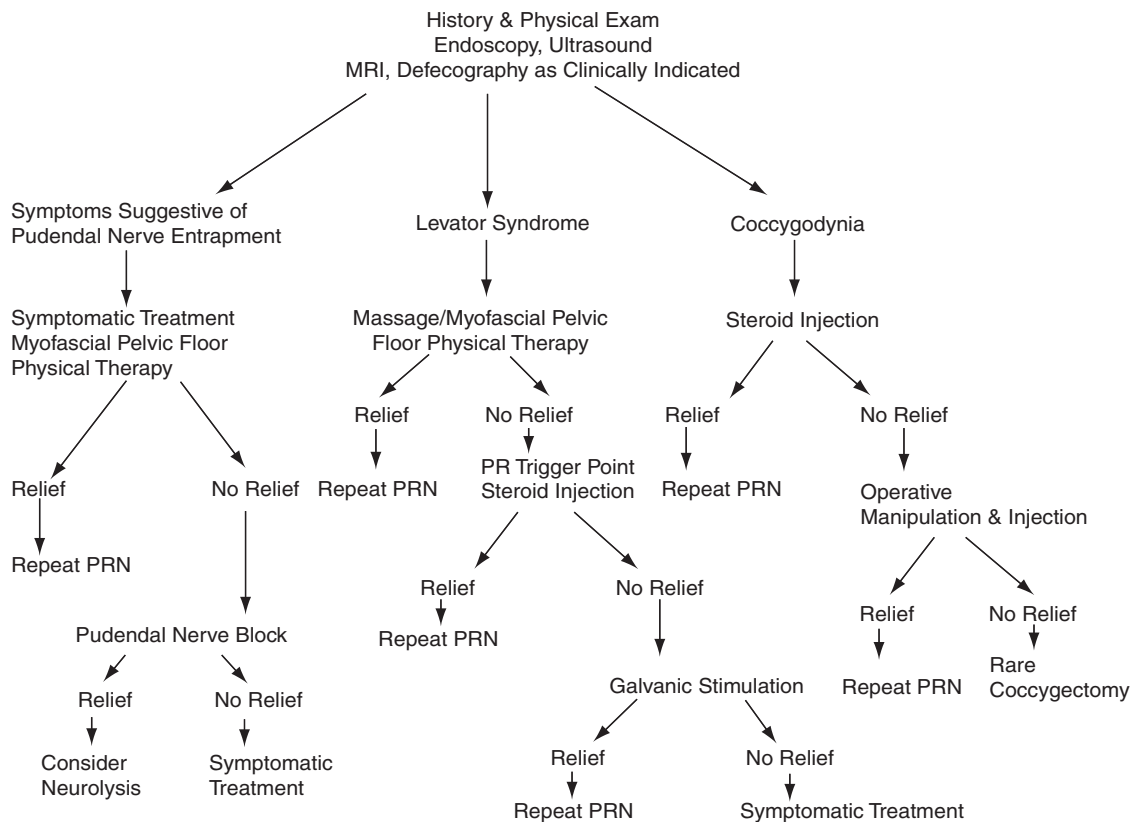

FIGURE 49-2. Algorithm for management of chronic anorectal pain.

coccygodynia as incorrect. Other observers have noted the radiation of the pain to the vagina in women and the association with the feeling of incomplete evacuation.<sup>19</sup>

The prevalence of this symptom complex in the general population is approximately 6%.<sup>12</sup> It is more common in women. The Committee on Functional Anal/Rectal Disorders at a conference to develop diagnostic criteria for Functional Gastrointestinal Disease (Rome II)<sup>20</sup> described the pain of levator syndrome as a vague, dull ache or pressure sensation high in the rectum, often worse with sitting or lying down, that lasts for hours to days. They differentiated between a "highly likely" diagnosis in patients with these symptoms in which posterior traction on the puborectalis reveals a tight levator ani musculature and tenderness or pain, and a "possible" diagnosis if only the symptoms are present. These diagnoses should be entertained only after the presence of alternative diseases are excluded with careful physical examination, endoscopy, and ancillary studies such as defecography, ultrasound, computed tomography, or magnetic resonance imaging (MRI).

The utility of electromyography, anal manometry, and pudendal nerve studies has not been established. No consistent abnormalities in any of these tests have been demonstrated in the majority of patients.<sup>21,22</sup>

A wide variety of treatments have been described. Thiel first recommended digital massage. The massage was given daily for 5 or 6 days. Grant et al.<sup>18</sup> used two to three massages 2–3 weeks apart, combined with heat and diazepam, and had good results in 68% of the patients and moderate improvement in 19%. Poor results were obtained in 13%. A small number of these patients were salvaged with injection of methylprednisolone and lidocaine into the puborectalis sling or "rectal divulsion under anesthesia." (Manual dilation of the anal sphincter, a procedure no longer recommended by this group). (Salvati EP, personal communication.)

Kang et al.<sup>23</sup> described a series of 104 patients in which transanal injection of triamcinolone rendered 37% of patients pain free. Thirty-five percent experienced a greater than 50% reduction in pain. Several investigators have tested electrogalvanic stimulation of the levator muscles via a transrectal probe. The electrical stimulation induces fasciculation and eventual fatigue in the spastic muscles. There is quite a bit of variance in the schedule of treatments as well as length of follow-up in the reported series. The percentage of patients with excellent or good results varies from 19% to 91%.<sup>19,24–29</sup>

Biofeedback has been used with some success. Both Grimaud et al.<sup>30</sup> and Heah et al.<sup>31</sup> reported small series of patients who had excellent results with biofeedback. Gilliland et al.<sup>32</sup> reviewed a larger series of patients with levator-type pain with biofeedback, 37% of whom also had constipation. One-third of the patients noted improvement. The presence or absence of constipation did not seem to matter. The poorer results in the larger series may well be a reflection of a different patient population. Epidural lidocaine and steroid injections were used in a small number of patients with

chronic intractable rectal pain, but had no long-term effect on these patients who exhibited levator spasm as part of their pain syndrome. It did, however, sort out those patients who had no initial relief of their pain at the time of injection. These patients were considered to have pain from a high central, autonomic, or psychogenic origin.

Other modalities have been used for chronic pelvic pain, although not in the narrowly defined group with levator syndrome. Static magnetic field therapy<sup>33</sup> and pulsed magnetic stimulation<sup>34</sup> seem to have some salutary effect. Electrical sacral nerve stimulation, which has been used for voiding disorders and fecal incontinence, has also successfully reduced the severity of pain in patients who were broadly characterized as having chronic pelvic pain.<sup>35</sup> Investigators using linearly polarized near-infrared irradiation have also reported some success in participants with intractable anorectal pain.<sup>36</sup>

Anxiety and depression have been associated with chronic pelvic pain syndrome and these conditions should be considered in the comprehensive approach to the management of these patients with pelvic pain.<sup>37</sup>

## Coccygodynia

Coccygodynia, although may be part and parcel of the whole group of pelvic floor musculoskeletal problems, is distinguished by the distinct pain evoked with pressure or manipulation of the coccyx. Several rare tumors of the sacrum or sacral nerve structures have been demonstrated in patients with coccygodynia.<sup>38–40</sup> The condition has also been attributed to trauma, avascular necrosis, or referred pain from a prolapsed lumbar disk.<sup>41,42</sup> When no obvious explanation was available, it often was attributed to a psychosomatic manifestation of hysteria or depression. Although coccygectomy was popular at one time, in recent times, it has generally been regarded as ill conceived by most surgeons. Wray and his group<sup>43</sup> from Leicester studied a group of 120 patients with coccygodynia. They randomized them between treatment with injections of methylprednisolone and bupivacaine alone or injections and manipulation of the coccyx under general anesthesia. Injections alone were successful in 60% and injections plus manipulation was successful in 85% of the patients in that arm of the study. The 23 patients who failed either of these two treatments came to coccygectomy and 21 of 23 had a good result, suggesting that this operation may not be inappropriate in those patients who have failed a trial of less invasive therapy. This success rate with coccygectomy is similar to that reported in two other retrospective series.<sup>44,45</sup>

## Proctalgia Fugax

Proctalgia fugax, as the name implies, is a fleeting pain in the area of the rectum lasting no more than a minute or two. The pain is too transient to study very well, but, presumably, it is secondary to spasm of the rectum itself or muscular components of the pelvic floor. In a British survey of a healthy

population, 14% of the patients reported that this phenomenon occurred at least once a year and 5% reported the phenomenon more than six times per year.<sup>46</sup> Kamm et al.<sup>47</sup> has described a family with a hereditary internal anal sphincter myopathy in which the proctalgia fugax was a very frequent occurrence.

The role of the physician in these cases is mainly to assure the patient that this is not a symptom of any serious disorder. The use of perianal nifedipine in the same doses and method as for anal fissure and hypertrophic internal anal sphincter may be of benefit. There are no randomized trials to document improvement.

## Pudendal Neuralgia

Pudendal neuralgia is a symptom complex, which is manifest by chronic pelvic/perineal pain in the distribution of one or both pudendal nerves. It may be manifest as vulvodynia, orchalgia, proctalgia, or prostatodynia. The pain patterns overlap with those of levator syndrome, coccydynia, and urethral syndrome. It is attributable to compression or entrapment of the pudendal nerve and often is positional in nature. Some have also attributed disordered defecation to pudendal nerve entrapment and have reported resolution with nerve decompression.<sup>48</sup> This diagnosis should be entertained if there is a history of trauma, either a distinct episode or chronic perineal trauma such as seen in cyclists or rowers.<sup>49</sup>

The pudendal nerve arises from S2, S3, and S4 of the sacral plexus. The nerve leaves the pelvis beneath the piriformis muscle through the greater sciatic foramen. It then passes on to the sacrospinous ligament medial to the ischial spine and reenters the pelvic cavity. While beneath the levator ani muscles, it runs ventrally through Alcock's canal, a thickening of the obturator internus fascia. In the ischioanal fossa, it gives off an inferior rectal and perineal branch. The two documented sites of pudendal nerve entrapment are between the sacrotuberous and sacrospinous ligament and in the pudendal (Alcock's) canal. Antolak et al.<sup>50</sup> have hypothesized that many patients with chronic pain have induced hypertrophy of the pelvic muscles caused by athletic activities in their youth, which has in turn caused remodeling of the ischial spine and rotation of the sacrospinous ligament and nerve compression. The diagnosis of pudendal neuralgia is supported by reproduction of the pain with pressure on the ischial spine although this is not a constant finding. Pudendal nerve latency is often prolonged when it is tested. Nerve block under computed tomography<sup>51</sup> or ultrasound guidance<sup>52</sup> has been used to sort out those patients who would likely benefit from neurolysis. Mauillon et al.<sup>53</sup> surgically decompressed the pudendal nerve in 12 patients after evaluating them with a nerve block under computed tomography guidance. After 21 months of follow-up, three patients were completely relieved of their pain and one slightly improved. Eight patients remained in pain. In the three patients who were completely relieved of their pain, the nerve block had eliminated their pain for 2 weeks on two separate occasions. Pain relief was obtained with nerve block

in only one of the nine patients in whom nerve decompression was unsuccessful.

## Conclusion

Various benign anorectal conditions may cause considerable trouble for patients. A stepwise, scientifically sound approach to the evaluation and treatment of these disorders may offer a prompt diagnosis and treatment. Referral of patients who continue to suffer despite the physician's best treatment efforts is encouraged.

## Laparoscopy

Peter W. Marcello and Tonia Young-Fadok

Until recently, there has been a relatively slow adoption of laparoscopic colectomy into the surgeon's practice. The persistence of the learning curve, the modest advantages reported, and the concerns regarding the safety of laparoscopic resection for curable colon cancer are but a few of the reasons that the percentage of laparoscopic colorectal procedures has not dramatically increased. With the publication of the several large prospective, randomized trials for colon cancer, however, there seems to be a renewed interest in minimally invasive procedures for the colon and rectum. This chapter will review these issues and provide a current assessment of the field for the common disease processes to which laparoscopic techniques have been applied.

### Learning Curve

Laparoscopic colorectal surgery has met with certain challenges that distinguish it from other minimally invasive procedures. In comparison to laparoscopic cholecystectomy, the surgeon performing laparoscopic colectomy has to work in multiple quadrants of the abdomen. This requires a better understanding of depth perception and proprioception. A coordinated team consisting of a surgeon, an assistant, and often a camera person is required. All three must work together along with the nursing and anesthesia teams. The surgeon may also need to work in reverse angles to the camera. All of these combined add to the complexity of the procedure and result in the need to perform a number of cases before the surgeon and surgical team will become proficient. Numerous previous studies have evaluated the "learning curve" of laparoscopic colectomy.<sup>1-3</sup> It is estimated that with conventional laparoscopic techniques and instruments that the learning curve for laparoscopic colectomy is at least 20 cases and more likely 50 cases.

Recent publications have suggested the learning curve is more than 20 cases. In a prospective, randomized study of colorectal cancer in the United Kingdom, the "CLASICC" trial, surgeons had to perform at least 20 laparoscopic resections

before they were allowed to enter the study.<sup>4</sup> The study began in July 1996 and was completed in July 2002. Despite the surgeons' prior experience, the rate of conversion decreased from 38% to 16% over the course of the study, suggesting that a minimum of 20 cases may not be enough to reach the plateau of the "learning curve." In the COLOR trial from Europe,<sup>5</sup> another recent prospective randomized study for colon cancer that required a prerequisite experience in laparoscopic colon resection before surgeons could enter patients into the study, surgeon and hospital volume were directly related to a number of operative and postoperative outcomes. The median operative time for high-volume (>10 cases/year) hospitals was 188 minutes compared with 241 minutes for low-volume (<5 cases/year) hospitals, and likewise conversion rates were 9% versus 24% for the two groups. High-volume groups also had more lymph nodes in the resected specimens, fewer complications, and shortened hospital stay. These two recent studies would suggest that the learning curve is clearly greater than 20 cases and that surgeons need to perform a minimum yearly number of procedures to maintain their skills.

The difficulty with the broad application of laparoscopic colectomy is that most general surgeons perform fewer than 50 segmental colon resections per year. In a review of 2434 general surgeons who were taking the recertification examination for the American Board of Surgery, all of whom supplied their operative lists from the previous year, most surgeons performed fewer than 20 colon resections in 1 year.<sup>6</sup> In fact, the mean number of colon resections performed by a surgeon was 11. Even at the 90th percentile, only 23 colectomies were performed by a surgeon in a single year. If the average surgeon performs 11 resections and only half are eligible for a laparoscopic approach, assuming a learning curve of 40 cases, it would take a surgeon 8 years to feel comfortable performing laparoscopic colectomy. Most surgeons cannot afford to go through such a learning curve. Either the learning curve will need to be shortened, as some have suggested by the use of hand-assisted laparoscopic (HAL) techniques, or we will need to limit the performance of

laparoscopic colectomy to surgeons who perform a greater number of colon resections per year.

## Conversions

The rates of conversion are inconsistent in the literature, with reports as low as 0% to as high as 48%. Most series report the need to convert in 10%–25% of cases. Although surgical proficiency would likely decrease the need to convert, this is counterbalanced by the surgeon's desire to perform more complex cases. Several patient- and disease-related factors such as obesity, prior abdominal surgery, acuity of inflammation (i.e., abscess and fistula formation), tumor bulk or contiguous involvement, and disease location, may also affect the rate of conversion. Obesity, defined as a body mass index  $>30$  kg/m<sup>2</sup>, was once considered a relative contraindication for a laparoscopic colon resection. For a surgeon early in their learning curve it should probably remain a relative contraindication. However, once more experience is gained by the surgeon, several current reports have demonstrated that obesity itself is not a contraindication to a minimally invasive approach.<sup>7–9</sup> For inflammatory conditions such as Crohn's disease and diverticulitis, the presence of an abscess or fistula may result in the need for conversion in up to 50% of cases.<sup>10,11</sup> More recent studies of laparoscopic surgery involving enteric fistulae suggest a conversion rate of 25%–35%.<sup>12–14</sup> The presence of a fistula or small abscess is not a contraindication to a minimally invasive approach, but should alert the surgeon to consider a variation in operative approach if obstacles cannot be overcome. Conversion from a laparoscopic to conventional resection should not be viewed as a failure of the laparoscopist. It is difficult to predict based on preoperative studies which cases cannot be completed laparoscopically. More crucial than the rate of conversion is the time spent before conversion. An initial laparoscopic survey may quickly identify a complex process, allowing a speedy alteration in the operative plan. If the approach is expeditiously changed, little additional time or costs need be incurred. Earlier reports suggested a poorer outcome for patients who required conversion; however, more recent studies, including a recent presentation of the COST trial results, suggest that if conversion is made early the outcome of converted cases is similarly matched with patients undergoing conventional surgery.<sup>15,16</sup> The goal is to perform a preemptive conversion once it is determined the case cannot be completed laparoscopically, rather than a reactive conversion to a complication that occurred because of adverse conditions that the surgeon could have avoided.

## Outcomes

In comparison to conventional colectomy, the proposed benefits of laparoscopic colectomy include a reduction in postoperative ileus, less postoperative pain and concomitant reduction in the need for analgesics, an earlier tolerance of

diet, a shortened hospital stay, a quicker resumption of normal activities, improved cosmetic results, and possibly preservation of immune function. This is offset by a prolongation in operative time, the cost of laparoscopic equipment, and the learning curve of these technically challenging procedures. When reporting the outcomes of laparoscopic colectomy, there is however, a natural selection bias when comparing conventional and laparoscopic cases. More complex cases are generally not suitable for a laparoscopic approach and therefore are performed "open." Also, in many series the results of the successfully completed laparoscopic cases are compared with conventional cases and the cases converted from a laparoscopic to conventional procedure. Few studies, with the exception of the larger prospective, randomized studies, leave the "converted" cases in the laparoscopic group as part of the "intention to treat" laparoscopic group. This clearly introduces selection bias. In addition, there is wide variability in the types of laparoscopic procedures performed, the reporting of results, and cultural variations in patient management.

Although the results of prospective, randomized trials are becoming more available, the majority of studies of laparoscopic colectomy are retrospective case control series or noncomparative reports. The conclusions regarding patient outcomes, therefore, must come from the repetitiveness of the results rather than the superiority of study design. For any one study, the evidence is weak, however collectively, because of the reproducibility of results by a large number of institutions, even with different operative techniques and postoperative management parameters, the preponderance of evidence favors a minimally invasive approach with respect to postoperative outcomes. Also, the prospective, randomized studies that are available corroborate the findings demonstrated in nonrandomized studies.

## Operative Time

Nearly all the comparative studies provide information regarding operative times. The definition of the operative time may vary with each series, and there may be different groups of surgeons performing the laparoscopic and conventional procedures. With the exception of a few reports, nearly all studies demonstrated a prolonged operative time associated with a laparoscopic procedure. In prospective, randomized trials, the procedure was approximately 40–60 minutes longer in the laparoscopic groups. As the surgeon and team gain experience with laparoscopic colectomy, the operating times do reliably decrease, but rarely do they return to the comparable time for a conventional approach.

## Return of Bowel Activity and Resumption of Diet

Reduction in postoperative ileus is one of the proposed major advantages of minimally invasive surgery. Nearly all of the historical and prospective studies comparing open and

laparoscopic colectomy have shown a statistically significant reduction in the time to passage of flatus and stool. Most series demonstrate a 1- to 2-day advantage for the laparoscopic group. Whether the reduction of ileus relates to less bowel manipulation or less intestinal exposure to air, or some other factor, during minimally invasive surgery remains unknown.

In clinical studies, it is difficult to eliminate all the biases of the treating physician and the higher expectations of the patient undergoing laparoscopic surgery. Psychological conditioning of the patient preoperatively may interfere with an objective assessment of bowel activity postoperative. To more formally answer this question, both human and animal studies have evaluated the return of gastrointestinal motility. Both canine and porcine models have confirmed an earlier return of intestinal myoelectric activity after laparoscopic resection.<sup>17,18</sup> Another study in dogs demonstrated a quicker return to preoperative motility, using radionuclide techniques in animals subjected to laparoscopic resection.<sup>19</sup> These studies clearly demonstrate a quicker return of bowel activity without the subjective bias that may be introduced in clinical studies.

With the reduction in postoperative ileus, the tolerance by the patient of both liquids and solid food is quicker after laparoscopic resection. The time to resumption of diet varies from 2 to 7 days, but in the majority of comparative studies, this still remains 1–2 days sooner than in patients undergoing conventional surgery. Again, the physician and patient were not blinded, which may alter patient expectations. The overwhelming reproducible data reported in both retrospective and prospective studies of laparoscopic procedures, however, do likely favor a reduction of postoperative ileus and tolerance of liquid and solid diet.

## Postoperative Pain and Recovery of Pulmonary Function

To measure postoperative pain, a variety of different assessments have been performed to demonstrate a significant reduction in pain after minimally invasive surgery; some studies use an analog pain scale, whereas others measure narcotic requirements. Physician bias and psychological conditioning of the patients may interfere with the evaluation of postoperative pain. There are also cultural variations in the response to pain. Three of the early prospective, randomized trials have evaluated pain postoperatively and all three have found a reduction in narcotic requirements in patients undergoing laparoscopic colectomy.<sup>20–22</sup> In the COST study,<sup>23,24</sup> the need for both intravenous and oral analgesics was less in patients undergoing successfully completed laparoscopic resections. Numerous other nonrandomized studies have shown a reduction in postoperative pain and narcotic usage.

Closely related to the severity and duration of postoperative pain is the return of pulmonary function. Adequate pain management allows the patient to inspire more deeply. After conventional abdominal surgery, suppression of pulmonary function is a well-known sequelae. Several studies of

laparoscopic colectomy have evaluated the return of pulmonary function. In the randomized clinical trial of patients undergoing surgery for colon cancer from the Cleveland Clinic, preoperative and postoperative spirometry was performed every 12 hours in 55 patients in the laparoscopic group and 54 patients in the conventional group.<sup>20</sup> An 80% recovery of baseline-forced vital capacity and forced expiratory volume in one second was measured in each patient. The median recovery for the laparoscopic group was 3 days which was half the recovery (6 days) seen in the conventional group. A similarly designed study by Schwenk et al.<sup>22</sup> confirmed these same results. Whether subject to bias, the results of comparative studies suggest a quicker recovery of pulmonary function and reduction in postoperative pain in patients subjected to laparoscopic colectomy.

## Length of Stay

The quicker resolution of ileus, earlier resumption of diet, and reduced postoperative pain have resulted in a shortened length of stay for patients after laparoscopic resection when compared with traditional procedures. Recovery after conventional surgery has also been shortened by early feeding practices introduced more recently, but this is not consistent throughout the literature. In the absence of minimally invasive techniques, it would seem unlikely that the length of stay could be further reduced. In nearly all comparative studies, the length of hospitalization is 1–6 days less for the laparoscopic group. In an attempt to minimize the differences between a conventional midline incision and a laparoscopic incision, Fleshman et al.<sup>25</sup> compared the outcomes of 35 patients whose surgery was performed through a minilaparotomy (12 cm, mean incision length) with 54 laparoscopic patients. Outcome was similar for both groups with a mean day of discharge of 6.9 days (range, 3–15 days) for the minilaparotomy group and 6.0 days for the laparoscopic group (range, 1–15 days). However, when the results of successfully completed laparoscopic cases (75%) were compared, the results favored the laparoscopic group (5.3 days; range, 1–14 days). Therefore, despite an attempt to minimize the incision, the overall length of stay was significantly longer.

Although psychological conditioning of the patient cannot be helped and likely has a desirable effect, the benefits of minimally invasive procedures on the overall length of stay cannot be discounted. The benefit, however, is more likely a 1- to 2-day advantage only. The more recent introduction of clinical pathways both in conventional and laparoscopic surgery has also narrowed the gap, but seems to be more reliable in patients undergoing a minimally invasive approach.<sup>26,27</sup>

## Quality of Life and Return to Work

If laparoscopic colectomy results in less postoperative pain and earlier return to normal activities, then one would anticipate that the quality of life after a laparoscopic procedure

should be improved when compared with conventional procedures. Unfortunately, despite the numerous reports of laparoscopic colectomy, few have objectively examined the patient's assessment of recovery. In a nonrandomized study, Psaila et al.<sup>28</sup> evaluated the recovery of hand-grip strength and the patient's quality of life using an SF-36 symptom score 2 months and 4 months postoperatively. Hand-grip strength, as a measure of protein loss, recovered more rapidly after laparoscopic surgery. Using the SF-36 questionnaire, in six of eight areas of questioning, there was less impairment of health after laparoscopic colectomy. By 4 months postoperatively, this trend persisted, but to a lesser degree. In the COST study, quality of life was evaluated by three complementary viewpoints: patient self-reported symptoms, patient self-reported functional status, and a third more objective measurement scale of compliance to treatment referred to as Q-TWIST (quality-adjusted time without symptoms of disease and toxicity of treatment).<sup>23</sup> Because of a high conversion rate of 25% in the initial study report, and the "intention to treat" design of the study, there were no significant differences between the conventional and laparoscopic groups with the exception of a global rating score 2 weeks after surgery. In every category, however, the results of patients who had a laparoscopically completed procedure were improved compared with conventionally performed procedures and in laparoscopic patients who required a conversion to open surgery. However, this did not achieve significance. The results of the CLASICC trial in the United Kingdom found similar results.<sup>4</sup>

Only a few studies have assessed the ability of patients undergoing laparoscopic colectomy to return to work. With less postoperative pain and reduced narcotic usage, one would presume that patients undergoing a minimally invasive approach would return more quickly to normal activities and employment compared with patients undergoing a conventional resection. In a nonrandomized comparison, patients undergoing laparoscopic procedure returned to full activities and to work sooner than matched patients undergoing conventional resection [mean, 4.2 versus 10.5 weeks, 3.8 versus 7.5 weeks, respectively ( $P < .01$  for all)].<sup>29</sup>

## Hospital Costs

One of the proposed disadvantages of laparoscopy is the higher operative costs related to longer operative times and increased expenditure in disposable equipment. Whether the total cost of the hospitalization (operative and hospital costs) is higher after laparoscopic colectomy is debatable. A case control study from the Mayo Clinic has looked at total costs after laparoscopic and open ileocolic resection for Crohn's disease.<sup>30</sup> Sixty-six patients underwent laparoscopic ( $n = 33$ ) or conventional ( $n = 33$ ) ileocolic resection during the same time period (10/95–7/99) and were well matched. Patients in the laparoscopic group had less postoperative pain, tolerated

a regular diet sooner by 1–2 days, and had a shorter length of stay (4.0 versus 7.0 days). In their cost analysis, despite higher operative cost, the overall mean costs were \$3273 less in the laparoscopic group. The procedures were performed by different groups of surgeons at the institution, and although the surgeon may have introduced biases, this study was undertaken during the current era of cost containment in which all physicians are encouraged to reduce hospital stay. Other studies by Dupree et al.<sup>31</sup> and Shore et al.<sup>32</sup> have confirmed these findings with a mean reduction of \$438 in costs and \$7465 in hospital charges, respectively, in patients undergoing laparoscopic compared with conventional ileocolic resection. The results are similar for elective sigmoid diverticular resection with a mean cost savings of \$700–\$800.<sup>33</sup> Clearly, if operative times and equipment expenditure are minimized, the overall cost of a laparoscopic resection should not exceed a conventional approach.

## Crohn's Disease

Laparoscopy in the setting of inflammatory bowel disease has its own set of unique challenges that must be overcome. For patients with Crohn's disease, the dissection is hampered by inflammatory changes in the mesentery, difficulty in assessing bowel involvement and identifying normal anatomic landmarks, along with the development of associated abscess and fistulous disease often seen in the Crohn's patient. For the ulcerative colitis patient and the patient with isolated Crohn's colitis, the challenges are more technical because of the difficulty in performing laparoscopic total colectomy.

Crohn's disease of the terminal ileum seems an ideal model for the application of a minimally invasive approach. The disease is usually limited to one area of the abdomen and only mobilization and vascular pedicle ligation are required laparoscopically. The resection and anastomosis are generally performed extracorporeally. Patients with Crohn's are typically young and are interested in undertaking a procedure that minimizes incisional scarring. Additionally, because many of these patients will require reoperation over their lifetime, a minimally invasive approach is appealing. Early reports of laparoscopic ileocolic resection showed it to be feasible and safe, but were typically small nonrandomized uncontrolled studies. More recent studies (Table 50-1) have a larger experience in which to draw more meaningful conclusions.<sup>35–47</sup> The majority of studies, however, are retrospective case control series. Most series report the rate of conversion from 10% to 20% with the mix of complex cases (abscess, fistula, or reoperative surgery) ranging from 40% to 50%.

As expected, the outcomes after laparoscopically assisted ileocolic resection for Crohn's disease mirror those seen in other studies of laparoscopic colectomy for benign and malignant disease. In comparative studies (Table 50-1), laparoscopic ileocolic resection is associated with a quicker return of bowel function and an earlier tolerance of oral diet. The

OP, operative; LOS, length of stay; LAP, laparoscopic; CON, conventional.

quicker resolution of ileus, earlier resumption of diet, and reduced postoperative pain has resulted in a shortened length of stay for patients after laparoscopic resection when compared with traditional procedures. Milsom et al.<sup>43</sup> published a prospective, randomized trial comparing conventional and laparoscopic ileocolic resection for refractory Crohn's disease. Sixty patients were randomized to either conventional or laparoscopic resection after an initial diagnostic laparoscopy to assess feasibility of a laparoscopic resection. The results favor a laparoscopic approach with regard to pulmonary function, morbidity, and length of stay. There were no apparent short-term disadvantages. All patients had oral intake withheld for 3 days to evaluate nutritional parameters. This impacted on the timing of dietary intake and was likely responsible for a delay in discharge in some patients. The total length of stay in this randomized study was 1 day shorter in the laparoscopic group (5 versus 6 days) but did not reach statistical significance. Had dietary intake not been withheld, a shortened length of stay of the laparoscopic group might have achieved significance.

With the loss of tactile sensation, one of the remaining concerns of performing laparoscopic surgery in the patient with terminal ileal Crohn's is missing an isolated proximal lesion. Many patients after ileocolic resection will develop a symptomatic recurrence proximal to the ileocolic anastomosis, but whether patients undergoing a laparoscopic procedure will present with unrecognized proximal disease remains unclear. There are now, however, several studies that have reported recurrence rates after laparoscopic ileocolic resection. In a recent article, the long-term follow-up (mean 39 months) of 32 patients over 7 years who underwent a laparoscopic ileocolic resection were compared with 29 patients undergoing open resection.<sup>46</sup> The rate of Crohn's recurrence was high but similar in both groups (48% laparoscopic, 44% conventional) as was the disease-free interval (24 months). In another recent review of long-term outcome, Bergamaschi et al.<sup>47</sup> reported the results of 39 laparoscopic and 53 conventional ileocolic resections with a 5-year follow-up. Recurrent disease was determined by patient symptoms and confirmed both radiographically and endoscopically in 27% of patients undergoing a laparoscopic procedure and in 29% of patients with a conventional resection. Interestingly, the incidence of small bowel obstruction was significantly less in the laparoscopic group (11% versus 35%,  $P = .02$ ). This was thought to be the result of less adhesion formation after a laparoscopic procedure. Laparoscopic ileocolic resection does not seem to offer any advantage over conventional resection with regard to symptomatic recurrence, but it also did not lead to a higher rate of recurrence or discovery of a missed lesion.

Laparoscopic ileocolic resection for Crohn's disease seems to be safe and feasible and offers the advantages seen in other reports of laparoscopic colorectal procedures. For the inexperienced laparoscopist, the initial uncomplicated terminal ileal resection is an ideal procedure in which to gain laparoscopic experience. An initial laparoscopic survey

should be performed in the majority of patients with refractory ileal Crohn's disease with a low threshold to alternate the approach if a complex case beyond the skill of the surgeon is encountered.

## Ulcerative Colitis

There are no prospective, randomized studies of laparoscopic proctocolectomy for ulcerative colitis. The only results available for analysis are prospective and retrospective case control studies and noncomparative reports (Table 50-2).<sup>48-59</sup> Several reasons likely account for the slow acceptance of laparoscopic proctocolectomy including the steep learning curve to performing even segmental colectomy, the technical challenges of transverse colon resection, and the unfavorable early reports of laparoscopic total colectomy. The group from Cleveland Clinic Florida attempted laparoscopic proctocolectomy for patients with ulcerative colitis in the early 1990s and published several comparative reports.<sup>60,61</sup> The results showed a longer operative time and higher blood loss than matched open procedures with no apparent benefit. The authors discouraged the use of minimally invasive techniques for patients requiring total colectomy. This was an appropriate recommendation during the early era of laparoscopic colectomy. However, with advances in technology and experience gained with segmental resection, many groups have reevaluated the role of laparoscopic total colectomy for inflammatory bowel disease.

The majority of reports have shown that laparoscopic total colectomy and laparoscopic proctocolectomy with and without ileoanal pouch construction are technically feasible and share the same advantages of minimally invasive surgery as segmental colonic resection. Laparoscopic proctocolectomy has been performed in the elective setting, but several groups have performed laparoscopic total colectomy on an urgent basis for the patient with unresolving acute colitis. These procedures, however, are still not recommended for the patient with toxic colitis.

Even though some groups perform this procedure routinely, the procedures remain technically challenging with operative times in the 3- to 5-hour range. In an effort to reduce operative times, several groups have recently reported the use of hand-assisted techniques for restorative proctocolectomy.<sup>57,59</sup> In a small comparative study from the Lahey Clinic, the effectiveness of the HAL approach was compared with a conventional laparoscopic method in patients undergoing laparoscopic proctocolectomy.<sup>57</sup> Both groups [10 HAL versus 13 standard laparoscopy (SL)] were well matched, with no differences in age, sex, ASA level, operative indication, steroid usage, or diagnosis. The results demonstrated no differences in incision size (mean 8 cm), operative blood loss, rate of conversion (HAL 10% versus SL 0%), or complications (HAL 40% versus SL 31%). The operative times progressively decreased in the hand-assisted group (mean

TABLE 50-2. Recent studies of laparoscopic colectomy for ulcerative colitis

Nakajima et al. <sup>59</sup>	2004	16	Hand-assisted technique, favorable results

IPAA, ileal pouch–anal anastomosis; EBL, estimated blood loss; LOS, length of stay.

247 minutes) while remaining constant in the laparoscopic group (mean 300 minutes,  $P < .05$ ) over the period of study. This 1-hour reduction in operative is significant to the busy practicing surgeon and may open the door to more surgeons in performing laparoscopic restorative proctocolectomy. Another recent study by Nakajima et al.<sup>59</sup> showed similar advantages of hand-assisted total colectomy for ulcerative colitis. It seems that hand-assisted restorative proctocolectomy can be accomplished without detriment to bowel function, length of stay, or patient outcome.

The role of laparoscopic total colectomy for patients with inflammatory bowel disease is not well defined, but is likely to expand as surgeons become more comfortable with segmental resection. Advantages seen in segmental resection have recently been reproduced in patients undergoing laparoscopic total colectomy. Again, although the evidence based on study design and size for any one report is not optimal, the reproducibility of the results among many institutions provides adequate evidence to demonstrate clear advantages of laparoscopic total colectomy for ulcerative colitis over a conventional approach. The use of HAL for ulcerative colitis patients requiring surgery is likely another venue that may shorten operative time while maintaining the benefits of a minimally invasive approach.

## Diverticulitis

Laparoscopic sigmoid resection remains the leading indication for minimally invasive colon resection for benign disease. The surgery is hampered by both the fibrotic changes associated with elective resection of recurrent disease and the inflammatory changes associated with acute disease. As surgeons acquire their laparoscopic skills, more complex cases involving abscess and fistulous communications have been successfully completed laparoscopically. There are now a large number of studies evaluating laparoscopic surgery for diverticulitis (Table 50-3).<sup>62–75</sup> These are both large case series and nonrandomized comparative studies with open resection. Most series report an operative time of 2–3 hours with a conversion rate of 10%–20% for most larger series. The largest series of diverticular resection comes from a German multi-institutional study of 1545 patients accumulated over 7 years at 52 institutions.<sup>68</sup> The study demonstrated a low morbidity and mortality with an overall conversion rate of 6.1%. As experience increased, the percentage of complex cases increased without significantly altering the morbidity or rate of conversion. High-volume centers performed more of the complex cases with a similar conversion rate to the low-volume centers that performed less complex cases.

§Minilaparotomy.

Nearly all comparative studies of laparoscopic to open sigmoid resection demonstrate a benefit to the laparoscopic approach including a shorter duration of ileus, shortened length of stay, but as in other studies, with a prolonged operative time. Early reports suggested a higher overall cost associated with a laparoscopic approach for diverticular resection; however, more recent studies (Table 50-4) have demonstrated a cost saving with the laparoscopic approach. This cost reduction has been noted not only in the United States, but also in European countries. It should be noted that these are generally the elective uncomplicated cases with fewer patients presenting with abscess or fistula formation. For more complex cases, in which the operative times are longer and the rate of conversion is higher, the cost savings benefit of a laparoscopic approach may be lost. This highlights the importance of case selection when considering a laparoscopic approach. Less-experienced surgeons should consider an early conversion of complicated diverticular resection or potentially an alteration in the approach to a hand-assisted technique in which the difficult pelvic dissection can be guided by the hand laparoscopically or by conventional means through the open wound.<sup>76</sup>

## Rectal Prolapse

As with other disease processes, the field of laparoscopy has expanded to the treatment of rectal prolapse. Full-thickness rectal prolapse repaired by an abdominal fixation procedure is potentially an ideal procedure for a laparoscopic approach because there is no specimen to remove or anastomosis to create. There are many studies that have evaluated not only laparoscopic fixation procedures but also the combination of sigmoid resection and rectopexy for the treatment of rectal prolapse (Table 50-4).<sup>77-98</sup> The magnified view into the pelvis with the laparoscope provides unparalleled visualization into the pelvic floor and the relative laxity of the rectal fixation to the presacral area is beneficial to performance of a laparoscopic procedure. This likely is the reason for the relatively low rate of conversion (<10%) for a laparoscopic rectopexy or resection and rectopexy in comparison to other laparoscopic colorectal procedures. The mobilization of the rectum for rectal prolapse is an ideal procedure in which to learn the laparoscopic technique of rectal mobilization which may then be applied to other procedures such as laparoscopic proctocolectomy or total mesorectal excision for rectal cancer.

In addition to case series results, there have been several nonrandomized comparative studies of laparoscopic versus conventional rectopexy and resection rectopexy.<sup>87,88,94</sup> These studies showed a longer operative time of 45–60 minutes with the laparoscopic procedures but with a shortened length of stay of 2–3 days. Functional results after surgery were similar in laparoscopic and conventional groups, with the majority of patients reporting an improvement in incontinence and constipation. Solomon et al.<sup>93</sup> also reported a prospective, randomized study of 40 patients with full-thickness rectal prolapse. This was a well-designed study with the use of blinded

observers, and a standardized clinical pathway for both groups. As expected, the mean surgical time was 153 minutes in the laparoscopic group compared with 102 minutes in the open group ( $P < .01$ ). In the laparoscopic group, however, 75% of patients followed the clinical pathways as compared with only 37% of patients in the conventional group. The mean length of stay was also less (3.9 versus 6.6 days,  $P < .01$ ) with 19/20 patients in the laparoscopic group discharged by postoperative day five as compared with 9/19 patients in the conventional group. There were no differences in postoperative pain scores but total intravenous narcotic usage was less in the laparoscopic group. Functional outcomes of surgery were equivalent, and there were no recurrences of prolapse in either group with a short mean follow-up of 24 months. Although the study is small in size, the outcomes mirror the results of other prospective, randomized studies of laparoscopic surgery for other diseases and procedures. A later cost analysis of this study demonstrated an overall mean cost savings of \$500 per patient in the laparoscopic group.<sup>98</sup>

One of the major issues when discussing surgery for rectal prolapse is the rate of recurrent prolapse. For an abdominal approach, the risk of recurrence should be less than 5%–10% over 5 years. Unfortunately, the majority of reports on laparoscopic surgery for rectal prolapse have limited follow-up (less than 3 years). The reported rate of recurrence ranges from 0% to 6% in these studies (Table 50-4). Recently, however, there have been two studies with a mean follow-up of 5 years.<sup>95,97</sup> In a study of 42 patients by D'Hoore et al.,<sup>95</sup> with a mean follow-up of 61 months, the rate of recurrent prolapse was 4.8%. In the largest study of laparoscopic surgery for rectal prolapse by Ashari et al.,<sup>97</sup> with 117 patients over a 10-year period and a mean follow-up of 62 months, the rate of recurrent full-thickness prolapse was only 2.5%. The study, however, noted an 18% rate of mucosal prolapse, which is somewhat concerning. Further long-term follow-up of these patients is needed to ensure that the rate of recurrence remains acceptable. If the rate of recurrent prolapse is confirmed to occur at a rate equal to conventional surgery, a minimally invasive approach to rectal prolapse seems to be an ideal operation for surgeons with laparoscopic skills.

## Colorectal Cancer

It is estimated that more than 105,500 new cases of colon cancer and 42,000 new cases of rectal cancer were diagnosed in the United States in 2003.<sup>99</sup> Before 2004, fewer than 5% of resections for colon and rectal cancer were being performed laparoscopically. Early in the history of laparoscopic resection of colorectal cancer there was controversy related to the phenomenon of cancer implants at incision sites. Data from randomized, controlled trials, however, have laid to rest these controversial aspects of the minimally invasive approach. The percentage of cases performed laparoscopically is expected to increase, as more surgeons become familiar with these techniques.

## Background

After the success of minimally invasive techniques for cholecystectomy, reports of laparoscopic colon resections soon appeared.<sup>100</sup> Sadly, the specter of wound implants, or recurrence of cancer in the laparoscopic incisions, followed shortly thereafter. In retrospect, it seems that in the attempt to allow patients to benefit from minimally invasive techniques, operations for colon cancer were being attempted that did not fulfill accepted oncologic principles, i.e., shortcuts were being taken with the extent of resection. Larger series by experienced surgeons showed that wound implants were not an inevitable accompaniment of the laparoscopic approach, but the damage was done. From 1994 to 2004 there was nearly a moratorium on laparoscopic resection for colon cancer, with some national surgical societies calling for these procedures to be performed only under the auspices of randomized, controlled trials or with other means of careful prospective data collection.<sup>102</sup> These concerns prompted an unprecedented number of randomized, controlled trials<sup>4,5,20–24,102,103</sup> and a new field of tumor and immunology investigation as they pertain to the pneumoperitoneum.

Lacy et al.<sup>103</sup> published the first large single-center randomized controlled trial in 2002. With median follow-up of 39 months, Lacy and his colleagues reported higher cancer-related survival for the laparoscopic arm. Specifically, they showed no difference between arms for Stage II cancers, but an improved survival for the laparoscopic approach in Stage III cancers where the outcome was similar to that of Stage II patients. This was followed in 2004 by the results of the large multicenter COST study group.<sup>24</sup> With almost 900 patients randomized either to the open or the laparoscopic arm of the study, no differences were found in overall survival or disease-free survival. Further reassurance was provided in finding that there were only two wound recurrences in the laparoscopic group, and one in the open arm. Another of the large prospective randomized studies, the “CLASICC” trial from the United Kingdom, has also recently published results with similar findings except a higher rate of conversions was noted.<sup>4</sup> The results of these recent trials (Table 50-5) have demonstrated that similar oncologic resections can be achieved by experienced surgeons performing laparoscopic colorectal resections.

## Laparoscopic Resection of Colon and Rectal Cancer

The following description regarding the safe performance of laparoscopic resection for curable colon and rectal cancer is based on current literature and experience. The attention to technical detail is in response to the early concerns regarding oncologic outcomes. It is predicated on the understanding that patients with curable colon and rectal cancer are treated by

experienced surgeons whose minimally invasive skills fulfill the Credentialing Recommendations endorsed jointly by ASCRS (American Society of Colon and Rectal Surgeons) and SAGES (Society of American Gastrointestinal and Endoscopic Surgeons).<sup>104,105</sup>

## General Considerations

After detection of a colon or rectal cancer, routine evaluation incorporates preoperative staging, assessment of resectability, and determination of the patient’s operative risk. As part of this assessment, a laparoscopic approach may be contemplated. There are several factors to consider, primarily in terms of gauging the difficulty of the procedure and the likelihood of being able to perform it laparoscopically. The site of the tumor is important, because right and sigmoid colectomy are generally less technically demanding than, for example, low anterior resection. Documented extensive adhesions may preclude a minimally invasive approach, although laparoscopic resection is frequently possible in patients who have had prior abdominal operations. Obesity, and particularly the distribution of abdominal fat, may preclude laparoscopic resection, especially in the case of a rectal cancer in an obese male patient with a narrow pelvis. The patient should be informed of both laparoscopic and open alternatives, and the possible need for conversion. Above all, the surgeon must have adequate experience before embarking on resection for a potentially curable malignancy. Patients are increasingly sophisticated regarding their health care, and the surgeon must be prepared to answer questions about experience with the procedure.

## Tumor Localization

The entire colon and rectum should be evaluated to eliminate synchronous lesions.<sup>106,107</sup> This is usually achieved with colonoscopy, but this has limitations in terms of localization, particularly if a minimally invasive approach is being considered. Colonoscopy is most accurate for localization of a tumor in the rectum and cecum only. Lesions elsewhere in the colon may be inaccurately localized by colonoscopy in up to 14% of cases.<sup>108</sup> A laparoscopic approach requires accurate localization of the tumor to a specific segment of the colon, because even a known cancer may not be visualized from the serosal aspect of the bowel during laparoscopy. The wrong segment of colon may be removed if accurate localization has not been performed.<sup>109</sup>

A variety of other options is available to localize a lesion including preoperative colonoscopic marking with ink tattoo or metallic clips, barium enema, or intraoperative endoscopy. The area adjacent to a cancer or polyp may be marked either by endoscopic clips or submucosal india ink injection. If clips are placed, immediate abdominal X-rays films should be taken, otherwise intraoperative imaging with laparoscopic ultrasound

or fluoroscopy is necessary to localize the clip's location. This procedure is not frequently used because it requires an experienced radiologist and/or endoscopist. Preoperative endoscopic tattooing is a common method of tumor localization.<sup>110,111</sup> India ink is a nonabsorbable marker that has been reported in more than 600 cases for tumor localization since 1975. The ink is injected into the submucosa in three or four quadrants around the lesion, or 2 cm distal to the lesion if the tumor is in the distal colon and distal margins are potentially an issue (typically 0.5 cc per site). During diagnostic laparoscopy, the ink marking can be identified even at the flexures or transverse colon. India ink injection seems to be safe with few reported complications. Intraoperative endoscopy is hampered by persistent bowel distention, prolongation of operative times, and need for equipment and endoscopist intraoperatively. More recent studies have evaluated CO<sub>2</sub> colonoscopy which allows for more rapid absorption of the intracolonic gas which may facilitate its use during laparoscopic procedures.<sup>112</sup>

## Preoperative Staging

Guidelines are available for standard practices in preoperative assessment for open resection of colon or rectal cancer.<sup>113,114</sup> There are additional considerations with a laparoscopic approach to ensure accurate staging of the liver. In patients with colorectal cancer, the liver should be thoroughly evaluated using computed tomography (CT) with intravenous contrast, ultrasound, or magnetic resonance imaging. Because of limitation in tactile sensation associated with laparoscopy, these studies should be performed preoperatively. Alternatively, intraoperative laparoscopic ultrasonography offers the ability to fully evaluate the liver at the time of colorectal resection. Several studies have confirmed the feasibility and efficacy of laparoscopic ultrasound in the evaluation of liver metastasis from colorectal cancer.<sup>115–117</sup> Preoperative CT or ultrasound was a requirement of the COST randomized, controlled trial.<sup>24</sup> No excess of Stage IV disease was noted in the laparoscopic arm, suggesting that routine preoperative evaluation of the liver was equivalent in terms of oncologic outcome to palpation of the liver intraoperatively in the open arm of the study.

These considerations do not apply to rectal cancer, where staging CT scan and transanal rectal ultrasound should be routine.<sup>114,118</sup> Preoperative CT of the abdomen and pelvis, or hepatic ultrasound are routinely used in planning resection of rectal cancer, because the results may markedly alter the need for neoadjuvant therapy and the timing of the operative approach.

## Preparation For Operation

Perioperative guidelines address the use of outpatient bowel preparation, prophylactic antibiotics, blood cross matching, and thromboembolism prophylaxis.<sup>106</sup> None of these aspects

of patient care are affected by a laparoscopic approach, although some surgeons prefer to modify the bowel preparation. Despite lack of clear evidence of benefit from meta-analysis<sup>119</sup> and randomized, controlled trials,<sup>120–124</sup> a mechanical bowel preparation is frequently used in North America. Aside from the aesthetic aspects, an empty colon facilitates manipulation of the bowel with laparoscopic instruments. Use of large-volume mechanical bowel preparations may occasionally leave fluid-filled loops of small bowel that are more difficult to handle with laparoscopic instruments. A smaller-volume preparation may be used or the large-volume preparation may be followed by use of laxatives such as bisacodyl to reduce the volume of residual fluid. Some surgeons use 2- to 3-day periods of preparation rather than the usual 24 hours, especially if a completely laparoscopic approach and intracorporeal anastomosis is contemplated.<sup>125</sup>

## Operative Issues

Certain operative principles pertain specifically either to the colon or to the rectum. Other issues are relevant to both.

### Operative Techniques—Colon

Oncologic principles must not be compromised by a laparoscopic resection for colon cancer. Guidelines for colon cancer surgery outline recommendations for proximal and distal resection margins (based on the area supplied by the named feeding arterial vessel); mesenteric lymphadenectomy containing a minimum of 12 lymph nodes; and ligation of the primary feeding vessel at its base.<sup>126</sup> The randomized trials of laparoscopic colectomy adhered to these standard principles<sup>4,24,103</sup> and showed no significant difference in bowel margins, lymph nodes harvested, and, in the COST study, perpendicular length of the mesentery (a guide to the length of the vascular pedicle).<sup>24</sup> Inability to achieve these aims laparoscopically should prompt conversion to an open procedure.

These principles guide which steps of a procedure performed for cancer may be completed intracorporeally or extracorporeally. In the individual with a normal body mass index (BMI) undergoing right colectomy, it may be possible to divide the origin of the ileocolic pedicle extracorporeally using a small periumbilical extraction incision which overlies the base of the pedicle, and achieve an oncologically correct proximal ligation; intracorporeal ligation is obviously also an acceptable approach. In patients with BMI > 25, this ligation should be performed intracorporeally to ensure that the base of the pedicle is ligated. Intracorporeal ligation is required for proximal division of all other vessels unless a larger incision such as used for hand-assisted devices permits access via the incision to the origin of the vascular pedicle.

## Operative Techniques—Rectum

Similar guidelines exist for oncologically appropriate open rectal cancer surgery, with levels of evidence and grades of recommendation.<sup>114,118</sup> These include a distal margin of 1–2 cm, removal of the blood supply and lymphatics up to the origin of the superior rectal artery (or inferior mesenteric artery if indicated), and appropriate mesorectal excision with radial clearance. Again, these principles of adequate clearance of the primary tumor and supporting tissues should not be compromised by a laparoscopic approach.

There are no randomized trials evaluating laparoscopic resection of rectal cancer except for those patients included in the CLASICC trial.<sup>4</sup> Current opinion among laparoscopic experts is that the principles outlined apply equally to laparoscopic as to open procedures. Prospective<sup>127,128</sup> and retrospective<sup>129,130</sup> case series indicate that laparoscopic rectal resection is possible in selected patients. Compared with colonic resection, additional technical challenges are associated with operating within the confines of the pelvis. Multiple factors affect feasibility of an oncologically adequate laparoscopic resection for rectal cancer: tumor factors such as bulkiness, proximal or distal location; and patient factors, e.g., width of the pelvis, obesity, presence of a bulky uterus, and obscuration of tissue planes by prior radiation. Inability to perform an appropriate resection should prompt conversion.

## Contiguous Organ Attachment

En bloc resection is recommended for locally advanced adherent colorectal tumors.<sup>126</sup> A bulky tumor invasive into an adjacent organ may be detected by preoperative imaging, such as CT scan, and guide the recommendation for an open resection. A known T4 colonic cancer will prompt an open approach in the vast majority of cases,<sup>126</sup> although some experienced surgeons may complete en bloc resection of involved small bowel or abdominal wall laparoscopically. If a T4 lesion is discovered intraoperatively, conversion is indicated unless the surgeon is capable of performing en bloc resection.

## Prevention of Wound Implants

Port site recurrences, or wound implants, have been reported at both extraction site and trocar site incisions.<sup>131,132</sup> This unanticipated phenomenon has prompted extensive investigation. Current consensus is that wound implants should be kept at a rate less than 1% by correct oncologic technique and experience.

In vitro and in vivo animal models, not clinical practice, have generated most recommendations for avoidance of wound implants. Avoidance of the pneumoperitoneum and alternative gases have been evaluated. Gasless laparoscopy has shown decrease in port site metastases,<sup>133,134</sup> and no effect.<sup>135,136</sup> Tumor growth may be proportional to insufflation pressure.<sup>137</sup> Carbon dioxide is associated with increased

tumor implantation and growth,<sup>138</sup> but is clinically the safest and most widely used gas. Helium decreases tumor implants but is not easily adapted to the clinical setting.<sup>139–141</sup> Wound excision may either decrease<sup>142</sup> or increase<sup>143</sup> the rate of tumor implants.

Some experimental results are easily adapted to the clinical setting. The significance of aerosolization of tumor implants is controversial,<sup>144,145</sup> but because evacuation of the pneumoperitoneum via the ports rather than via the incision is easily performed, some experts advocate this practice.<sup>146</sup> Gas leakage along loosely fixed trocars (the “chimney effect”) may be associated with increased cancer wound implantation<sup>147</sup> so some surgeons fix the trocars to prevent slippage. Irrigation of the abdominal cavity and/or trocar site incisions with a variety of substances (e.g., povidone-iodine, heparin, methotrexate, cyclophosphamide, tauridine, and 5-fluoro-uracil) has decreased wound implants in animal models.<sup>136,140,148–153</sup> An expert panel convened by the European Association of Endoscopic Surgery (EAES) reported that half the members irrigated the port sites and all members protected the extraction site and/or extracted the specimen in a bag.<sup>146</sup>

The most important developments in the issue of wound implants are experience and the refinement of laparoscopic techniques and equipment that permit a true oncologic resection to be performed. Early reports of implant rates of 2%–21%<sup>131,132</sup> have not been reproduced in large retrospective series by experienced surgeons, who reported rates of 1% or less.<sup>154</sup> This is similar to the incisional recurrence rate for open colorectal cancer resection.<sup>155</sup> The multicenter randomized trial from the COST study group reported tumor recurrence in the surgical wounds in 2 of 435 laparoscopic cases (0.5%) and in one of 428 patients in the open colectomy group (0.2%,  $P = .50$ ).<sup>24</sup> Lacy et al.,<sup>103</sup> in a single center randomized trial, reported one implant in 111 patients for a rate of 0.9%. The COST study required all surgeons to have performed at least 20 colorectal resections before participation in the trial.<sup>24</sup> The member surgeons at Lacy’s institution had extensive experience. In the clinical setting, the experience of the surgeon is considered the most important factor in the prevention of implants.

## Training and Credentialing in Laparoscopic Colorectal Surgery

In terms of technical complexity, laparoscopic colon and especially rectal operations are considered toward the higher end of the spectrum. Adequate resection mandates mobilization of a large structure, arranging ports to facilitate dissection in several quadrants of the abdomen, ligation of large blood vessels, extraction of a bulky specimen, and creation of a safe anastomosis. Oncologic resections have the additional requirements of adequate distal and proximal margins, wide lymphadenectomy, ligation of the origin of the primary feeding vessel, and safe handling of the bowel.

Early studies estimated the learning curve for laparoscopic colectomy to be 20–50 cases.<sup>1–3</sup> The randomized, controlled multicenter COST study on laparoscopic versus open colectomy for colon cancer required each participating surgeon to have performed 20 cases.<sup>24</sup> This was also seen in the CLAS-ICC trial.<sup>4</sup> This figure became the basis of the Approved Statement from the ASCRS and endorsed by SAGES after the publication of the results of the COST study.<sup>104,105</sup> Because the results of this trial showed that the oncologic outcomes for laparoscopic colectomy were equivalent to those of open colectomy, the statement took the unusual step of defining a specific number of cases based on the study entry criteria. The following is the approved statement:

Laparoscopic colectomy for curable cancer results in equivalent cancer related survival to open colectomy when performed by experienced surgeons. Adherence to standard cancer resection techniques including but not limited to complete exploration of the abdomen, adequate proximal and distal margins, ligation of the major vessels at their respective origins, containment and careful tissue handling, and en bloc resection with negative tumor margins using the laparoscopic approach will result in acceptable outcomes. Based on the COST trial,<sup>24</sup> pre-requisite experience should include at least 20 laparoscopic colorectal resections with anastomosis for benign disease or metastatic colon cancer before using the technique to treat curable cancer. Hospitals may base credentialing for laparoscopic colectomy for cancer on experience gained by formal graduate medical educational training or advanced laparoscopic experience, participation in hands-on training courses and outcomes.<sup>104,105</sup>

The issue of defining numbers for credentialing purposes is a source of considerable controversy. National surgical societies have traditionally avoided specifying required case numbers in credentialing guidelines, trying to balance the needs of their member surgeons with the safety of patients. The learning curve for laparoscopic colectomy likely varies depending on the actual procedure (because the term “laparoscopic colectomy” in this case encompasses a wide variety of procedures), the underlying pathologic diagnosis, and the prior laparoscopic experience of the surgeon coupled with innate skill. The COST study, however, provides a basis for specifying a minimum experience. For perspective, a resident completing a General Surgery Residency Program in 2003 and entering practice had performed a mean of 120 cases on the large intestine (mode 106, Residency Review Committee for Surgery, Reporting Period 2002–2003). Of these, an average of 50 cases required resection and anastomosis. Thus, the guideline for 20 laparoscopic cases is not excessive or unreasonable in terms of attaining comparable experience before independent practice.

## Hand-assisted Laparoscopy

HAL colectomy has been advocated as an alternative to straight laparoscopic techniques. The reintroduction of the hand back into the abdomen during laparoscopy may overcome

some of the technical challenges associated with laparoscopic colectomy. Because an extraction site is required for specimen removal, supporters of a hand-assisted approach believe the hand should be placed through that wound to facilitate dissection and mobilization of the colon. The development of new sleeveless hand-assist devices provides for hand exchanges without the loss of pneumoperitoneum, allowing surgeons to perform the procedures without disruption.

There have been a number of randomized and nonrandomized studies that have evaluated HAL colectomy.<sup>156–167</sup> Ou,<sup>156</sup> in 1995, reported his initial experience in 12 patients undergoing colectomy by hand-assisted methods and compared it with 12 patients undergoing a conventional open method. He demonstrated that the hand-assisted procedures required on average 135 minutes compared with 100 minutes for the standard open method. Length of stay was reduced in the hand-assisted group with an average of 5.6 days compared with 8.3 days for open patients. Randomized trials by the HALS Study Group<sup>159,160</sup> and Targarona et al.<sup>162</sup> have demonstrated that hand-assisted colectomy provides similar functional results to straight laparoscopic resection with fewer conversions. In a randomized study by Kang et al.<sup>165</sup> comparing hand-assisted versus open colon resection, the hand-assisted approach resulted in shortened postoperative ileus, shortened length of stay, and smaller incision size with no difference in operative time or complications. Differing results were seen in another randomized study by Maartense et al.,<sup>166</sup> which compared the results of open proctocolectomy with ileoanal pouch construction to a hand-assisted approach. In this study, there was no difference in length of stay (>10 days) and longer operative times in the hand-assisted group. The majority of patients, however, were not diverted at the time of procedure which likely impacted the results of the operation. In a study of straight laparoscopic proctocolectomy with ileoanal pouch, patients who were not diverted had a prolonged hospitalization in comparison to those who were diverted.<sup>49</sup> The long length of stay in the Maartense study may relate to the avoidance of proximal fecal diversion and likely influenced their results and conclusions.

Nonrandomized studies have shown benefit to the hand-assisted approach in comparison to a straight laparoscopic technique, but most have a limited number of any single procedure.<sup>3,4,7–10,12</sup> A recent study by Chang et al.,<sup>76</sup> however, did report on a large series of laparoscopic and hand-assisted sigmoid resection. The results of 85 straight laparoscopic sigmoid resections were compared with 66 hand-assisted procedures. The patients shared similar demographics including a mean BMI of 29 kg/m<sup>2</sup>. The rate of conversion was significantly less in the hand-assisted group (0% versus 13%,  $P < .01$ ) with a shortened mean operative time (189 versus 205 minutes). The mean size of the extraction was larger in the hand-assisted group (8 versus 6 cm,  $P < .01$ ) but there was no difference in return of bowel function (mean, 2.5 versus 2.8 days) or the median length of stay (4 days). In the United States, there is currently a prospective,

randomized study underway that is comparing straight laparoscopic total colectomy and left colectomy to a hand-assisted approach. If the results of this trial are similar to those of the Chang study, surgeons may be more willing to adopt a hand-assisted technique, particularly to ascend the learning curve.

By returning the hand back to the abdomen, one of the potential advantages of a HAL colectomy is that surgeons with less laparoscopic skills may be able to perform these complex procedures more easily. In the study by Chang, colorectal surgeons without a large laparoscopic experience participated in 27% of hand-assisted resections compared with only 16% ( $P < .05$ ) of the straight laparoscopic procedures.<sup>76</sup> In a similar study comparing 85 straight laparoscopic total colectomy procedures to 45 hand-assisted operations, less-experienced surgeons were able to perform 20% of the hand-assisted procedures and only 5% of the straight laparoscopic operations.<sup>167</sup> These two studies, from a single institution, would suggest that a HAL colectomy may be easier to adopt than a straight laparoscopic approach, but this will need to be reproduced by other centers.

## Future Considerations

The field of laparoscopic colon and rectal surgery is slowly expanding. With advancement in techniques and technology along with the further training of our surgical and colorectal residents, the percentage of colorectal procedures that are performed by minimally invasive techniques will likely continue to increase. Surgeons who are more than 5–10 years from their residency and perform more than 20 colon resections a year will need to obtain advanced training and credentialing before performing laparoscopic colon resection. Hand-assisted technology and procedures may be used to expand the field of minimally invasive colorectal surgery. The results of the large multicenter prospective randomized trials comparing open to laparoscopic surgery for curable colon cancer have demonstrated modest short-term advantages to a laparoscopic approach while maintaining the oncologic integrity of the operation, when performed by experienced surgeons. There is less of a concern now for local port site recurrences of colon cancer, as was seen in the earlier reports. The laparoscopic resection of rectal cancer remains in the forefront and is likely the next area to be critically evaluated and advanced by laparoscopic surgeons.

# Pediatric: Hirschsprung's, Anorectal Malformations, and Other Conditions

Alberto Peña and Marc Sher

## Hirschsprung's Disease

Hirschsprung's disease (congenital megacolon) is an anomaly characterized by functional partial colonic obstruction caused by the absence of ganglion cells. It occurs in approximately 1 in 5000 births. Boys are more frequently affected than girls and it is more common in Caucasians. A deletion in the long arm of chromosome 10 has been found.<sup>1</sup> The functional disturbances in this condition are attributed to the absence of ganglion cells from the Auerbach's myenteric plexus (located between the circular and longitudinal layers of smooth muscle of the intestine), the Henle's plexus (located in the submucosa), and the Meissner's plexus (in the superficial submucosa). The absence of these cells probably produces uncoordinated contractions of the affected colon. This is translated into a lack of relaxation of the colon that results in partial colonic obstruction.

The length of the aganglionic colonic segment varies. In the most common type, the aganglionic segment includes the rectum and most of the sigmoid colon. Nearly 80% of all patients have this type. In approximately 10% of the patients, the aganglionosis extends to the area of the splenic flexure or the upper descending colon. Total colonic aganglionosis occurs in another 8%–10% of the patients. In those cases, the absent ganglion cells sometimes extend to the distal terminal ileum. In the so-called "ultrashort" aganglionosis, the ganglion cells supposedly are lacking only a few centimeters above the pectinate line of the rectum. This is a rather controversial condition. Very rarely, one can see patients who have universal aganglionosis, meaning that the ganglion cells are absent in the entire gastrointestinal tract, which is a lethal condition.

The clinical manifestations are those of a partial colonic obstruction. In addition, these patients have a poorly characterized immunologic mucosal defect that may explain why they suffer from an inflammatory process called enterocolitis, which is the main cause of death. In addition, fecal stasis seems to promote the proliferation of abnormal colonic flora (*Clostridium difficile*) as well as production of endotoxins that contribute to the aggravation of the clinical condition.

Usually the patient becomes symptomatic during the first 24–48 hours of life. Delayed passage of meconium (more than 24 hours), abdominal distention, and vomiting are the most common symptoms. A rectal examination may produce explosive passage of liquid bowel movements and gas, which dramatically improves the baby's condition. This clinical improvement only lasts for a few hours, after which the symptoms recur. If the colon is not decompressed, the infant usually suffers from sepsis, hypovolemia, and endotoxic shock. Cecal perforation may occur. About 25%–30% of these babies die when unrecognized or not treated.<sup>2</sup> Patients that do survive unrecognized and without treatment, ultimately develop the classic clinical picture initially described for this condition. They have severe constipation, a huge megacolon, and an enormously distended abdomen. This clinical situation is extremely rare nowadays in developed countries. Occasionally, these patients are misdiagnosed as having idiopathic chronic constipation. In the latter condition, the patients are not seriously ill, and it is very common for them to have overflow pseudo-incontinence (encopresis). A rectal examination discloses a rectum full of fecal matter. On the contrary, patients with Hirschsprung's disease usually have malnutrition, lack of normal development, an empty aganglionic narrow rectum, and they do not have soiling.

The presence of the symptoms described in a newborn must alert the clinician to the diagnosis of Hirschsprung's disease. An abdominal film shows massive dilatation of small bowel and colon. It is almost impossible to differentiate colon from the small bowel, in a plain abdominal film during the newborn period. A contrast enema is used in most institutions to clarify the diagnosis. The catheter should be introduced only a few centimeters into the rectum in order to be able to visualize the nondilated aganglionic segment of the rectosigmoid, followed by a transitional zone and then a proximal dilatation. These typical changes are often not obvious during the neonatal period. The older the patient, the more obvious the size difference between normal and aganglionic segment. In patients with total colonic aganglionosis, the entire colon is not distended; the dilatation affects the small bowel only.

A manometric study may show an absent rectoanal inhibitory reflex. However, this study is not considered reliable for this diagnosis early in life but more helpful in the adolescent or adult with unrecognized short segment disease.

The definitive diagnosis is based on both the histologic absence of ganglion cells, and the presence of hypertrophic nerves in a rectal biopsy. These can be taken as full-thickness rectal biopsies under direct vision. More recently, a suction biopsy has gained wide acceptance. The specimen, however, must include mucosa and submucosa. An important diagnostic alternative is the determination of acetylcholinesterase activity in the mucosa and submucosa.<sup>3</sup>

## Medical Management

Colonic decompression and irrigation with saline solution is the most valuable tool for the emergency management of newborn babies. This maneuver may dramatically improve a very ill neonate. Irrigations should not be confused with enemas. An enema is a procedure in which an amount of fluid is instilled into the colon. It is expected that this fluid will be spontaneously expelled. Patients with Hirschsprung's disease are, by definition, incapable of expelling this fluid and, therefore, enemas are contraindicated. A colonic irrigation, however, promotes the expelling of the rectocolonic contents through the lumen of a large rubber tube, which is cleared with small amounts of saline solution. Rectocolonic irrigations may save the baby's life, but are not the ideal long-term form of treatment. Once the histologic diagnosis has been established, the baby must remain with nothing by mouth, and the irrigations must continue in preparation for the surgical treatment.

## Surgical Treatment

The basis of the surgical treatment consists of the resection of the aganglionic segment and pullthrough of a normoganglionic segment to be anastomosed to the rectum, immediately above the pectinate line. This should guarantee the preservation of bowel control. There are several ways to achieve these basic goals. The surgical treatment has evolved significantly since 1948 when the first surgical technique was described.<sup>4</sup>

Originally, these patients were subjected to a staged treatment. The first stage consisted of the opening of a diverting colostomy. The second stage included the resection of the aganglionic segment and pullthrough of the normoganglionic bowel, and the third stage was the colostomy closure. Subsequently, surgeons adopted a two-stage modality that included the opening of the colostomy during the newborn period. The second stage consisted of the pullthrough, leaving the patient without a colostomy.

More recently, the treatment most often used consists of a neonatal primary procedure without a protective colostomy.<sup>5,6</sup> This approach is less invasive and avoids the morbidity of a

stoma and multiple surgeries. However, approaches may vary from country to country as with the surgeon's experience. In addition, a primary procedure, without a protective colostomy, requires the presence of an experienced clinical pathologist, familiar with the interpretation of frozen sections. Also, in the case of a very ill, low-birth-weight newborn, or a very sick baby, a colostomy is still the optimal way to protect the patient. In the presence of an experienced pathologist, the colostomy must be open in a normoganglionic portion of the colon. In the absence of an experienced pathologist, the surgeon must open the colostomy, proximal to the transition zone. If the transition zone is not evident, the colostomy should be done in the right transverse colon. In the event of a nondilated entire colon, the patient should receive an ileostomy.

The definitive procedure (resection of the aganglionic segment and pullthrough of the normal ganglionic colon) can be done in different ways. Swenson and Bill<sup>4</sup> described an operation consisting of an intraabdominal resection of the aganglionic segment including a part of the normoganglionic dilated colon, and pullthrough of a normoganglionic bowel, with a perineal anastomosis of the normoganglionic bowel to the rectum, above the pectinate line.

Duhamel<sup>7</sup> described an operation designed to avoid pelvic dissection and potential nerve damage. He proposed to preserve the aganglionic rectum, dividing the colon at the peritoneal reflection. The normoganglionic colon is then pulled through a presacral space, created by blunt dissection and anastomosed to the posterior rectal wall above the pectinate line.

Soave<sup>8</sup> designed an ingenious and appealing procedure consisting of an endorectal (submucosal) dissection of the aganglionic colon, leaving a seromuscular cuff. He carried this dissection down to the rectum above the pectinate line. The normally innervated colon is passed through the muscular cuff and anastomosed to the rectum. The purpose of this operation, again, was to avoid the perirectal dissection and its potential negative effects caused by denervation of pelvic organs.

The original Soave procedure was performed in two stages. During the first stage, the colon was pulled down, but was not anastomosed to the rectum; it was left protruding outside the rectum. In the second stage, a week later, the protruded bowel was resected and the anastomosis was performed. Subsequently, Boley<sup>9</sup> proposed a primary anastomosis.

The abdominal portion of all of these operations can be done laparoscopically. This has been advocated by a number of pediatric surgeons recently.<sup>10-12</sup> Georgeson and colleagues<sup>10,11</sup> described their technique of laparoscopically obtained seromuscular biopsies in 80 patients to successfully determine the transition point. They preserved the marginal artery establishing a colonic pedicle for anastomosis through four ports, laparoscopically.

In 1998, De la Torre-Mondragon and Ortega-Salgado<sup>13</sup> and subsequently Langer et al.<sup>14</sup> reported a novel, transanal approach for the management of this condition.

They demonstrated that the whole procedure can be done transanally provided that the patient does not have a long segment type of aganglionosis. A special retractor (LoneStar™; Lone Star Medical Products Inc., Houston, TX) is used to expose the dentate line as well as the rectal mucosa.

We recommend the use of multiple fine sutures taking the rectal mucosa 1 cm above the pectinate line. These allow the surgeon to exert a uniform traction on the rectal mucosa. Peripheral to this series of silk stitches, an incision is performed with cautery and a circumferential dissection of the rectum is performed applying uniform traction. The dissection can actually be performed submucosally or full thickness, depending on the experience of the surgeon. As the surgeon progresses in the dissection, full-thickness biopsies are taken to determine the place where the normoganglionic portion of the colon is reached. The peritoneal reflection is soon found. It is recommended to continue the dissection until one reaches an area 4 cm above the transition zone to be sure that normoganglionic bowel is pulled down. The normoganglionic bowel is transanally anastomosed to the anal canal, 1 cm above the pectinate line. Because the majority of patients have a transition zone in the sigmoid colon, it is possible to repair the entire defect using this technique, without a laparotomy or laparoscopy.<sup>13,14</sup> When the transition zone is located higher, the surgeon determines when he or she needs a laparoscopic-assisted procedure or a laparotomy. We specifically recommend resecting not only the aganglionic segment of the colon, but also the very dilated part of the colon because we have learned that a very dilated colon also has very poor peristalsis.

De la Torre-Mondragon and Ortega-Salgado<sup>13</sup> and Langer et al.<sup>14</sup> perform the rectal dissection submucosally, in a similar way to the reoperative ileoanal pouch repairs for pouch-vaginal fistulas in adults described by Fazio and Tjandra.<sup>15</sup>

Complications and postoperative sequelae can be divided into two categories: preventable and nonpreventable. Preventable complications should not occur because they are caused by technical errors. A feared preventable sequela is fecal incontinence. This is likely related to injury to the continence mechanism. All these procedures were originally designed to prevent this from happening, provided they are performed correctly. Dehiscence, retraction, stricture, abscess, and fistula are all considered preventable because they are usually caused by technical errors. During the pullthrough, the surgeon must be familiar with the manipulation of the blood supply and the arcades of the colon to guarantee a good blood supply in the pullthrough colon. The anastomosis should be done without tension.

A nonpreventable complication is enterocolitis. This is also unpredictable, and a rather mysterious condition. Despite receiving a technically adequate operation, patients may have this condition. The frequency of this condition varies<sup>16</sup> and its etiology is unknown. We believe that fecal stasis is the most important predisposing factor. Fecal stasis occurring in the colon in a normal individual produces constipation.

In patients with Hirschsprung's disease, stasis frequently results in proliferation of abnormal bacteria, ulcerations of the colon, absorption of endotoxins, shock, and sometimes perforation. These patients respond to colonic irrigations; occasionally they require a colostomy and a secondary pullthrough.

Constipation may also occur after these procedures. It is more common in patients in whom the aganglionic segment was resected, but a dilated portion of the colon was pulled down. This is a partially preventable condition. Most cases of constipation can be avoided by resecting not only the aganglionic segment but also the dilated portion of the colon.

Each one of the techniques described has its own advocates. The analysis of different series shows that the most important factor that affects the clinical results is the experience and familiarity of the surgeon with each one of those procedures. Some surgeons claim that the Swenson operation exposes the patient to nerve damage that may provoke urinary and sexual disturbances. The Duhamel procedure is frequently followed by severe problems of constipation and dilatation of the aganglionic piece of colon left in place. In the Soave operation, patients may experience fecal incontinence, as well as perianal fistulas and abscesses because of the presence of islets of mucosa left in place during the endorectal dissection.

Advocates of a transanal approach cite the decreased morbidity and enhanced recovery as a consequence of a procedure without the intraabdominal dissection.<sup>17,18</sup> In addition, this approach permits early postoperative feeding, shorter length of stay, faster recovery, and possibly less chance for postoperative adhesions. Langer<sup>17,18</sup> compared the standard open approach to transanal Soave versus selective laparoscopic visualization and reported a shorter hospitalization and significantly less overall cost to the healthcare system. There was a trend of lower complication rates, specifically less incidence of adhesive bowel obstruction. They recommended only selective laparoscopy for children with long segment disease.

## Surgical Management of Total Colonic Aganglionosis

We believe that the ideal treatment for this very serious condition has not yet been found. The current treatment consists of resection of the entire aganglionic colon and pullthrough of the normal aganglionic terminal ileum to be anastomosed to the rectum. To avoid fluid losses and in an attempt to decrease the number of bowel movements per day, as well as to promote water absorption, Martin<sup>19</sup> proposed to leave a part of the rectosigmoid and descending aganglionic segment in place. The normoganglionic terminal ileum is anastomosed in a laterolateral manner to this colon and finally connected to the posterior aspect of the rectum as in the Duhamel procedure. Kimura et al.<sup>20</sup> proposed the use of a right colon patch with the hope of creating a reservoir for water absorption. Another option is the ileoanal J-pouch anastomosis; however, risks associated with a

pelvic dissection are obviously higher. All these approaches have proved to be rather simplistic. The stasis of stool in the small bowel produces bacterial proliferation and enterocolitis. Rather than absorbing water, very often the intestine secretes fluid into the lumen, producing a secretory diarrhea. Therefore we, as others, believe that a straight ileorectal anastomosis is the preferred option, acknowledging that all patients with this condition will have a poor quality of life.

### Surgical Treatment of Ultrashort Hirschsprung's

The surgical treatment of the ultrashort-segment aganglionosis is as controversial as the existence of this condition. Normal individuals have an area of aganglionosis above the pectinate line. The length of this aganglionic area has not been accurately or scientifically determined. This is the reason why the diagnosis of ultrashort Hirschsprung is so controversial. Some surgeons propose an operation called myectomy, consisting of the resection of a strip of smooth muscle from the anal verge up to the area where ganglion cells are found. The results of this procedure, again, are highly controversial and there is no scientific basis to explain why this may improve the condition. More scientifically conducted studies are required to clarify this issue.

Most cases of Hirschsprung's disease are diagnosed early in life, but a few patients reach their late teens and some are in adulthood before a diagnosis is made. Hirschsprung's disease in adults must be distinguished from other causes of megacolon such as Chagas' disease, volvulus, colonic inertia, Ogilvie's syndrome, and other disorders of central nervous system. Typically, the disease in adults is of the ultrashort segment variety. An internal sphincterectomy may yield a satisfactory result as performed after a failed pullthrough procedure.

This operation involves removing a thin strip of the internal sphincter muscle in the posterior midline starting 1 cm above the dentate line. The strip should extend as far proximal as exposure allows, possibly up to 15 cm. Lynn describes a transanal approach, but we prefer a posterior sagittal approach to enable a high myectomy.<sup>21,22</sup> Anal manometry may aid in assessment of the adequacy of the myectomy, because the resting tone pressure should be less than 30 mm Hg.

### Neuronal Intestinal Dysplasia

Neuronal intestinal dysplasia (NID) refers to a histologic condition that includes hypertrophy of ganglion cells, immature ganglia, hypoganglionosis, hyperplasia of the submucosal and myenteric plexus, giant ganglion cells, as well as hypoplasia or aplasia of the sympathetic innervations of the myenteric plexus. These histologic abnormalities have been described as occurring in a localized or disseminated manner.<sup>23</sup>

The histologic diagnosis of NID requires a high index of suspicion as well as the availability of special histologic techniques and expertise. Not all pathologists agree as to the existence of this condition.

NID has become popular because most surgeons expect to find histologic abnormalities in patients who have undergone a technically correct operation for Hirschsprung's disease and still have symptoms of enterocolitis or constipation. It was also expected that these histologic abnormalities would explain the pathophysiology of other colonic motility disorders.

Unfortunately, a precise correlation between histology and clinical manifestations is lacking. The histologic diagnostic criteria have not been standardized among different pathologists and different countries. In addition, the precise options for therapy have not been clearly established.<sup>24</sup>

### Anorectal Malformations (Imperforate Anus)

Anorectal malformations represent a spectrum of defects characterized by the absence of an external anal orifice. The overwhelming majority of the patients have an abnormal communication between the rectum and the perineum (perineal fistula), the vestibule (vestibular fistula), or the vagina (vaginal fistula) in the female. In some female patients, rectum, vagina, and urethra are fused together forming a common channel (cloacal malformation) and open into a single external orifice. In the male, the communication is with the urethra (rectourethral fistula), or the bladder (rectobladder neck fistula). Only 5% of the entire spectrum of patients are born with no fistula. Anorectal malformations occur in about one in every 5000 newborns. Males seem to have this condition slightly more frequently than females. The most common type of defects seen in boys is a rectourethral fistula and the most common type in girls is vestibular fistula. Table 51-1 shows our proposed classification of anorectal malformations.

### Associated Anomalies

Urogenital abnormalities occur in about 50% of all patients with anorectal malformations.<sup>25</sup> The higher and more complex the anorectal malformations, the higher the incidence of

Complex malformations

urologic associated defects. Urologic malformations are a common source of morbidity in these patients. About 90% of patients with a rectobladder neck fistula in males as well as in cases of cloacas with a common channel longer than 3 cm, have an associated urologic problem. Unilateral renal agenesis is the most common urologic anomaly encountered in children with these defects. Vesicoureteral reflux is the second most common abnormality. Other important abnormalities include cryptorchidism, hypospadias, renal ectopia, and hydronephrosis.

Sacral and spinal abnormalities are also very common in patients with anorectal malformations. The sacrum is frequently abnormal. The sacral abnormalities also represent a spectrum that varies from a completely absent sacrum to a completely normal one, including different degrees of hypodevelopment. There seems to be a direct relationship between the degree of sacral abnormality and the final functional prognosis. These patients also have hemivertebrae and as a consequence different degrees of scoliosis. The presence of hemivertebrae also seems to be related to a poorer functional prognosis.

Twenty-five percent of patients with anorectal malformations have a defect called tethered cord.<sup>26</sup> The majority of patients with tethered cord have a bad functional prognosis. In this condition, the cord is abnormally attached (tethered) to the spine. During the natural growth of the baby, it is believed that the spine grows faster than the cord, producing traction on the nerve fibers that may produce functional disturbances in the motion of the lower extremities and may contribute to sphincter problems.

Hemisacrum is sometimes associated with an anorectal malformation and there is always a mass located in the area of the sacral defect. An anorectal malformation with hemisacrum and a presacral mass is known as the Currarino triad. The most common sacral masses in these patients are a dermoid, teratoma, lipoma, anterior meningocele, or a combination of all these. These patients also have a poor functional prognosis.

Approximately 8% of all patients with anorectal malformations have esophageal atresia. These patients usually have a very high anorectal defect and other associated anomalies, especially urologic.

About 30% of patients with anorectal malformations also have some sort of cardiovascular congenital anomaly. Most frequently seen are patent ductus arteriosus, atrial septal defect, ventricular septal defect, tetralogy of Fallot, as well as other more complex malformations. Fortunately, only 10% of patients have a cardiovascular malformation with significant hemodynamic repercussions that requires surgical treatment.

The main concern in a patient with anorectal malformation is whether or not the patient will have bowel control, urinary control, and sexual function in the future. The higher the malformation, the worse the functional prognosis will be.

The higher the anorectal defect, the more likely the child will have fecal incontinence, but the lesser the chance of

having constipation. Conversely, the lower the malformation the higher the incidence of constipation and the lower the incidence of fecal incontinence will be.

## Description of Specific Defects

### *Males*

#### Perineal Fistula

This is the simplest of all defects. The rectum opens anterior to the center of the external sphincter in the area known as the perineum. The rectal orifice is usually incompetent, meaning that it is too narrow to allow normal passage of stool. Sometimes, the end of the rectum lies immediately below a very thin layer of epithelium with an external opening located at the base of the scrotum or sometimes at the base of the penis. The meconium sometimes can be seen below that very thin layer of epithelium giving an impression of a black ribbon. The overwhelming majority of these patients have a normal sacrum, and less than 10% of them have associated defects. The final functional prognosis is excellent,<sup>27</sup> provided these patients receive adequate treatment. These patients can be operated on during the newborn period. The ideal operation consists of moving the orifice back to the center of the sphincter creating a normal-sized anus.

#### Rectourethral Fistula

In this group of malformations, the rectum connects to the urethra. In the most common subtype, the rectum opens into the lower part of the posterior urethra known as bulbar urethra and, therefore, the defect is called rectourethral bulbar fistula. The rectum passes through a funnel-like striated sphincter mechanism to reach the lowest part of the posterior urethra. Eighty-five percent of these patients achieve bowel control when treated properly.<sup>27</sup> Approximately 30% of them have other associated defects.<sup>27</sup>

In the second subtype, the rectum opens into the upper part of the posterior urethra (prostatic) and therefore it is called rectoprostatic fistula. Only 60% of these patients achieve bowel control later in life. Sixty percent of them have important associated defects.<sup>27</sup>

Most of these patients (rectourethral fistula) require a colostomy at birth and subsequently (usually 1 month later) they receive the final repair of the malformation. Lately, some of the patients with rectourethral bulbar fistula have been repaired primarily during the newborn period without a protective colostomy.

The perineum of patients with anorectal malformations have characteristic features that must be recognized by the clinician. The higher the malformation, the more tendency to have a flat perineum (flat bottom), meaning that the natural midline groove is absent and there is no distinguishable anal dimple. The lower the malformation, the more prominent the midline groove and the anal dimple. In patients with

rectourethral bulbar fistula, there is a recognizable midline groove as well as an anal dimple and in patients with recto-prostatic fistula, there is conspicuous tendency for the perineum to be flat. Also, the anal dimple tends to be closer to the scrotum, the higher the malformation. One can also frequently see a bifid scrotum in cases of prostatic fistula.

#### Rectobladder Neck Fistula

This is the highest of all defects in male patients. The rectum is connected to the bladder neck. Ninety percent of these patients have important associated defects. The perineum is frequently flat. The rectum is located above the funnel-like sphincter mechanism (levator). These patients are the only ones that require a laparotomy or laparoscopy in addition to the posterior sagittal approach to be repaired. Only 15% of these patients achieve bowel control later in life.<sup>27</sup>

#### Imperforate Anus Without Fistula

This is a rather unusual anomaly that occurs in 5% of all children with anorectal malformations. Half of them also have Down's syndrome. More than 90% of all patients with Down's syndrome, who have an anorectal malformation, have this specific type of defect. Eighty percent of the babies with Down's syndrome and this malformation will eventually have bowel control when they receive an adequate operation. Approximately 90% of patients with this defect and without Down's syndrome also have bowel control.<sup>28</sup> Patients with this malformation usually have a good sphincter mechanism and a good sacrum.

#### Rectal Atresia

This malformation occurs in only 1% of all cases. It consists of a complete or partial interruption of the rectal lumen located between the anal canal and the rectum. The external appearance of the perineum is normal. The malformation is usually discovered when a nurse tries to take the rectal temperature in a baby. The sacrum is normal as well as the sphincter mechanism. One hundred percent of these patients will have bowel control after a correctly performed operation.<sup>25</sup>

### *Female Defects*

#### Perineal Fistula

In these female babies, the rectum opens in what is called the perineal body between the normal location of the anus and the female genitalia. All that was described about this defect in males is true for females. These patients can be repaired at birth without a colostomy. The prognosis is excellent.<sup>27</sup>

#### Vestibular Fistula

This is by far the most common defect seen in female patients. The rectum opens in the vestibule of the female

genitalia just outside the hymen. Rectum and vagina share a very thin common wall. About 30% of these babies have associated defects. Ninety-three percent of these babies will have bowel control when properly treated.<sup>27</sup> The sacrum is usually normal.

Vestibular fistula is frequently misdiagnosed as a recto-vaginal fistula.<sup>29</sup> Vaginal fistula is an extremely unusual defect. It represents less than 1% of all the female defects. In those unusual cases of vaginal fistula, the rectum opens into the posterior vaginal wall deeper to the hymen.

Most of the vestibular fistula cases are successfully operated on at birth without a colostomy. Unfortunately, many of those patients have dehiscence and retraction when the surgical technique used is not adequate. A secondary operation in these cases does not render the same good result as in cases of a well-done primary procedure.

#### Imperforate Anus Without Fistula

It is uncommon to see this type of defect in females. All that was mentioned about this defect in males is true about this defect in females.

#### Rectal Atresia

This condition does not differ from the same defect in males.

#### Cloaca

A cloaca is defined as a malformation in which the rectum, vagina, and urinary tract are fused together forming a common channel. This single channel opens where the normal urethra is located in females. Externally, these babies have rather small-looking genitalia. Separation of the small labia allows the observer to see a single orifice, which confirms the clinical diagnosis of a cloaca. Cloaca represents another spectrum of defects. The length of the common channel varies from 1–7 or even 10 cm. The length of the common channel is directly related to the final functional prognosis for bowel and urinary control. The turning point seems to be around 3 cm. Patients with a common channel shorter than 3 cm can be repaired posterior sagittally without opening the abdomen and the prognosis for bowel and urinary control is good. However, cloacas with a common channel longer than 3 cm represent a serious technical challenge. The operation frequently requires not only a posterior sagittal approach but also a laparotomy. The repair of those complex defects requires experience and familiarization with pediatric urology. The final functional prognosis is not very good in cases with a long common channel.<sup>30</sup>

Associated defects occur in about 90% of all patients with a common channel longer than 3 cm.

About 40% of patients with cloaca have hydrocolpos (a very dilated vagina full of fluid). The dilated vagina compresses the trigone and may produce ureterovesical obstruction, megaureters, and hydronephrosis. Approximately 40%

of the patients with cloaca also have different degrees of septation of the vagina and the uterus. This has important future implications, impacting menstrual flow,<sup>31</sup> as well as obstetric potential.

## Initial Management

### *Male Babies*

Perineal inspection and urinalysis allows determination of the likely type of malformation in about 90% of the cases.

The presence of a perineal orifice, by definition makes the diagnosis of a perineal fistula. This is also true when the baby has an external defect called "bucket-handle" malformation that is a skin bridge in the midline in the area of the anal dimple. The presence of a good midline groove and an anal dimple, as well as meconium in the urine, means that the patient has a rectourethral fistula. A flat bottom and bifid scrotum are signs of a very high malformation.

Diagnostic studies should be done after 24 hours of life, but not later than 36 hours. The reason for this is that it is necessary to wait until the most distal part of the rectum is distended in order for it to be seen by any of the diagnostic modalities [magnetic resonance imaging (MRI), ultrasound, CAT scan, or simple X-ray films]. Before 24 hours, the most distal part of the rectum is usually collapsed and it is difficult to see by these diagnostic modalities. Also, in order for meconium to be forced through a tiny distal fistula, it is necessary to wait until the intraluminal pressure is high enough to overcome the tone of the striated muscle that surrounds the distal rectum, which usually happens after 24 hours. During the first 24 hours, the clinician must try to answer two very important questions: Does the baby have an associated defect that threatens his/her life? Does the baby need a primary repair or a colostomy?

These questions should be answered in this order. The baby should be examined to rule out the presence of cardiovascular defects. The patient will remain with nothing by mouth, and insertion of a nasogastric tube is recommended to avoid vomiting and potential risk of aspiration. An ultrasound of the abdomen is indicated to rule out the presence of hydronephrosis. An ultrasound of the spine is also useful to rule out the presence of tethered cord. An X-ray film of the lumbar spine and the sacrum will rule out the presence of hemivertebrae and sacral abnormalities. A very abnormal sacrum is usually associated with a very high defect. If after 24 hours the surgeon is still not sure as to the type of defect that the baby has, a cross-table lateral film with the baby in prone position and the pelvis elevated should be performed. This will show the location of gas inside a distended rectum. If the rectum is visualized below the coccyx and the surgeons have experience with the neonatal repair of this malformation, the patient can be approached primarily. However, if the rectum is located higher than the coccyx, or the surgeons have no experience with these neonatal operations, it is better

to perform a diverting colostomy and to postpone the main repair for a later date.

### *Females*

It is also true in females that simple inspection of the perineum will allow the surgeon to make a correct diagnosis during the neonatal period in most cases.

The presence of an anal opening in the perineum makes the diagnosis of perineal fistula.

Sometimes it is difficult to see the opening of the rectum in the vestibule because the female genitalia are swollen at birth because of the effect of the maternal hormones. The presence of a fistula in the vestibule establishes that diagnosis. To make the diagnosis of a rectovaginal fistula (extremely unusual defect) one would have to see meconium coming from inside the vagina, deeper than the hymen. The presence of a single perineal orifice makes the diagnosis of a cloaca.

If none of these signs are present after 24 hours, the baby should have a cross-table lateral film in prone position. Most likely the baby has an imperforated anus with no fistula (which represents 5% of all cases).

During the first 24 hours of life, the baby should be subjected to the same tests described for the male patient. If the baby has a cloaca, an ultrasound of the abdomen should be performed not only in the upper abdomen to rule out hydronephrosis, but also in the lower abdomen to rule out the presence of hydrocolpos. Most babies with a cloaca need a diverting colostomy. These babies should not be taken to the operating room unless the surgeon has already ruled out the presence of hydrocolpos. The hydrocolpos must be drained at birth, particularly when the baby has hydronephrosis. Before trying other procedures for the treatment of the hydronephrosis and megaureter, the hydrocolpos must be drained, which usually will take care of these problems.

### *Colostomy*

Colostomies in babies with anorectal malformation should be totally diverting. Loop colostomies are contraindicated; they may allow the passing of stool from the proximal into the distal colon, producing direct fecal contamination of the urinary tract. The ideal colostomy should be created in the descending colon, with separated stomas. Both stomas should be separated enough as to allow the placement of a stoma bag over the proximal stoma. Distal to the mucus fistula, the baby should have enough length of colon to allow a comfortable pullthrough at the time of the main repair.

In cases of cloaca, the surgeon must also drain the hydrocolpos through the abdomen. When the vagina is so distended that it reaches the upper abdomen, it can be drained in the form of a vaginotomy, suturing directly the vaginal wall to the abdominal wall. When the vagina is not that large, it can be drained with a tube that is exteriorized through a separate hole in the abdominal wall.

Two weeks after the colostomy, a high-pressure distal colostogram should be performed.<sup>32</sup> This consists of injection of hydrosoluble contrast material through the distal limb of the colostomy to delineate the anatomy of the distal colon and to establish an accurate anatomic diagnosis. This is, by far, the most important diagnostic study in anorectal malformations. Trying to repair these malformations without a good distal colostogram exposes the babies to serious injuries of the urinary tract, particularly in males.<sup>33</sup>

## Main Repair

### *Males*

Perineal fistulas can be repaired performing a minimal posterior sagittal anoplasty. The baby is placed in prone position with the pelvis elevated. Multiple stitches are placed at the mucocutaneous junction of the fistula orifice. An incision dividing the sphincter mechanism, posterior to the anal orifice, is performed, and the rectum is carefully dissected to be moved back and relocated within the limits of the sphincter. During the dissection of the anterior rectal wall, special care must be taken to avoid injury to the posterior urethra, which is the most common and feared complication in these operations. The babies must have a Foley catheter in the urethra during this operation. If the surgeon does not have enough experience and the baby has a very narrow fistula orifice, a simple procedure called cutback can be done, consisting of a posterior cut of the fistula to make the orifice wider. Another alternative in a very sick baby or when the surgeon does not have enough experience is simply to subject the patient to dilatations of the fistula.

In cases of rectourethral fistulas, the patients are subjected to a posterior sagittal anorectoplasty. The baby is placed in prone position with the pelvis elevated and with a Foley catheter in place. A posterior sagittal incision is performed between both buttocks running from the middle portion of the sacrum to the base of the scrotum. The entire sphincter mechanism is divided exactly in the midline using an electrical stimulator to be sure to leave an equal amount of sphincter muscle on both sides of the midline.

The posterior rectal wall is identified and is opened in the midline. The fistula is identified and multiple fine silk stitches are placed taking the rectal mucosa immediately above the fistula in order to exert uniform traction to facilitate the dissection and separation of the rectum from the urethra. A submucosal plane is established in the anterior rectal wall to avoid damage to the urinary tract. About 1 cm above the fistula site, the dissection continues full thickness until the rectum is completely separated from the urinary tract. After this, a circumferential dissection with division of extrinsic vessels of the rectum is performed until enough length has been gained to bring the rectum down to the perineum and to anastomose it without tension to the skin in the area of the anal sphincter. Occasionally, we find that the rectum is very dilated

and cannot be accommodated within the available space of the sphincter mechanism. Under those circumstances, it is recommended to taper the posterior rectal wall as much as necessary so as to be able to accommodate the rectum within the limits of the sphincter. It must be the posterior rectal wall that is tapered, rather than the anterior wall so that a suture line is not opposed to the urethral fistula that was closed. The limits of the sphincter are electrically determined. The only difference in the surgical treatment between the rectourethral bulbar fistula and the retroprostatic fistula is that the latter requires a more significant dissection to bring the rectum down.

### Rectobladder Neck Fistula

Fortunately, this malformation occurs in only 10% of male patients.<sup>27</sup> This is the only defect that requires a laparotomy or laparoscopic assistance in addition to the posterior sagittal operation.<sup>34</sup> This is because the rectum is located too high to be reached from below. The posterior sagittal incision is only performed to create the path through which the rectum should be pulled down. A midline laparotomy or laparoscopy is performed. The rectum is dissected above the peritoneal reflexion. The surgeon must create a plane of dissection as close as possible to the bowel wall, but without injuring the rectal wall. One must keep in mind that the ureters and vas deferens run in the same direction toward the bladder neck and, therefore, one must keep those structures under vision during the dissection of the rectum. The bladder neck is located about 2 cm below the peritoneal reflexion and, therefore, it is very easy to find the end of the rectum and to divide and suture the fistula site. The rectum then must be mobilized to be pulled down through the tract that has been previously established through the posterior sagittal incision.

### Imperforate Anus Without Fistula

In cases of imperforate anus without fistula, the operation is not necessarily easier than in patients with a fistula because the rectum is still intimately attached to the posterior urethra. These patients are approached posteriorly, the posterior rectal wall is opened in the midline, and multiple stitches are placed in the edge of the rectal wall to exert uniform traction and to facilitate the separation of the rectum from the urinary tract.

Special care must be taken during the dissection of the anterior wall to separate it from the urinary tract. These patients more often require a rectal tapering, because usually they have a more dilated rectum.

### Rectal Atresia

These patients also require a posterior sagittal approach. The entire sphincter mechanism is divided posteriorly. Both rectum and anal canal are opened posteriorly. The dilated proximal rectum is anastomosed to the anal canal and

then the sphincter mechanism is meticulously reconstructed in the midline. These patients have an excellent prognosis.

### *Female defects*

#### Perineal Fistula

The repair of this malformation is the same that was described for male patients, except that the rectum is usually separated from the vagina so there is no risk of vaginal injury.

#### Vestibular Fistula

The complexity of this malformation should not be underestimated. The patient is placed in prone position with the pelvis elevated. Multiple fine silk stitches are placed at the rectal vestibular orifice. A posterior sagittal incision is performed, dividing the sphincter mechanism to find the posterior rectal wall, which is easy to recognize. The main technical challenge in the repair of this defect is represented by the common wall that exists between the rectum and vagina. There is no plane of separation between these two structures. One must make two walls out of one. This is achieved by a meticulous dissection applying uniform traction with multiple silk stitches into the rectal lumen. The dissection must continue until the rectum has been completely separated from the vagina. Usually the rectum of these patients requires very little mobilization because it is located significantly low. The limits of the sphincter are electrically determined, the perineal body is reconstructed, and the rectum is placed within the limits of the sphincter.

#### Rectovaginal Fistula

This is an extremely unusual defect.<sup>29</sup> These malformations can be repaired posteriorly sagittally. The repair is the same as described for vestibular fistula, except that these patients require much more mobilization of the rectum in order to move it down and relocate it in the center of the sphincter.

#### Cloaca

Cloaca repair represents a significant technical challenge, particularly in patients with a long common channel.<sup>30</sup>

*Repair of Cloaca with a Common Channel Shorter Than 3 cm.* These patients are approached posteriorly sagittally. The entire sphincter mechanism is divided in the midline and the posterior sagittal incision is extended down to the single perineal opening. The common channel is also opened in the midline to expose the anatomy of the defect. The entire defect can be repaired through this incision without opening the abdomen. Once the anatomy has been exposed, the first step is to separate the rectum from the vagina, which is performed in the same manner as was described for a rectovestibular fistula. Once the rectum is separated, it should be mobilized to gain length and to be placed in a normal location. The next step consists of mobilizing both vagina and urethra together,

following a specific technical maneuver called "total urogenital mobilization."<sup>35</sup> Multiple 6-0 silk stitches are placed in the edge of the open common channel as well as the edges of the vagina. These stitches allow the surgeon to exert uniform traction on the entire urogenital structure. The urogenital channel is divided full thickness approximately 5 mm proximal to the clitoris, creating a plane of dissection that is very easy to find, between the common channel and the posterior aspect of the pubis. In a matter of a few minutes, one can reach the upper portion of the pubis. Conspicuous fascial attachments exist between the vagina, the genitourinary structures, and the upper part of the pubis. These fascial attachments are avascular and are known as suspensory ligaments of the vagina and urethra. These are divided and the retropubic fat is identified. By dividing these suspensory ligaments, one can gain approximately 2 cm of mobilization of the urogenital structures. Some extra dissection of the lateral walls of the vagina as well as its dorsal wall gains another centimeter, and by doing that, one can repair the urethra and the vagina in a very satisfactory manner. More than 50% of the patients with cloacas have a common channel shorter than 3 cm and, therefore, it is possible to repair most of these defects with this reproducible technique. The blood supply after this mobilization is excellent. Urethra and vagina are then sutured to the labia in their new position.

The limits of the sphincter are electrically determined and marked with temporary silk stitches. The perineal body is reconstructed with long-term absorbable sutures, the rectum is placed within the limits of the sphincter, and the anoplasty is performed. The total urogenital mobilization does not change the final functional prognosis. Patients with a common channel of less than 3 cm and a good sacrum have more than an 80% chance of having bowel control and an 80% chance of having urinary control without bladder intermittent catheterization.<sup>28</sup> After the urethra and vagina have been repaired, the urethral meatus is now located 5 mm deeper to the clitoris in a position that makes it perfectly visible which is important if the baby needs catheterization. Twenty percent of these babies will require intermittent catheterization post-operatively in order to empty the bladder.

*Surgical Repair of Patients with Cloaca with a Common Channel Longer Than 3 cm.* We specifically recommend these patients to be referred to specialized centers dedicated to the treatment of complex malformations. The repair of these defects usually requires not only a posterior sagittal approach, but also a laparotomy and a series of decision-making steps that require experience and special training in urology. The first part of the operation consists of performing a total body preparation so that the patient can be approached through the perineum (posteriorly sagittally) and through a laparotomy. The posterior sagittal approach and total urogenital mobilization is attempted because occasionally one can achieve a total repair in patients with a common channel up to 4 cm. If this maneuver is not enough to make

the vagina comfortably reach the skin of the perineum, one has to go into the abdomen and continue the dissection of the vagina as well as its separation from the urinary tract. This is a difficult and tedious maneuver. The bladder must be opened and the ureters must be catheterized because they run through the common wall that separates the bladder and the vagina. Once the vagina has been entirely separated from the urinary tract, then the surgeon evaluates whether or not the vagina reaches the perineum. If that is not possible, then he or she has to make an important decision as to the best way to repair the malformation. In very specific cases, with bilateral hydrocolpos, the surgeon can perform a maneuver called "vaginal switch," consisting of resecting one of the hemiuteri, resecting the vaginal septum, tubularizing both hemivaginas to create a single one and switching down what used to be the dome of one hemivagina to the perineum, taking advantage of the fact that the distance between both hemiuteri is longer than the vertical length of both hemivaginas. This maneuver is only feasible if the patient has two large hydrocolpos.

If this maneuver (vaginal switch) is not feasible, then the surgeon must replace the vagina. The alternatives are first to replace it with rectum. The distal part of the rectum can be used to replace the vagina, which can be done in two different manners. If the patient has enough length of rectum, one can use the most distal part (preserving its blood supply), to be separated from the fecal stream, mobilized forward, and replacing the distal part of the vagina.

In other cases, if the rectum is very dilated, one can divide it longitudinally. The anterior portion is tubularized and moved forward to form the neovagina preserving the necessary vessels from the inferior mesenteric branches. The posterior aspect will serve as a rectum. The blood supply of the posterior aspect will be provided intramurally from the branches of the inferior mesenteric vessels. The rectum has an excellent intramural blood supply.

If these maneuvers are not feasible, the next choice could be sigmoid colon. If the colostomy interferes with these maneuvers, then one can use the small bowel.

In cases of extremely high malformations, one may find two little hemivaginas attached to the bladder neck. The rectum also may open in the bladder neck. The separation of these structures is performed through the abdomen. Once the separation has been performed, one may notice that there is no bladder neck left. Under those circumstances, the surgeon must have enough experience to decide whether or not the bladder neck can be reconstructed or whether it is better to permanently close the whole distal part of the bladder and open a vesicostomy. Those patients will require a continent diversion later in life. Because these patients have the highest incidence of vesicoureteral reflux, this operation through the abdomen represents a good opportunity to reimplant the ureters.

Patients with a common channel shorter than 3 cm are left with a Foley catheter, which stays in place for 2 or 3 weeks. Patients with a common channel longer than 3 cm require a

suprapubic cystostomy or vesicostomy at the end of the operation. One month after surgery, through the suprapubic tube, a cystogram is performed, the tube is clamped, and the patient is observed to see if she is capable of emptying her bladder spontaneously or if she requires intermittent catheterization.

The most common sequela from the urinary point of view in babies with cloaca is the incapacity to empty the bladder. These babies do not have the type of neurogenic bladder that is seen in patients with spina bifida and myelomeningocele. These patients rather have a floppy large bladder that does not empty. Most of the cloaca patients have a competent bladder neck. The combination of a competent bladder neck with a floppy hypotonic bladder makes these patients ideal candidates for intermittent catheterization, which allows them to remain completely dry.

When the bladder neck was not present at birth or was destroyed during surgery, these patients will need a continent diversion later in life. This operation usually will consist of a bladder augmentation and creation of a conduit with a one-way valve mechanism that allows the patient to be catheterized intermittently in order to empty the bladder without urine leakage.

## Results of Treatment of Anorectal Malformations

About 75% of all patients with anorectal malformations (when subjected to a good operation), have bowel control.<sup>27</sup> The bowel control is not perfect. This becomes evident when the patients have severe constipation, which may produce overflow pseudoincontinence, and soiling. Also, a severe episode of diarrhea may show that the bowel control is not normal. Twenty-five percent of all patients have fecal incontinence and require some form of medical management.

Because anorectal malformations cover a wide spectrum of defects, the clinical and functional results vary depending on the specific type of malformation. Patients with a cloaca with a common channel longer than 3 cm usually have fecal incontinence and require intermittent catheterization to empty the bladder. Patients with cloaca with a common channel shorter than 3 cm and a normal sacrum have bowel control 80% of the time and only 20% of them require intermittent catheterization to empty the bladder and remain completely dry. Ninety-four percent of all patients with rectovestibular fistulas have bowel control. Babies with perineal fistulas have bowel control 100% of the time. Rectobladder neck fistula patients only have bowel control 20% of the time, rectoprostatic fistula 60%, and rectourethral bulbar fistula 85%.<sup>27</sup> Patients with imperforate anus with no fistula will have bowel control between 80% and 90% depending on whether or not they have Down's syndrome.<sup>29</sup>

Constipation is a problem in most patients with anorectal malformations in whom the rectum was preserved during the main repair of the defect. Constipation should not be underestimated as a problem. When not treated properly, the

patients develop megacolon and chronic fecal impaction, which may end up producing overflow pseudoincontinence.

## Medical Management of Fecal Incontinence

For the group of patients who have fecal incontinence (25% of cases), there is a bowel management program that aims to keep those patients completely clean of stool and to make them socially accepted. The basis of this treatment is to teach the family or the patient to clean the colon every day with an enema or colonic irrigation. Because most patients have constipation, the cleaning of the colon with an enema will prevent the patient from passing stool for 24–48 hours.<sup>36</sup>

Occasionally, however, we find patients that had a different type of repair and lost the rectosigmoid during the main repair or have intractable diarrhea or malabsorption. In those cases, the bowel management is technically more demanding because it includes not only cleaning the colon with an enema, but also the use of a constipating diet or medications to decrease the colonic motility in order to keep the patient free of stool for more than 24 hours.

The bowel management program is implemented over a period of 1 week by trial and error. Every patient needs a different kind of enema to clean the colon. The cleaning of the colon is monitored, taking X-ray films of the abdomen every day, and readjusting the volume and concentration of the enema by trial and error. The goal is to find the enema that is well tolerated by the patient, is easy to administer, and keeps the patient completely clean. When the patient complains about the rectal enema and feels embarrassed about their parents giving the enema, an operation called the Malone procedure (continent appendicostomy) is an option.<sup>37,38</sup> This consists of creating a connection between the tip of the cecal appendix and the umbilicus. The cecum is plicated around the appendix, to create a one-way valve that allows the introduction of a catheter through the umbilicus into the colon and prevents the colon from passing stool through the orifice. The patient is able to sit on the toilet, pass a little feeding tube through the umbilicus, administer the enema himself/herself, evacuate the colon, and remain clean the following 24 or 48 hours. This allows the patient to become independent.

A significant number of patients do not have an appendix. One can be created with a vascularized flap of the colon (continent neoappendicostomy). Then again, the colon is plicated around the new appendix to make it continent.<sup>38</sup>

### Relevant Aspects for Adult Colorectal Surgery

Many adolescent and adult patients may still have fecal incontinence despite successful repair in infancy. Work-up of these patients should include a detailed history and physical, i.e., type of defect the patient was born with, bowel movement and voiding pattern, type of perineum, location of rectal opening,

presence of an anal dimple, and strength of sphincter contraction. A water-soluble enema or defecography, voiding cystourethrogram, sacral films, MRI with a rectal coil to assess the location of the rectum are essential. Manometry, anal ultrasound, and pudendal nerve terminal motor latency may also be helpful.

We then classify patients into four groups.<sup>39</sup> “Group one” appears untrainable. They have a poor sacrum, flat perineum, poor muscles, no sensation, and poor bowel movement pattern and usually are incontinent to both urine and all types of stool. These patients are good candidates for a bowel management program. If this program is unsuccessful, alternative techniques such as the artificial bowel sphincter or stimulated gracilis muscle flap may be tried<sup>40</sup>; however, a permanent stoma is usually best suited and truly appreciated by these patients.

“Group two” have clinical and MRI evidence of a mislocated rectum with a good sacrum and well-developed muscles. They benefit from a secondary pullthrough procedure by an experienced surgeon with the aid of the Peña stimulator.

“Group three” has severe constipation and a contrast enema shows a severely dilated mega rectosigmoid. They benefit from a sigmoid resection.

“Group four” are patients born of the good prognostic type and have a well-located rectum, good sacrum, and good muscles but are still incontinent. They may benefit from biofeedback or other behavior modification programs to help them evacuate the rectum at controlled and predictable times.

Some children develop an irritable bowel syndrome as they mature after a successful repair and then have difficulty later on in life. They may benefit from regulation of colonic motility with diet, medication, or possibly an intestinal pacemaker that is on the horizon. It is the author's opinion that control of rectosigmoid motility and coordination will be of more value in the future than any artificial or perhaps transplanted anal sphincter.

## Other Pediatric Colorectal Disorders

### Idiopathic Constipation

Constipation of unknown origin represents a serious problem in the pediatric population. At least 6% of pediatric consultations are related to this particular problem.<sup>41</sup> We consider this condition to be the result of a colonic hypomotility disorder with different degrees of severity, affecting mainly the rectosigmoid and sometimes the entire colon. The spectrum of colonic hypomotility or colonic inertia varies from mild constipation that can be controlled by dietetic measures, to severe hypomotility disorders that may fall into the realm of what is called “intestinal pseudoobstruction.”

Constipation means an incapacity to empty the colon on a daily basis or incapacity to empty it completely. As a consequence, the colon stores a large amount of stool, and becomes

very dilated (megacolon). Megacolon produces constipation and constipation produces more megacolon, creating a vicious cycle. The final result is what we call chronic fecal impaction, which provokes overflow pseudo-incontinence (encopresis).

The cause of this condition is unknown. Many authors claim that the origin is a behavior problem, whereas others believe that it is a consequence of a dietetic problem. There are those who think that it is a consequence of a lack of relaxation of the internal sphincter or a consequence of ultrashort segment aganglionosis. None of these theories have been scientifically documented, and that is why we call this condition idiopathic.<sup>42</sup>

So far, the treatment for this condition consists of trying to find the amount of laxatives that is capable of producing a bowel movement that empties the colon completely every day. The amount is different in every individual and has to be determined by trial and error. When the laxative requirement is so high that it creates a problem in terms of quality of life, we offer the patient a surgical treatment consisting of the resection of the most dilated portion of the colon (usually the rectosigmoid), creating an anastomosis between the nondilated part of the descending colon and the rectum.<sup>43</sup>

By doing that, even when we are aware of the fact that we do not cure this mysterious condition, we make the problem more manageable and reduce significantly the amount of laxatives that the patient needs.

## Rectal Prolapse

Rectal prolapse occurs in children because of well-known conditions such as myelomeningocele and spina bifida. The lack of sphincter tone explains the severe prolapse from which these patients may suffer. Also, patients with cystic fibrosis or some patients with inflammatory bowel disease or intestinal parasites may have rectal prolapse.

Most pediatric patients afflicted by this condition are of the idiopathic type. The surgeon must try to identify one of the predisposing conditions already mentioned. If this is not possible, one must try to avoid those factors that we know exacerbate the problem, such as to avoid constipation and treat any irritating conditions of the colon, such as milk allergy. If all this fails, the surgeon can offer a palliative surgical treatment.

An old operation designed to treat rectal prolapse includes a placement of a nonabsorbable suture around the anus to restrict its caliber. The long-term results of these procedures are not good because eventually the patients develop megacolon and an anal stricture.

Other surgeons have tried the injection of sclerosing substances in both perirectal spaces. This has been followed by severe complications including nerve damage and bowel and urinary incontinence. A posterior sagittal approach has also been used which allows the surgeon to anchor the posterior rectal wall to the cartilage of the coccyx and the sacrum. Most of the patients are cured after this procedure, but there are

occasional failures. If all these procedures are unsuccessful, the patient can be subjected to an abdominal approach and fixation of the rectum to the presacral fascia, usually with a sigmoid resection. More recently, a perineal rectosigmoidectomy (modified Altemeier procedure) has emerged as a treatment option in these children mimicking a one-stage pullthrough for Hirschsprung's disease. The advantages are the same in that one avoids an abdominal operation and the procedure may be repeated for recurrences.

## Perianal Fistula

Perianal abscess and fistula in pediatrics seems to be a completely different condition to that seen in adults.

During the first year of life, many babies (mainly males), have perianal abscesses that eventually become perianal fistulas. The orifice seen externally next to the anus communicates with one of the crypts of the pectinate line. Traditionally, these patients have been subjected to a fistulotomy, consisting of identifying the fistula tract and cutting all the tissue, and bowel wall, from inside the rectal lumen leaving the wound open for granulation.

Our experience has been that this is a benign condition that does not require any treatment. If the babies have a perianal abscess, they do not require antibiotics. Very soon, the abscess drains by itself and, if not, with a minimal incision and drainage. After that, for a period of months, it drains intermittently without any discomfort to the patient. All fistulas disappear after 1 year of age.<sup>44</sup>

Occasionally, one can see a school-age child with a perianal fistula. This is extremely unusual. The surgeon should investigate the patient for the presence of inflammatory bowel disease before trying any of the currently available surgical techniques used in adults.

## Juvenile Polyps

Around 4 years of age, patients might have polyps in the rectum and in the colon. These polyps are benign. They grow and eventually amputate and disappear. The polyps are mostly located in the posterior rectal wall. A rectal examination makes the diagnosis in most cases. These polyps have a long pedicle. The symptoms in these patients are the presence of blood surrounding the fecal matter. They do not produce any pain. Occasionally, the parents describe the presence of a polyp that prolapses through the anus. The polyps can be easily resected under general anesthesia in order to confirm the histologic diagnosis. Histologically, these are benign inflammatory polyps. Once the diagnosis is made, they can be predicted to have a benign course.

Even if the patient has another polyp, we know that eventually it will self-amputate. These polyps do not produce significant bleeding.

Occasionally, one may see juvenile polyposis that may require more aggressive treatment, but that is extremely rare.

## Anal Fissure

Anal fissures in pediatric patients are always a consequence and not a cause of constipation. The fissure represents a laceration that was produced with the passage of a hard large piece of fecal matter. The patient has painful bowel movements and that contributes to the constipation problem, because the patient becomes a stool retainer. Stool retention may provoke more constipation and more constipation will make the fissure worse.

The main treatment for this condition is to make the parents understand the nature of the problem. It is necessary to give enough laxatives so as to guarantee that the patient will have soft stool passing through the rectum for several weeks until the fissure heals. No surgical treatment is necessary in fissures in children.

Recently, 0.2% NTG (glyceryl trinitrate) ointment has been used for intractable cases to cause a reversible chemical sphincterotomy. Tander et al.<sup>45</sup> reported successful healing in 83.9% of children compared with 35% treated with placebo. This is a simple alternative treatment because the long-term sequelae of an internal lateral sphincterotomy in children is not known and is likely to be associated with some type of incontinence especially in childbearing females.

## Healthcare Economics

David A. Margolin and Lester Rosen

“It was the best of times it was the worst of times.” How prophetic was Charles Dickens when applied to health care in America today.<sup>1</sup> We are currently experiencing unprecedented technologic and therapeutic advancements; however, these come at a tremendous price. Healthcare expenditures have increased by double digits for the past decade, physician reimbursement has decreased over the past 10 years, and hospitals have closed and healthcare systems have filed for bankruptcy.<sup>2</sup> Furthermore, healthcare expenditures are forecasted to grow more than 7.0% per year over the next 10 years<sup>3</sup> (Figure 52-1).<sup>4</sup>

Multiple interrelated events have led to the current state of healthcare finance. With the advent of the resource-based relative value system (RBRVS), physicians have shifted from price setters to price takers. Technology costs, although providing an improvement in patient care, have skyrocketed. Although the life expectancy of the population has not increased dramatically over the past decades, the “baby boomers” are here and continue to shift the average age of the American population to one that requires increased utilization of healthcare resources. In 2003 it was estimated that forty-five million or 15.6% of Americans had no health insurance, and millions more were underinsured, putting a strain on state and federal budgets to provide care.<sup>5</sup> Last but not least is the current professional liability crisis, resulting in increased malpractice rates and driving specialists from specific locations. Despite this, physicians still are able to provide quality care for their patients and receive reasonable compensation. Nonetheless, in the ever-changing face of the socioeconomic landscape, physicians need a solid basis that allows them to function in today’s practice environment.

This chapter covers the RBRVS and Medicare reimbursement, the types of contractual agreement between insurers and practitioners and insurers and patients, and what to expect in the future.

### The Reimbursement Process

#### Medicare

The key to begin to understand the business of medicine is to understand the basics of Medicare. While private payers vary in their reimbursement rates and policies, most are tied in some form to the Medicare system. Medicare was created in 1965 by the federal government as a social insurance program designed to provide all adults over the age of 65 with comprehensive healthcare coverage at an affordable cost. Medicare is administered by the Center for Medicare and Medicaid Services (CMS), formerly known as the Health Care Financing Administration. When the program began in 1966, 19.1 million persons were enrolled; in 2004, Medicare had more than 41 million enrollees and is forecasted to include almost 80 million people by 2030 (Figure 52-2).<sup>6</sup> Medicare is divided into several parts.

Medicare Part A, also known as hospital insurance, helps pay for inpatient hospitalizations, skilled nursing care (SNF), home health and hospice care. Part A is financed primarily through federal payroll taxes (FICA) paid by both employees and employers. In 2004 the current FICA tax was 7.65% of earned income, of which 1.45% went toward Medicare Part A. Individuals who receive social security benefits or railroad retirement benefits are automatically enrolled in Part A. Individuals under 65 who receive social security disability or those with end-stage renal disease for more than 24 months are also eligible for Part A. Despite current misconceptions, Medicare Part A is not free. Although there is no monthly premium, Medicare enrollees are responsible for copayments associated with the services provided. In 2004 there was an \$840 copay for each hospital stay of 1–60 days, and after 150 days of inpatient hospitalization all costs were the patient’s responsibility. Part A covers nothing for the first 20 days of SNF care and only \$105 for days 21–100.

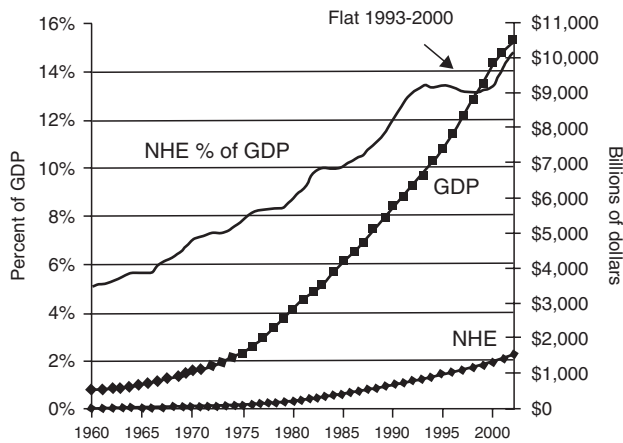

FIGURE 52-1. Healthcare expenditures.<sup>4</sup> The green line shows the percentage of the gross national product going to national health expenditure. The scale on the left axis measures it. The purple line, for gross domestic product (GDP), and the blue line, for national health expenditure (NHE), in billions of dollars, measured by the right axis scale. <http://hspm.sph.sc.edu/Courses/Econ/Classes/nhe00/>.

Similar to inpatient hospitalization, there was no coverage for SNF after 100 days.

Medicare Part B, also known as Medical Insurance, provides coverage for payments to physicians for services provided. This includes outpatient medical and surgical services, supplies, diagnostic testing, and some home health care. Part B is funded by a combination of the federal government’s general revenues (75%) and individual monthly premiums (25%). In 2004 Part B did not cover routine physical examinations. However, the federal government has responded to citizens’ urging and has instituted a physical examination when one enters into Medicare and covers screening for some specific diseases. Part B covers screening for breast cancer, cervical cancer, prostate cancer, and colorectal cancer.

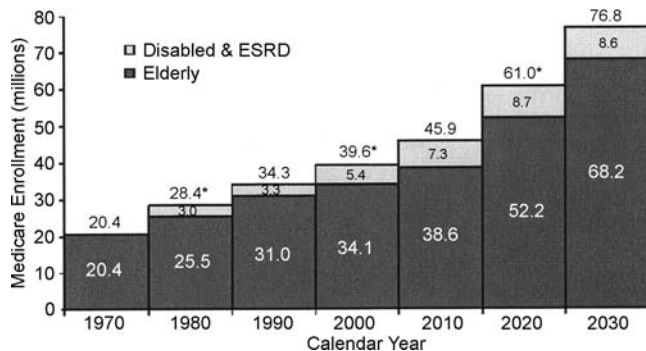

FIGURE 52-2. Expected number of Medicare beneficiaries. The number of people Medicare serves will nearly double by 2030.<sup>6</sup> Note: \*Numbers may not sum because of rounding. (Source: CMS, Office of the Actuary. From Centers for Medicare & Medicaid Services, June 2002 edition, section III.B.1, p 4).

Medicare covers fecal occult blood testing every 24 months, flexible sigmoidoscopy every 48 months, colonoscopy for high-risk individuals once every 24 months or for average risk individuals every 10 years. Medicare also covers barium enemas every 24 or 48 months depending on your risk stratification. New in 2004 was a prescription drug benefit plan available to Medicare beneficiaries in 2006.

Unlike Part A, Medicare Part B has monthly premiums. In 2004 the premium for those who enrolled at the onset of eligibility was \$66.60 per month. If one enrolls at eligibility, this premium is deducted from your social security or railroad retirement check. You can opt out of Part B. Similar to Part A, Part B enrollees are responsible for copayments and deductibles. For physician services, deductible was \$100 per calendar year and a 20% copayment of Medicare-approved rates. Copayments for outpatient procedures were charged at a different rate than office services, and the copayment varied based on the procedure performed.

Whereas Part A and B are considered traditional Medicare, Medicare Part C or Medicare + choice is the government’s plan to shift the cost and risks of Medicare patients to the private sector. In Part C, private payers receive a monthly payment per covered individual (capitated amount) to provide all of Part A and B services. Private payers then tailor these plans to cover anticipated needs. These plans often provide benefits not seen in traditional Medicare, such as prescription drugs, routine physicals, preventative care, eyeglasses, and hearing aids. However, because these plans are privately administered, individual choice is often severely limited with regard to physicians and hospitals.

In late 2003, the federal government instituted another new category of Medicare. Medicare Part D, prescription drug coverage, was signed into law in December 2003. In response to the cost of prescription drugs for seniors, in December, the government instituted a program that will start in 2006. This program will provide for prescription drugs with an initial deductible of \$250 dollars and a monthly premium of \$35. There will be a 75% subsidy for drug cost between \$251–\$2250. The federal government will pay for all drugs after a recipient pays \$3600 or \$5100 in total cost. Special assistance will be provided for low-income seniors as well. New to Part D is the institution of means testing. Individuals with incomes \$160,000 and above will be subjected to higher Part B and Part D premiums.

### Medicare Resources

According to the Office of Management and Budget, Medicare in 2004 had a budget of \$302 billion forecasted to grow to more than \$317 billion by 2008.<sup>7</sup> That budget is determined by legislation and is formula based. It involves the Medicare Economic Index, a weighted index, and the sustainable growth rate. The sustainable growth rate compares the cumulative actual spending for physicians’ services since 1997 to a cumulative target amount of spending over the same

time period. Without new federal spending legislation, Medicare spending is not allowed to grow by more than \$20 million/year (budget neutrality). However, the government has made exceptions to increases in Medicare spending for new technologies and pilot programs. For more details, the complete Medicare fee schedule can be found in the Federal Register online at <http://www.gpoaccess.gov/fr/index.html>.

### Hospital (Part A) Reimbursement

Until the mid-1980s, the federal government and most private payers reimbursed hospitals retrospectively for all reasonable costs involved in the care of a covered individual. With this form of reimbursement, to compete and remain solvent, hospitals invested in the latest, most advanced technology. This allowed hospitals to increase patient care volume and expand services; however, it was done without regard to cost or efficiency. Although this methodology had its advantage, it led to a continuing upward spiral in healthcare costs and a significant duplication of services.

In response to sharply increasing hospital costs, the federal government instituted a prospective payment system. This was modeled after a system developed by Fetter and associates at Yale University that categorized patients based on primary and secondary diagnosis, primary and secondary procedures, age and length of stay, and then set a uniform cost for each category.<sup>8</sup> These diagnostic related groups (DRGs) set a maximum amount that would be paid for the hospital care of Medicare patients for a specific problem. In 2003 there were 538 DRGs. Each DRG contains a list of specific diagnoses and procedures based on the International Classification of Diseases, Ninth Revision, Clinical Modification (ICD-9-CM).<sup>9</sup> ICD-9 is a coding system that lists specific diseases, diagnoses, and medical acuity. By using this system, Medicare has grouped related ICD-9 codes that use similar hospital recourses in specific DRGs.

Private payers have followed Medicare's lead and began using a prospective payment system. It was believed that by using a prospective payment system, hospitals would have a true incentive to improve efficiency and keep cost low. Although this may have initially slowed the growth of hospital costs and forced improved efficiency in healthcare delivery, it has not been the panacea that was expected. Hospital costs, although initially controlled, returned to double-digit increases by 2002.<sup>10</sup> Although the reasons for the continued increase in hospital costs are multifactorial, the failure of DRGs to truly control cost can best be summed up this way: "Hospitals prefer management strategies that are designed to enhance revenues over cost control measures that may be resisted by the physician staff."<sup>11</sup>

Despite the reluctance of physicians to change practice patterns, hospitals have tried to increase their efficiency, and with technologic advances, it has been possible to shift procedures from the inpatient setting to outpatient/ambulatory center. Although this had some albeit minimal impact in physician

reimbursement, it helped decrease resource utilization. In response to this, to account for this shift in location, Medicare has developed a prospective payment system called the ambulatory payment classification (APC). APCs, similar to DRGs, are specific reimbursement groupings that Medicare pays to facilities. For these outpatient services, Medicare pays a specific rate per procedure determined by the APC in which the procedure is grouped. Specific medical devices and drugs are exempt from this and are reimbursed in addition to the APC fee. These are called pass throughs. Other devices that do not receive pass through are often charged to the patient by private payers. In 2004, four APC classifications covered the majority of outpatient anorectal procedures. APCs reimburse facilities between \$209 (APC 148, lateral internal anal sphincterotomy) and \$1210 (APC 150, hemorrhoidectomy) with a patient copayment between \$41 and \$437.

With changes in location of services in a constant state of flux, Medicare needed to develop an appropriate and timely methodology to respond to this shift. To add some stability to APC payments and achieve these goals, the Secretary of Health and Human Services (head of CMS) appointed an Advisory Panel on APC Groups. This panel of physicians deals with issues concerning resource use, assigning new current procedural terminology (CPT®) codes to APCs, and reassigning codes to different APCs.

### Physician Reimbursement

Currently physician reimbursement from Medicare is a three-step process: 1) appropriate coding of the service provided by utilizing CPT®; 2) the appropriate coding of the diagnosis using ICD-9 code; and 3) CMS determination of the appropriate fee based on the RBRVS.

CPT® is a uniform coding system that was developed by the American Medical Association (AMA). CPT® originated in 1966 and has undergone yearly updates based on changes in medical and surgical procedures and the development of new technology. CPT® is a proprietary product of the AMA. The CPT® editorial panel is composed of 16 members in multiple specialties as well as the insurance industry. Advisors from more than 90 medical and surgical specialties advise them. They meet four times a year to consider additions and deletions to the code list. A service may be brought before the CPT® editorial panel by any specialty, private physician, insurer, or device manufacture. To receive consideration for a new code, a procedure must meet certain requirements: it must be done by a reasonable number of the specialty that presents the code, be performed at reasonable frequency, be done throughout the country, and have peer-reviewed literature supporting its efficacy. The editorial panel allows advisors from other specialties to comment on any proposal. The editorial panel then reviews the clinical description of the procedure or service that describes the typical patient. After assuring that it meets all of the above requirements and that the service should not be coded with a preexisting code,

the committee will give the service a unique CPT® code. The code then moves to the Relative Value Update Committee (RUC) where it receives a value relative to other codes (RVU). CPT® also uses a series of modifiers in addition to the original code to better describe the service provided. This allows not only for better data collection regarding the frequency and complexity of services but also for appropriate reimbursement by Medicare.

Medicare implemented the RBRVS in 1992. Previously physicians were reimbursed based on “usual, customary and reasonable charges” (UCR). UCRs were based on the physician’s most frequent charge for the service (usual), the average charge for that service in the area (customary), and the actual charge for the service (reasonable).<sup>12</sup> Individuals within the federal government, private insurers and non-procedure-based medical specialties thought that this system perpetuated increasing healthcare costs and inequities in medical care. These individuals believed that this system served as an incentive for physicians to inflate charges even in those instances in which actual costs were decreasing and to continue the inequities in fees between proceduralists and nonproceduralists. In response to this, the federal government instituted the Medicare fee schedule.

The Medicare fee schedule was based on the work of a research team led by William Hsiao, a Harvard economist under contract to CMS.<sup>13–15</sup> The Harvard study ranked procedures and services relative to each other based on the amount of physician work necessary to perform the procedure or service. Work was defined as a combination of the time used to perform the service and the complexity of service (mental effort, knowledge, judgment and diagnostic acumen, technical skill, physical skill, psychological stress, and potential iatrogenic risk).<sup>16</sup> Work was then broken down into three time periods, preservice, intraservice, and postservice.

Preservice work for surgical procedures has come to be defined as the physician work provided from the day before, until the time of the operative procedure (i.e., skin incision). This may involve any or all of the following: hospital admission work-up, the preoperative evaluation including the procedural work-up, review of records, communicating with other professionals, patient and family, and obtaining consent; and, dressing, scrubbing, and waiting before the operative procedure, preparing patient and needed equipment for the operative procedure, positioning the patient, and other non-“skin-to-skin” work done in the operating room before incision. Preservice work does not include the consultation or evaluation at which the decision to provide the procedure was made.

Intraservice work includes all “skin-to-skin” work that is a necessary part of the procedure. The time measurement for the intraservice work is from the start of the skin incision until the incision is closed.

Unlike preservice work, postservice work varies depending on the magnitude of the procedure. In an effort to accurately assign the amount of postprocedure work, specific CPT®

codes have been assigned specific global periods. There are currently three postprocedural global periods: 0 days, 10 days, and 90 days. Routine postprocedure care includes physician work after skin closure that is done on the day of the procedure, including non-“skin-to-skin” work in the operating room. This includes patient stabilization in the recovery room, communicating with the patient and other professionals (including written and telephone reports and orders), and patient visits on the day of the procedure. For a surgical service with a global period of 10 or 90 days, the postservice work includes all of the above, and in addition postoperative hospital care, including the intensive care unit if needed; other in-hospital visits; discharge day management services; and office visits within the assigned global period of 10 or 90 days.<sup>17</sup>

For nonsurgical services such as office evaluation and management (E&M) services, the preservice work includes preparing to see the patient, reviewing records, and communicating with other professionals. The intraservice work includes the work provided while the physician is with the patient and/or family. This includes the time in which the physician obtains the history, performs a physical evaluation, and counsels the patient. The postservice work for nonprocedural services includes arranging for further services, reviewing results of studies, and communicating further with the patient, family, and other professionals, including written and telephone reports as well as calls to the patient.

Whereas the study by Hsiao and colleagues<sup>14</sup> initially valued only 200 codes and ranked them according to physician work, the RUC subsequently valued and ranked each CPT® code relative to other codes. New codes were valued using provider surveys to obtain an appropriate work value. These surveys allow for individuals who perform the procedures to value pre-, intra-, and postservice work relative to established codes. According to federal law, the relative value of codes is reviewed every 5 years by the RUC allowing for corrections in the relativity of the codes. Currently, physician work is not the only value used to calculate an RVU. Whereas the work RVUs (wRVU) makes up the majority of the total RVUs (tRVU) for a specific CPT® code, RVUs are also calculated for practice expense (peRVU) and malpractice (mRVU) for each code. Similar to wRVUs, peRVUs are calculated based on the amount of resources used in the pre-, intra-, and postservice time. This includes not only the nursing and ancillary staff key to the procedure or service but also supplies used during the pre- and postprocedure periods. If the procedure is performed in the office, intraservice personnel and supplies are included. For procedures done in a facility, usually a hospital, these costs are reimbursed based on the DRG (Part A) and paid to the healthcare facility and not to the physician. Malpractice RVUs are calculated from actual malpractice premium data obtained throughout the country. Using previous CMS claims, a value for each CPT® code is determined based on a risk factor for the dominant specialty that provides service.<sup>18</sup>

Final physician reimbursement by CMS is then multiplied by a geographic practice cost index (GPCI), which is supposed to adjust payments for differences in physician practice costs across geographic areas. For a given service, multiplying the service-specific Physician Work, Practice Expense, and Malpractice Expense RVUs by their respective GPICs determines the payment amount in a given geographic area. Next, these three products are summed, yielding a geographically adjusted RVU total for the service. This number is then converted to dollars by a conversion factor, which in 2004 was \$37.3374 per RVU. It is expected to increase 1.5% in 2005. As an example, in 2004 for CPT® code 44140 (colectomy, partial; with anastomosis)  $\{(wRVU * wGPCI) + (peRVU * peGPCI) + (mRVU * mGPCI)\} * 37.3374 = \$ CMS reimbursement$ . As seen, the amount paid varies per region:

San Francisco, CA:  $(20.97 wRVU * 1.068 wGPCI) + (8.69 peRVU * 1.458 peGPCI) + (2.58 mRVU * 0.669 mGPCI) * 37.3374 = \$1373.72$

Boston, MA:  $(20.97 wRVU * 1.041 wGPCI) + (8.69 peRVU * 1.239 peGPCI) + (2.58 mRVU * 0.803 mGPCI) * 37.3374 = \$1294.43$

New Orleans, LA:  $(20.97 wRVU * 1.0 wGPCI) + (8.69 peRVU * 0.945 peGPCI) + (2.58 mRVU * 1.240 mGPCI) * 37.3374 = \$1209.03$

Little Rock, AR:  $(20.97 wRVU * 1.000 wGPCI) + (8.69 peRVU * 0.847 peGPCI) + (2.58 mRVU * 0.389 mGPCI) * 37.3374 = \$1095.26$

Although Medicare is an extremely large and at times an unwieldy way to manage healthcare and healthcare-related costs, understanding it is key to understanding both hospital and physician reimbursement by private payers. Most private payers today use CPT® codes to identify physician services. Although private payers do not have to follow the rules set forth by the federal government (for instance, they often do not recognize surgical modifiers), they find that CPT® is a well-established and familiar system allowing for correct physician coding. Private payers in noncapitated contracts often set reimbursement based on a percentage of the Medicare fee schedule. The percentage reimbursement will often vary by region. The larger payers have taken this one step further using Medicare to develop their own fee schedule. Again using CPT® terminology, companies will adjust payment based on the individual service provided; for example, paying E&M codes 105% of Medicare, office-based procedures 110% of Medicare, and surgical procedures 115%. This is often modified regionally based on the rules of supply and demand. In areas with a paucity of a specific specialty, reimbursement is high as opposed to a saturated market where the insurance company can play one physician or group against another to obtain a favorable contract. Hospital payments are similar. Private payers reimburse hospitals either as a percentage of the DRG or on a per diem based on the service provided. For outpatient procedures, hospitals are often reimbursed as a percentage of the APC.

## Private Payers

Whereas the impact of Medicare on the economic landscape of medicine is clear, the role and type of private payers is more cloudy. Health insurance comes in many forms and has different relations with its customer and its physician providers. Traditionally, there were two types of nongovernmental insurance, individual insurance and group insurance. Individual insurance allows a person to buy health insurance for themselves and their family. However, because of the inability of the insurer to spread the financial risk among many people, individual insurance is becoming prohibitively expensive. The majority of people obtain health insurance through some type of group. This allows for cheaper individual payments as group purchasing allows the insurer to spread the risk over a larger number of people. Group insurance can be obtained through employers, professional societies (ACS, etc.), or other organizations (AARP, etc.).

Regardless of how insurance is purchased, the types of insurance plans are distinctly different. The most costly is the fee-for-service plan, also known as an indemnity plan in which individuals are free to seek care from any physician or hospital they choose. No preapproval is required. Individuals submit the bills to their carrier and if the deductible has been met, if there is one, the insurance company pays for medical services at the UCR. These plans are often structured so that there is a copayment for all services. The use of copayments and deductibles by insurers is a method of risk sharing. Not only do these costs help defray the cost of providing care for the insurers, but they are designed to make individuals think twice before seeking unnecessary care. In traditional fee-for-service plans, an individual may be responsible for 20% of the bill. Also, they may be responsible for the difference between the UCR and the billed charges.

To help control increasing healthcare costs and stimulate a more efficient use of healthcare resources, managed care organizations were developed. Since the early 1990s they have evolved into a variety of complex organizational structures. They use a variety of tools to manage preauthorization functions, control healthcare costs, and share the risks associated with group coverage.

Health maintenance organizations (HMOs) were designed to meet these ends. Although HMOs are still in the process of evolution, they characteristically represent the most restrictive type of health maintenance organization. In this model, the HMO restricts patient access in nonemergency incidents to HMO-contracted physicians and hospitals. Out-of-pocket costs for individuals are traditionally low for HMO physicians; however, individuals are responsible for all costs for non-HMO physicians.

Most HMOs initially used a “gatekeeper” or primary care physician for specialist referral. Subsequently, HMOs have loosened gatekeeper requirements for specialist referral. This model has propagated the development of healthcare systems, multispecialty groups that are either owned by or contracted

with the HMO to provide complete patient care. In these instances, the physicians function as employees of the system. The physician group is then paid a capitated fee (amount per patient per month to provide total care) which is divided among the medical care providers at a rate determined by the medical group administration.

The next iteration of managed care organizations is the preferred provider organization (PPO). Similar to HMOs, PPOs enter into contracts with healthcare providers and hospitals to provide member care. Often more choice and flexibility are available to the patient than in the traditional HMO model but at the cost of higher beneficiary premiums. Unlike HMOs, PPOs do not own physician practices. To have access to the PPOs beneficiaries and be listed in the “network,” physicians often agree to reduce their normal fees. PPOs traditionally do not use a “gatekeeper,” thus allowing patients increased access to self-referred specialty care.

The most recent variation in managed care organizations is the development of “Point of Service” plans, a mixture of traditional HMO and PPO plans. In this type of plan, if a patient first sees their primary care physician to receive a referral, much like an HMO, the copay, if present, is negligible. Patients are also able to see “network” physicians with minimal financial responsibility. Patients may seek care from someone outside the “network” without a referral. In these instances, the physician is paid a rate less than is characteristically billed, usually the same rate as in network physicians, and the patient is responsible for the difference. This provides increased patient flexibility but at increased cost.

## The Future

Despite hopes that managed care would provide cost stability to health care in America, after costs initially slowed, they have continued to increase at a rate higher than the consumer price index and personal income (Table 52-1).<sup>19</sup> Is this a failure of managed care or has managed care reached its capacity with regard to improving efficiency and cost containment? The answer is unclear; however, experts now tout a “consumer-centric” or “consumer-driven” healthcare model as the future of healthcare delivery. Harvard Professor Regina Herzlinger initially described a system that allows users to become active consumers.<sup>17</sup> Similar to making any large purchases, individuals are given the opportunity to choose from specific benefit packages that will fit their particular need. Aside from having choice, individuals are given information allowing them to make educated and informed choices. Herzlinger and others envision a healthcare market place similar to a successful industry in which individuals are given control, choice, and information. With the increasing number of consumers in need of healthcare resources, these experts see the Internet as a way of rapid dissemination of healthcare information.<sup>20-23</sup>

Although consumer-centric health care and health reimbursement arrangements (HRAs) seem to be recreating the way health care is funded, there are potential problems. This model assumes that consumers are sophisticated enough to make sound healthcare choices, not just those based on cost. As Abramowitz notes, “Choosing based on price is impossible for consumers to do intelligently. The bottom line is that consumers lack the information necessary to use the money wisely. So consumer driven health care, as it is being discussed today, will be a market failure.”<sup>24</sup> Another potential problem is that individuals will feel obligated to use all of their HRA or employer contributions, especially as the year end approaches and individuals run the risk of losing their contributions.

The initial manifestation of a hope to address some of the potential pitfalls of consumer-centric health care is the development of defined contribution plans in which employers provide a set amount to individuals for health care, along with information regarding employer-approved healthcare choices. Often these are tied to a safety net for catastrophic cost. The idea is to empower individuals and to give them the necessary information to make good choices. Further development of consumer-driven health care is the development of HRAs. This IRS plan gives a tax advantage to employers who contribute defined contributions to employee-controlled accounts for healthcare spending. Any monies not spent during the year are rolled over to help fund the following year’s plan. The thought was that this combined with a high deductible plan would lower healthcare costs. These types of plans also raise some questions: is the unused portion of the plan eligible to be rolled over in an IRA/401K? Can these funds be used for nontraditional health care? What about domestic partners? Are these funds portable? These questions will only be answered by time and possibly federal legislation. Will this next generation of changes significantly help to control healthcare costs? The answer is unclear; however, one current benefit is the increasing individual awareness and education that these plans foster.

Despite the many and varied attempts to control healthcare costs, an unacceptably large number of Americans are still unable to obtain adequate healthcare coverage. This has led to the call in some quarters for the development of universal coverage. Senator Edward Kennedy put it best in a 2003 editorial: “Health care is not just another commodity. It is not a gift based on the ability to pay.”<sup>25</sup> Proponents of universal coverage envision a system that provides access to care when needed and effective preventative care in a cost-effective manner that is delivered and paid for in an equitable way. Although these are laudable goals, practical application remains a long way off. As seen from above, the increasing role and complexity of Medicare and Medicaid has not even incrementally achieved these objectives. Will the government be willing to push forward with universal health care and the subsequent development of a two-tiered healthcare system, one for the wealthy and one for the remainder of Americans? Only time will tell.

TABLE 52-1. Selected national economic indicators: 2000–2004

# Ethical and Legal Considerations

Ira J. Kodner, Mark Siegler, Daniel M. Freeman, and William T. Choctaw

## Considerations for Surgeons

### General Concepts

#### *Defining the Problem*

Professional responsibilities have been a concern of surgeons since antiquity; however, the last 25 years have displayed a dramatic growth of both professional and societal attention to moral and ethical issues involved in the delivery of health care. This increased interest in medical ethics has occurred because of such factors as the greater technologic power of modern medicine, the assigning of social ills to the responsibility of medicine, the growing sophistication of patients and the information available to them, the efforts to protect the civil rights of the increasing disadvantaged groups in our society, and the continued rapidly escalating costs of health care including medical malpractice costs. All of these factors contribute to the urgency of dealing with ethical and moral issues involved in the delivery of modern surgical care.<sup>1</sup>

The terms *ethics* and *morals* are often used interchangeably to refer to standards regarding right and wrong behavior. *Morals* refer to conduct that conforms to the accepted customs or standards of a people. They vary with time and with the nature of society at that time. *Ethics* is the branch of philosophy that deals with human conduct, and can be described as applied morals. *Medical ethics* refers to the ethics of the practice of medicine. *Clinical ethics* refers to the ethics of delivering patient care. The term *bioethics* includes the ethics of all biomedical endeavors and encompasses both medical and clinical ethics.<sup>2</sup> The *law* serves to delineate the *formal rules of society*. It expresses a kind of minimal societal ethical consensus, which society is willing to enforce through civil judgments or criminal sanctions. The law does not always prohibit behavior deemed unethical, however it will usually set a minimal standard for conduct. Those of us who practice clinical surgery often have trouble differentiating *ethical issues* from *legal issues*. It will be the purpose of this chapter to clarify this dichotomy. It should be stated from the outset that it is more important to understand the *process* of

dealing with these issues than to assume that anyone can clearly state what is ethically right or wrong in a complex medical/surgical dilemma. The law, however, can be very explicit and can vary from state to state.

Surgeons live and practice an intense form of applied ethics. We deliver bad news; we guide patients and their families through complicated decisions to arrive at appropriate informed consent; we live a code of truth and trust among ourselves, our patients, and our trainees; we must deal with the end-of-life issues; and we make plans for extended, palliative, and hospice care. Finally, as only we surgeons know, we must go to bed at night knowing that in the morning we will spend hours with someone's life literally in our hands.

In recent decades, although we can technically and scientifically do more for our patients than ever before, our personal, trusting relationship with them has deteriorated to the point where it is sometimes adversarial. We have allowed medicine to become a business, guided in many cases by the financial bottom line, rather than by the uncompromising concern for a sick person. Within this fast-moving corporate system, we see too many patients, do too much surgery, and do not have time to develop a close mentoring relationship with our chosen role models, nor with our trainees.<sup>3</sup> The cherished patient-physician relationship has been undermined by our own successful advances. Many of the operations that we do on a routine, daily basis were not even imagined as possible only a few decades ago. Not only can we do more, but also our patients have come to expect perfection from us. Our society seems willing to accept flaws from many sources, but not from physicians and the medical delivery system. This situation is made even more complicated by a system in which individuals purchase their healthcare coverage when they are well and willing to buy the cheapest plan possible; but they utilize their coverage, especially for surgical problems, when they are sick and want the maximum that the system can deliver, without regard to time and cost. No individual has ever admitted that they purchased a cheaper plan, and therefore understood that only limited care should be provided to a loved one who is ill.

Despite these difficulties, we surgeons cannot abandon the needs of our patients and their families. To help them make informed choices, we must communicate completely and compassionately the requisite information about the disease, treatment options, and long-range plans. To do so, we must learn and apply the ethical principle of *truth telling* and the doctrine of *informed consent* for the effective care, which has taken us so long to master. We must also take into account that high-speed communication via the Internet will necessitate reevaluation of issues such as *patient's rights* and *confidentiality*. Surgeons must lead in forging this new era rather than leave it to bureaucrats, politicians, lawyers, and others not intimately involved in patient care.

We cannot rely on intuition or on our own personal value system. Learning the ethical aspects of delivering patient care must become an integral part of the surgical training program, and we must be held accountable for mastering the skillful application of these bioethical principles. After all, the concept of good clinical medicine and surgery implies the best use of scientific, technical, and *ethical* considerations. Just as with medicine and science, bioethics and legal underpinnings of bioethical decision making are evolving all the time. In this chapter, we will not discuss all possible bioethical issues, but will limit ourselves to those that may be of concern to colon and rectal surgeons and to surgery in general. Important issues relating to such matters as professionalism, research ethics, family, business and financial pressures, genetics, and reproductive considerations will be discussed as well.

### *What Makes the Surgeon Special?*

Undergoing major surgery is an extreme experience, which changes people's lives. Surgeons are repeatedly involved in these extreme experiences of others. That makes surgeons uniquely placed among healthcare professionals to understand the experiences of their patients.

Miles Little<sup>4</sup> explains that there are special ethical considerations for surgeons. These include: Rescue, Proximity, Ordeal, Aftermath, and Presence. These terms help to define the ethical relationship between the surgeon and his or her patients. *Rescue* he describes as the first pillar of surgical ethics. It deals with the fact that surgery conveys power, and that power is socially endorsed and may be reinforced by the surgeon's individual charisma; but as with all power it must be constantly renewed and revalidated. Patients have no choice but to acknowledge surgical power when they consult a surgeon. There is always an element of surrender in the surgical relationship, but it is a surrender that presupposes rescue. Accepting rescue as a legitimate principle justifies respect for dependence in the surgical relationship. Surgeons, themselves, sometimes need help and rescue from colleagues when they have trouble with complicated diagnosis, management, or operative procedures. *Proximity* occurs in surgery as in no other act. To operate on persons involves entering their bodies and becoming privy to secrets even denied to the

owner of the body. Little states, "To get to my body, my doctor has to get to my character. He has to go to my soul. He doesn't only have to go through my anus." This proximity to the patient can make special ethical demands on the surgeon. This proximity carries with it the penalties of closeness, and particularly the pains of failure. Some surgeons find that distancing themselves from their patients makes failure easier to bear. Understanding the privileges and risks of proximity is critical for the compassionate surgeon. *Ordeals* are periods of extreme experience, capable of disrupting our lives. The author, Little, explains that all medical encounters are ordeals. Patients yield autonomy, acknowledge dependence, place trust, face risk, confront embodiment and mortality, lose control over time and space, experience alienation, pain, fear, discomfort, suffering, and boredom. Surgeons observe and participate in the lives of patients with serious illnesses. A surgeon, who understands the ordeal of the surgical episode, can better help his or her patient through such extreme experiences. *Aftermath* deals with the reality that surgery leaves physical and psychological scars that may persist for life. It is very difficult to communicate the concept of suffering to someone who has not suffered himself. Little describes surgeons as being in a unique position to understand the existential threats that their patients experience, the sense of mortality and bodily frailty they live with, and the difficulty of explaining extreme experience to others. When death approaches our patients, we must remember, not deny, our own mortality. Such an approach takes courage and a sense of personal security, and this does not suit everyone, neither patient, nor surgeon. *Presence*, as a virtue and a duty, is what the patient desires of the surgeon during all phases of the surgical encounter. Most surgeons have the stamina and cognitive ability to be present for their patients, but not all of us process the personal attributes of charisma, confidence, energy, and empathy, which are necessary to engender *trust* from our patients and our staff. Sometimes, amazingly, our mere presence means more to our patients than defects in the manner with which we deal with them. Even if we cannot teach sensitivity, we can emphasize the importance of surgical presence.

Thus, surgeons are privileged to lead lives of great complexity and moral richness. We can acquire a profound understanding and recognition of patient experience and suffering. Our proximity to patients seeking rescue, facing ordeals, and experiencing the aftermath of surgery, presents us with a great challenge.

### *Unique Problems of Surgery*

Surgeons, unlike other members of the healthcare team, take on a different level of responsibility as they encounter patients. For the surgeon, the initial contact may just be the beginning of a longer-term relationship. With no previously established doctor-patient relationship, the surgeon and the patient may well be heading to the operating room for sometimes massive

and sometimes potentially “futile” surgery. The surgeon and the surgical team take on the continued responsibility of the operative procedure itself, the postoperative care, and usually the long-term follow-up and management of any complications and dilemmas that may result from the initial encounter. This intense relationship is often established very quickly and under frequently adverse circumstances. The family and religion may not be known, the patient may be unconscious, and certainly will be once the procedure starts.

Arthur R. Derse nicely delineates the array of ethical issues that arise in delivering surgical care. These include: *informed consent*, *refusal of treatment*, *determination of decision-making capacity*, *treating patients despite their refusal*, *maintaining confidentiality* while respecting the duty to warn others, *limiting treatment* over issues of “futility,” *treating pain* at the end of life, and acting as a *Good Samaritan*. Unlike surgeons, people in most professions have the luxury of time, and the opportunity to redo their work to remedy any mistakes. Attorneys can appeal their cases. Accountants can file an amended return. Movie directors can yell, “Cut! Take two!” and reshoot the scene. All doctors understand that they will probably be second-guessed. As everyone who has ever watched a television police drama knows, the first thing a police officer must say to an arrested person is the famous *Miranda* warning. What most people do not realize is that the requirement for those warnings is the result of a Supreme Court decision rendered in June of 1966. As a practical matter, the court was telling the arresting police officer, in the heat of making an arrest, that he should have known something, which took the court system 3 years to contemplate and research. The bottom line for surgeons who work under the same kinds of time pressures is to do what you think is best. You must use your judgment, based on your medical knowledge and your experience. You are on the front line, and you do not have the luxury of waiting 3 years for the Supreme Court to tell you how to handle a potential situation. However, you also want to be as scrupulous as possible in making sure that bioethical and legal guidelines are followed, both for the benefit of the patient, and, frankly, as protection for yourself.

Although it is crucial for the practice of medicine in all fields to be familiar with bioethical concepts, it is unrealistic to be expected to be knowledgeable about the nuances requiring detailed understanding of controversial bioethical dilemmas. However, it is important for surgeons to have a working knowledge of general medical ethical principles and how these principles affect decisions involved with treating patients. Our goal will be to distill these general bioethical concepts and their underlying applications to specific situations, which you may face, into a cogent and concise tool for surgeons to use routinely, to include as part of their training, and to have as a reference resource. For specific dilemmas, time permitting, surgeons should obtain an opinion from the hospital ethics consultation service and/or from hospital counsel. By doing so, one can gain the experience and imprimatur of opinions from those who have dealt with such issues

and whose training gives them the experience to deal with them in a knowledgeable way. It also serves as a cushion of knowledge for the physician when discussing the matter with a patient or the family. Surgeons should do all they can for the patient, while at the same time, doing what they need to do to protect themselves from personal risk and possibly from negative legal ramifications.

Similarly, doctors have a duty to themselves to avoid situations that violate their own personal beliefs, whether religious or medical. This includes thinking a step or two ahead of the current situation to know what the ramifications of a course of treatment may be. If the anticipated actions may violate a doctor’s own personal tenants, he or she should refer the patient to another physician. The most obvious of these situations comes up with regard to religious beliefs. If, for example, a doctor has religious beliefs that would preclude *withdrawal of life support*, the doctor should be very careful about getting into a situation with a patient that might later dictate putting someone on life support. It may, down the line, become bioethically or medically appropriate to *withdraw* life support. If a physician cannot do that, she needs to know that up front and be prepared to withdraw from the case. A similar situation involves doctors who do not believe in *abortion*. They should not get themselves into medical situations in which an emergency termination of a pregnancy may become the best medically viable option. You must always be prepared to protect yourself *and* your patients and must recognize your duties, both legal and ethical. You need to be aware of these duties and to avoid situations in which they may come into conflict. This may be very difficult at times.

## Principles of Bioethics

### General Concepts

#### *Philosophical Principles*

Two major fundamental theoretical philosophical concepts exist for constructing a theory of ethics: *deontologic* and *consequentialist*. A deontologic theory relies on *rules* whereas a consequentialist theory relies on *outcomes*.<sup>2</sup> From these theories are derived *principles of ethics*, such as those delineated by Beauchamp and Childress<sup>5</sup>: respect for *autonomy* (patient self-determination), *beneficence* (“doing good”), *nonmaleficence* (“do no harm”), and *justice* (fairness).

#### Respect for Autonomy

Adult patients with decision-making capacity have a right to their preferences regarding their own health care. This right is grounded on the legal doctrine of *informed consent*. This means that patients must give their voluntary consent to treatment after receiving all appropriate and relevant information about the nature of their problem, the expected consequences of the recommended treatment, and treatment alternatives.

This is probably the most crucial legal concept in bioethics. It simply means that you as a physician cannot *touch* a person without first getting permission, and without telling the individual of the possible ramifications of that “touching.” Touching someone without his or her consent is, in legal terms, a “battery,” which could result in a lawsuit for damages. Therefore, the principle is: *medical treatment without consent is a battery*. The first major case in this area said “Every human being of adult years and sound mind has a right to determine what shall be done with his own body; and a surgeon who performs an operation without his patient’s consent commits an assault, for which he is liable in damages. . . . This is true except in cases of emergency where the patient is unconscious and where it is necessary to operate before consent can be obtained.”<sup>6</sup> This case was decided before the concept of *living wills* and *durable powers of attorney* came into being. These documents both facilitate and complicate the consent process because *consent* must be obtained, if time permits, through these documents or via surrogate decision making. Subsequent cases refined the requirements of consent to add to the concept of *informed consent*. The courts now require the patient not only to *consent* to the procedure, either themselves or through a proper surrogate, but to be given sufficient information to make an *informed* decision. The courts have held that the quality and quantity of information given to the patient must be sufficient for the reasonable patient to understand, not the doctor. The law has established the doctrine of the *reasonable man* to be used in deciding what is acceptable in many areas of delivering emergency surgical care.

Doctors are duty bound to respect the autonomy of each competent patient. The patient is the ultimate decision maker about what he or she wants. The doctor may differ, even vehemently, with the patient’s decision; however, the patient has the final say. There are exceptions to this rule also, such as the patient who demands a certain kind of treatment that the doctor knows will not be efficacious. Permitting *autonomy* to trump *nonmaleficence* poses a serious problem. A simple example of this is a patient who demands antibiotics to treat a viral infection. Giving the requested antibiotic complies with the *autonomy* principle; however, in the long run, it is conceivable that giving an antibiotic in such a case would violate the principle of *nonmaleficence*, would impose the concept of *futility*, and in the long run might enhance the capacity of bacteria to become resistant to certain antibiotics, thus even bringing into play the concept of *justice*. Even this simple example illustrates how medical ethical conundrums are frequently the result of *conflicting duties*.

If the patient is unable to make his or her own decision, the treating surgeon must respect the decision made by a surrogate decision maker, such as one designated in a healthcare *durable power of attorney*.

### Beneficence

The principle of *beneficence*, simply stated, involves the duty of the physician to act in the best interest of his or her

patients. *Beneficence* is *doing good*, and is the reason most of us chose to become doctors. Beneficence, or doing good, is probably the universal tenet of the medical profession.

### Nonmaleficence

*Nonmaleficence* is essentially the old philosophical principle, “first, do no harm.” It derives from knowing that patient encounters with surgeons can prove harmful as well as helpful. This principle includes not doing harm, preventing harm, and removing harmful conditions. For those physicians caring for patients in an emergency environment, it also includes the concept of security, protecting oneself and one’s team, as well as the patient, from harm.<sup>7</sup>

This concept also incorporates the principle of *avoiding killing*. This seems very obvious on its face value; however, what is a doctor to do when confronted with a situation in which the administration of sufficient medication to alleviate the pain of a patient might have the *secondary effect* of diminishing respiration, and actually hastening the patient’s death? This is, of course, the crux of the major debate that is ongoing over *physician-assisted suicide*, if not actual *euthanasia*. There are other situations in which avoiding killing must be taken into account. *Abortion* presents another situation which, depending on your personal beliefs, might fall into that same category. This could create a conflict between the duty to respect the autonomy of the patient and the personal religious beliefs of the treating physician. This same conflict has recently, and intensely, come into play over the issue of research and therapeutic utilization of *embryonic stem cells*.

### Justice

*Justice* is *fairness*. It is required to ensure that medical decisions are made with reason and honesty. Selfish or biased influences must be recognized and avoided.<sup>8</sup> For many, the term justice includes the concept of *distributive justice*. This form of *justice* includes not only the surgeon’s obligation to an *individual patient* but to fairness in the allocation of resources for the good of the *broader society*. It is this concept of justice that becomes the basis for society-wide healthcare policy determination. *Distributive justice* implies that all individuals and groups should share in society’s benefits and burdens. This presents an ethical challenge for the surgeon, dealing with an individual patient, who mistakenly believes that she should limit or terminate care based on a need to limit healthcare resource expenditures for the *good of society*.<sup>7</sup> It was this temptation to place the good of society before the good of an individual that led the physicians of Europe to fall prey to the fallacious doctrines being promulgated by the Nazi government.<sup>9</sup>

Surgeons should be prepared to respect and seek to understand people from many cultures and from diverse socioeconomic groups. In the United States, emergency facilities are obligated to provide necessary care to all patients, regardless of ability to pay. Our current business-based medical delivery system makes it difficult to abide by the principle of having

access to appropriate inpatient and follow-up medical care dictated by the patient's financial situation. Provision of emergency, and most elective, surgical treatment should not be based on gender, age, race, socioeconomic status, or cultural background. No patient should ever be abused, demeaned, or given substandard care.<sup>1</sup>

### *Religion and Medical Ethics*

In many societies, religion has been looked upon as the determinant of ethical norms. In our American society, we are multicultural with no single religion holding dominance over the entire population. Therefore, a value-based approach to ethical issues depends on the individual patient's values. However, religion still influences bioethical concepts and decisions. Clinical bioethics, in fact, uses many decision-making methods, arguments, and ideals that originated from religion. It is also important for the individual clinician to understand his or her own personal spirituality in order to relate better to patients and families, representing a broad diversity of religious and ethnic backgrounds. Although religions may appear dissimilar, most are based on some form of the Golden Rule, which holds "do unto others as you would have them do unto you." Problems frequently arise when trying to apply religion-based rules to specific clinical, ethical situations. In so-called modern times, the United States began turning away from a reliance on religious principles, relying instead for answers based on more generic secular principles; and the medical/surgical community was no exception. As previously described, we have come to rely instead on the four ethical principles of *autonomy*, *beneficence*, *nonmaleficence*, and *fairness*. These are the principles that have guided medical ethical thinking and have become instrumental in forming healthcare policies in the United States and other Western countries over the past three decades.<sup>7</sup>

In a recent survey of physicians' attitudes toward spirituality in clinical practice, 85% said physicians should be aware of the patient's religious and spiritual beliefs. The survey went on to show that although many physicians believe that they should inquire about their patients' beliefs, fewer than 10% of doctors actually do so, even for their dying patients. There is no hard data to support the benefits of taking a spiritual history, but there is some indirect evidence in support of the practice. It is known that religion is one of the most common ways by which patients cope with medical illness. Religious beliefs are known to be significant influences on medical decisions, especially those made by patients with serious illnesses. In addition, the faith community is a primary source of support for many medically ill patients, and such social support is associated with better adherence to therapy and improved medical outcomes. Several surveys have revealed that, from the patient's point of view, satisfaction with the emotional and spiritual aspects of care had one of the *lowest* ratings among all clinical care indicators and was one of the highest areas in need of quality improvement.<sup>10</sup>

The purpose for taking even a brief spiritual or religious history is to learn how patients cope with their illnesses, the kinds of support systems available to them in the community, and to learn of any strongly held beliefs that might influence the delivery of medical care. Venturing into this delicate area is obviously fraught with some hazards. We must be extremely cautious about prescribing religion to nonreligious patients, forcing a spiritual history on patients who are not religious, causing patients to believe our practice and specific ways, attempting to provide spiritual counsel to patients, and arguing with patients over religious matters.<sup>10</sup> It is also imperative for us as surgeons to be comfortable enough with our own beliefs to allow our patients to *pray for us*, according to the faith of their own religion. No comment more than a simple and sincere "thank you" is usually indicated.

## Legal Principles

### General Concepts

#### *Types of Law*

In the United States, law is created in one of two systems: *Federal* or *State*, and is made by judges (*common law*), legislatures (*statutory law*), and executive agencies empowered by legislatures (*regulatory law*). The fundamental document that creates and delineates these powers is the Constitution. *Civil law*, including malpractice, is usually enforced by *monetary judgments*. *Criminal law*, including physician-assisted suicide, is usually enforced by *fines* and/or *imprisonment*.<sup>2</sup>

There are three kinds of law that affect the practice of surgery: *statutes*, *regulations* promulgated by an administrative agency, pursuant to a statute, and *case law*. The legislatures are the designated policy-making entities in our system; *regulations* are written to comply with legislative directives; and the courts are charged with resolving disputes between parties, usually as directed by *statute*, if there is a relevant one. Courts issue written opinions when there is a conflict that results in a lawsuit, especially when the interpretation of a statute or a regulation is in question. The most difficult situations are those in which the court is faced with a matter of "first impression," which the legislature has not specifically addressed. The courts, and their written opinions, on this type of case, frequently ask the legislature for guidance in future situations. Until the legislature acts, the written opinion of the court is the only guidance physicians have, and hospital counsel sometimes must interpret this.

Doctors should be generally familiar with *state law*. There are different state laws on many bioethical matters, such as definition of death, competency, organ donation, and now the use of embryonic stem cells, even for research only. Many doctors move from state to state during their careers, and general understanding of state laws governing situations that may confront them in surgical situations is crucial. However, most important legal principles that apply to ethical dilemmas in delivering surgical care are widely accepted among several

states. There are some glaring discrepancies in these commonalities, including the neurologic *criteria for death* (a person may be legally dead in one state and not in another) and the legality of *physician-assisted suicide* (punishable as a crime in all states except Oregon).

### Statutory Law

Statutory law is made by legislatures and includes such issues as *the statute of limitations*, which defines how long after an adverse event a patient is able to sue a physician for malpractice, and, in some states, statutes on *informed consent*.

The Emergency Medical Treatment and Labor Act (EMTALA) is another example of a *federal statutory law*. It was originally enacted as part of the Consolidated Omnibus Budget Reconciliation Act of 1986. Congress enacted EMTALA as a remedy for “patient dumping.” The legislature was particularly concerned about hospitals refusing to render emergency care because of lack of insurance or the economic ability to pay, but soon came to realize that care was also being refused on the basis of race or other discriminatory criteria. The Act requires that a basic screening examination be provided to all patients seeking care. It therefore became illegal, as well as unethical, to withhold therapy from the poor just because they do not have the ability to pay.<sup>11</sup>

Compilation of statistics from major county hospitals across the country concluded that as many as 650,000 patients were “dumped” annually, and the resulting transfer led to substandard care and/or life-threatening situations in 25%–33% of that number. The economic impact of EMTALA on hospitals and physicians has been enormous. Patients without the means to pay for medical care know that they cannot be turned away from the emergency room. Therefore, they use it as their *primary care facility*. That means that hospitals, physicians, and surgeons are carrying the burden of the nation’s uninsured, often without adequate compensation. For many healthcare facilities, this money lost in the emergency room can mean the difference between bankruptcy and solvency.<sup>12</sup>

### Regulatory Law

These administrative laws are created by regulatory agencies including State Medical Boards. Recent examples of regulatory law include not only EMTALA but also the recently implemented Health Insurance Portability and Accountability Act of 1996 (HIPAA). HIPAA, as EMTALA, was intended to protect patients’ rights of privacy and to guarantee them continuation of health insurance coverage should they change employers. Also, like EMTALA, HIPAA has taken on many ramifications threatening a huge economic impact on the escalating costs of delivering medical care. Although the good aspects of it are necessary and noble, the burdens of increased costs will be crippling to some healthcare facilities and will probably significantly curtail many clinical research endeavors.

## Malpractice

The public and the legal community do not seem to understand that there is an element of uncertainty and unpredictability in a biological system. They seem to understand that 11 men on a playing field cannot score a touchdown on every play, but a surgeon is held to a standard of achieving perfection on every operation. An ethical, as well as legal, consideration is: what to do when we fall short of perfection or, worse, make a blatant error while trying to do the best we can. Several factors come into play. Who is responsible if you did not actually do the damage yourself? What do you tell the patient and the family? How do you comply with the policies of legal counsel and risk management within your own institution?

Many successful legal actions against surgeons have been based on withholding information about risks, complications, or adverse outcomes. A surgeon must be able to admit to unwanted events in an honest and compassionate manner. It is clearly possible to accept *responsibility* without admitting *negligence*. It never hurts to admit that you are sorry things had not gone exactly as planned, but that you must go forward, as efficiently as possible, to correct the situation. At this point a surgeon should never hesitate to seek consultative assistance whenever it might seem helpful. It is never helpful to shift blame to a resident, an assistant, a nurse, a referring physician, or the institution itself. If anyone is to be sued, everyone will be sued, and divisiveness usually damages everyone. Unfortunately, it is also of little help to blame the patient and to invoke the existence of adequate *informed consent*. How nice it would be to tell the morbidly obese person that his postoperative complications should be blamed on his own indiscretions. Even informed consent, including risks based on the patient’s known status of precarious health, is of little help. A surgeon is not absolved of responsibility and concern by claiming, “I told you so!”

Judges, not the legislature, establish the standards that constitute medical malpractice. The familiar elements of medical malpractice include *duty, breach, causation, and damages*. Decisions are based on the standard of care, and judges have developed the methods of determining the standards over many years, after the review of many cases. Thus, the courts rule on a specific set of facts that have already occurred. This is extremely frustrating for those practitioners of surgery who need to know what the law *would say* in a particular situation, as it is occurring, not in retrospect.

Unfortunately, resolution of controversy over medical and surgical ethical issues has been the domain of law, not philosophy or medicine. So far, perhaps because of legal constraints, medicine has been unable to “police itself.” Because the law has come to champion individual rights and hold physicians liable for malpractice, it has served to condemn medical *paternalism* as it has elevated *patients’ rights*. This has had the damaging effect of encouraging many physicians to become more concerned with avoiding litigation than with “doing the right thing.” The law has had understandable

difficulty in sorting out the complicated *physician–patient relationship*, and thus law does not mandate ethical behavior in these relationships.

## A Familiar Case-management System

### Physician-based Ethics

#### *General Principles*

Mark Siegler, a physician, and his coauthors of “Clinical Ethics,” the fifth edition, present a technique for using *case analysis* as a practical approach to solving ethical dilemmas in clinical medicine. Contrary to most texts on healthcare ethics that are organized around the ethical *principles* of respect for *autonomy*, *beneficence*, *nonmaleficence*, and *fairness*, their publication provides a straightforward *method* for clinicians to use in sorting out the pertinent facts and values of any case into an orderly pattern that facilitates the discussion and resolution of ethical problems.<sup>13</sup> Their technique corresponds to the way in which clinicians usually analyze actual cases. It assimilates the ethical principles and circumstances that comprise a method to facilitate the analysis of cases involving ethical issues.

### *The Clinical Ethics System*

Jonsen and his colleagues<sup>13</sup> suggest that every clinical case, especially those raising an ethical dilemma, should be analyzed by means of the following four topics: 1) *medical indications*, 2) *patient preferences*, 3) *quality of life*, and 4) *contextual features*, defined as the social, economic, legal, and administrative context in which the case occurs. The authors emphasize that although the facts of each case can differ, these four topics are always relevant. The topics organize the various facts of the particular case and at the same time call attention to the ethical principles appropriate for each case. Their intent is to show clinicians that these four topics provide a systematic method of identifying and analyzing the ethical problems occurring in clinical medicine. See Table 53-1.<sup>13</sup>

We find it extremely helpful to use this case management system, which is very similar to our usual approach of managing a patient and his or her problem by taking a history in an organized manner and proceeding to do a physical examination, analyze the laboratory data, and arrive at a plan for managing the case. Examination of the table shows that the authors have clearly related to clinical situations the basic ethical principles previously described. They go on to emphasize that most ethical conflicts can be resolved by

TABLE 53-1. The four topics: case analysis in clinical ethics

<p>■ <b>MEDICAL INDICATIONS</b></p> <p>The Principles of Beneficence and Nonmaleficence</p> <ol style="list-style-type: none"> <li>1. What is the patient’s medical problem? history? diagnosis? prognosis?</li> <li>2. Is the problem acute? chronic? critical? emergent? reversible?</li> <li>3. What are the goals of treatment?</li> <li>4. What are the probabilities of success?</li> <li>5. What are the plans in case of therapeutic failure?</li> <li>6. In sum, how can this patient be benefited by medical and nursing care, and how can harm be avoided?</li> </ol>	<p>■ <b>PATIENT PREFERENCES</b></p> <p>The Principle of Respect for Autonomy</p> <ol style="list-style-type: none"> <li>1. Is the patient mentally capable and legally competent? Is there evidence of incapacity?</li> <li>2. If competent, what is the patient stating about preferences for treatment?</li> <li>3. Has the patient been informed of benefits and risks, understood this information, and given consent?</li> <li>4. If incapacitated, who is the appropriate surrogate? Is the surrogate using appropriate standards for decision making?</li> <li>5. Has the patient expressed prior preferences, e.g., Advance Directives?</li> <li>6. Is the patient unwilling or unable to cooperate with medical treatment? If so, why?</li> <li>7. In sum, is the patient’s right to choose being respected to the extent possible in ethics and law?</li> </ol>
<p>■ <b>QUALITY OF LIFE</b></p> <p>The Principles of Beneficence and Nonmaleficence and Respect for Autonomy</p> <ol style="list-style-type: none"> <li>1. What are the prospects, with or without treatment, for a return to normal life?</li> <li>2. What physical, mental, and social deficits is the patient likely to experience if treatment succeeds?</li> <li>3. Are there biases that might prejudice the provider’s evaluation of the patient’s quality of life?</li> <li>4. Is the patient’s present or future condition such that his or her continued life might be judged undesirable?</li> <li>5. Is there any plan and rationale to forego treatment?</li> <li>6. Are there plans for comfort and palliative care?</li> </ol>	<p>■ <b>CONTEXTUAL FEATURES</b></p> <p>The Principles of Loyalty and Fairness</p> <ol style="list-style-type: none"> <li>1. falling back on the *medical indications* that represent the medical facts of the case. This information, plus the second category of *patient preferences*, almost always will lead the clinical surgeon to a resolution of the ethical problem. If the ethical dilemma results from conflict among the patient, the family, the healthcare team, or institutional policy, then adequate resolution may become dependent on applying analysis of the additional categories, *quality of life* and the array of *contextual features*. It is amazing how often reviewing and relying on what the medical facts of the situation actually are can clarify the intensity and emotion of even the most complex situation.

## Specific Dilemmas of Colon and Rectal Surgery

### Special Considerations for Colon and Rectal Surgeons

Attempting to explain, much less to justify, a career in colon and rectal surgery is never simple. The words, and the title itself, create consternation and the need to tell us the last circulating joke, which most of us have heard multiple times over. Telling what we do and who we are is never good dinner conversation and can present seemingly insurmountable challenges to represent ourselves at our children's eighth-grade career-day programs. We understand, however, that we have chosen a surgical career that includes resolving perplexing problems of anal-rectal disease, pelvic floor malfunction, and incontinence which cause daily significant discomfort for the patient and have frequently been mismanaged, for a long period of time, by our nonspecialized colleagues. This places us, frequently, in the position of not only having to resolve the technical surgical aspect of the problem, but also having to explain the previous misdiagnosis or mismanagement by other physicians, a challenging *ethical dilemma*.

In addition to the seemingly simple anorectal disease, most of our careers also encompass management of some of the most complicated inflammatory bowel disease and cancer. This casts us into a position of daily having to deal with multiple components of the modern healthcare team. We know that no one should ever have to die from colorectal cancer because it can be prevented or diagnosed at an early, or even premalignant, stage. Thus, we become actively involved with screening, preventive measures, understanding genetic predisposition to disease, and even the need for what has come to be called *preemptive surgery*. Because of the diseases that we treat, we must understand the science of current genetics as well as the appropriate clinical utilization of genetic testing, including the challenges of respecting *confidentiality* and requesting *genetic counseling* to deal with the long-term aspects involving not only the patient but family members who may not wish to be included in the discovery

of genetic predisposition to disease. All of this presents intense need for dealing with frequent ethical challenges, especially the need for increasing *preemptive surgery*, subjecting a *well person* to major surgery with significant risk of complications or impact on lifestyle and body image. In fact, because of our experience and expertise in the construction and management of intestinal stomas, we are often confronted with such *quality-of-life* issues as body image and impairment of sexual function.

Dealing with our many patients, and their families, who have such inflammatory bowel diseases as Crohn's disease, requires us to maintain long-term, perhaps for generations, contact with and care for our patients, much the contrary of our public image of being just "technicians" who do a short-term repair job and then have no other, ongoing relationship with our patients.

Because of the complexity of the diseases on which we operate, including those in areas with difficult access and high risk of postoperative complications and recurrence of malignant processes, we often find ourselves on the leading edge of surgical innovation and instrumentation. This creates the ethical challenges of differentiating acceptable surgical *innovation* from truly *investigative* ventures that require research protocols and institutional approval. We must deal with the interpretation and implementation of *autonomy* verses *paternalism* as we guide our patients to the best choices for their care. Sick patients and those with advanced cancer will grasp at straws. They want anything on earth that might help. In such a situation, it is important for the surgeon-scientist to avoid exploiting this universal hope of sick patients by performing an operation that is inadequately tested.<sup>14</sup> Because of these challenges of innovation, we are also frequently thrust into the complex relationship between ethical surgery and the pharmaceutical and instrumentation industries.

Needless to say, because of the many things that we have to offer and the need to be concerned with our own long-term financial security in the face of reimbursement and legal challenges, we must walk the narrow line between providing the best care possible for all of our patients and complying with our own personal needs and those of our families. Claude Organ explained that, "So much of our orientation today serves to erode our spirit as caregivers." He goes on to say that surgery is under increased public surveillance, and we are consumed by endless paperwork, administrative hassles, ponderous bureaucracy, professional liability concerns, inadequate reimbursement for our work, limited access for our patients, an impersonalized system, and increasingly burdensome documentation. He cites the increasing federal mandates of the Health Insurance Portability and Accountability Act, the Emergency Medical Treatment and Active Labor Act, and the Program for Appropriate Technology in Health audits. He quotes the highly respected surgical mentor, Haile Debas as saying, "Professional status is not an inherent right but one granted by society. . . . This obligates surgeons to put their patients' interests above their own."<sup>15</sup>

## Categories of Patient Encounters

### Severe Emergency: Life in Immediate Jeopardy

An example would be a critically ill person brought in from a severe motor vehicle accident or one who has suffered a serious gunshot wound. Certainly there is no preestablished doctor–patient relationship, there is little chance that there will be a reliable surrogate, and many ethicists have questioned if a patient in such dire straits ever has *decision-making capacity*.

### Urgent: Serious Problem Needing Surgery

An example would be a patient brought in with peritonitis. The individual may be in hypovolemic shock, is terrified, is in great pain, but is still cognizant of the situation and what is happening. There certainly is no preexisting *doctor–patient relationship*, and no one is absolutely sure of the *decisional capacity*, especially if the patient disagrees with the recommendation of the surgical team. In a case such as this, in which there is some but not much time, the presence of a *surrogate* and clearly described *advance directives* would be extremely helpful.

### Semi-elective: Will Probably Need Surgery

An example would be an elderly patient with known extensive intraabdominal cancer who presents with a significant, unresolved intestinal obstruction. It is clear that the obstruction can only be relieved by surgery, but it is not clear that this will be beneficial to the patient. In this case, determination of *decisional capacity*, the existence of *advance directives*, or the presence of a reliable *surrogate* is very important; and there is enough time to pursue the intended desires of this patient.

## Autonomy/Decision-making Capacity/Competency

### General Concepts

#### *Autonomy Versus Paternalism: Trust Is the Bridge*

*Individual freedom* is one of the basic tenets of modern bioethics. This freedom is usually referred to as *autonomy*. This principle implies that a person should be free to make his or her own decisions. It is somewhat the antithesis of the medical profession's long practiced *paternalism* whereby the physician acted on what he or she thought was *good* for the patient, whether or not the patient agreed. The concept of *autonomy* applies to many interpersonal relationships, and is essentially a respect for each person as an individual.

It has been difficult for many physicians, perhaps especially surgeons, to accept the principle of *patient autonomy*. This is not difficult to understand because accepting this

principle implies a change in the physician's relationship with the patient. The physician must now be a partner in his or her patients' care; must become an educator, teaching uninformed patients enough about their diseases to make rational decisions; and most distressing, to allow autonomous patients to make foolish choices. For physicians dedicated to helping their patients, allowing them to select what the physician considers a terrible treatment option, or even refusing treatment altogether, is a very frustrating change.<sup>7</sup>

However, experienced surgeons know that their patients significantly rely on them for guidance through complicated choices, often where life itself is on the line. This is, of course, a form of *paternalism* which our patients request and to which they are entitled. The key to accomplishing this ethically and successfully is based on the principle of *trust*. For surgeons, the establishing of this trust must begin at the inception of the relationship, and sometimes must be very quickly accomplished. It is sometimes very difficult for our non-surgical colleagues to understand and accept this element of *paternalism* required in the surgeon–patient relationship.

The crucial issue for the surgeon seeking autonomous informed consent is the *decision-making capacity* or *competence* of the patient involved. Understanding the differences between these terms is important, especially if the patient disagrees with the advice of the surgeon or refuses potentially life-sustaining treatment.

The determination of *decision-making capacity* involves more than just completing a mental status examination and includes the ability of the patient to take in information, to evaluate a decision based on personal values, to make a decision, and to communicate the choice of decision to the physician. The concept of medical *decision-making capacity* is one based on the evaluation by the team providing medical and surgical care. This is distinguishable from a *legal determination of incompetence*. A patient is always assumed to be *legally competent* unless a *court* has declared otherwise. For example, patients may not have been declared incompetent by a court but may have lost the capacity to make decisions about their medical care because of their current medical status, including such conditions as intoxication, stroke, hypoxia, blood loss, dementia, or severe trauma. The determination of *decision-making capacity* varies in stringency with the seriousness of the impact of the decision. For example, the more severe the risk posed by the patient's decision, the more stringent should be the standard of determining capacity. This provides an increased protection for patients of questionable capacity when the potential harm from their decision is greater. This reaches the pinnacle of importance when a patient refuses treatment for a potentially life-threatening condition. These decisions are often difficult to make in the emergency environment, and the treating surgeon must sometimes make practical ethical decisions that go beyond the basic law of informed consent.

## Refusal of Treatment

Ethical dilemmas usually occur when there is disagreement among the patient, the family, and the healthcare team. The clearest example is a patient's refusal to accept the recommended treatment. This is especially critical for the patient who has *decision-making capacity* and refuses potentially life-sustaining treatment. The United States Supreme Court, in the *Cruzan case*, upheld the right of persons to refuse lifesaving medical treatment, including resuscitation, ventilators, artificial nutrition and hydration, and lifesaving blood transfusions. The court based its decision on "the right of every individual to the possession and control of his own person, free from all restraint or interference of others, unless by clear and unquestionable authority of law under the *liberty interest*, protected by the Due Process clause of the Fourteenth Amendment of the Constitution." The Courts have, however, identified four *state interests* that override the refusal or termination of medical treatment on behalf of competent and incompetent persons, including the preservation of human life, the protection of the interests of innocent third persons, the prevention of suicide, and the maintenance of the integrity of the medical profession.

In exercising their rights under the autonomy principle, each competent patient has a right to refuse treatment, even if the results of such refusal will be their death. This type of situation comes up most often in the case of religious or cultural beliefs. Jehovah's Witnesses are probably the most familiar example of this type of dilemma. They refuse to accept blood transfusions, based on their religious beliefs. Such refusal, especially where major surgery is indicated, clearly poses the likelihood of avoidable death. Still, the competent patient's *autonomy must rule*. There may be situations in which the treating surgeon believes that the competency of the patient refusing treatment may be in doubt. In such a case, if time permits, in order to protect the doctor and the hospital; it may be appropriate to get a court order permitting the indicated procedure or blood transfusion. The courts will weigh the possible benefits of the treatment against the potential negative effects, risks, and the potential burdens on the patient; and they will issue a ruling. This ruling will insulate the treating physician and the institution from legal liability. There are situations in which parents or guardians are involved in refusal to accept and allow treatment on behalf of minors. These are the most common instances in which court intervention is sought, and to resolve the problem the courts must balance the best interests of the child against the desires of the parents.

For sure, *refusal* of a life-sustaining medical treatment should be accompanied by a full assessment of *decision-making capacity* and by an understanding from the patient of the consequences of refusal. If uncertainty prevails, the surgeon on the firing line should still "err on the side of life."

## Telling the Truth/Disclosing Errors

### General Concepts

Physicians have a duty to tell the truth to their patients. This seems so obvious that it merits no further discussion. However, there may be circumstances where telling the *whole truth* to a patient will have a negative impact on his or her overall well-being. If the physician believes that telling the patient everything about the condition in question, which is a duty, will have a dramatic negative effect on the patient's well being, the physician must decide which duty is more important in each particular situation.

*Truth telling* also would apply in situations involving *medical mistakes*, even those mistakes that are minor and arguably have no detrimental effect on the patient. To illustrate this point, let us consider a doctor awakened in the middle of the night who orders 1 mg of a drug, when the appropriate dose is 0.1 mg. The overdose has no detrimental effect on the patient, so does the doctor still have a duty to reveal the error that he made? Ostensibly, this question would seem to be easy to answer: just tell the truth! However, if informing a patient whose confidence in the medical profession is very low, and his mental stability might be diminished by finding out about a medical error, notwithstanding the fact that the error had no detrimental effect, do doctors still have a duty to tell the truth? In this situation, it might violate the duty of nonmaleficence by doing something that will hurt the patient.

### Prognosis: Balance Between Giving False Hope and Removing All Hope

We are all involved in operations in which the desired outcomes are not met. Managing these patients through the entire course of their disease, and sometimes death, is an important part of being a good physician and surgeon. This becomes even more important as the population ages and we encounter older patients with multiple comorbidities. Especially in these older, high-risk, patients, even what is anticipated to be a fairly straightforward operation may have unexpected, adverse results. It forces us to remember the old adage that not everyone needs to die with an incision. Predicting prognosis, much less conveying it well to the patient and the family, is a difficult skill with little data to help us. We need to communicate with the public the fact that we would welcome the ability to accurately forecast outcomes especially for older patients, with higher risks, and in emergency situations. We truly cannot distinguish which ones may actually do well from such high-risk operations. This necessitates us, as surgeons, to assume an important role in providing *palliative care* even when complete surgical *cure* is no longer a possibility.<sup>16</sup>

Discussing prognosis with our patients and their families is one of the situations that forces us most carefully to choose our words precisely. Even when we are forced by patients and

families to use specific statistics, we must use them in a manner that is helpful and not totally destructive of hope. It helps to explain that statistics are better for 100 people rather than for any given individual. It can be very expeditious for us to use statistics as a form of *truth dumping*, but such an act can be devastating to a terrified, desperate, and inadequately informed patient who is desperately clinging for any possible hope.

## Patients with Impaired Decision-making Capacity

Examples of patients having impaired decision-making capacity include minors, mentally handicapped persons, those with organic brain disease or in toxic states, and those with psychiatric conditions, including suicidal risk. Determining the point at which a minor has the capacity to make medical decisions is often very complicated and varies with the laws of an individual state.<sup>17</sup> For example, an “emancipated” minor can make his or her own medical decisions. This includes individuals younger than the age of majority who are living on their own, are married, or are in the military.

Even patients with *Alzheimer’s disease* cannot all be regarded as having lost their *decision-making capacity*. Depending on the severity of their disease, they may well be able to participate in much of the decision-making process. This of course depends on the status of their disease and on the complexity and implications of the decision to be made.

## Suicidal Patients

Respect for autonomy has always had its limits. When treating a suicidal patient, the surgeon is faced with a conflict between the ethical principle of *beneficence* and *respect for autonomy*. Sorting out this dilemma is usually based on whether the suicidal patient is currently capable of making a rational, autonomous decision. It also raises the perplexing question: “Can suicide sometimes be a rational choice?” Generally, surgeons intervene with the suicidal patient based on the assumption that the person is suffering from mental illness and impaired judgment. This assumption is usually correct, with 90% of suicides being found to be associated with mental illness such as depression, substance abuse, or psychosis.<sup>18</sup>

Therefore, relying on the principle of beneficence, surgeons almost always treat the injuries inflicted by suicidal patients despite their expressed intention to die. The conflict arises when the reasons for suicide appear “good,” such as in the case of the terminally ill cancer patient with severe, uncontrollable pain. Is the application of lifesaving intervention truly a beneficent act in the patient’s best interest? Several studies have shown that physicians rendering care in the emergency department are not likely to recognize

treatable depression in their patients. These studies go on to confirm that 80% of patients who attempted suicide subsequently show that they do not continue to wish to die. Thus, although some patients might make a rational decision to commit suicide, in most cases, the surgeon delivering care must assume that the person’s judgment is impaired, and proceed with full indicated, lifesaving measures.<sup>18</sup>

## Advance Directives

### General Principles: Talking About Death

Facility in routinely addressing end-of-life issues with surgical patients is critical because it allows the surgeon to raise difficult questions with patients during the earlier phases of their disease process. Often the issues that are most difficult to address when patients near the end of life are those that have not been attended to earlier in the patients’ course of treatment. Such early discussion allows the surgeon and the patient to discuss limits on treatment at a time when the patient is able to participate in the process. Usually, we surgeons are intent on cure, and the prospect for death after most of our routine procedures seems very remote. However, these discussions are more important than ever because we now have more options available to prolong life than existed just a few decades ago. In addition, social changes have led to greater participation by patients in the medical decision-making process. With the increasing mobility of our society and the changing allocation of primary care physicians, we as surgeons often do not have the backup of a well-established physician–patient relationship. Add to this the very visible increase in public debate over *ethanasia* and *physician-assisted suicide* and we can understand the concern the public has over perceived, or actual, deficiencies in how patients are managed at the end of life.<sup>19</sup>

When a patient does not have the decision-making capacity to give informed consent, or there is no time to ask the patient or his or her surrogate about treatment preferences, *advance directives* express in written form what the patient’s choices would have been if he or she had decision-making capacity. Advance directives include living wills, durable powers of attorney, and other written documents. In 1991, the federal government passed the Patient Self-determination Act (PSDA), which required that healthcare institutions advise and educate patients regarding advance directives. This affected all institutions participating in the Medicare and Medicaid programs. This law was supposed to increase the use of advance directives and thus prevent unwanted care. In fact, a major study of advance directives and seriously ill patients revealed that the PSDA had little impact on health care in the United States. This was revealed in the Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatments (SUPPORT), which showed that only

20% of seriously ill patients had advance directives even after the SUPPORT intervention and the PSDA.<sup>20</sup>

Despite these studies, it is still imperative for surgeons to understand the principles involved and the advantages of advocating for appropriate advance directives for our patients and their families. An *advance directive* is any proactive document stating the patient's wishes in various situations, should they be unable to state their own wishes.

Some states have specific language for each of these documents and provide reciprocity for other states. Both the *living will* and a *durable power of attorney* can be prepared without the benefit of state-approved language as long as the intention of the person executing the document is clear. Such directives provide advanced informed consent for a myriad of courses of treatment, whether it be related to pain medication, "do not resuscitate orders," or management should the individual enter some level of persistent vegetative state. In a complete set of these documents, the patient has given full thought to all of the possibilities that might occur, and has decided what course of treatment would be his or her choice. Unfortunately, most patients have not executed these documents, or they have not given sufficient thought to what their wishes are. Furthermore, many times when a power of attorney is granted to a surrogate decision maker, the surrogate has not had a full discussion of the wishes of the signatory.

## Living Will

The *living will*, which was adopted by many states in 1990, is a document suitable for *terminally ill patients* in which the treating physician accepts the patient's wishes regarding withholding of care, including requests restricting heroic resuscitative efforts, in advance. Many state that no life support be used in cases in which meaningful recovery will not occur. In a *living will*, the signatory indicates what his or her choices would be for medical treatment in the situation in which *death is imminent*, and the individual's wishes are unable to be communicated to the treating physician. Under most state laws, *living wills* indicate the signatory's desire to die a natural death and indicate unwillingness to be kept alive by so-called "heroic measures." This usually amounts to a "Do Not Resuscitate" order. In some states, that also indicates the patient's wishes concerning the level of pain medication, hydration, and nutrition, which the patient would desire if he or she lapses into a nondecisional condition. In most states, the activation of the terms of a living will require an *imminent demise* and a second physician's opinion corroborating that determination. Unfortunately, many people believe that the *living will* is the best form of advance directive and do not realize that it is only intended for the *terminally ill*.

## Durable Power of Attorney

A *durable power of attorney for health care* specifies a surrogate decision maker in the event that the patient no longer has

the capacity to make medical decisions. The *durable power of attorney* is a written document that gives the authority to another person, usually a spouse or relative, to make decisions regarding health care if the patient is incapacitated and unable to make decisions for himself or herself. The reason it is called "durable" is to ensure that the signatory knows that it can be revoked and/or changed at any time. This provides the freedom to change both who the surrogate is and what the patient's stated wishes, if any, are. This is important in situations such as divorce in which the person executing the power of attorney may want to change the surrogate before the divorce becomes final or in those family situations in which dynamics create a desire to change the surrogate.

Thus, the patient designates a *surrogate decision maker* who should participate in all significant treatment decisions and be kept up to date regarding the patient's health care. The *durable power of attorney* works best when the patient has discussed with a surrogate his or her values and beliefs, because these would apply in making complex decisions regarding healthcare issues. If there is no durable power of attorney, surrogate decision makers may be sought based on state laws. There is usually a defined hierarchy regarding surrogate decision makers: spouses, adult children, siblings, and so forth. Such a surrogate decision maker must be acting in the best interest of and according to the wishes and values of the patient. The *durable power of attorney* is a better form of advance directive than the *living will* because, in the former, a surrogate can be educated about the nuances and options regarding each stage of treatment or nontreatment.<sup>20</sup>

## Problems

In many situations the surrogate has the legal authority to make a decision, but is not aware of what the patient would want. This is the fault of the patient. All persons, when naming a surrogate decision maker, have a responsibility to fully explain what they would want in certain medical treatment situations. Failure to do so puts the burden on the surrogate to speculate what the patient would do were they able to make the decision.

There are two standards that apply in the situation in which the surrogate has not been informed of the patient's wishes. One is the *substitute judgment* standard. When using this standard, the surrogate bases a decision on a prior expressed statement of the patient's preferences or on an in-depth knowledge of the personality of the patient and a willingness to do what the surrogate believes the *patient*, not the surrogate, would want in that specific situation. The second standard is that of the *best interest* of the patient. This is obviously a far more nebulous concept and occurs when the surrogate has not had any specific communication with the patient about the specific type of situation and is not cognizant of any particular patient preferences. In this situation, the surrogate is supposed to do what he believes is in the best interest of the patient. This is an important distinction to make and

emphasizes the difference between doing what the patient would want done in a given situation, as opposed to having someone else decide what he or she thinks is best.

A further problem with advance directives that limit full implementation of medical care is the application of such directives in situations for which they were not intended. An example that confronts the colon and rectal surgeon is an elderly patient who is recovering from a complicated colon resection for curable cancer and develops postoperative pneumonia requiring presumed short-term ventilating support. Should such a patient not be intubated because of an advance directive indicating, “do not resuscitate”? In such a case, it would be a serious error to respect the advance directive and not to treat the patient aggressively. It is clearly probable that the patient would have wanted treatment under these circumstances.

There must also never be confusion when the patient is able to relate his or her preferences to healthcare providers. *Verbal communication takes precedence over any written advance directive.* In addition, when there is any confusion about the advance directive, disagreement among family members, or concern that it was not meant for the clinical circumstance at hand, *advance directives limiting treatment should be ignored in favor of prudent medical care.* In general, it is always wise for healthcare providers to err on the side of life and to begin standard medical treatment. Treatment options, such as mechanical ventilation and hemodynamic support, can always be withdrawn at a later time once issues are resolved and the family is present. In such situations, the hospital *ethics consultation service* can often prove very helpful.

Perhaps the major problem, at this point in time, is that there is little evidence that advance directives have made a significant impact on healthcare delivery in the United States.<sup>20</sup> We, as surgeons, should do all within our power to reverse this situation.

## Informed Consent

### General Concepts

Studies have revealed that doctors do not adequately inform patients, patients may not understand the information, and such information rarely affects the patient’s decision to follow the physician’s recommendations. Despite these facts, American courts have long held that a patient’s *informed consent* to a medical or surgical procedure or test is *essential*. The physician must give the patient sufficient information to make an intelligent decision before any action is performed. The laws dealing with informed consent require the surgeon to describe to the patient the nature of the procedure, risks, benefits, and alternatives, including no treatment at all. Ethical consensus on just how much disclosure is adequate is still very controversial. What is clear is that permission must be given *voluntarily*, that is, *without coercion* from the

physician or anyone else involved in rendering health care or, especially, those participating in the implementation of a *research* project.

The current interpretation of the law requires several elements to constitute *informed consent*. These are the *criteria* that the physician must disseminate to the patient or acting surrogate to meet that standard:

- a. What is the treatment that the doctor wishes to pursue, including a full explanation of the procedure and what it involves, including the necessity for anesthesia and other support functions?
- b. For what reason has the doctor selected this particular treatment, including the doctor’s judgment as to why this procedure is chosen to alleviate, cure, or minimize the medical/surgical problem?
- c. What are the risks of the recommended treatment, including an explanation of both the risks of the treatment itself and of any corollary threats to the patient? Surgeons should, in satisfying this requirement, include discussion of their own particular *experience with the procedure* as well as that of the hospital and the medical/surgical colleagues who will be assisting.
- d. What benefits will the patient receive from the proposed treatment? This is similar to the choice of treatment information previously described in that it requires the doctor to explain what the potential benefits will be from the procedure.
- e. What are the chances that the proposed treatment will remedy the problem? This is similar to the information included when describing “benefits and risks” and should also include a description of the *past experience* of the surgeon in performing this specific procedure, as well as the *outcomes* that the surgeon has obtained.
- f. What alternative treatment options exist for the given problem? This is similar to explaining the choice of treatment but emphasizes what other treatment options are available, and why this surgeon has chosen this particular procedure.
- g. What effect will refusal to accept the proposed treatment have on the patient? This must entail a frank discussion of the ramifications of failure to receive the suggested treatment and whether it is life threatening, or of a lesser degree of medical difficulty. This is the part of the discussion in which the surgeon must be most sensitive to the patient’s religious, cultural, and ethnic background.

Here the law requires that the sufficiency of the level of information will be judged from the *patient’s point of view*, not the doctor’s. If a surgeon explains a proposed treatment to the patient in terms that only another surgeon can understand, then the patient is not truly *informed*. This simply boils down to communication skills and the obligation to accurately *record* this discussion in the medical chart before performing the recommended surgical treatment. Every profession has its own terms of terminology or jargon. Physicians must strive to ensure that the language they use is clearly understandable.

Achieving acceptable levels of communication may be complicated by language, cultural, and socioeconomic factors. A manager responsible for building a new jetliner was credited with saying, "The main problem with communication is the illusion that it has actually occurred." All too frequently patients and families come away from discussions with surgeons in which the surgeon thinks he has effectively communicated, and the patient and family seemed to understand, but they did not. Sometimes it just boils down to faith in the doctor, or an individual's unwillingness to reveal his or her lack of comprehension. The physician must use *common sense* in determining whether fully informed consent has truly been granted, taking into account that some cynics claim, "The problem about common sense is that it is not common."

As with every rule of law, there are certain *exceptions* to the requirement for informed consent. When there is an emergency situation that could result in the death of the patient, time is of the essence, and there is no surrogate decision maker present, the *consent requirement is waived*. Similarly, when the situation is not an emergency, but the patient is for one reason or another not able to give consent because of unconsciousness, coma, mental disability, or other cause of inadequate decision-making capacity, and there is no advance directive or surrogate, informed consent is not necessary. There is also a *therapeutic exception* to the rule. If the physician believes that revelation of the normally required information would have a negative effect on the patient's health, fully informed consent is not necessary. This usually arises in the context of a psychiatric patient. Also, when a competent patient *refuses* to receive information upon which to base a decision, this requirement is waived. There can also be a waiver of the necessity for informed consent when the *government* requires certain medical tests or treatment in the face of possible medical or national security emergencies.

A common misconception among those rendering emergency care is that anyone who presents to an emergency facility falls into the *emergency exception* to informed consent. The *emergency exception* allows a physician to treat a patient without obtaining informed consent. This exception requires the following: the patient must be unconscious or without the capacity to make a decision, and no one else legally authorized to make such a decision is available; time must be of the essence in avoiding risk of serious bodily injury or death; and, under the circumstances, the action proposed would be that to which a *reasonable person* would consent. The emergency exception does not apply if the patient has decision-making capacity and is able to communicate a decision about medical care.<sup>2</sup>

## Patient–Surgeon Relationship

Siegler<sup>21</sup> explains that the three central ethical aspects of modern surgical practice are: 1) clinical competence; 2) respect for patients and their healthcare decisions; and 3) maintaining the primacy of the patient's needs in the face of

external pressures in a changing social, economic, and political climate. Successful clinical practice has always been a unique blend of technical proficiency and ethical sensitivity, which together constitute the art of the physician and surgeon. Once sought out by the patient, the surgeon becomes involved in the patient's problem. He or she is no longer a mere observer. Over the last few decades, the relationship between patients and physicians has been evolving from one of *pater-nalism*, in which surgeons make choices for their patients, to a more equal and *autonomous* relationship of shared decision making by which surgeons provide information that allows competent adult patients to make their own choices.<sup>21</sup> For complicated surgical dilemmas, this can never evolve completely because patients depend on the surgeon and their other physicians to guide them to the correct choice.

Sometimes surgical procedures considered "standard of care" by the surgeon are refused based on the patient's values and beliefs. Such cultural challenges can affect the success of the patient–surgeon relationship and ultimately the health outcome for the patient. Ultimately, the surgeon must learn to take into account the cultural components of the relationship and find ways to respond to them in an ethically and medically responsible manner. To deal with these complicated situations, the surgeon is often required to reassess and be secure in his or her own religious and cultural foundations.<sup>22</sup>

As Peter Angelos<sup>19</sup> explains, the relationships that individual patients have with their surgeons are as varied as the different types of surgical problems with which patients present. Perhaps patients are required to have a great deal of trust in their surgeons because of the nature of surgical intervention itself. This may result in patients frequently feeling a deeper personal bond with their surgeon than with many other physicians who may be involved in their care. Surgeons as well as their patients frequently feel the closeness of this bond. Angelos quotes Charles Bosk as explaining:

The specific nature of surgical treatment links the action of the physician and the response of the patient more intimately than in other areas of medicine. . . . When the patient of an internist dies, the natural question his colleagues ask is, "What happened?" When the patient of a surgeon dies his colleagues ask, "What did you do?"

When patients consider the surgeon to be "their doctor," the surgeon must not ever underestimate the importance of maintaining this relationship even, or perhaps especially, as the patient approaches the end of life. The impact of a concerned surgeon on a patient who is dying, or is curable, can serve to dramatically affirm the appropriateness of comfort care instead of desperate, ineffective, and costly attempts to ward off death.<sup>19</sup>

## Communication and the Internet

It seems so easy to be able to respond to a patient's problem or to deliver information to them and their physicians by e-mail. With e-mail delivered via the Internet, there is no problem with timing of the conversation, no recordings, no time

on “hold” for the doctor or for the patient. The only limitation seems to be the typing and spelling skills of the surgeon, usually problem enough.

Most of us have learned not to deliver complicated or bad news by telephone, unless we have made a previous agreement with the patient and family to convey such information in order to save significant travel or other inconveniences that are significant enough to preclude a face-to-face personal communication. Such situations are now increasingly complicated because communication by the Internet is usually not secure, and the information delivered can become a permanent part of the patient’s record. A patient’s employer and family can usually acquire easy access to the electronic message, potentially to the detriment of the patient, and potentially leaving this sending physician legally liable.

For the medical and medical/legal aspect, some of the material we send by e-mail we would never consider sending by “hard copy” unless we had obtained the patient’s specific permission to release such information. Currently, there are no guidelines available for the ethical transfer of confidential medical information via the Internet. Until such exists, and it is critical for physicians to participate in the establishment of such principles, all doctors are probably well advised to record in the patient’s permanent record that discussions were held and permission was given to communicate *specific* information electronically. Especially with the implementation of HIPAA requirements, until clearer guidelines are defined, surgeons should err on the side of no sensitive information to be delivered by e-mail or telephone.<sup>19</sup>

Of course, the other massive impact of the Internet is the availability of unlimited access to potentially confusing and harmful information to our patients. Remember, there is no quality control for the Internet. Unlike traditional publications with editors, peer review, standards and vigorous screening, on the Internet, anyone with a computer can be a self-designated author, editor, and publisher. And this can be done anonymously with no attached responsibility. This will continue to have an enormous impact on the patient–physician relationship because “knowledge is power,” and our patients and families are making use of that power.<sup>23</sup> Not infrequently patients come to us with confusing and conflicting material from the Internet. A new part of our responsibility, as surgeons, is to not only guide our patients to appropriate and helpful Web sites but to actively participate in the construction and quality control of electronic information provided by the Internet in our own areas of expertise.

## Using Newly Deceased Patients for Teaching Purposes

A unique problem exists for the medical/surgical team caring for patients in the emergency department of a teaching hospital. It involves using the newly dead for teaching purposes. This usually involves teaching medical students and residents the techniques of endotracheal intubation. The issue is, of

course: do we have the right to perform procedures on this newly deceased person without obtaining permission (informed consent) from the surviving family. The dilemma is complicated by the fact that no better teaching opportunity exists for our trainees who can then go forward, when adequately trained, to save lives and relieve suffering in the future. Clearly, no harm can be done to one who is dead. Furthermore, to our knowledge, there are no state statutes that specifically prohibit the teaching of procedures using newly dead patients, and no court has considered this issue. Although before death a patient has Constitutional protection against nonconsensual invasion of his or her body, it has been established by various state courts that constitutional rights do terminate at the time of death.

Although the law in this situation is very forgiving, compassionate and ethical considerations should supervene. Several medical studies have found that patients and families are likely to consent to such procedures but prefer to be asked permission first. Even the law advises that in this day and age of increasing recognition of personal autonomy, it is probably prudent to approach the next of kin for permission before performing procedures on the newly deceased.<sup>24</sup>

## Special Concerns for Participation in Research/Innovation

### General Concepts

Surgeons, by our very nature, are innovators. Sometimes, the only way we can complete an operative procedure is by making a deviation from what has been standard procedure in the past. Because we operate on biologic systems, we can never predict exactly what will be required for a given procedure. We often use old procedures for new purposes, and without much hesitation use new equipment to accomplish old tasks. Thus, we often find ourselves in what McKneally<sup>25</sup> refers to as “the zone of innovation” where it is unclear whether what we are doing is an evolutionary variation on a standard procedure, a unique departure from accepted standards, or the first stage of what should become recognized as a formal surgical research project. When should our deviations be subjected to full evaluation by an institutional review board? How can a surgeon participate, with *equipoise* (the presumption that both arms of a study are equally efficacious) in a prospective, randomized trial to evaluate a change that the surgeon has created to be better than the known standard? As Martin McKneally explains, most of the important advances in the history of medicine, such as anesthesia, appendectomy, antibiotics, intensive care, and immunization, were introduced through an informal, unregulated innovative process that has been enormously productive but can easily lead to ratification of an effective or even harmful treatment by well-intended physicians.<sup>25</sup>

Look at the recent challenges facing colon and rectal surgeons. We adopted the construction of ileal and now colonic

pouches to improve the quality of life of our patients with inflammatory bowel disease and rectal cancer. The true efficacy of these innovations came significantly later than their description and implementation by many of our colleagues. The use of minimally invasive techniques to accomplish what we were all trained to do via abdominal incisions was clearly initially driven by the new technology and by enthusiastic entrepreneurs who wanted to work on the frontier of innovation. The premature exposure of these new techniques to the lay literature drove the process with even more intensity. Only recently have completed prospectively randomized trials verified the realistic advantages of the new technology. We continue to sort out the appropriate use, for the benefit of our patients and their quality of life, such issues as circular stapled hemorrhoidectomy, the treatment of anal fissures with nitroglycerin, botulinum toxin, or nifedipine, and even the destructive scarification of anal tissue to correct incontinence. What we need is a process for evaluation of surgical innovation, which provides ethical oversight without the ponderous slow pace inherent in most institutional review board approved protocols. Surgical investigators and ethicists are currently crafting such a mechanism, which protects the rights and well being of our patients without stifling progress and creativity.

Good research is described as that which enhances our ability to prevent illness or injury, to improve the quality or decrease the cost of care, or to improve the lives of our patients. Such research also must protect subjects and patients from harm, preserve their confidentiality, and allow them to enter freely as participants. Subjects and patients must be allowed to make an informed choice to participate, or not, without fear that their treatment might be compromised if they decline the request of the investigator. For a research project to be ethical, it must also be well designed and must investigate an issue of importance for which the answer does not yet exist. Protocols must be scientifically sound and likely to yield meaningful conclusions. Good research is therefore ethical, and bad research is unethical.<sup>26</sup>

In June 1966, Henry Beecher published an analysis of "Ethics and Clinical Research."<sup>27</sup> This benchmark article accelerated the movement that brought human experimentation under rigorous federal and institutional control. Although Beecher was not the first to direct attention to abuses in human experimentation, this presentation of 22 examples of investigators who endangered "the health or the life of their subjects" without informing them of the risks or obtaining their permission was a critical element in reshaping the ideas and practices governing human experimentation.<sup>28</sup>

Special issues for informed consent arise when the surgical patient is asked to participate in a *research project*. The time for decision making is usually short, and the principle investigator of the project may also be the one administering care. This raises not only the issue of adequate informed consent but of the *risk for coercion* of the patient to participate in the study. The surgeon researcher should abide by basic

principles as outlined by the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research and by the Declaration of Helsinki. There are also prevailing federal, institutional, and professional guidelines that govern human and animal research. To be ethical, studies must be well designed and worth the risk to patient and society. The institution's review board should approve the study, and the investigator should take the responsibility to assure adequate informed consent, confidentiality, and appropriate protection of the patient's well being.<sup>1</sup>

All physicians must ensure that trials involving human subjects are of potentially significant value and are conducted ethically. The Nuremberg Code obligates researchers to prepare descriptions of the probability and magnitude of all physical, psychological, social, and economic risks, and to minimize unnecessary pain and suffering. Consent must be voluntary and without any element of force, coercion, or deceit.<sup>11</sup> When discussing the potential *risks* of a proposed procedure, it is essential for the person seeking consent to quantify minimal, low, or high-risk using examples from everyday life. Potential benefits from a research project may apply to the individual, to society, or to both. When discussing the benefits of a proposed study, one must distinguish clearly between *therapeutic* and *nontherapeutic* research. Researchers must clearly differentiate, for the patient, the balance between *potential benefit* to the patient and any *potential risks* associated with the protocol. No matter how great the benefit to society, it would not be ethical to expose a subject to anything greater than minimal risk if there is little direct benefit to the patient.<sup>26</sup>

Consent must never be assumed. Many would question the validity of truly "informed" consent rendered by someone who is acutely ill or severely injured. Especially for research, the principle still holds that for consent to be valid, it must be informed, understood, and voluntarily given. Subjects, or their surrogates, must have enough information, in comprehensible form, to enable them to make a proper judgment as to whether or not to participate in the requested study. Normally, this requires time for reflection before a decision to enroll. This concept is frequently stressed in the emergency situation. In an emergency, the surgeon may be forced to act in the patient's best interests and to presume consent on the basis of necessity. Clearly, this is only appropriate for interventions that will benefit the patient directly, and actual consent should be obtained as soon as possible afterward. In a research context, the intervention must be part of a protocol approved by an independent institutional committee, such as an institutional review board, and should present no more than minimal risk to the patient.<sup>26</sup>

## Placebo Surgery

As investigators sort out the mechanism for ensuring that surgical research is performed ethically and with true *informed consent*, the issue of the use of *placebo surgery* seems based

on recently published trials. Hornig and Miller,<sup>29</sup> commenting on these trials in the *New England Journal of Medicine*, comment that the issue of using *placebo surgery* in clinical trials seems to violate the fundamental ethical principles of *beneficence* and *nonmaleficence*. Specifically, this means that surgeons should not invade the body except for purposes of cure or amelioration of suffering. In evaluating the studies, they emphasize the fact that clinical research always involves the inherent tension between the ethical values of pursuing science and those of protecting subjects from harm. To be considered ethical, overall, they must present a favorable risk–benefit ratio. The burden is on the investigators to justify *placebo surgery* as a warranted means of evaluating the efficacy of a surgical procedure. They conclude that absolute prohibition of *placebo surgery* is not appropriate, but the standard of justification for its use must be extremely high and rigorously enforced.<sup>29</sup>

## Conflict of Interest: Industry and Drug Money

Many colon and rectal surgeons interested in research have difficulty obtaining extramural support for their projects and thus turn to private sources, namely, the biomedical and pharmaceutical industry. Industry support for biomedical research now exceeds the financial support from all federal funding sources. The liaison between academic surgery and industry introduces the possibility of remarkable benefits especially to our patients; however, differences between the fundamental goals of physicians and industry can create serious conflicts. Industry strives to complete clinical trials expeditiously and to publish positive results. Conversely, the primary goal of the surgical investigator is to advance and disseminate knowledge by the unimpeded exchange of ideas, despite secondary professional, financial, institutional, and sociopolitical objectives. Critics maintain that the physician–industry relationship will only serve to potentiate bias, and loss of objectivity will fundamentally poison the way research is conducted. Currently, however, the lifeblood of clinical research is external support requiring a productive relationship with the biomedical industry. This potential conflict of interest can only be resolved by scrupulously implementing the principles of integrity, honesty, respect, and equity. Even the mere appearance of a conflict of interest could jeopardize the investigator’s integrity and undermine public trust. Surgeon investigators involved with industry-sponsored research should meticulously divorce themselves from any personal or commercial conflict that could compromise patient loyalty or well being.<sup>11</sup> Ethical recruitment of patients into research protocols is especially challenging for surgeons who, under the current system of financial remuneration, may receive more money by having the patient participate in a study than he/she would receive for doing the surgical procedure indicated for the patient.

A common challenge involves investigators who receive industry-funded materials, discretionary funds, research equipment, and trips to meetings. They must be aware that subsequent restrictions and expectations can create conflicts of interest. These seemingly innocent economic factors become a conflict anytime they influence study design, interpretation of results, or the timing and method by which results are reported. The personal gain of the investigator such as ownership of stock or receipt of funds for testing drugs or devices can introduce bias and compromise objectivity. However, it is not inappropriate for an investigator to receive economic rewards from a drug or device that is commensurate with his or her efforts involved in the development of the product. It is also acceptable for investigators to receive consultant and lecture fees from companies whose product they are testing, provided that the remuneration is proportionate with his or her efforts, and that it is clearly reported, in advance, of all presentations and is clearly stipulated in any publications. It is unethical, however, to sell or purchase stock or have a direct financial interest in the product under investigation until the relationship between the investigator and the company has been terminated, and the results of the research have been published or made public. Although opponents argue that disclosure cannot heal the financial conflicts of interest, it does recognize public concerns, protect the credibility and reputation of investigators, and alerts readers as they access the published report.<sup>11</sup>

The practice of pharmaceutical companies bestowing gifts on physicians is well documented. These gifts, however, cost money, and that cost is ultimately passed on to our patients without their explicit knowledge. The biomedical industry has clearly made outstanding contributions toward the advancement of modern scientific medicine; however, obvious conflict of interest occurs when physicians accept personal gifts that have no benefit to their patients. Acceptance of individual gifts that did not benefit patients, such as trips and subsidies for medical educational conferences in which physicians are not speakers, are strongly discouraged. The acceptance of even small gifts has been shown to affect clinical judgment and to heighten the perception (or reality) of a *conflict of interest*. Until specific guidelines are established, common sense should always prevail: no gifts should be accepted if suspected *strings are attached*.<sup>11</sup>

## Confidentiality

### General Principles

Surgeons are bound by the same rules of *confidentiality* as other doctors. Especially with the new restrictions and significant penalties imposed by HIPAA, all healthcare personnel must be very cognizant of preserving *confidentiality*. In the hectic morass, which is the waiting area of most big hospitals, it is sometimes difficult to take the time to ensure that doctors

convey sensitive and private information to patients, families, or surrogates in a full and complete manner, and yet ensure the confidentiality of their information. Certain health information can be very significant in the treatment of a patient, including medication history and psychiatric history. Yet, some patients or families might be reluctant to give such information to the treating physician if the situation is not conducive to confidential communication. Similarly, the families and the patient are most certainly due confidentiality of the information, which the physician is going to impart. It is critical for the surgeon to establish a trusting relationship, so that the best and most important information relevant to treatment can be given and received. An exception to this rule occurs when the law requires disclosure of information to officials, as in the case of certain infectious diseases or in situations in which a third-party might be injured as a direct result of the physician's failure to report information.

A surgeon's duty to maintain confidentiality regarding information disclosed by the patient has been a long-held medical precept. On occasion, however, the ethical duty to prevent harm to others overrides the duty to keep confidences of a given patient. Although the law generally prevents the divulgence of confidential information, it also *mandates certain exceptions*, such as reporting patients with infectious disease and those who are likely to harm others, the latter being elucidated by the famous 1976 Tarasoff case in which nondisclosure of a patient's homicidal thoughts resulted in the death of the threatened person. This case raises a confusing possibility of preventing harm to others becoming a legal, not just an ethical, duty. This broadens the concept of mandatory reporting to include more than the currently accepted requirements for reporting child, elder, or domestic abuse. Such legal requirements may force us to compromise the ethical norm of respecting our patient's decisions with regard to confidentiality.<sup>2</sup>

## Making and Managing a Genetic Diagnosis

As the results of untangling the mystery of the human genome are translated into clinical considerations, the ethical challenges to the colon and rectal surgeon become significant. Although the presumption is that facility and managing genetically predetermined disease is the lot of the primary care physician, in fact, patients with phenotypic presentation of genetic disease such as colon and rectal cancer depend on surgeons for final diagnosis, administration of surgical treatment, initiation of long-term follow-up, and clarification of the implications of the genetically predetermined cancer for other family members and other generations. Most often we deal with the autosomal dominant mutations, which cause familial polyposis or hereditary nonpolyposis colorectal cancers.

The ethical hazard involves obtaining the results of a genetic test without adequate counseling of the patient to determine what will be done with results once obtained.

Clearly, this should all be determined before obtaining the information. Many individuals fear that determination of a genetic abnormality will have adverse effect on their insurability and employability. These risks are supposed to be protected by law, but many members of our society are not willing to take that chance. Because of these fears, many patients and their family members refuse to have genetic testing done in the first place. Once the test is done, a patient may insist on absolute confidentiality to prevent dissemination of the information to others, even those at risk, in the family. Think of the dilemma in which this places the surgeon. You may know that 50% of children and siblings of the patient are at risk for potentially fatal cancer. Yet the patient has forbidden you to inform them. This situation can even ethically and illegally justify the physician breaching the patient's confidentiality to save the lives of those potentially at risk. There have even been cases in the courts in which the treating physician has been held liable for not divulging such risks to family members.

Most of these unpleasant situations can be avoided by appropriate genetic counseling before any genetic information is required. This should ideally involve the use of professional genetics counselors because most of us surgeons have not been adequately trained in the skills required.

## Abuse of the Elderly

It is claimed that approximately 2 million elderly Americans are mistreated each year, with a significant number falling into the definition of abandonment. Although this treatment of elders is a problem that has occurred for centuries, only recently has society become significantly concerned. The problem and concern will increase as do the elderly components of our population. Surgeons are ideally suited to have a significant role in the detection, management, and prevention of elder abuse and neglect. The surgeon may be the only person, outside the family, who sees the older adult and is qualified to intervene in a preventive way. This means we should be aware of risk factors and their detection. It requires an astute clinician to detect abuse based on history alone. Even in the face of injuries, such as fractures at uncommon sites, the elderly patient may continue to conceal the possibility of abuse for fear of embarrassment or abandonment by the abuser. It may well be the surgeon called to see the patient for injury or neglect, who picks up the clues such as evidence of pressure sores, malnutrition, old injuries, or new injuries in unusual locations, such as on the scalp or behind the ears.

The first priority of the physician is to ensure this victim's safety. The surgeon should never hesitate to ask for social service consultation or to report suspicions to the appropriate adult protective services. Such acts are not breaches of confidentiality; they represent implementation of the most sincere duty of the physician.<sup>30</sup>

## Futility/Withholding Treatment

### General Concepts

Significant, and perhaps inappropriate, concern continues to exist in medicine with regard to the difference between *withholding* and *withdrawing* medical treatment. This has become more of an issue as the potential for resuscitating critically ill patients has become a progressive reality. Depending on the clinical situation, surgeons and other physicians attribute higher legal risk of one procedure over another. Apparently because of this fear of legal retribution, or ridicule and condemnation by professional peers, using full, almost ritualistic, resuscitation has become the default position of those delivering critical care in cases in which no advance directive exists. In fact, no physician has ever been successfully prosecuted for withholding or withdrawing of medical care from any dying patient in the legal history of the United States. This leaves one wondering what actually fuels the fears of legal retribution for making the wrong decision.<sup>31</sup>

The dilemma could of course be alleviated by early meaningful discussion with patients, families, and surrogates with regard to care *options at the end of life* and honest estimates of *prognosis*. Studies have shown, however, that many physicians and surgeons fail to take these opportunities. A disturbing example of this inadequacy can be found in the 1995 Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatment (SUPPORT). This expensive, multi-institutional study demonstrated the physicians' *failure to meet all outcome markers*: failure to include patient and family in pivotal care discussions, failure to provide realistic estimates of outcomes valued by patients, failure to treat pain adequately, and failure to prevent prolonged death in patients with extremely poor prognoses.<sup>31</sup>

Sometimes confusion is created over the venue in which surgical or medical care is delivered. In the usual setting, a decision to *withhold* further medical treatment is done quietly, often without input from the patient or the surrogate decision maker, whereas *withdrawal* of ongoing medical treatment can be more obvious and difficult. Some clinicians and ethicists believe that the *withholding* of medical treatment is more problematic than later *withdrawal* of unwanted or useless interventions. This discrepancy in the urgent situation probably exists because the physicians involved usually lack the vital information about their patients' identities, medical conditions, and expressed wishes. In addition, perhaps because of frequent, but inaccurate, representations on television, society has come to expect only spectacular results in the delivery of surgical care in the United States. This concept is in marked contrast to the attitude that those clinicians who *withdrew treatment* (an act leading to death) were more culpable than those who *withheld treatment* (an omission leading to death); this distinction between acts and omissions is now thought to be more of a difference in psychological preference than an ethical norm.<sup>32</sup> For all of these reasons, despite the fact that

the law has clearly spoken, the distinction between *withdrawal* and *withholding* of medical treatment will continue to be a challenge.

The surgeon's decision to limit or withhold treatment can be based either on the patient's refusal or on the physician's determination that the treatment would not be of benefit. Although the patient has the ethical and legal right to forego treatment, the physician must be very careful about withholding a treatment that might be beneficial. Such issues are usually intensified by the need for rapid intervention versus the desire to verify the meaning of the patient's current or pre-existing desires. The classic example is the patient who is unresponsive, has reversible pulmonary or cardiac disease, needs cardiopulmonary resuscitation, but is said to have a preexisting DNR order (do not resuscitate).

Withholding treatment because of a judgment of *futility* is even more of an ethical challenge. *Futility* has been defined as "any effort to achieve a result as *possible*, but that reasoning or experience suggests is *highly improbable*, and cannot be systematically produced." Physicians, as moral agents, should exercise professional judgment in assessing patient's requests. If the request goes beyond well-established criteria of reasonableness, the surgeon ought not feel obliged to provide it. Some ethicists believe that the appropriate *allocation of resources* is another important consideration when one is making decisions regarding invasive, costly, or lengthy procedures. John Lantos even stated that, "Given limited resources, it is ethically justifiable to limit access to treatments that are expensive and offer minimal benefit. . . . Decisions by doctors to curtail use of those treatments are socially responsible."<sup>33</sup> *Futility* is such a complicated word that it may be of little use in most situations. The classic challenge is the decision not to start resuscitation when a patient with extensive metastatic cancer and cachexia presents in cardiac arrest. The initial emotional inclination is to treat the patient; however, the medical situation, as emphasized by Siegler,<sup>13</sup> leads to a judgment that such a resuscitation will not be beneficial. This requires the difficult objective determination of *ineffectiveness*, rather than any subjective decision based on the worth of the intervention or on the *value* of the patient's continued life.<sup>2</sup> It should be noted that assertions of *futility* come about in two contradictory situations. One is where the patient or surrogate wants the doctor to refrain from a further treatment, which the doctor thinks is not futile; and the other is where the doctor wishes to refrain from treatment that he or she believes to be futile. The only measure of what should be done is the standard of care in a given region for similar cases. Dealing with this concept of *futility* or other *end-of-life* concerns is usually only a problem when disagreement arises among the patient, the family, and the healthcare team.

Many ethicists agree that physicians are under no obligation to render treatments that they ascertain to be of little or no benefit to the patient. Many, however, believe that it would be advantageous to abandon the word "futility" and to use instead the construct of "clinically nonbeneficial interventions."

We all know that one of the greatest fears of both patients and families is their *abandonment* by the healthcare team. It is easy to fall into this trap by declaring that further treatment for a given patient is *futile*. When it is decided that certain interventions should be appropriately withheld, special efforts should be made to maintain effective communication, comfort, support, and counseling for the patient, family, and friends. Although we, as surgeons, may not always proceed with potential technologically advanced nonbeneficial interventions, we always must continue to *care* for the patient and the family.<sup>34</sup>

## DNR and the Need for Surgery

There is, and should be, confusion regarding operating on a patient with existing “do not resuscitate” orders. Because there is no universal agreement as to how this situation is to be handled, each surgeon must be aware of specific institutional guidelines. First of all, it is not at all unusual for surgery to be indicated for patients in whom *cure* is no longer the goal of treatment. Even patients with advanced cancer or severe medical conditions will be offered surgical relief of acute intestinal obstruction or an abscess causing sepsis and pain. The problem usually gets defined when administering anesthesia becomes a consideration because, after all, it can be accurately stated that the act of anesthesia is *ongoing resuscitation*. As amazing as it seems, most hospitals have a policy that allows suspension of the DNR order during the procedure and administration of anesthesia, only to have it resume when the surgery and required anesthesia have been concluded.

## Withdrawal of Treatment

### General Principles

Taking into account the preceding discussion, an important line of reasoning for the moral and legal equivalents for the two actions of *withholding* or *withdrawing* is the important concept that if a medical intervention will not result in the desired or beneficial results intended for the patient, it makes no difference whether the clinician withholds the intervention before beginning it or discontinues its use after it has been started and found to be not effective.<sup>32</sup>

Special moral issues may arise in the care of *terminally ill patients*. We must be willing to respect a terminally ill patient's wish to forego life-prolonging treatment, as expressed in a living will or through a healthcare surrogate appointed via a durable power of attorney for healthcare. Those of us caring for patients should be willing to honor DNR orders appropriately executed on behalf of terminally ill patients. We should also understand the established criteria for the *determination of death* and should be prepared to

assist families in decisions regarding the donation of the patient's organs for transplantation. This involves knowing the specific regulations in our own states and in our own specific institutions, especially the criteria for death and the mechanisms for initiating the conversation relative to organ donation. It is usually not the surgeon, or any member of the treating team, who first raises the issue with family regarding donation of the dying patient's organs for the purpose of transplantation.

## Euthanasia/Physician-assisted Suicide/Terminal Sedation

The terminology of activities related to the end of life are confusing to the public, have been misused in the press relative to the notorious activities of individuals such as Dr. Kevorkian, and, in fact, are probably not clearly differentiated by many surgeons. The terms all have separate meanings and implications, requiring us to understand them and not use them interchangeably.

First is *euthanasia*, which literally means “good death.” Its consideration arises when patients or surrogates claim that the quality of life is so diminished, the pain and suffering is so unbearable, or they have become such a burden on others that they request their physicians to *cause* their deaths quickly and painlessly. Specifically this implies “mercy killing” of an individual, by a physician, to relieve pain and suffering. Such terms as “voluntary,” “nonvoluntary,” and “involuntary” have been applied in an attempt to clarify the various ramifications of this process, but, in fact, *euthanasia* is the act of killing by a physician and is *not legal* anywhere in the United States.<sup>13</sup>

*Physician-assisted suicide*, however, implies a death that a competent person, with decision-making capacity, chooses and *causes* by self-administration of drugs that a physician has prescribed but *did not administer*. Advocates believe that prescription of drugs that a patient can take at will removes the physician from direct participation. The decision and the act of ending life remain in the patient's control. This invokes the important fall-back concept for physicians and nurses who deal with patients who are suffering, in an irreversible medical condition, and near the end of life: the distinction between “killing and allowing to die.” This distinction is invoked during the process of *terminal sedation* as well as for participation in *physician-assisted suicide*. Currently, the latter is legal only in the state of Oregon.<sup>13</sup> Even there, it has been complicated by the recent, and unique, intervention by the federal government, via the Food and Drug Administration, to criminalize the act of overprescribing pain medication by physicians where the act could be interpreted as intentionally facilitating a patient's death.

*Terminal sedation*, another frequently misunderstood term, is the practice of sedating a patient to unconsciousness in order to relieve the horrible symptoms, which may occur during the process of dying, including pain, shortness of breath,

suffocation, seizures, and delirium. As the sedating medication is administered, other life-sustaining treatments are withdrawn, including ventilatory support, dialysis, artificial nutrition, and hydration. It is critically important to understand that in this frequently used process, *no lethal doses of opiates or muscle relaxants are administered*. Thus, the intent of the act is to relieve suffering and symptoms by making people unconscious and unable to eat or drink, so that they will die within a short period of time. As in *euthanasia*, *terminal sedation* directly intends the death of the patient.<sup>13</sup> The difference is that, in the latter, the sedating medication is not the agent of death. This differentiation is of utmost importance to avoid the feeling of killing by *double effect* (which will be later explained in more detail) on the part of the healthcare team. It invokes the concept of “letting nature take its course” as opposed to the homicidal act of “killing.” Cynics claim they are the same, and those of us who claim otherwise are not being honest with ourselves.

## Applying the Principles

To comply with the principle of *autonomy*, when a competent patient requests, or demands, the withdrawal of further treatment, the treating physician is in a situation analogous to that of the patient who initially refuses treatment. *Autonomy governs!* The surgeon should ensure that the patient is given all the information necessary to allow proper informed consent regarding withdrawal of treatment, but once that is done, it is the ethical duty of the surgeon to withdraw the specified treatment. This is true no matter what the patient requests, whether it be withdrawal of feeding tubes, ventilators, or nutrition and hydration. As long as the patient is fully aware of the consequences, both short-term and long-term, his or her stated wishes should be respected and acted upon appropriately by the healthcare team.

The same principle should be invoked if the patient is not able to understand but has provided, in an advance directive, an indicated desire with respect to withdrawal of treatment under specified circumstances. It is still the duty of the physician to withdraw the specific treatment because the patient has, in the advance directive, given prior informed consent. The duty of the physician is identical if a designated surrogate requests or demands the withdrawal of treatment. This is the patient speaking through the surrogate, and once again, *autonomy governs*.

When the surgeon determines that withdrawal of treatment is appropriate and further treatment would be ineffective, consent of the family or surrogate should be sought. In this situation, it is very important and helpful to know what if any *surrogacy laws* exist. These do vary from state to state, and those surgeons faced with potential decision making should know in advance the laws of their state. In states where such laws exist, they can be very helpful in delineating the hierarchy of surrogate designation. In the absence of advance

directives, surgeons have the responsibility to judge what they believe the patient would want, or what is in the best interest of the patient. If no family is available, close friends of the patient may be asked to give their opinions about what the patient would want.

Courts have upheld the principles of *autonomy* and *self-determination*, affirming the right to refuse life-sustaining treatment. The classic illustrations of this include the 1976 ruling by the New Jersey Supreme Court that Karen Ann Quinlan, a woman in a persistent vegetative state, had the right to decide to be removed from a respirator and that this right could be asserted, on her behalf, by her family. This right was extended to include the withdrawal of nutrition by the 1990 Cruzan case in which the United States Supreme Court ruled that a life-sustaining feeding tube could be removed from another young woman in a persistent vegetative state.<sup>18</sup>

Should the surgeon have moral or religious beliefs that would preclude her from *withdrawing* treatment, she should remove herself from the case. It is important to recognize this possibility of need for withdrawing treatment at the beginning of the clinical encounter because a physician with such beliefs should extricate herself from the case at the earliest possible stage. As the clinical course evolves, and the surgeon develops a relationship with the family and the patient, it becomes progressively more difficult to remove herself from the treatment team.

## Palliative Care/Hospice

### General Principles

Focusing on making the last months, not minutes, of life meaningful is especially appropriate where death has a significant predictability. Chronic progressive diseases such as cancer, congestive heart failure, and chronic obstructive pulmonary disease account for 50%–70% of deaths, compared with the sudden death attributed to stroke, heart attack, trauma, and suicide. In the United States, patients' perceptions of human finitude lead them to deny death and to rely on medical achievements that they think will let them live forever. Physicians grapple with their technologic power, the imperative to tell the truth about fatal conditions, and despair at denying hope and the promise of cure for their trusting patients. It is probably this mutual self-deception that becomes the central issue in rendering appropriate end-of-life care. It is the management of these intense psychological and spiritual challenges facing terminally ill patients that has come to form the basis of what is called *palliative care*.<sup>31</sup>

A brief definition of *palliative care* would be: the act of *total* care of patients whose disease is not responsive to *curative* treatment. Although *palliative care* has been a major focus in Europe for the past 20 years, interest in the United States only became significant in the late 1990s with an Institute of Medicine report that evaluated end-of-life care.

It revealed significant deficiencies in how we manage end-of-life care. These deficiencies include the management of pain and other symptoms, including nausea and vomiting, dyspnea, depression, and anxiety. Geoffrey Dunn explains that: "Palliative care is not a concept defined in terms of the amount of time remaining in a patient's life or the terminal nature of his disease. It is defined in terms of the type of need that is being met by the care."<sup>35</sup>

The concept of *palliative surgery* refers to surgery for which the major intent is alleviation of symptoms and improving quality of life, *not necessarily cure*. As the age of our surgical patients increases, we will be progressively involved in performing operations whose desired outcomes are not met. Managing these patients through the entire course of their disease, including death, is an important part of being a good physician and a good surgeon. Surgical emergencies are often the first encounter with older patients, and they often have multiple comorbidities. An example is the 80-year-old person who presents with an acute abdomen. The risk of surgery will be high, the prognosis may be poor, and cure may be impossible. Perhaps, offering surgical treatment would even be inappropriate. Thus we, as surgeons, are immediately thrust into contemplating *palliative care* for the surgical patient, and it becomes clear that surgeons need to be aware of the concepts involved in delivering such care.<sup>35</sup>

## Pain Relief and the Doctrine of "Double Effect"

### Confusing Principles

When it comes to adequacy of pain control, especially for patients near the end of life, physicians and surgeons have been caught in a complicated dilemma. On the one hand, most of us entered medicine to relieve suffering. On the other hand, we know that administration of excessive doses of pain medication can suppress respiration and run the risk of contributing to the death of patients already near the end of life. At the same time that we are criticized for not giving enough pain medication to our suffering patients, we are also challenged by the law for prescribing medication with the *double effect* of potentially *hastening death*. This doctrine of *double effect* is intended by the courts to recognize the difference between provision of adequate pain treatment that unintentionally causes death and the ordering of medication that intentionally causes a patient's death. This concept of *intent* is confusing not only for the courts but also for the physician who is ordering the pain medication.

### Double Effect

The application of the principle of *double effect* is controversial because it places significant weight on physician *intent*, which is impossible to prove, and no weight on a patient's

right to self-determination. This seems to contradict a paramount principle of American bioethics: *patient autonomy*. Why, when death is on the line, should concern over the physician's *intention* take precedence over the *patient's informed consent*? The physician's fear over misinterpretation of his or her actions often leads to inadequate use of pain medication, leaving patients unjustifiably suffering. It is clearly recognized that opioids should be considered early in the care of the dying patients and in dosages that often exceed the standard range. These analgesics are not only effective in reducing painful sensation, but also have an effect in adjusting the sense of well being, thereby improving the patient's ability to cope with pain. Adjustment of dosage can be aided by using one of the known *pain scales* or by observation of patients' objective signs of distress, especially useful in the noncommunicative patient. Despite its significant effect on several components of respiration, respiratory arrest from opioids, in the absence of other central nervous system depressants, is rare. In caring for dying patients, surgeons must acknowledge that they are one part of the often-fragmented medical team. They must accept the goal of providing care where they can, comfort always, consult when necessary, and coordination of the remaining end of life issues.<sup>31</sup>

### Hastening Death: The "Code"

Because the overwhelming admonition to the physician is "above all do no harm," society has implored the surgeon, in life-threatening situations, to waive informed consent requirements and to act presumptively to save life or limb in situations in which the usual consent is impossible to obtain. This leads to our current default in dealing with the critically ill or moribund unknown patient: resuscitating with "a full code" and asking questions later. This practice is probably acceptable as long as the surgeon realizes that *withdrawing life support* is just as acceptable as *withholding life support* initially. The initial full resuscitation may make it possible to assess the patient's end-of-life desires more fully and carefully. If the initial intervention is unsuccessful or is inconsistent with the patient's preference, it can and should be withdrawn, consistent with the patient's identified goals.

What are ethically frowned upon are such deceitful practices as the "slow code," a charade consisting of a halfhearted resuscitation that seems to allow the surgeon to take the moral middle ground by giving the family a false impression of respecting patient autonomy, while knowing full well that the act will not be effective. Experience suggests that this hedge is used fairly often. Although no ill is usually intended, the slow code is usually an indication that the surgeon has not realistically communicated with the patient and family to express the medical opinion that resuscitation, in the face of cardiac or respiratory arrest, would be inappropriate.<sup>31</sup>

The concept of "no code" should be clear, and is usually instituted at the request of the patient, his advance directive, or an appropriate surrogate. It is ethically inappropriate for

the physician to disrespect the patient's autonomous decision even when faced with despairing surrogates requesting interventions over a clear directive to the contrary. The patient with decision-making capacity is, of course, free to change any prior stipulation, even those written in an advance directive. In the absence of any directive, including a decisional patient, the physician must use *best interest standard*, which requires implementing what a *reasonable patient* would want done in a similar situation.

To understand these previously discussed concepts, the surgeon must realize the implications of the three means of accelerating death for patients in the United States: *double effect*, *voluntary euthanasia*, and *physician-assisted suicide*. The *rule of double effect*, as previously described, involves the dichotomy of treatment versus side effects, in which death is the *unintended* side effect of adequate symptom control. *Voluntary euthanasia*, that which is requested by the patient, can be either active or passive. *Passive euthanasia* is the result of withdrawing or withholding life support in situations judged to be medically futile. In the United States, this is both ethically and legally acceptable. However, *active euthanasia* occurs when the physician *intentionally* administers an agent to cause a patient's death. This act is considered *unethical* and *illegal* everywhere in the world except in the Netherlands where it is practiced openly. *Physician-assisted suicide* occurs when a physician supplies a death-causing agent to a patient with the knowledge that the patient intends to use this agent to commit suicide. In the United States, this practice is legal only in the state of Oregon.<sup>31</sup>

Of great concern to all physicians in the United States is a recent action by the Attorney General of the United States with regard to the Oregon Death with Dignity Act, a law that authorized doctors to help their terminally ill patients commit suicide. The doctors were allowed to prescribe, but not to administer, such drugs. Attorney General Ashcroft, in 2001, directed that doctors who help their patients commit suicide could be prosecuted under the federal Controlled Substances Act. This was the first example, in United States, of the *federal government* interceding in the practice of medicine, historically entrusted to *state lawmakers*. In May of 2004, the United States Court of Appeals for the Ninth Circuit, in San Francisco, rebuked the Attorney General and upheld the Oregon law.<sup>36,37</sup>

### Know Your Intent

For all physicians, the concept of avoiding killing seems obvious. However, what is a doctor to do when confronted with a situation whereby the administration of sufficient medication to alleviate the pain of a patient might have the secondary effect of diminishing respiration, and actually hastening the death of the patient? This is, of course, the crux of the major debate over *physician-assisted suicide* and *euthanasia*. There are other situations, such as abortion, in which a physician must take avoiding killing into account. Confronting such

issues challenges a surgeon not only with the duty to respect the autonomy of the patient but also to be aware of situations that might put the individual doctor in the uncomfortable situation of confronting conflict with his or her own personal beliefs.

In multiple decisions, the courts have emphasized the importance of distinction between "letting a patient die and making that patient die."<sup>18</sup> This, in our opinion, is the most distressing conflict for the physician who must make such decisions. We know full well that when we give high-dose opioids or withdraw ventilatory support, we may be hastening the patient's death. The callous ones among us see this as euthanasia and strongly criticize those who claim otherwise. When confronted with this challenge, in a personal communication, Dr. Edmund Pellegrino, one of our most respected medical ethicists, immediately responded with his comforting interpretation of such a situation. In his mind, and in his conscience, he recognizes and acts upon the difference between actively and intentionally hastening a patient's death as opposed to relieving pain and suffering or withdrawing artificial life-support, thus "letting nature take its course."

### Determination of Death

The attending physician has the discretion and the responsibility to determine death. Statutes in different states use different criteria for death. In some cases, they have not caught up with the science available. Some states use the "irreversible cessation of cardiopulmonary function" criteria, as do some religions. The complete cessation of respiration and circulation constitute "death" under this definition. The concept of *intensive care* has advanced dramatically since these statutes were enacted and have superseded this now antiquated definition. In most states where this is the statutory definition, the courts have now ruled that "brain death" suffices.

Most states use the brain death criteria. There is debate currently about whether the "whole brain" definition of death is no longer valid, and that the appropriate ethical standard for definition of death is cessation of "higher brain" function. Higher brain function includes the cognitive functions or the capacity for consciousness. Once there is irreversible cessation of that capability, a judgment usually made in consultation with a neurologist, then death can be declared. Most neurologists are trained to determine whether death has occurred or whether the patient is in a "permanent vegetative state."

It should be noted that in some states the definition of death includes *either* the *cessation of cardiopulmonary function* *or* *irreversible cessation of all brain function*, including the brain stem.

The healthcare team, however, should realize that no matter which criterion is being used, it may be appropriate to continue cardiovascular support for the purpose of maintaining perfusion during the eminent birth of a fetus, or to sustain viability of transplantable organs.

## Organ Donation

Criteria for organ donation are not always clearly understood. Many patients and families are mistakenly concerned about having death declared prematurely just to facilitate the harvesting of organs for transplantation. Here the surgeon's bioethical responsibilities are clear. The medical ethical principle of *patient autonomy* dictates that the desires of the patient and the family be respected.

Federal law requires most hospitals to make an inquiry of all patients, during their admission, for any procedure, whether emergency or elective, about their wishes to be a potential *organ donor*. Although this can be somewhat of a shock to patients who are coming in for elective surgery, especially a minor procedure, it obviates the need for physicians to make the painful inquiry when a patient is actually facing eminent death. If the admitting personnel ask for this information on a routine basis, the patient is more likely to render a competent decision, and the potential problems of dealing with surrogates, sometimes under difficult circumstances, is alleviated.

However it is obtained, *informed consent* of the *donor* is required. Most states provide organ donor options on driver's licenses, and many people possess other documents such as donor cards, which indicate their desire to become organ donors. In some cases, donors request limits on the organs they wish to donate. For example, some donors have indicated that they do not wish to donate their eyes or some other specific organ. Even though patient autonomy should guide the physician, there are circumstances in which the family emphatically wishes to override the clearly stated intention of the donor. These situations are difficult, and although the surgeon's clear ethical duty is to respect the wishes of the donor, the body of the donor, after death, belongs to the family. The treating physician would be well advised to leave the resolution of this situation up to the transplant coordinator. In fact, it is usually inappropriate for anyone on the treating team to initiate the discussion of organ donation. Most hospitals have in place a procedure whereby the discussion of potential organ donation is initiated by a person specifically trained for this purpose. It is often the transplant coordinator, a social worker, or a hospital chaplain.

Insisting on compliance with the donor's clearly stated wishes, in the face of strong family opposition, does not affect the legal position of the surgeon, but it can result in unfortunate lawsuits because of the animosity created with the family. In cases in which there are no previously expressed wishes by the potential donor, the family, as custodians of the body, may agree to organ donation. The duty of the physician in this case is to obtain the consent of the family *before* doing anything to preserve the functioning of the organs for potential transplantation.

In cases in which there is no surrogate or family, or any evidence of previously stated intention to donate, the ethical position of the doctor is less clear, but absent permission to do something to the body in a situation that is no longer an emergency, assuming that the organs should be harvested for

transplantation, would seriously violate the concept of informed consent. Although it can be argued that the dead person cannot give informed consent, the family whose property the body is would have to give their consent to have any procedure done at all to the newly dead person. In cases with no directives at all, the best course of action, unfortunately, is to do nothing postmortem.

## Ethics/Legal Consultation

Most surgeons work within an institution. Most of these institutions provide a mechanism for obtaining help in sorting out challenging ethical dilemmas. This help usually comes in the form of consultation from the hospital *Ethics Committee* or from in-house *legal consultation*. It is critical to realize that utilization of such resources does not commit the surgeon to accepting an arbitrary decision of what is right and what is wrong in a complicated ethical situation. Consultation is meant to provide a process for most expeditiously sorting out the issues which have arisen and for providing rapid access to the potential mechanisms for solving the problem. Hospital ethics committees are specifically charged to advise physicians, patients, and families who face ethical dilemmas. These situations usually arise when there is *disagreement* between these groups and the healthcare team. Consultation from the ethics committee is usually rapidly facilitated through such agencies as the hospital nursing service. Consultation should be available, instantly, 24 hours a day. Frequently, it is the hospital chaplain who facilitates the consultation. By bringing in appropriate resources and facilitating meeting with the healthcare team, patients, and families, consultation with the ethics committee should help resolve even the most complicated medical ethical challenges. The hospital ethics committee should be charged with what is the right thing to do for the patient. It should have no vested interest in protecting the institution at the risk of embarking on an action, which is ethically unsettled for the good of the patient.

A word of caution, however, is necessary for surgeons working within a given institution. Once *legal counsel* or *risk management* is brought in to deal with a complicated situation, it must be remembered that *they work for the institution*. Their job is to protect the institution, and the advice that they give will be aimed toward that end. This commitment to the institution is important for the physician to realize if there is potential for placing oneself in personal jeopardy. It is also important to realize that legal standards are not always reliable guides to determining what are the best ethical and medical decisions.

## Good Samaritan

### A Case

The most skilled colon and rectal surgeon in town is out to dinner. At the next table he sees the local crime boss choking to death over a piece of prime beef. What are the ethical and

legal ramifications he must consider before performing an emergency tracheotomy? What is he ethically obligated to do? Is the old medical oath binding? Can anyone give consent? Must he identify himself? If he performs the procedure, and there is a bad outcome, is it malpractice? What if he is a medical student instead of a famous surgeon? Is a bad outcome here considered battery? What should the surgeon do when the emergency medical technician arrives and wants to take the dying crime boss to a known inferior local hospital? What are the obligations and risks for the surgeon?

## General Concepts

Good Samaritan acts or deeds are defined as those in which aid is rendered to a person in need, where no fiduciary or legal obligation exists to provide such aid, and neither reward nor remuneration for the aid is anticipated. The aid provided can include a survey of the situation, protection of the victim, notification of other care providers, or personal provision of immediate treatment. The Good Samaritan ethic is one that is generally endorsed by our culture, which strongly supports assisting an individual who is in danger or in need of help. Surgeons may be regarded as having a greater responsibility to provide Good Samaritan aid than a lay person by reason of the special training and knowledge and commitment to duty for the benefit of individuals and society that generally drive us to become physicians and surgeons. Clearly, in a situation of sudden medical need, a surgeon will be better able to assess the medical condition of the victim and to render immediate treatment if indicated and feasible. Many believe that the mere status of being a physician entails the duty to use one's skills and knowledge in cases of sudden or emergency need; for some, this duty is an inherent feature of the role and even of the definition of a physician.<sup>38</sup>

Briefly stated, in almost every state, an off-duty surgeon who comes across a person with an emergency medical condition has no *legal duty* to come to the aid of that person. However, a physician's *ethical obligation* inspires him to help in such an emergency. All states in the United States have enacted so-called "Good Samaritan" statutes, which protect the physician from liability incurred for good-faith efforts to help at the scene of an accident or emergency. The ethical duty should far exceed the legal excuse for inaction.<sup>2</sup>

Generally, Good Samaritan acts include the following principles. 1) There is no legal obligation of doctors to answer or treat emergencies. 2) If the doctor chooses to intervene, the expected standard of care is modified by circumstances of the situation. 3) If aid is given, it need be stabilization only and not definitive treatment. 4) Implied consent exists to treat the victim if he or she lacks the capacity to consent. 5) These criteria apply whether or not the physician is paid for his or her services rendered. Despite the establishment of these principles, the extensive coverage in the media of spectacular medical malpractice suits causes many surgeons to develop a strong aversion to the performance of Good Samaritan acts. To alleviate this apprehension, Good Samaritan laws were

enacted, the first in California in 1959. Since then every state has enacted such law. The laws all share the following provisions: there is no legal obligation to provide aid, there is immunity from malpractice suit if aid is provided, there is exception from immunity for gross negligence or lack of "good-faith," acts are restricted to application outside of hospitals, and there is withdrawal of legal immunity if the doctor accepted payment for aid rendered.<sup>38</sup>

## Professionalism and Interpersonal Relations: Working as a Team

### General Considerations

There is an ever-increasing challenge to deliver the very best surgical care in the current medical environment which thrives on its speed and frequently impersonal delivery of generic medical care, often at multiple institutions, and without one consistent team of support. Often it becomes difficult to fulfill the responsibility requiring communication, collaboration, respect, and confidentiality as we interact with the components of our healthcare team which frequently includes nurses, enterostomal therapists, primary care physicians, consulting physicians, surgical and medical trainees, and the vast array of ancillary services required within our institutions.

### Teaching Residents and Fellows

Learning and teaching are critical components in our career choice of medicine, and especially, surgery. At some point in our training, a more senior person turns over to each of us the responsibility to perform the major part of an operative procedure. And then, the converse occurs: each of us, in turn, relinquishes the major part of an operation to one of our trainees. We know how the process works and the importance of a surgical team with "graded" responsibility. The ethical challenge arises when, often the night before surgery, the patient asks: "Who is going to do my surgery?"<sup>39</sup> The honest answer becomes blurred, especially for those colon and rectal surgeons working in a program with trainees who are senior residents or fellows. We usually fall back on the explanation that we, the attending surgeon, will be present and responsible, even when we know that the trainee will be doing the critical part of the procedure. What is the truth? The fellow claims on the training record that he or she did the case, and we charge the payer as if we did the procedure. What is true *informed consent* in such situations?

### Previous Suboptimal Care

#### General Concepts

As colon and rectal surgeons, we are specialists, frequently seeing patients as requested consultation by and referral from other physicians and even other surgeons. It makes the nature

of our care, often, “the end of the road.” We have no place else to send the patients and frequently find ourselves in the position of correcting or undoing the poor results of the action of another surgeon. This becomes an ethical and personal challenge especially when the patient or the family asks: “Why wasn’t that done by the other surgeon, or what did she do wrong?” We can easily become caught up in the dilemma between taking credit for heroic restoration of health and condemnation of the other surgeon, or, covering up for incompetent care in an attempt to avoid litigation against another doctor and/or preserving a lucrative source of referrals.

Generally our surgical and specialty training does not prepare us for the ethical differentiation between “bailing out” and “condemning,” responding to patients’ pointed questions, communicating with the doctor responsible for the suboptimal care, and certainly not “blowing the whistle” on another surgeon and going to court, when requested, as an “expert witness.” Albert Wu<sup>40</sup> suggests that a surgeon who discovers a major error made by another physician has several options, which include: waiting for the other doctor to disclose the mistake, advising the other physician to disclose the error, arranging a joint meeting to discuss the mistake, or telling the patient directly. He and his coauthors believe that, based on the requirements of the doctor–patient relationship, surgeons have an obligation to facilitate disclosure. Many surgeons are reluctant to say anything because they are not 100% sure of what actually happened, they fear hurting the feelings of colleagues, they wish not to strain professional relationships, or because of the terrifying thought that “there but for the grace of God go I.” Wu et al. further suggest that we fulfill our obligation to our patient by advising the doctor who erred to inform the patient; but he goes on to say that if that fails, it is our duty to tell the patient what happened.<sup>40</sup> Each of us must then rely on compassion and tact to tell our patients the truth without unduly condemning the other physicians. We surgeons need to realize that what we take for granted in our weekly *morbidity and mortality* conferences, especially in a teaching hospital, is not the norm for other branches of medicine. We know, and perhaps are obligated to pass on to others, that admitting a mistake may help us to accept responsibility for it and may help to make changes in our practice. Physicians should be able to learn vicariously from mistakes made by others, and thus avoid making the same mistake themselves.<sup>40</sup>

## “Blowing the Whistle” and Going to Court

The next echelon of concern and potential activity, of course, involves serving as an “expert witness” in medical malpractice litigation. Again, this is an arena of involvement in the medical care system for which we surgeons are generally ill prepared. Just recently, the American College of Surgeons and the American Society of Colon and Rectal Surgeons have issued some guidelines in an attempt to ensure that surgical

specialists not abuse the system by offering false testimony or by presenting as “experts” in areas beyond their expertise. Many of our true experts refuse to serve in this capacity when it involves saying something against another surgeon; yet, when any of us are involved as the accused, we want only the finest experts available and are repulsed when “hired guns” with little knowledge boldly testify against us. The problem seems to be that many of us do not differentiate *malpractice* with severe damage to a patient from the poor results from proper treatment that we surgeons all experience in dealing with the complex biologic system of the human body. Again, the principle of not stepping up to the plate for fear of the dictum, “There but for the grace of God go I.” We should understand that credibility in the medical-legal system should be based on true expertise and on telling the truth, be it for the plaintiff or for the defense of our colleagues, and, in fact, we can be of much greater help to inappropriately accused physicians by establishing such a record of credibility.

## Managed Care

### Patient Advocacy

All of us in the current system participate in some form of managed care, whereby someone other than the treating physician becomes involved in the mechanism of delivering care to our patients, usually without sharing in the responsibility of rendering the care and the untoward outcome that may be engendered by that care. This presents a true dichotomy for doctors, most of whom have taken an oath or by law are committed to being *advocates* for our patients. It seems an impossible, and perhaps unethical, task to make a decision that favors the economic advantage of a managed care organization over what we know, medically, is required by an individual patient in need.

### Rationing Care/Cutting Corners

Surgeons have a special obligation to deal with these systems because of the loneliness of making the decision and ultimately doing a surgical procedure on another human being. It is a desperate feeling to realize, in the middle of an operation, that our quest for perfection has been compromised by some inadequacy in preoperative management foisted on us by another remote physician hired by a managed care organization to protect the financial interests of a group. We know, as well as others, that medicine, as a system, is in trouble, but the problem is rarely to be solved by rationing or withholding what we know is surgically best for our individual patients. Perhaps it is our job to invoke our “surgical personalities” to become the strongest of all patient advocates and to fully participate in achieving needed improvements in the overall system. We must communicate to others the special understanding and compassion few outside of the field of surgery understand.

## Personal Challenges: Competition of Interests

### Professionalism

McKneally describes the profession of medicine and surgery as a vocation that requires extensive knowledge and skill. It also requires a high level of discretion and trustworthiness, even in individual practice. The social contract between the profession and the public holds professionals to very high standards of competence and moral responsibility. He goes on to explain that a profession is literally a declaration of a way of life “in which expert knowledge is used not primarily for personal gain, but for the benefit of those who need that knowledge.”<sup>15</sup> In our current society, bombarded by endless advertising and hype, many groups call themselves “professionals” sometimes to the point of humor, but for those of us in medicine, and especially surgery, the definition means that when confronted with a choice of what is good for us or what is good for our patient, we choose the latter. This occurs and is expected sometimes to the detriment of our own good and that of our families. Tom Krizek<sup>41</sup> even goes so far as to question if surgery is an “impairing profession.” Perhaps it really is an *ethical* concern, which is encouraging us to modify the working hours and conditions for our trainees to offer more of an incentive to enter the surgical specialties. Now that we have appropriately tended to the training programs, it behooves us to explore the same lifestyle improvements for ourselves. It is neither an ethical breach nor a sign of weakness to allocate high priority to our families and to our own well being.

### Family

As financial and professional pressures become more intense, the challenge increases to appropriately prioritize and balance the demands of patient care, family, education, teaching, and research. Mary McGrath presents an all too frequent dilemma for the surgeon: choosing between attending a child’s graduation or operating on an old patient who requests you instead of your extremely well-trained associate who is currently seeing the patient. How many times have we not chosen wisely! Someone else can competently care for your patient, but only you can be a parent to your child.<sup>19</sup> Time literally flies, and we must often remind ourselves that our lives are not just a “dress rehearsal”!

Among the many considerations of *family* is the issue of caring for, and perhaps even operating on, our own family members. What is not only ethical, but what is appropriate for the practice of medicine and surgery with regard to this issue is not as clear as you might, at first, believe. For example, if your spouse cuts her leg while skiing, and the only available physician is a psychiatrist who is covering the emergency room, should you, a training surgeon, suture her laceration? However, if you feel that you are the most experienced colon

and rectal surgeon in the community, what should you do when your own mother is found to have a complicated cancer of the low rectum? After all, if you are the “best” why would you deny the best care to your own mother? Many hospitals have dealt with this issue and have a stated policy. The American Medical Association has issued a statement on “Self-treatment or Treatment of Immediate Family Members.” In essence it speaks against treating family except in emergent situations and for short periods of time. It is, of course, based on the risk of compromise of professional objectivity and influence on medical judgment because of the influence of personal feelings, thus interfering with the care that needs to be delivered.<sup>42</sup>

### Competence/Impairment/Insight

Surgical certifying organizations are currently struggling with the definition and determination of *surgical competence*. McKneally<sup>15</sup> stresses that a patient’s trust is based on the surgeon’s diligent pursuit of competence in both judgment and technical skill. Surgical training programs have diligently attempted to guarantee the competency of individuals completing the process. The board certification process attempts to ensure that the interests of society are represented in these professional processes. Thus, competency is an integral part of the *entry-level*. The problem arises in maintaining a level of competence and assuring that established surgeons who take on new procedures both acquire and maintain competence in these new skills.<sup>15</sup> Perhaps the most obvious recent example for us colon and rectal surgeons has been the advent of laparoscopic, minimally invasive surgical procedures. Now that they are part of all fellowship training programs, it is less of a problem. But the issue will arise again with the next new wave of technology: how to teach old surgeons new skills.

Related to competence is the issue of *impairment*. Jones<sup>43</sup> emphasizes that drug and alcohol abuse, with the associated functional impairments, are the leading cause of sanction against physicians by professional oversight bodies in the United States. More than one in every seven physicians is affected by substance abuse at some time in their careers. He goes on to explain that the surgical patient is potentially at greatest risk in the care of a cognitively or physiologically impaired physician because the surgeon’s competence requires simultaneous application of fine neuromuscular, cognitive, and intellectual skills. This is coupled with the emotional composure and critical judgment required to make urgent decisions and the physical endurance of standing for long hours at the operating table. He cites Percival’s admonition that the medical profession is a “public trust” that should be relinquished when a physician or surgeon no longer possesses the skills that are essential to clinical care. Unfortunately, most surgeons do not possess or exercise the insight required to know when we are impaired or when it is time to retire.

Jones goes on to quote Verghese's observation on the impaired physician: "the doctors had one common feature—namely, exquisite denial—that allowed them to believe they could still care for patients perfectly well."<sup>43</sup> These observations place great responsibility on those of us who observe *impairment* or *incompetence* in our colleagues who at times may also be our close friends. We should never hesitate to request intervention because correction of substance abuse in physicians is highly successful. If we stand by and allow patients to be mismanaged by inadequate physicians, we will not only see the patients suffer but will allow our colleagues and friends to be destroyed professionally and perhaps devastated emotionally by malpractice suits, condemnation by institutions and colleagues, loss of licensure, and eventually the ravages of substance abuse or personal humiliation.<sup>43</sup> Most state boards of healing arts function best when it comes to providing support for physicians in trouble.

## A Final Thought

Perhaps Richard Hayward,<sup>44</sup> who compares a surgeon to the young sea captain in Joseph Conrad's novel "The Shadow-Line," best describes a successful career in surgery. Hayward explains that there are so many variables in the interaction between patient, surgeon, and disease that it is not surprising that the prediction of results becomes uncertain. Even routine procedures can produce complications and can become much more difficult than had been anticipated. As the surgeon crosses Conrad's Shadow-Line, energy, enthusiasm, ability to make firm decisions and then act upon them, optimism, self-confidence, and resilience in the face of adversity become necessities without which an individual will have difficulty coping with the pressures of a surgical practice, especially one involving the care of critically ill emergency patients. There becomes a time when a surgeon must learn to come to terms with the inadequacies and, sometimes, downright failures of his or her actions that will be the inevitable companions during a surgical life.<sup>44</sup>

# Critically Reviewing the Literature for Improving Clinical Practice

Clifford Y. Ko and Robin McLeod

As the science of surgery continues to advance, it is important for the practicing clinical surgeon to remain up to date on the current issues in the field. Many surgeons remain updated by reading the literature—and although this is an excellent way to stay current, it is paramount that the reader understands how to critically read the literature, and evaluate the importance, relevance, and validity of the published works.

The current chapter is written to assist the reader in critically evaluating the literature. It is organized in a building block manner—with fundamental issues being discussed initially, after which more complex issues are addressed. Specifically, we begin by addressing study designs for clinical research with most of the section being devoted to important issues surrounding randomized, controlled trials (RCTs). After this, a discussion of how study designs dictate the level and grading of evidence is given. There are several grading systems, of which two are presented. The third section addresses the notion of best evidence and highlights the use of metaanalysis and practice guidelines. The fourth and final section discusses critical evaluation of the literature, and covers statistics, risk adjustment, and quality of life (QOL) studies. For the interested reader, further readings are available in the references.

## Study Designs: Case Series, Case Control, Cohort, and RCTs

### Providing the Evidence

Various hierarchies have been proposed for classifying study design.<sup>1,2</sup> In simplest terms, studies can be classified as case series, case control studies, cohort studies, and RCTs. The case series is the weakest and the RCT is the strongest for determining the effectiveness of treatment (Table 54-1).

#### *Case Series*

Case reports (arbitrarily defined as 10 or fewer subjects) and case series are the typical surgical studies performed. There is no concurrent control group although there may be a histori-

cal control group. Patients may be followed from the same inception point and followed prospectively—not for the purpose of the study—but in the normal clinical course of the disease. Typically, data from patient charts or clinical databases are reviewed retrospectively. Thus, the outcome of interest is present when the study is initiated. Despite the limitations of this study design, the importance of results from case series should not be minimized. It is because of careful observation that innovations in surgical practice and techniques have been and continue to be made. However, results from case series should be likened to those observations made in the laboratory. Just as those observations should lead to generation of a hypothesis and performance of an experiment to test it, an RCT should be performed to confirm the observations reported in a case series. Case series are plagued with biases such as selection and referral biases, and because data are not collected specifically for the study, they are often incomplete or even inaccurate. Therefore, incorrect conclusions about the efficacy of a treatment are common and surgeons should not rely solely on evidence from case series.

#### *Case Control Studies*

The case control study is the design used most frequently to study risk factors or causation. There are typically two groups of patients: the case group, composed of subjects in whom the outcome of interest is present, and the control group in whom it is not. Controls are selected by the investigator rather than by random allocation so the likelihood of bias being introduced is real and thus there is a risk of making an erroneous conclusion. Generally the controls are matched to the cases with respect to important prognostic variables other than the factor that is being studied. Although it is important to match the subjects to avoid an incorrect conclusion about the significance of the factor being studied, it is equally important not to overmatch the controls so that a true difference is not observed. In case control studies, as in case series, data are collected retrospectively. Thus, the outcome is present at the

TABLE 54-1. Types of study designs

	Control group	Prospective follow-up	Random allocation of subjects
Case series	No	No	No
Case control study	Yes	No	No
Cohort study	Yes	Yes	No
RCT	Yes	Yes	Yes

start of the study. As an example, Selby and colleagues<sup>3</sup> performed a case control study to make inferences about the effectiveness of flexible sigmoidoscopy in preventing rectal cancer. The cases were HMO patients who had been receiving regular yearly examinations and developed rectal cancer (the outcome of interest). The controls were individuals from the same cohort of patients who had not developed rectal cancer. They were matched to the cases with respect to age, sex, and date of entry into the health plan. Selby and colleagues found that cases were less likely to have had a flexible sigmoidoscopy than controls in the preceding 10 years (8.8% of cases versus 24.2% of controls).

### Cohort Studies

Cohort studies may be retrospective or prospective. There are two or more groups but subjects are not randomly allocated to the groups. One group receives the treatment or exposure of interest whereas other groups of subjects receive another treatment or no treatment or exposure. The inception point may not be defined by the study and the intervention and follow-up may be ad hoc. However, the outcome is not present at the time that the inception cohort is assembled. There is less possibility of bias than a case control study because cases are not selected and the outcome is not present at the initiation of the study. However, the likelihood of bias is still high because subjects are not randomly allocated to groups. Instead, there is some selection process either by the subject or the clinician that allocates them to groups. For instance, subjects may be allocated to groups by where they live (when the effect of an environmental toxin is being studied), by choice (when a lifestyle factor such as dietary intake is being studied), or by physician (when a nonrandomized study of a treatment intervention is being performed). Retrospective cohort studies differ from prospective cohort studies in that data analysis and possibly data collection are performed retrospectively but there is an identifiable time point that can be used to define the inception cohort. Such a date could be the date of birth, date of first attendance at a hospital, etc. Cohort studies typically are performed by epidemiologists studying risk factors where randomization of patients is unethical. An example of a cohort study would be the use of a database to follow patients who had an anal mucosectomy versus no mucosectomy as part of restorative proctocolectomy, to determine the effect of the mucosectomy on long-term outcome.

### Randomized, Controlled Trials

The RCT is accepted as the best trial design for establishing treatment effectiveness. There are several essential components of the RCT. First, subjects are randomly allocated to two groups: a treatment group (in which the new treatment is being tested) and a control group (in which the standard therapy or placebo is administered). Thus, the control group is concurrent and subjects are randomly allocated to the two groups. Second, the interventions and follow-up are standardized and performed prospectively. Thus, it is hoped that both groups are similar in all respects except for the interventions being studied. Not only does this guard against differences in factors known to be important, it also ensures that there are no differences as a result of unknown or unidentified factors. This latter point is especially important. Statistical techniques such as multivariate analysis can be used to adjust for known prognostic variables, but they obviously cannot adjust for unknown prognostic variables. There are multiple examples of studies showing differences between groups that cannot be accounted for by the known prognostic variables.<sup>4</sup>

Where differences in treatment effect are small, the RCT may minimize the chance of reaching an incorrect conclusion about the effectiveness of treatment. There are, however, some limitations to RCTs. First, RCTs tend to take a long time to complete because of the time required for planning, accruing, and following patients and finally analyzing results. As a consequence, results may not be available for many years. Second, clinical trials are expensive to perform, although their cost may be recouped if ineffective treatments are abandoned and only effective treatments are implemented.<sup>5</sup> Third, the results may not be generalizable or applicable to all patients with the disease because of the strict inclusion and exclusion criteria and inherent differences in patients who volunteer for trials. In addition, not all patients will respond similarly to treatment. Fourth, in situations whereby the disease or outcome is rare or only occurs after a long period of follow-up, RCTs are generally not feasible. Finally, the ethics of performing RCTs is controversial and some clinicians may be uncomfortable with randomizing their patients when they believe one treatment to be superior even if that is based only on anecdotal evidence.

There are elements common to all RCTs. The first and perhaps the most important issue in designing an RCT is to enunciate clearly the research question. Most RCTs are based on observations or experimental evidence from the laboratory. RCTs should always make biologic sense, have clinical relevance, and be feasible to perform. The research question will determine who will be included, what the intervention will be, and what will be measured. Frequently, a sequence of RCTs will be performed to evaluate a particular intervention. Initially, a rather small trial that is highly controlled using a physiologic or surrogate endpoint may be performed. This trial would provide evidence that the intervention is effective in the optimal situation (efficacy trial). However, it might lack

clinical relevance especially if the endpoint were a physiologic measure. However, if it were positive, it would then lead to another trial, with more patients and a more clinically relevant outcome measure. If this were positive, a very large trial might be indicated to assess the effectiveness of the intervention in normal practice (effectiveness trial). Such an example would be studying the effect of a chemoprevention agent in colon cancer. Initially, the agent might be prescribed to a group of individuals at high risk for polyp formation (e.g., patients with familial polyposis coli) for a short time with the outcome measure being a rectal biopsy looking for proliferative changes. A subsequent trial might look at polyp regression in this same cohort of patients with subsequent trials aimed at the prevention of significant polyps in average-risk individuals who were followed for several years. As one can see, the selection of subjects, the intervention, duration of the trial, and the choice of outcome measure may vary depending on the research question. Ultimately, however, investigators wish to generalize the results to clinical practice so the outcome measures should be clinically relevant. For this reason, QOL measures are often included.

Although there are elements common to all RCTs, there are issues of special concern in surgical trials.<sup>6</sup> The issue of standardization of the procedure is of major importance in surgical trials. Standardization is difficult because surgeons vary in their experience with and in their ability to perform a surgical technique. There may be individual preferences in performing the procedure, and technical modifications may occur as the procedure evolves. Moreover, differences in perioperative and postoperative care may also impact on the outcome. There are two issues related to standardization of the procedure. First, there is the issue of who should perform the procedure: only experts or surgeons of varying ability. Implicit in this is the definition of an "expert." Second, there is the issue of standardization of the procedure so it is performed similarly by all surgical participants and it can be duplicated by others following publication of the trial results. The implications of these two issues are different and strategies to address them differ.

The first issue is analogous to assessing compliance in a medical trial. Thus, if the procedure is performed by experts only in a very controlled manner, this is analogous to an "efficacy trial." The advantage of such a trial is that if the procedure is truly superior to the other intervention, then this design has greatest likelihood of detecting a difference. The disadvantage, obviously, is that the results are less generalizable. Like most issues in clinical trials, there is no right or wrong answer. If the procedure is usually performed by experts, then it probably is desirable to have only experts involved in the trial. However, if a wide spectrum of surgeons perform the procedure, then it would be appropriate not to limit surgical participation.

Regardless of the number of surgeons involved in the trial and their desire to mimic routine practice, there must be a certain amount of standardization so that readers of the trial results can understand what was done and can duplicate the

procedure in their own practice. There are several strategies to ensure a minimum standard. First, all surgeons should agree on the performance of the critical aspects of the procedure. It may not be necessary that there is agreement with all of the technical aspects but there should be consensus on those that are deemed to be important. Furthermore, if there are aspects of the perioperative and postoperative care that impact on outcome (e.g., postoperative adjuvant therapy), they should be standardized. Teaching sessions may be held preoperatively and feedback given to surgeons on their performance during the trial. As well, obtaining documentation that the procedure has been performed satisfactorily (e.g., through postoperative angiograms to document vessel patency or pathology specimens to document resection margins and lymph node excision) may contribute to ensuring that the surgery is being performed adequately. Finally, patients are usually stratified according to surgeon or center to ensure balance in case there are differences in surgical technique among centers or surgeons.

Blinding is often a difficult issue in surgical trials. It may not be an issue if two surgical procedures are being compared but is a major issue if a surgical procedure is being compared with a medical therapy. There is often a placebo effect of surgery. The classic example was observed in a series of 18 patients in which 13 patients underwent ligation of the internal mammary artery for coronary artery disease and five patients underwent a sham operation.<sup>7</sup> All of the patients in the latter group reported subjective improvement in their symptoms. In the 1990s, it would be difficult ethically to perform a sham operation so it might be impossible to conceal which treatment the patient received. The lack of blinding is especially worrisome if the primary outcome is a change in symptoms or QOL rather than a "hard" outcome measure such as mortality or morbidity. In these situations, if a hard outcome measure is also measured and it correlates with the patient's assessment, there is less concern about the possibility of bias. Assessments may be performed by an independent assessor who is unaware of the treatment group that the patient is in. Finally, if criteria used to define an outcome are explicitly specified a priori, it may minimize or eliminate bias (e.g., criteria to diagnose an intraabdominal abscess). Investigators may also choose in this situation to have a blinded panel review the results of tests to ensure that they meet the criteria.

The issue of timing of trials is difficult. Chalmers<sup>8</sup> has argued that the first patient in whom a procedure is performed should be randomized. Most surgeons would argue, however, that a learning curve exists in any procedure and that modifications to the technique are made frequently at its inception. By including these early patients, one would almost certainly bias the results against the new procedure. The introduction of laparoscopic cholecystectomy and the initially high rate of common bile duct injuries or the laparoscopic versus open inguinal hernia trial are good examples of this.<sup>9</sup> However, it may be difficult to initiate a trial when the procedure is widely accepted by both the patient and surgical community.

The paucity of RCTs testing surgical therapies supports this latter contention. This dilemma arises because, unlike the release of medical therapies, there is no regulating body in surgery that restricts performance of a procedure or requires proof of its efficacy. Probably, RCTs should be performed early before new procedures become accepted into practice, recognizing that future trials may be necessary as the procedure evolves and surgical experience increases. This is analogous to medical oncologic trials in which new trials are being planned as one is being completed. However, a surgical procedure must first be established adequately to avoid investing a large amount of money and time into a valueless trial.

Finally, patient issues may be of greater concern in surgical trials. In a medical trial, patients may be randomized to either treatment arm with the possibility that, at the conclusion of the trial, they can receive the more efficacious treatment if the disease is not progressive and the treatment is reversible. Surgical procedures, however, are almost always permanent. This may be of particular concern if a medical therapy is being compared with a surgical procedure or the two surgical procedures differ in their magnitude or invasiveness. Patients may have a preference for one or the other treatments and therefore refuse to participate in the trial. There also tends to be more emotion involved with surgery and patients may be less willing to leave the decision as to which procedure will be performed to chance. Surgeons themselves may be uncomfortable in discussing the uncertainty of randomization with patients requiring surgery.<sup>10</sup> Thus, accruing patients for surgical trials may be more difficult than for medical trials. In a survey of subjects who had already participated in a trial of maintenance therapy for Crohn's disease, Kennedy et al.<sup>11</sup> found that 91% would agree to participate in a trial again if it involved comparison of two medical treatments but only 44% would agree to participate if it included a surgical arm. Although accrual may be more difficult, there are notable examples of important surgical trials that have been performed.<sup>12-14</sup> Thus, they can be performed although it may require a larger pool of eligible patients from which to sample.

## Levels of Evidence: Grading the Evidence

### Levels of Evidence

There are several grading systems for assessing the level of evidence.<sup>1,15-18</sup> The first was developed by the Canadian Task Force on the Periodic Health Examination in the 1970s (Table 54-2) and has been adopted by the United States Task Force. Although differing in some respects, most systems consider the a priori design of the study and the actual quality of the study. Studies in which there has been blinded random allocation of subjects are given highest weighting because the risk of bias is minimized. Thus, an RCT will provide Level I evidence provided it is well executed with respect to the issues discussed earlier in this chapter.

TABLE 54-2. Canadian task force levels of evidence

Level	Type of evidence
I	Evidence obtained from at least one properly RCT
II-1	Evidence obtained from well-designed controlled trials without randomization
II-2	Evidence obtained from well-designed cohort or case-control analytic studies, preferably from more than one center or research group
II-3	Evidence obtained from comparisons between times or places with or without the intervention; dramatic results in uncontrolled experiments (such as the results of treatment with penicillin in the 1940s) could also be included in this category
III	Opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert committees

Although this system is of value because of its simplicity, difficulties may arise when readers wish to pool results from several studies, either informally during their reading or when performing systematic reviews or developing guidelines. Decisions must be made on whether studies should be included or excluded depending on the quality of the study.<sup>19</sup> As well, the systems are not sensitive to the relevance of the findings of studies. For instance, neither the clinical relevance of the outcome measures, the baseline risk of the effect, nor the actual results of the studies (e.g., study results that are not consistent with results from other RCTs) are considered in any system.

In the American Society of Colon and Rectal Surgeons (ASCRS), the Standards Committee in 2003 decided to adopt the grading system shown in Table 54-3.<sup>16,18</sup> This system identifies the level of evidence based on the available literature. Moreover, this system also provides a grade for the

TABLE 54-3. Levels of evidence and grade of recommendation used by the ASCRS Standards Committee

Level	Type of evidence
I	Evidence obtained from metaanalysis of multiple, well-designed, controlled studies. Randomized trials with low false-positive and low false-negative errors (high power)
II	Evidence obtained from at least one well-designed experimental study. Randomized trials with high false-positive and/or false-negative errors (low power)
III	Evidence obtained from well-designed, quasi-experimental studies such as nonrandomized, controlled, single-group, pre-post, cohort, time, or matched case-control series
IV	Evidence from well-designed, nonexperimental studies such as comparative and correlational descriptive and case studies
V	Evidence from case reports and clinical examples

Grade	Grade of recommendation
A	There is evidence of Type I or consistent findings from multiple studies of Type II, III, or IV
B	There is evidence of Type II, III, or IV and findings are generally consistent
C	There is evidence of Type II, III, or IV but findings are inconsistent
D	There is little or no systematic empirical evidence

recommendation that depends on both the level of evidence and the consistency of the results from the different studies.

## Assessing the Best Evidence

### What Is the Quality of Evidence Evaluating Surgical Practice?

There is certainly a perception that surgeons are not adequately assessing surgical procedures. In an editorial in the *Lancet* in 1996 entitled "Surgical Research or Comic Opera: Questions but Few Answers," Richard Horton criticized surgeons for their high reliance on case studies and stated that if surgeons wished to retain their academic reputations, they must find imaginative ways to collaborate with epidemiologists to improve the design of the case series and to plan randomized trials.<sup>20</sup> Furthermore, he quoted a medical statistician, Major Greenwell, who stated, "I should like to shame surgeons out of the comic opera performances which they suppose are statistics of operations."<sup>20</sup> This quote dated back to 1923. In a similar condemnation, Spodick<sup>21</sup> complained of the "repeated reporting of biased data from uncontrolled or poorly controlled trials, giving an illusion of success due to sheer quantity," and stated that "a thousand zeros look impressive on paper, but they still amount to zero."

So what is the evidence of the evidence? As one would predict, repeated studies have shown that there is a predominance of case studies and a relative paucity of RCTs published in the literature. Solomon and McLeod<sup>2</sup> reviewed three surgical journals—*British Journal of Surgery*, *Surgery*, and *Diseases of the Colon and Rectum*—over two time periods—1980 and 1990. They found that only 7% of all published clinical articles were RCTs despite the fact that almost half of the articles addressed issues of treatment effectiveness. Furthermore, the proportion differed neither between 1980 and 1990 nor among the three journals. Another examination of the *Diseases of the Colon and Rectum* showed that the numbers of RCTs published were 5 (in 1990), 13 (in 1995), and 17 (in 2000).<sup>22</sup> Similarly, Barnes<sup>23</sup> noted that only 5% of abstracts accepted at the annual joint meetings of the Society for Vascular Surgery and the International Society for Cardiovascular Surgery dealt with RCTs. Haines<sup>24</sup> reported that only 5% of articles in the *Journal of Neurosurgery* between 1973 and 1977 were controlled clinical trials. More recently, Horton<sup>20</sup> noted that 7% of articles published in nine surgical journals were reports of RCTs.

What clinical trials are being performed by surgeons? Solomon et al.<sup>25</sup> were able to identify 204 RCTs published in the literature in 1990, which were published by surgeons, were from a surgical department, or contained at least one surgical arm. They estimated that their search retrieved approximately half of the surgical RCTs that were published. Of these trials, the majority (75%) compared two medical therapies whereas trials comparing two surgical therapies

comprised only 18% and trials comparing a medical to a surgical therapy comprised only 5%. Thus, trials comparing antibiotic prophylactic regimens and adjuvant chemotherapy regimens were not uncommon, whereas trials comparing two different operative procedures were infrequent. Furthermore, the published trials tended to be small: almost two-thirds were single center trials, and in half there was no significant difference detected, probably because the sample size was small and the trial lacked adequate power. Unfortunately, surgeons were the primary authors in only a small proportion of studies, even those comparing two surgical procedures and in areas almost exclusively surgical in nature (e.g., trauma). The quality of the trials tended to be poor, especially if they contained one or two surgical arms or were published in surgical journals. Hall and colleagues<sup>26</sup> reviewed the published surgical trials in 10 journals between 1988 and 1994. They also found that the trials tended to be of poor quality.

Given the relative paucity of RCTs reported in the literature, Solomon and McLeod<sup>27</sup> then wished to determine whether it should be possible to perform RCTs in more instances or whether it is not possible, as has been suggested by some. To address this issue, they identified a sample of 260 questions in the surgical literature relating to the efficacy of general surgical procedures. From this analysis, it was estimated that it should be possible to perform an RCT to answer approximately 40% of questions. In contrast, only 4.6% of the articles reviewed reported results of RCTs and more than 50% of the articles were case reports or case studies. Although methodologic issues unique to surgical trials are frequently cited as the reason for not being able to do an RCT, in fact, they believed that methodologic issues would preclude doing an RCT only 1% of the time.

The most common issues to preclude performing an RCT would be strong patient preferences for one or the other treatments or the infrequency of the condition. However, with respect to the former, this was an assessment made by clinicians and trials, such as those comparing mastectomy and lumpectomy and carotid endarterectomy to medical therapy, illustrating that it is possible to do trials even when the alternative treatments differ significantly in magnitude.

Although one cannot argue that surgeons do seem to rely on case series rather than RCTs to evaluate new surgical techniques, it is also important to point out that some noteworthy surgical trials that have had a high impact have been performed: mastectomy versus lumpectomy trials, carotid endarterectomy and ECIC bypass trials for stroke prevention, and the laparoscopic versus open colorectal cancer trial.<sup>12,13,28,29</sup> Furthermore, we must not forget the pioneering work of John Goligher<sup>30</sup> who performed a series of trials assessing the surgical management of peptic ulcer disease long before RCTs were in vogue. However, although internists may criticize surgeons for not performing more trials, it is also important to realize that perhaps the greatest impetus for medical trials is the requirement by regulating agencies of evidence from clinical trials before release of new

medication and, therefore, the availability of funding from industry to test them.

Beyond the issue of the performance of RCTs, it is important for the reader to be able to critically evaluate the literature, which means that certain important information must be included in the manuscript. A recent article examined the quality of reporting for RCTs in the *Diseases of the Colon and Rectum*. The authors found that 77% of 11 basic elements were reported appropriately. The best reported items were eligibility criteria, discussion of statistical tests, and accounting for all patients lost to follow-up. The worst reported item involved power calculations. Only 11% appropriately reported power calculations. For the critical reader, the reporting of appropriate methods, limitations, and data is important. To this end, standards have been recommended regarding the publication of RCTs (i.e., CONSORT—Consolidated Standards of Reporting Trials) and includes 22 items (Table 54-4).<sup>31</sup>

## The Best Evidence

Practicing evidence-based medicine might be a daunting task for the clinician who has a busy clinical practice, must look after the administrative and financial aspects of his or her practice, and then try to keep current with the latest information. It is physically impossible for clinicians to read all published medical journals, even in one's own specialty, much less stay abreast of information that is distributed on the Internet and non-peer reviewed sources. Thus, the busy clinician must learn ways to access the best information and be able to critically appraise it to determine its worth and relevance to his or her practice. There may be two scenarios for which clinicians wish to obtain information: for specific patient problems encountered daily and for general maintenance or updating of knowledge. Although clinicians will need to have the skills to retrieve information and critically appraise it, there are several information sources that may be of particular help including systematic reviews and evidence-based practice guidelines.

## Systematic Reviews or Metaanalyses

The terms systematic review and metaanalysis have been used interchangeably. However, systematic reviews or overviews are qualitative reviews, whereas statistical methods are used to combine and summarize the results of several studies in metaanalysis.<sup>32</sup> In both, there is a specific scientific approach to the identification, critical appraisal, and synthesis of all relevant studies on a specific topic. They differ from the usual clinical review in that there is an explicit, specific question that is addressed. As well, the methodology is explicit and there is a conscientious effort to retrieve and review all studies on the topic without preconceived prejudice. The value of metaanalysis is that study results are combined so conclusions can be made about therapeutic effectiveness, or if there is not a conclusive answer, to plan new studies.<sup>33</sup> They are especially useful when results from several studies disagree with regard to the magnitude or the direction of effect, when individual studies are too small to detect an effect and label it as statistically not significant, or when a large trial is too costly or time consuming to perform. For the clinician, metaanalyses are useful because results of individual trials are combined so he or she does not have to retrieve, evaluate, and synthesize the results of all studies on the topic. Thus, it may increase the efficiency of the clinician in keeping abreast of recent advances.

Metaanalysis is a relatively new method for synthesizing information from multiple studies. Thus, the methodology is constantly evolving, and similar to other studies, the quality of individual metaanalysis may be quite variable. There has been a call for standardization of the methodology used in metaanalysis.<sup>34,35</sup> However, because the rigor of the methodology of many published metaanalyses may be quite variable, the clinician should have some knowledge of metaanalysis

TABLE 54-5. Guidelines for using a review

- 
1. Did the overview address a focused clinical question?
  2. Were the criteria used to select articles for inclusion appropriate?
  3. Is it unlikely that important, relevant studies were missed?
  4. Was the validity of the included studies appraised?
  5. Were the assessments of the studies reproducible?
  6. Were the results similar from study to study?
  7. What are the overall results of the review?
  8. How precise were the results?
  9. Can the results be applied to my patient care?
  10. Were all the clinically important outcomes considered?
  11. Are the benefits worth the harms and costs?
- 

methodology and be able to critically appraise them. Published guidelines are available (Table 54-5).<sup>36</sup>

There are some basic steps that are followed in performing a metaanalysis. First, the metaanalysis should address a specific healthcare question. Second, various strategies should be used to ensure that all relevant studies (RCTs) on the topic are retrieved. These include searching various databases such as MEDLINE and EMBASE. In addition, proceedings of meetings and reference lists should be checked and content experts and clinical researchers are consulted in order to ensure all published and nonpublished trials are identified. Reliance on MEDLINE searches alone will result in incomplete retrieval of published studies.<sup>27</sup> Third, as in other studies, inclusion criteria determining which studies will be included should be set a priori. Fourth, data from the individual studies should be extracted by two blinded investigators to ensure that this is done accurately. As well, these investigators should assess the quality of the individual studies. Fifth, the data should be combined using various statistical techniques. Before doing so, statistical tests to determine the “sameness” or “homogeneity” of the individual studies should be performed.

Whereas some have embraced metaanalysis as a systematic approach to synthesizing published information from individual trials, others have cautioned about the results of metaanalysis and some have been completely skeptical of the technique.<sup>37</sup> LeLorier et al.<sup>38</sup> compared the results of 19 metaanalyses with the results of 12 large trials published subsequently. If the subsequent trials had not been performed, an ineffective treatment would have been adopted in 32% of cases and a useful treatment would have been rejected in 33%. Others have pointed out that metaanalyses on the same clinical question have led to different conclusions.<sup>39</sup> Some of these are attributable to methodologic problems. Failure to use broad enough search strategies may result in exclusion of all relevant studies. Usually, unpublished studies are excluded and these are more likely to be “negative trials” (so-called publication bias).<sup>40</sup> As well, there is evidence that omission of trials not published in English journals may bias the results.<sup>41</sup> Finally, there is a strong association between statistically positive conclusions

of metaanalyses and their quality (i.e., the lower the quality of the studies, the more likely that the metaanalysis reached a positive conclusion).<sup>42</sup> One of the values of metaanalysis is that the generalizability of the results is increased by combining the results of several trials. However, if there is great variation in studies, including patient inclusion criteria, dosage and mode of administration of medication, and length of follow-up (so-called heterogeneity), it may be inappropriate to combine results. If this is done, it may produce invalid results. Other reasons for discrepancies may be the use of different statistical tests and failure to update the metaanalysis. Finally, metaanalysis has generally been restricted to combining the results of RCTs even though there is also a need for combining data from nonrandomized or observational studies.

In response to the problems in disseminating the results of individual RCTs, the Cochrane Collaboration was established<sup>43</sup> to prepare, maintain, and disseminate systematic reviews of RCTs of healthcare interventions. It was named after Archie Cochrane, an eminent statistician in the United Kingdom. The Cochrane Collaboration is a voluntary international organization that encourages the participation of interested individuals. Cochrane groups are organized by areas of interest (e.g., upper gastrointestinal, inflammatory bowel disease, colorectal cancer, hepatobiliary). In addition to preparing reviews, journals are hand searched and a database of all published RCTs is maintained. Systematic reviews are constantly being updated. The Cochrane Library is available on CD ROM on a quarterly basis (The Cochrane Library. Update Software Inc. 936 La Rueda, Vista, CA 92084). It includes several databases including the Cochrane Database of Systematic Reviews. This is a valuable source of high-level information for practicing clinicians. Unfortunately, it is of somewhat more limited use to surgeons because of the paucity of published surgical RCTs and metaanalyses.

## Practice Guidelines

Practice guidelines have been defined by the Institute of Medicine as “systematically developed statements to assist practitioner and patient decisions about appropriate health care for specific clinical circumstances.”<sup>44</sup> Guidelines are not standards that set rigid rules of care for patients. Rather, guidelines should be flexible so that individual patient characteristics, preferences of surgeons and patients, and local circumstances can be accommodated.<sup>45</sup>

Guideline development has occurred for several reasons.<sup>46</sup> First, as discussed earlier, there is growing evidence of substantial unexplained and inappropriate variation in clinical practice patterns, which is probably attributable in part to physician uncertainty. Second, there is evidence that the traditional methods for delivering continuing medical education are ineffective and that clinicians have difficulty in assimilating the rapidly evolving scientific evidence. Third, there is

concern that as healthcare resources become more limited, there will be inadequate funds to deliver high-quality care if current technology and treatments are used inappropriately or ineffectively.

Practice guidelines have been promoted as one strategy to assist clinical decision making to increase the effectiveness and decrease unnecessary costs of delivering healthcare services.<sup>46</sup> Many clinicians are wary of guidelines and believe that they are simply a means to limit resources and inhibit clinical decision making and individual preferences. Guidelines have also been criticized for being too idealistic and failing to take into account the realities of day to day practice. The argument is that patients differ in their clinical manifestations, associated diseases, and preferences for treatments. Thus, guidelines may be either too restrictive or irrelevant. Also, clinicians may be confused because of conflicting guidelines. Finally, guideline development may be inhibited because there is a lack of evidence upon which to base guidelines.

Many groups and organizations have begun to develop practice guidelines. Guidelines are developed using different methods.<sup>47</sup> Guidelines can be developed based on informal consensus. The criteria upon which decisions are made are often poorly described and there is no systematic approach to reviewing the evidence. More often, these guidelines are based on the opinion of experts. Readers are unable to judge the validity of the guidelines because even if a systematic approach was followed, the process is not documented. In many instances, guidelines are self-serving and used to promote a certain specialty or expertise. The National Institutes of Health and others have produced guidelines based on a formal consensus approach. Although this approach tends to be more structured than the informal consensus, it has the same potential flaws in that it is less structured and susceptible to the biases of the experts.

Evidence-based guidelines are the most rigorously developed guidelines.<sup>15-46,48</sup> There should be a focused clinical question and a systematic approach to the retrieval; assessment of quality and synthesis of evidence should be followed. Guideline development should also be a dynamic process with constant updating as more evidence is available. In addition to assessment of the literature, there is usually an interpretation of the evidence by experts and the evidence may be modulated by current or local circumstances (e.g., cost/availability of technology).

Whereas there has been much attention given to the preparation of guidelines, there has been less emphasis on the dissemination of and evaluation of the impact of guidelines. Unfortunately, there is some indication that evidence-based guidelines may not have as much impact either on changing physician behavior or improving outcome.

Because there are many guidelines available, including some with conflicting recommendations, clinicians require some skills to evaluate the guidelines and determine their validity and applicability<sup>15,48</sup> (Table 54-6).

TABLE 54-6. Guidelines for assessing practice guidelines

- 
1. Were all the important options and outcomes clearly specified?
  2. Was an explicit and sensible process used to identify, select, and combine evidence?
  3. Was an explicit and sensible process used to consider the relative value of different outcomes?
  4. Is the guideline likely to account for important recent developments?
  5. Has the guideline been subject to peer review and testing?
  6. Are practical, clinically important, recommendations made?
  7. How strong are the recommendations?
  8. What is the impact of uncertainty associated with the evidence and values used in guidelines?
  9. Is the primary objective of the guideline consistent with your objective?
  10. Are the recommendations applicable to your patients?

## Critically Evaluating the Literature (How to . . .)

### Critically Appraising the Literature

Critical appraisal skills must be mastered before evidence-based practice can be implemented successfully.<sup>49</sup> Critical appraisal skills are those that enable application of certain rules of evidence and laws of logic to clinical, investigative, and published data and information in order to evaluate their validity, reliability, credibility, and utility. Clinicians need critical appraisal skills because of the constant appearance of new knowledge and the short half-life of current knowledge. Clinicians cannot rely on facts learned from medical school. Instead, they must have the necessary skills to assess the validity and relevance of new knowledge in order to provide the best care to their patients.

Critical appraisal requires the clinician to have some knowledge of clinical epidemiology, biostatistics, epidemiology, decision analysis, and economics. Critical appraisal skills also improve with practice, and the clinician is encouraged simply to begin using the skills they already have and build on them. There are a variety of articles and books written on the topic. The McMaster Evidence Based Medicine Group has published a series of articles in the *Journal of the American Medical Association*.<sup>15,36,48,50-64</sup> Sackett and colleagues<sup>49</sup> have consolidated much of this information into a book entitled "Evidence Based Medicine." Interested readers are encouraged to seek further information from these and other sources.

To make decisions about a patient, clinicians generally need to know something about the cause of the disease, risk factors for it, the natural history or prognosis of the disease, how to quantify aspects of the disease (measurement issues), diagnostic tests and the diagnosis of the disease, and the effectiveness of treatment. In addition, clinicians now need to have some knowledge of economic analysis, health services research, practice guidelines, systematic reviews, and decision analysis to fully appreciate the literature and make use of all sources of information.

Many clinicians believe that critical appraisal only requires knowledge of statistics. As stated previously, an array of skills is required. Furthermore, in making decisions about the internal validity of the study (i.e., How good is the study and how confident am I that the results or conclusions are correct?), it is critical that the clinician can assess the study design and how well the study was actually performed. The statistical analysis, although important, is only one component of study design.

Generally, clinicians read articles so they can generalize the results of the study and apply them to their own patients. There are two potential sources of error, which may lead to incorrect conclusions about the validity of the study results: systematic error (bias) or random error. Bias is defined as “any effect at any stage of investigation or inference tending to produce results that depart systematically from the true values.”<sup>65</sup> For example, the term “biased sample” is often used to mean that the sample of patients is not typical or representative of patients with that condition. There are a number of biases that might be present, not just those related to patient selection. It may be difficult for the reader to discern the presence of bias and its magnitude. For instance, suppose two different treatments are compared in two groups of patients from two different hospitals. Although the authors could provide basic demographic information on the patient groups, one could not be certain that there were not differences in the patients, the severity of the disease, ancillary care, etc., at the two different hospitals and these differences, rather than the treatment, led to an improved outcome. The risk of an error as a result of bias decreases as the rigor of the trial design increases (see discussion of risk adjustment in the proceeding section). Because of the random allocation of patients as well as its other attributes, the RCT is considered the best design for minimizing bias. In observational studies, including outcomes research (where patients have not been randomized), various statistical tests (e.g., multivariate analysis) are frequently used to adjust for differences in prognostic factors between the two groups of patients. However, it is important to realize that it is possible to adjust for only known or measurable factors. In addition to these, there may be other unknown and possibly important prognostic factors that cannot be adjusted. Again, only if patients are randomly allocated can one be certain that the two groups are similar with respect to all known and unknown prognostic variables.

The other type of error is random error. Random error occurs because of chance, when the result obtained in the sample of patients studied differs from the result that would be obtained if the entire population were studied.<sup>65</sup> Statistical testing can be performed to determine the likelihood of a random error. The type of statistical test used will vary depending on the type of data. Some of the more common tests are shown in Table 54-7. There are two types of random error: Type I and Type II errors. The risk of stating there is a difference between two treatments when really there is not one is known as a Type I error. In the theory of testing hypotheses, rejecting a null hypothesis when it is actually true is called

TABLE 54-7. Types of statistical tests

Data type	Statistical tests (with no adjustment for risk factors)	Statistical tests (with adjustment for risk factors)
Binary (dichotomous)	Fisher exact test or chi square	Logistic regression
Ordered discrete	Mann-Whitney <i>U</i> test	
Continuous (normal distribution)	Student's <i>t</i> test	Analysis of covariance
Time to event (censored data)	Log-rank Wilcoxon test	Log-rank (Cox proportional hazard)

a Type I error. By convention, if the risk of the result occurring because of chance is less than 5% (a *P* value less than .05), then the difference in the results of treatment is considered statistically significant. There really is a difference in the effectiveness of the two treatments.

One of the issues regarding Type I errors is that of multiple comparisons. Specifically, the more comparisons being performed with a given set of data, the higher the likelihood of a Type I error (finding a difference, when one truly does not exist). Under these circumstances, a correction for multiple comparisons (e.g., a Bonferroni correction) should be performed by the authors.

Although a result may be statistically significant, the clinician must determine whether it is clinically relevant or important.<sup>49</sup> Typically, treatment effects can be written as absolute risk reduction (ARR) or relative risk reduction (RRR). The ARR is simply the difference in rates between the control group and the experimental group whereas the RRR is a proportional risk reduction and is calculated by dividing the ARR by the control risk. The advantage of the ARR is that the baseline event rate is considered. For instance, the RRR would be the same in two different studies in which the rates between the control and experimental groups were 50% and 25% and 0.5% and 0.25%, respectively. In other words, whereas the ARR would be 25% in the first study and 0.25% in the second study, the RRR for both studies would be 50%. Although the RRR is the same in both studies, the treatment benefit in the second scenario may be trivial.

Recently, Cook and Sackett<sup>66</sup> have coined the term “number needed to treat” (NNT) which may make more intuitive sense to clinicians rather than thinking in terms of ARR and RRR. It is calculated by dividing the ARR into 1. Thus, in the example mentioned above, four patients would have to be treated to prevent one bad outcome (the NNT is four) in the first study whereas 400 would have to be treated to prevent one bad outcome (the NNT is 400) in the second. It is up to the judgment of the clinician to decide whether the treatment benefit is clinically significant. The statistician can only determine whether a treatment benefit is statistically significant. Whether the effect is clinically significant will depend on the NNT, the frequency and severity of side effects (sometimes stated as the number needed to harm—NNH), as well as the cost of treatment and its feasibility and acceptability.

The other random error is the Type II error. A Type II error occurs when two treatments are, in reality, different but one concludes that they are equally effective. In the theory of testing hypotheses, accepting a null hypothesis when it is incorrect is called a Type II error. It is not uncommon for clinicians to read a study in which the results are not statistically significant and to wonder whether the two treatments are equally effective or whether there is a Type II error. When investigators plan a trial, they minimize the risk of a Type II error by calculating a sample size to ensure that there is adequate power (1-Type II error) to show a difference if one really exists. To calculate a sample size, both the probability of a Type I error and power are specified, plus the mean and standard deviation or event rate in the control group and the size of the difference that one wishes to detect. Not surprisingly, the more variable the subjects, the less frequent the event rate, or the smaller the difference in the effects of the treatment, the more subjects that are necessary to be certain a treatment effect has not been missed. Conversely, fewer subjects are necessary if there is less variability, the outcome occurs more frequently, or one expects a large difference in treatment effect. With regard to performing sample size calculations, several studies have examined whether such calculations have been made. Maggard et al.<sup>67</sup> examined all RCTs performed in three surgery-related journals for four consecutive years and found that 38% reported sample size calculations. Moreover, whereas only 50% of the studies were appropriately powered to detect a 50% effect change, only 19% were appropriately powered to detect a 20% effect change. Most striking, of the studies that were underpowered, more than half needed to increase sample size by more than 10-fold.

Whereas a power calculation is performed a priori, a more useful measure for the reader interpreting the study results is the calculation of 95% confidence intervals (CIs).<sup>68</sup> The 95% CI gives a range within which the true mean of the sample variable lies, with a probability of 95%.<sup>65</sup> The wider the CI, the less certain one can be that the two treatments are really similar in effectiveness. Conversely, if the CIs are narrow, one can be much more certain that the treatments are equally effective. To operationalize the notion of CIs, if the CIs overlap, then the means are not significantly different. If, however, the CIs do not overlap, then the means are different. Moreover, one frequently sees CIs when odds ratios are reported. In this case, if CI for the odds ratio overlaps 1, then there is no significant difference in odds. If the CI of the odds ratio is greater than one, then there is a significant increase in odds (i.e., a positive association between the predictor variable and outcome). Finally, if the CI of the odds ratio is less than one, then there is a significant decrease in odds (i.e., a negative association between the predictor variable and outcome).

## Risk Adjustment

For the surgeon reading the literature, an issue that is inherently related to systematic error, or selection bias, is that of

patient comorbidity. The methodology for controlling for differing patient disease severity is termed risk adjustment, and is an important issue for critically evaluating the literature—particularly when the study design is not an RCT. For example, given a specific disease, if one hospital (or surgeon) has a patient population with mostly frail, elderly patients and reports a case series of procedure Y with poor results, whereas another hospital provides care for primarily young and healthy patients, and reports a case series of procedure Z with good results, the reader may not be able to distinguish whether the results were attributable to the differences in the procedure, or the patients (i.e., comorbidities). This is one of the most common problems with evaluating the surgical literature.

The techniques of risk adjustment need to account for both the health status of the patient before treatment as well as severity (and acuity) of the current (i.e., morbid) illness.<sup>69</sup> A patient with many health problems such as insulin-dependent diabetes and steroid-dependent pulmonary disease will be less likely to do well after an operation compared with a patient who is free of comorbid health problems. Furthermore, there are also issues regarding the primary (or morbid) disease. It is well accepted that a patient who presents to the hospital with a perforated sigmoid cancer in septic shock is more likely to have a worse outcome than a patient with early stage disease who was diagnosed during a routine screening examination. Surgeons know these facts intuitively through training and experience; however, translating this notion into an adjustment method that appropriately accounts for preoperative factors is the challenge. This challenge, however, is an important issue when critically evaluating the literature.

Risk adjustment is generally accomplished by identifying and then accounting for the factors that determine, or are associated with, variations in outcomes. The degree of importance of these factors needs to also be assessed with subsequent weighting of the factors (individually or in categories). Many risk-adjustment methods have developed indices or formulas to calculate the level of risk.

One of the most difficult issues in performing risk adjustment is deciding which comorbid diseases or conditions to adjust for in the analysis. For the critical reader, one should ask whether the risk factors included by the authors are indeed the important ones to include, but also, it is important to think whether the authors have not omitted any important ones as well. Moreover, risk factors may include other aspects in addition to comorbidities. Such things as functional status (e.g., activities of daily living) and physiologic or laboratory parameters (e.g., albumin level) may (should) be included to adjust risk.

Overall, a reader should examine whether or not risk adjustment was performed, and if so, is there a validated method being used, and is this method adequate? There are several methods with varying ability to risk adjust; we will briefly discuss two common methods being used in the literature.

### Charlson Index

One of the most common indices for risk adjustment currently being used is the Charlson Index.<sup>70</sup> This index was designed as a method to help predict mortality for hospitalized patients and was originally developed using patient data that are obtained from patient records; later, however, the index was translated for use with administrative databases. Overall, the Charlson method predicts the risk of dying by assigning a score to each comorbid factor. Several comorbid conditions are included. The method itself is simple: points are summed for each of the comorbid conditions that are present to generate an index score; this score can then be used as a risk adjustment score for a patient's level of comorbidity. Some of the conditions (and weights) included in the Charlson Index are congestive heart failure (1), myocardial infarction (1), moderate or severe renal disease (2), moderate or severe liver disease (3), and acquired immunodeficiency syndrome (6). Because the Charlson Index has been frequently used in the literature, especially in population-based secondary analyses of administrative data, comparisons theoretically may be made among studies.

Another method for risk adjustment in surgery is seen in the Veterans Affairs (VA) developed system used in the National Surgical Quality Improvement Program (NSQIP).<sup>71-73</sup> The VA NSQIP method was established through the VA hospitals and was designed to compare the quality of surgical care. In brief, NSQIP was developed after a mandate that the VA report annual surgical outcomes. These outcomes were to be compared after adjustment for the severity of a patient's illness and comorbid factors. However, it soon became apparent that to appropriately compare outcomes, risk-adjustment models specific to surgical specialties and procedures had to be developed. NSQIP was created in response to these issues.

The NSQIP data were designed such that a clinical surgical nurse collects preoperative, intraoperative, and 30-day outcome data on nearly all major operations at all inpatient VA hospitals. Preoperative data include 10 demographic, 30 clinical, and 12 laboratory values. Additionally, intraoperative data consist of 15 variables, and postoperative data include 10 laboratory values. NSQIP collects 30-day outcomes, including 30-day mortality, 21 categories of 30-day morbidities, and length of stay. From the collection of these perioperative risk factors, a method of predicting adjusted outcomes was developed. Moreover, by determining the importance of individual risk factors for specific surgical specialties and procedures, individualized methods were created. Each method included the risk factors shown to have the greatest importance in adjusting for outcomes. Individualized models were created for many of the surgical specialties (including: general, orthopedics, urology, vascular, neurosurgery, otolaryngology, and thoracic) and for specific surgical procedures within these areas.

In addition to collecting perioperative items for risk assessment, these data can all be used in a predictive manner. For

example, the risk factors used in the NSQIP model can be used to predict 30-day mortality. A study by Longo et al.<sup>74</sup> examined the predictive factors for 30-day mortality after colectomy. They found the most important predictor to be an ASA class IV or V with an odds ratio of 4.7.

### Quality of Life

QOL is receiving increasing attention as a measure of outcome from patients, physicians, and even third-party payers. In colorectal surgery, there have been an increasing number of QOL studies; however, the quality of the studies themselves varies and certain methodologic details may make it difficult for the reader who is trying to critically evaluate the findings. One of the important issues in this regard is the instrument that is used to measure QOL. There are many types of measurement tools (e.g., generic versus disease-specific versus symptom specific, etc.) and this fact alone contributes to the difficulty with initiating the QOL studies in the literature.

The purpose of this section is to familiarize the clinical surgeon with some of the available tools and methods for measuring QOL such that a critical assessment of the colorectal QOL literature may be performed by the reader.

The most common way of measuring QOL is through patient self-assessment surveys. These surveys (also called questionnaires, tools, or instruments) are organized into a series of items that gather information on specific areas of interest related to QOL. For example, most surveys that address "overall" QOL include questions that cover the areas of physical, psychological, social, and overall well being.<sup>75-77</sup>

For a survey to be considered useful, the instrument should have reliability, validity, and responsiveness. It is important for the reader of QOL manuscripts to assess whether the QOL instrument was reviewed critically with regard to these items *before* its use in the particular study. Using instruments that have not been assessed for each of these attributes can lead to serious errors in measurement, uninterpretable data, erroneous conclusions, and nonreproducible results.

Reliability refers to the extent that a survey produces reproducible results. The more reliable an instrument is, the lower the element of random error. In practice, reliability refers to the extent to which the measure yields the same results in repeated applications in an unchanged population (which can be evaluated with a test-retest assessment).<sup>78</sup>

Validity refers to the ability of a survey to accurately measure what it is designed to measure. There are three types of validity that are frequently discussed in relation to surveys. The simplest is criterion validity in which the new measure is correlated with an accepted gold standard. The second form of validity is content validity or how well individual items cover the entire content of issues within a domain or scale. In general, similar to internal reliability, a greater number of items in an individual scale will result in greater content

validity. The third form of validity is construct validity or how well a survey measures unobservable phenomena (or constructs).<sup>79</sup>

Finally, responsiveness, or sensitivity to change, is the extent to which an instrument can detect true differences. In other words, it is a survey's ability to change as the patient's clinical status changes. Both increased numbers of questions and/or a greater range of possible responses on a single question will result in increased responsiveness. In general, disease-specific surveys offer greater sensitivity than generic instruments because of the number and focus of the questions directed toward the specific disease being treated.

For the critical reader, interpretability has been thus far the most elusive aspect of QOL measurement in the literature. Most of the difficulty in interpretation of QOL data stems from the fact that what is being measured is not observable. In this regard, it is difficult to determine the significance of the QOL change—i.e., what is a significant *clinical* change? This will be further addressed below.

Survey instruments may be categorized broadly into two types—generic versus disease specific. Generic surveys attempt to measure the global relationship between a patient's health and their well being. The strength of such an instrument lies in its ability to provide a bottom line assessment of well being as influenced by health status. An additional advantage of such an approach is that these instruments can be used to compare QOL across diseases. Examples of generic surveys that have been used in colorectal disease include Sickness Impact Profile (ulcerative colitis, colorectal cancer),<sup>80,81</sup> Nottingham Health Profile (colorectal cancer),<sup>82,83</sup> and the Short Form 36 (fecal incontinence, restorative proctocolectomy, familial adenomatous polyposis, and colorectal cancer).<sup>22,79,80,84</sup> The benefit in the use of an instrument across many diseases is an improvement in interpretability of results through greater criterion validity. Physicians are able to more easily make comparisons across diseases and possibly compare a change in disease status to that of a familiar disease.

Another benefit of these surveys is comparison of results with normative data, such as aged matched, healthy, control individuals. The SF-36 survey, for instance, has this advantage because scores (overall and for each of its eight domains) are available for the general population, and can be subsetted by such things as age and gender. In this regard, information may potentially be gained concerning the impact of a disease if the individual had similar QOL to the control population before the onset of his or her disease.

More clinically detailed than a generic survey, disease- or symptom-specific surveys offer the possibility of allowing the physician and patient to concentrate on the issues that can be expected to influence QOL in the context of the disease process in question. Because of this focus, these surveys should be more sensitive to the changes in QOL that may be expected with a specific problem, or its treatment, or both. This improved sensitivity, however, comes at the cost of a

lack of generalizability, in that the survey is only useful for those specific issues (e.g., disease, symptom, procedure). Some examples of targeted surveys for colorectal surgery include the European Organization for the Research and Treatment of Cancer's Quality of Life Questionnaire for ColoRectal cancer (EORTC QLQ-CR38),<sup>85,86</sup> the Inflammatory Bowel Disease Questionnaire,<sup>84,87,88</sup> and the Rating Form of Inflammatory Bowel Disease Patient Concerns.<sup>80,89</sup>

Although there have been an increased number of studies examining QOL as an end point, the critical reader needs to focus on whether the studies have taken the clinically important step of explaining the intrinsic meaning of the studies' results. As mentioned previously, one of the more significant factors preventing more widespread acknowledgment of QOL as an outcome is lack of interpretability of the data. This is a responsibility that the author of the study needs to carefully address in the discussion section of his/her paper. Part of the problem is related to the survey instruments themselves and lack of physician experience with them, but the ease of interpretation is also limited by the focus on *P* value and statistical significance rather than clinical significance.<sup>90</sup> For example, it is not clear what a 10% difference in mean physical functioning between two treatments actually means even if the *P* value is significant (e.g.,  $P < .01$ ). A better technique might be to decide before the study what the minimal important clinical difference in score is (and provide justification for this), then report the percentage of patients who achieve this level of improvement. This is an example of a minimum important difference approach that reports the percentage of patients who experience a specific change in QOL score. Most researchers in the field believe that this descriptive approach offers a more interpretable representation of the data compared with traditional statistical analysis. Minimum important difference, effect size calculations, NNT analyses, and anchor-based approaches have all been postulated as alternative forms of data reporting.<sup>91</sup> These alternate approaches to traditional statistical representation of results seem to be gaining a foothold and may increase the pace of progress in QOL research.<sup>90,92-94</sup>

For the reader who is critically evaluating the QOL literature, the above discussions are important to recognize. The meaning of QOL scores needs to be addressed in both methodologically rigorous ways as well as in regard to clinical relevance. Table 54-8 provides a summary of some of the key attributes for critiquing reports of QOL research. For both readers and authors of QOL studies, Staquet and colleagues<sup>94</sup> provide extensive suggested guidelines for the reporting of clinical trial that include QOL data.

In sum, increasingly more QOL studies are being published in the colorectal literature. With the increasing number of articles, critical evaluations of the methodology, as well as the reported results are important regarding how we should clinically interpret and potentially use the study findings.

TABLE 54-8. Attributes of well-performed QOL studies

Trial design	Prospective
Survey choice	Depends on intent, usually combination of generic, disease-specific, and/or modular; must justify survey(s) chosen
Survey psychometric characteristics	Valid, reliable, sensitive to change, interpretable
Total survey length	<100 questions (<30 min to complete)
Source of information	Patient whenever possible
Method of administration	Self-administered, if not possible at least consistent approach
Missing data	Defined approach (imputed, deleted), report number missing all and/or part of data
Scoring	Report source of algorithm used
Analysis	Both univariate and multivariate, include potential confounders in model; correct for multiple comparisons
Reporting	Report both descriptive and traditional statistics

## Conclusions

This chapter provides a foundation for the colorectal surgeon who is critically evaluating the literature. Such evaluation is important as evidence-based practice continues to increasingly become a focus for healthcare providers. It remains paramount, therefore, that the literature be interpreted appropriately and thoughtfully.

# Surgical Education: A Time for Change

Clifford L. Simmang and Richard K. Reznick

There is a coalescence of events: societal, financial, generational, and structural, which are challenging the status quo like it has never been challenged before. Throughout the world, there are echoes of the need for fundamental changes to postgraduate medical education, reverberating from faculty, trainees, and certification bodies.

The most pressing component of the concerns about surgical education is the diminishing attractiveness of our surgical programs and augmenting attrition once accepted to specialties. It would seem that lifestyle concerns dominate the landscape of resident choice and are at the heart of the reason surgical specialties are losing some of the best and brightest to specialties with a more controlled lifestyle. Further exacerbating this trend is the reality that surgical specialties no longer have a monopoly on interventional procedures, and levels of compensation that have historically favored surgical specialties no longer do.

In concert with a diminishing attractiveness of the specialty, there is the global move toward a diminished workweek for surgical trainees. Although many applaud a departure from the often-intolerable work demands of residency programs of the past, the irony may be that the net end result may be a lengthening of surgical programs. Unquestionably, surgery is different from other areas of medical practice and it requires a different approach. This is so largely because of the concomitant need to train individuals technically as well as in the breadth of other dimensions required to be an excellent practitioner. One of the problems with continuing on our current path and with our current methods is that our residents are graduating with less clinical and operative skills than their surgical teachers did. The reasons for this include: decreasing level of resident independence across the board; an appropriate increase in attention being given to patient demands and the reduction of medical error; inadequate opportunities for deliberate practice; a pressure for speed, often driven by financial realities; a working week that is reducing and a population of our core teaching hospitals with increased levels of tertiary and quaternary care.

Another issue is the fact that there is uneven exposure to many expected competencies. This is because training models are principally structured based on available opportunity as opposed to satisfying educational objectives. In addition, most programs maintain a hierarchical approach, especially with respect to opportunities to operate. In this regard junior residents often spend countless hours on wasted activity.

Another major issue in surgical education is that political and financial issues have yet to be met head on. It will be important to reconcile that currently teaching is undervalued and poorly compensated.

In this chapter, we will trace the history of basic tenets of surgical education. In so doing, we will focus on the essential features of cognitive and technical learning. We will highlight some recent structural changes for surgical residencies that are being advocated including the concept of a “strategically planned curriculum.” Finally, we will propose that more than ever, our surgical community will need to redefine basic methods of surgical teaching, and be open to novel curricular models.

The heritage of our modern residency training programs had its beginnings at the Johns Hopkins Hospital when in 1889, William Stewart Halsted was appointed as associate professor of surgery. A native of New York, he graduated from Yale University in the spring of 1874 with a newfound interest in medicine. That fall he enrolled in a college of physicians and surgeons in New York. According to the rules of the college, each student matriculated as a preceptee of a faculty member. After having devoted his college years to athletics, he devoted his years in Medical School to scholastic achievement and graduated among the top 10 men in his class allowing him to compete in a written examination for a prize of \$100.00. He won this with his thesis entitled “Contraindications to Operations.”

In October 1876, Halsted entered his internship at Bellevue Hospital, which he extended for a total of 18 months. He then served as house physician to the New York Hospital from July to October 1878. In November, he traveled to Vienna to begin the study of German. He subsequently spent 2 years visiting

and working at the great German speaking clinics, the world's leading centers of medical science at that time. It was this experience that would lay the foundation and approach he would use to develop his clinical investigation and educational program for the rest of his life. Although his School of Surgery was distinctly American, he would remain, as his colleague William Osler stated, "very much verdeutsched."

Halsted's plan of organization for service grew from the German system, which he described clearly in his 1904 Yale address.<sup>1</sup> Halsted was in charge of the service at all times. Except for his private patients, the beds were occupied by patients cared for by the house surgeon. This position was equivalent to our present day chief resident, with an average time in this position of 2 years. Before this, there was a 6-year pyramidal program as an assistant (interne), which was subdivided into two levels of graded responsibility. Going through the entire process took an average of 8 years. This was the origin of the surgical residency program in the United States. In 1952, B. Noland Carter wrote, "Of all the great teachers in the history of our art, only Theodore Billroth founded a more illustrious school of surgery."<sup>2</sup> One hundred years later, Halsted's organization and system for surgical training remains with very few changes. Our process for educating surgeons has not kept up with advances in many of the other sciences. In 1904, Halsted said, "Although we now have in the United States several moderately well-endowed medical schools with a University connection, the problem of the education of our surgeons is still unsolved. Our present methods do not by any means suffice for their training."<sup>1</sup> Notwithstanding Halsted's dissatisfaction with his method of surgical education more than 100 years ago, and notwithstanding the enormous changes the last century has brought, we still rely on a Halstedian approach to surgical education as our principal heuristic.<sup>3</sup>

## Cognitive Learning

Surgical education evolved throughout the 20th century with the creation and development of residency programs across the country. Training in the first half of the century involved primarily clinical experience and self-study. Formal educational programs began to develop in the second half of the century. Books and journals on surgical diseases were available; however, they were not incorporated into formalized educational curricula, but rather were used as references. In the second half of the century, more attention was given to didactic education. Textbooks that comprehensively cover general surgery and the subspecialties would form the foundation for the basic fund of knowledge and have remained the cornerstone from which new knowledge is built. Despite the availability of a growing body of current literature, regularly scheduled conferences to provide systematic reviews were uncommon. Robert McClelland recognized the need to provide such reviews of current literature. In 1964, at Parkland

Memorial Hospital, he began a program of journal review with the surgical residents. This began small and was intended to help the residents learn how to review the literature while reading current articles to critically assess new knowledge. In 1974, this review process evolved into what we now know as *Selected Readings in General Surgery*. This is a comprehensive program that in a 5-year cycle covers the breadth of general surgical knowledge adding a depth not found in standard textbooks. After graduation, many surgeons have continued to use *Selected Readings* as one means of staying current with the surgical literature. This program continues to be popular with about 4200 subscribers.

During this same time period, residency programs began holding regularly scheduled academic conferences. These often included Morbidity and Mortality (M&M), Case Presentations, and Grand Rounds. Although other conferences were held, these were the core around which the educational curriculum was built.

Perceived as a valuable educational endeavor, even to the extent that M&M is a requirement by the Residency Review Committees (RRC) for accredited surgery programs, there are differing opinions on how the conference should be conducted.<sup>4</sup> The role of M&M conference is to review the process of patient's medical care. Adverse events and errors are discussed with the goal of improving patient care. In this conference, the care of patients that have had a complication is reviewed to determine what factors likely contributed to this complication and what alternative interventions or management strategies could have been used to decrease the likelihood of the complication or its magnitude. This is where residents learn to articulate that a complication has occurred during a patient's stay in hospital and take responsibility for their involvement. It is important for the maturation of surgeons to have an approach to patient care that emphasizes continuous quality improvement. M&M has been referred to as the "Golden Hour" of surgical education because of its unique role in the lifelong education of the surgeon.<sup>5</sup>

There is evidence that surgical M&M conferences teach prospective surgeons the value of open and honest discussion about patient issues, including the analysis of medical error. A prospective analysis of 232 surgical and 100 internal medicine conferences revealed that the proportion of adverse events associated with an error did not differ significantly between the specialties. An error was defined as the failure of a planned action to be completed as intended, or the use of an incorrect plan to achieve a particular goal. Adverse events were unintentional injuries from medical management rather than disease. Errors resulting in adverse events were noted in 18% of internal medicine and 42% of surgical cases, a difference that was statistically significant.<sup>6</sup> In internal medicine conferences, errors were less likely to be discussed as errors, and more likely to be ignored. However, in surgical conferences, errors were likelier to be attributed to an individual, team, or system (79% versus 38%). Traditionally M&M conferences were held closed to all but surgical residents and

faculty. Many surgical programs carried a reputation for intimidation in which the residents were harassed during their presentations. In recent years, most M&M conferences have become more nurturing; however, a certain amount of fear may be healthy—fear that you could be the cause of the patient's demise and understanding one's own responsibility and accountability for patients.<sup>7</sup>

Case presentation conferences are used to present clinical scenarios about patients recently cared for highlighting certain aspects of their presentation, diagnosis, and treatment. As the clinical scenario is presented, a Socratic approach is used to question the participants. This allows the faculty to assess a resident's knowledge base and their ability to assimilate knowledge into a treatment plan. Because all of the residents in the audience could potentially be called on for each set of questions, this forces all of them to pay attention to the scenarios, consider the alternatives and options, and if they do not know the answer, when the answer is given this acquisition of knowledge is more deeply imprinted in memory. Another educational tradition in surgical programs is the Grand Rounds program. As with M&M conferences, a recent concern has been the issue of discoverability. With increasing access to patient information, and a decreasing emphasis on restricting attendance at conferences, some programs have found it necessary to pay stricter attention to what is said in fear of potential use or misuse of that information.

The first half of the 20th century saw the development of organized and structured surgical residency programs whereby the residents would learn as they assisted their mentors in performing patient care. The second half of the 20th century saw the progression and development of academic curricula emphasizing the educational component of surgical training. Many diseases are rare and are not frequently seen, but the requirement for a surgeon to be familiar with this condition still exists. A surgeon cannot make a diagnosis of a condition he is unaware of. This was the impetus to form and develop curricula. It was in that framework that the academic conferences matured.

## Technical Skills Acquisition

In the field of surgery, in addition to the assimilation of knowledge and development of surgical judgment, the ability to master technical skills is essential, and often separates the average surgeon from the master surgeon. In the traditional residency in surgery, technical skills are learned on patients by assisting in the operating room. There is the presumption that fundamental surgical principles, nuances of anatomy, and surgical technique can be learned through observation. However, there is a growing body of opinion that observational learning has its limits, and experiential learning results in a quicker ascent to competency. There was also a great deal of technical learning that occurred when more senior trainees helped junior trainees through an operation. As was discussed

earlier, the opportunities for independent operating have greatly diminished. This may ultimately have a negative effect on technical skill acquisition unless ancillary operative experiences are provided. In essence, we cannot afford to lengthen the learning curve of surgical procedures. The learning curve can be considered as a graphic representation of the relationship between experience with a procedure and an outcome variable such as operative times or complication rates.<sup>9</sup> A common feature of the curve for most procedures is that improvement occurs more rapidly during early experience. This is usually imbedded within the residency training; however, new techniques such as the evolution of minimally invasive surgery required practicing surgeons to learn these techniques without the benefit of the gradual and graded acquisition of skills under the tutelage of experienced surgeon mentors that occurs within residency.<sup>8</sup> This is one of the greatest challenges in surgical education.

One method to alter learning curves for surgical procedures is to shift some the training from the traditional environment of the operating room into an "ex vivo" laboratory. In so doing, there may be great promise in the deployment of surgical simulations. For more than 25 years, pilots for both industry and the military have had a significant part of their early training using simulation techniques. Simulators reproduce the cockpit of an aircraft, including the instrumentation and controls with a simulated visual field out the front window. Whereas the early simulators provided little more than instrument controls and a gray visual field, current training simulators are much more realistic and have become an essential element of pilot training. These simulators not only have enhanced visual effects but also provide the tactile sensation and feeling of change in altitude. In so doing, many flight situations can be reproduced, such as a smooth take off, turbulent air, or a rough landing. Pilots can become very familiar with a new aircraft and can have extensive practice with controlling the aircraft in a variety of situations, preparing them to handle most situations that would be encountered before their first flight. Many pilots believe that current simulators are very realistic and serve as significant preparation for actual flight. However, although realistic scenarios can aid in training optimal pilot behavior in emergency situations, high technology and automation have not been able to significantly improve flight safety in the last two decades.<sup>8</sup> The main cause of aviation accident was and is human error. Therefore, the most powerful tools to reduce risks would deal with the human operator on the flight deck including pilot selection, training, and teamwork.<sup>9</sup> This highlights the importance of M&M in surgery where human error, whether it be judgment, technical, or process oriented is reviewed. Learning from others' experience may be the most valuable process in preventing or solving similar problems for future patients.

Without a doubt, technical skills remain an essential ingredient to the complete surgeon. But can technical abilities be predicted before a prospective surgeon enters residency? This longstanding question remains controversial, and data

gathered to date are conflicting. Traditionally, the admissions process in surgery has relied on past academic performance, unstructured interviews, and a few personal references. The use of psychometric testing to evaluate an applicant's aptitude for surgery has been recently summarized.<sup>10</sup> The Association of Surgeons in The Netherlands has incorporated psychometric testing for surgical training since 1983, and the Royal College of Surgeons of Great Britain and Ireland has also considered taking this step.<sup>11</sup> The predictability of aptitude testing for successful completion of pilot training has been validated in the British Royal Air Force using a battery of tests relevant to being a pilot.<sup>12</sup> This analogy could be extrapolated not only for surgical residency selection, but even for practicing surgeons, where demonstration of competence may include psychometric performance which will be used to obtain credentials for certain procedures such as advanced laparoscopy or even incorporated into the new concept of maintenance of certification.

Minimally invasive surgery has introduced a new and unique set of psychomotor skills for a surgeon to acquire and master. At a meeting of the American College of Surgeons in New Orleans, 2001, 195 surgeons who had completed more than 50 laparoscopic operations participated by performing tasks designed to test psychomotor and not cognitive skills.<sup>13</sup> It was shown that between 2% and 12% of surgeons performed more than 2 standard deviations from the mean and some had performed 20 standard deviations from the mean. Studies like this may form the methodologic foundation for establishing criterion levels and performance objectives in the objective assessment of the technical skills component of determining surgical competence.<sup>13</sup>

Patients want to receive care and operations that reflect the newest technology and yet they do not want to be a part of a surgeon's learning curve. This desire presents a dilemma for the training and practicing surgeon. How can experienced care be provided to patients without gaining the experience by operating on patients? To address this issue, many residency programs in surgery today have begun to develop a Skills Training Program. There are many examples of excellent surgical training centers throughout the world. In general, laboratory curricula parallel training via graded responsibility in the operating room. Interns begin with the simple basics of suturing and knot tying. At each year level, there are skills that must be demonstrated for satisfactory performance and completion for that year. In a prospective, randomized trial done at the University of Texas Southwestern Medical Center, second and third residents were randomized to receive formal laparoscopic skill training with a control group.<sup>14</sup> Baseline performance was assessed. The trained group achieved significantly greater adjusted improvement in video-trainer scores and global assessments of operative performance compared with controls. In this study, intense training improved video hand-eye skills and translated into improved operative performance. Other studies have also shown improved patient outcome. At Jackson Memorial Hospital, a comparison of

non-laparoscopy trained gynecology residents was made with residents who received six 4-hour sessions of committed didactic, and bench instruction using inanimate models.<sup>15</sup> Residents with training performed operations in less time, had less blood loss, shorter hospital stay, and less conversions than the control group. Even experienced surgeons benefit from skills training. In a study to evaluate the validity of laparoscopic performance using one of three simulators, it was found that years of experience directly correlated with skills rating and competence ratings.<sup>16</sup> Task speed and overall performance increased with experience. This suggests that even expert surgeons can show significant improvement with simulation.

In addition to these studies, others have also shown that technical skills are improved with a skills curriculum.<sup>17-19</sup> The durability of the training effect has been variable. Some have suggested that after training with laboratory bench models performance improvements are durable.<sup>20</sup> However, Anastakis and colleagues<sup>21</sup> failed to demonstrate that training on a core procedure in a single session has a sustained effect after 2 years. Similarly, Sedlack and Kolars<sup>22</sup> found no advantage to simulator training for colonoscopy after performance of 30 procedures. Although advantages were limited to early procedural experience, this enhanced early learning curve may allow training faculty to be more efficient with their time and may provide a safer early experience for patients.

Summarizing a growing body of literature, it would seem at present that the report card on simulator training is mixed. It seems to have its major benefit for novice learners, durability of effect is an issue, and results to date have not been validated in large-scale studies. However, as computing power inexorably augments, and as the price of simulation equipment decreases, it is our prediction that in the future, most if not all surgical training programs will be devoting a substantial amount of curricular time to technical training using simulators.

## Educational Challenges

The structure of Graduate Medical Education is changing dramatically. For example, in the United States, in 2003, the Accrediting Council for Graduate Medical Education (ACGME) approved new duty hour standards for all accredited programs including an 80-hour weekly limit, rest periods, and limits on continuous duty hours. This reflects a worldwide trend to a reduction in workweek in general, and the surgical workweek in specific. In part, this has been a result over concerns of medical errors related to sleep deprivation. All residency programs had to comply with this regulation by July 1, 2003. The greatest impact from this has been on first-entry residency programs, such as General Surgery and Internal Medicine. However, many of the subspecialties have been impacted as well. Residents who take home call are allowed to work the following day. However, there is a 10-hour interval

required between the time the resident was last in the hospital and when he or she may return to work. The main issue that arises from this situation is how residents will be able to obtain the volume of experience previously encountered before the current restrictions placed on the time in which the resident can participate in patient care. This reality will force us to rethink our curricula, especially with a view to diminishing hours spent on “pure service requirements.” It may also force us to depart from a long-held surgical tradition that aspiring surgeons need a broad base of experiences, opting for a more focused approach to training.

The ACGME is placing increasing emphasis on educational outcomes in the accreditation of residency programs. To accomplish this, the so-called Outcome Project was initiated. The current model of the accreditation captures the potential of a GME program to educate residents by focusing on structure and process components. The ACGME currently measures a program’s potential to educate by determining compliance with existing requirements, such as educational objectives, an organized curriculum, biannual evaluation of the residents, resident evaluation of the program, demonstration of scholarly activity, and monitoring of resident work hours. Rather than concentrating only on the assessment of a program’s potential to educate, the future for GME as envisioned by the Outcome Project emphasizes a program’s actual accomplishments through assessment of program outcomes. Instead of documenting that there are educational objectives, documentation must reflect that the resident achieved learning of these objectives. One mechanism the ACGME has used to assess this change is to identify learning objectives related to the general competencies, and using outcome data to facilitate continuous improvement of both the resident and residency program performance.

The first major activity of the project was identifying six general competencies for residents. These were identified by attention to how adequately physicians are prepared to practice medicine in the changing Healthcare Delivery System. Six general competencies were endorsed by the ACGME in February 1999. The six general competencies are:

- Patient care
- Medical knowledge
- Professionalism
- Systems-based practice
- Practice-based learning and improvement
- Interpersonal and communication skills

The shift from emphasis on structure and process components to that of outcomes is a gradual transition. The ACGME acknowledges that the need for evidence of structures and processes will not disappear but will gradually become less critical to the overall accreditation process. Over the next few years, programs are expected to phase in assessment tools that provide useful and increasingly valid and reliable evidence that residents achieve competency-based educational objectives. At present, the RRC expects to observe progress in

teaching and assessing the competencies. To begin to implement this shift in emphasis from structure and process to educational outcomes, a program must become familiar with the components from the outcome project and review the basic principles of sound educational evaluation. Learning outcomes and objectives must be developed to reflect the general competencies. Then the program’s current assessment must be aligned with the competency-based learning objectives. The goal of this Outcomes Program is to provide a better measure of the quality of the educational program. It is believed that by measuring the product instead of the process, a more complete measure of the quality of the education received from that program will be measured. The availability of the educational outcomes-based data is necessary to inform discussions with policy makers and others who have become increasingly focused on issues related to funding for medical education and most recently on patient safety. It is now incumbent upon medical educators to demonstrate the effectiveness for educational programs and to be accountable for the education that we provide.

Surgical education has become increasingly complex with governmentally regulated limitations on the time available for learning and gaining experience occurring throughout the world. At the same time, there are augmented demands for outcomes and educational review. To meet this challenge, we believe that we need to incorporate strategically designed curricula to ensure comprehensive training is achieved.

## New Directions

### Strategically Planned Curricula

The 20th century saw little change in surgical education until the last decade. Over the last 10–15 years, there have been sweeping changes in the advancement of knowledge, development of new surgical techniques, and requirements by which we must educate residents. The question is how do we teach residents more information, more complex surgical procedures, which are both diagnostic as well as operative and accomplish this in less time? The answer may be forthcoming with the adoption of strategically planned curricula.

The tenets of a strategically planned curriculum include the following elements:

1. A restructuring of the education system to one that is modular, each module linked to specific objectives, including: cognitive knowledge, clinical skills, judgment, technical surgery, ethics, professionalism, and evidence-based training.
2. A linking of objectives to an appropriate curriculum that is characterized by the following: ensuring that most if not all competencies developed during residency training relate directly to the desired career outcome; an adherence to the principles of residency training as outlined in regulatory

bodies such as the ACGME; that the curriculum is populated to the fullest by activities aimed at satisfying specific educational objectives; that it is learner-based; that it makes liberal uses of technology such as Web-based curricular materials, access to point of care (wireless) information, and a focus on providing data for evidence-based decision making and that it reestablishes anatomy as a backbone of surgical teaching, and includes cadaver dissection, prosection, and the use of virtual reality-based anatomy training models.

3. Dramatically changing the pace of technical skill acquisition by: developing a "pre-program" of basic skills focusing on technical skills fundamental to surgery; dramatically ramping up skills laboratory (*ex vivo*) practice, using virtual reality models, cadavers, surrogate tissue, and inanimate training models; developing programs of structured and deliberate practice; placing a premium on participatory learning as opposed to observational learning; maximizing the number and focus of real-world operations performed by residents and ensure that all learners are actively engaged in each real surgical opportunity; maximizing each "real" patient experience by the use of preoperative technical sessions, by videotape review of self and experts, and by debriefing sessions; developing specific teaching teams for each module; developing programs of faculty development for teaching surgeons; creating a link of faculty compensation to educational deliverables; and maximizing the opportunities for resident involvement in surgery by strategic scheduling initiatives.
4. Diminish wasted time during residency (educational dead space) by: eliminating or minimizing time wasted secondary to a hierarchical model; minimizing time wasted doing noneducational activities; increasing support services, increasing nurse autonomy, rationalizing calls, and optimizing technologic solutions to service problems; critically assessing the need for and the context of night call and seriously addressing the issue of sleep deprivation.
5. Incorporate meaningful assessment into the day to day running of the residency program by: rigorous, reliable, and regular assessment; liberal use of formative assessment; linking evaluation instruments to goals, objectives, and desired competencies; training the evaluators focusing effort on performance-based evaluation systems; using a diverse array of assessors, including self, other health professionals, patients, peers, and faculty and documentation of technical proficiency within a learning module by testing for technical proficiency using sentinel cases.

An example of where we would have benefited from a planned curricular approach to education is the field of minimally invasive surgery. In 1987 the first laparoscopic cholecystectomy was performed. An explosion of laparoscopic procedures with mixed results followed this. Procedures performed primarily in one quadrant of the abdomen, with small vessels or no vessels to ligate, and with either a small

specimen or no specimen became rapidly accepted as the standard approach. Laparoscopic colectomy, which involves all four quadrants of the abdomen, major named vessels requiring ligation and division, retrieval of a large specimen, and the necessity for an anastomosis has made the acceptance of this technique slow. Difficulty with acquiring expertise in other advanced laparoscopic procedures while still in a general surgery residency remains challenging. Although basic laparoscopic procedures have become standard, more advanced procedures including gastric, splenic, and colorectal operations have been difficult to acquire during general surgery residency. The challenge facing colon and rectal surgery residencies is how to incorporate the needed number of required operative procedures with limitations on learning time.

The American Board of Colon and Rectal Surgery has identified 17 categories of operative procedures. Residents who display insufficient numbers in five or more categories are not allowed to enter the certification process until they are able to furnish sufficient case numbers to meet the requirements. As the list submitted and certified reflects their year of training, additional training would be required for a surgeon with five or more deficiencies in order to meet this requirement. There has been one resident who completed his training program with insufficient numbers to enter the certification process. This highlights the challenge of incorporating an increasing number of requirements that must be met. The solution again involves strategically planned rotations to ensure that residents are able to meet the requirements from the American Boards of Surgery, and Colon and Rectal Surgery.

## Technology and Efficiency

Surgical education has entered a new area. The acquisition of new information is fast outpacing that which can be absorbed intellectually. We have gone from the problem in which the difficulty was trying to identify information and acquire knowledge, to the problem of having so much information that the volume is overwhelming. We must rely on technologic advances.

For example, there may be efficiencies that can be gained by computer-based training (CBT). However, only a few studies have assessed the efficacy of CBT with traditional methods of surgical skills training. Summers and colleagues<sup>23</sup> randomized 69 medical students into three groups for basic skills instruction: a group learning through didactic methods, a group learning through watching videotapes, and a group learning through CBT. All of the material contained the same pictures, text, and audio. There were no differences between the groups before training. After training, the didactic group scored higher on multiple-choice examination. However, the videotape and CBT groups demonstrated statistically significant enhancement of technical skills compared with the didactic group. After 1 month, a calculated performance

quotient revealed statistically significant improvement in only the CBT group. CBT was considered as effective as and possibly more efficient than traditional methods for basic surgical skills training for medical students.

For a vast array of knowledge, ready retrieval with a device such as a handheld device that can be carried in a coat pocket may provide the answer. Currently, about 15% of physicians in the United States use personal digital assistants (PDAs) for medical purposes. A trial was conducted at the University of Kentucky, Lexington, KY, to evaluate the impact of PDAs in the general residency program.<sup>24</sup> At the start of the 2001 academic year, all of the general residents were given a PDA with Pocket®Word, Pocket Excel®, and Internet Explorer®, pre-installed and equipped with SIR IrDA infrared port. No training was given. Seven months later, the residents were queried. Seventy percent of residents reported that they used the PDAs frequently or very often. Most of the residents thought they would continue using them in their practice after graduation. Live broadcast of laparoscopic surgery to handheld computers has been performed.<sup>25</sup> A live laparoscopic splenectomy was transmitted live to eight handheld computers simultaneously through the institution's wireless network. This technology allows delivery of information to geographic sites remote from the actual event. We would envision that the surgical residency of tomorrow would have a bank of procedural videos that could be accessed remotely and viewed throughout the institution, much in the same way a movie from a menu can be selected in a hotel room. Residents could view a procedure that they are going to perform to review the details of the procedure just before the case.

Surgical education is changing and we must change to enhance our educational effectiveness. In so doing, we can continue to provide quality education for our residents so they can become the outstanding surgeons that our patients deserve. Notwithstanding the many challenges articulated in this chapter, the commitment to teaching by our academic surgical community remains strong. With rigorous analysis and improvement of our curricula, with deployment of modern educational technologies, and with openness to educational innovations, we can meet the many challenges of both present and future.

## Legal Considerations

Michael J. Meehan

The dawn of the twenty-first century brought with it many of the same legal challenges for physicians, including colon and rectal disease practitioners, as did the latter half of the twentieth century. The ever-increasing frequency and often crushing severity of malpractice claims and lawsuits, databank reporting, Web-based consumer claims data, new privacy requirements, increasing clinical demands, greater government regulation and enforcement activity, and spiraling malpractice premiums have caused many physicians to leave practice, retire early, or relocate to more defendant-friendly lawsuit jurisdictions. This chapter addresses issues related to these concerns—from communication to documentation, from practice to research—as they relate to colon and rectal surgeons.

### Medical Malpractice

#### Elements of Malpractice

In July 2003, a 12-day courtroom trial occurred in Seattle, Washington. The plaintiff, a married 53-year-old computer salesman, had presented to his family physician with rectal bleeding and a painful anal lump with the appearance of a hemorrhoid. When the condition did not improve with treatment, the patient was referred to a general surgeon. After evaluation, the surgeon concluded that the patient had a hemorrhoid and recommended a hemorrhoidectomy. The patient, saying he thought the condition was improving, declined the procedure. The surgeon informed the patient that a hemorrhoidectomy would be indicated if the condition did not continue to improve and resolve. The patient next returned to the surgeon 4 months later, at which time a hemorrhoidectomy revealed advanced anal cancer. The patient received chemotherapy and radiation, developed impotence, and suffered two recurrences of the cancer, from which he was expected to die. The patient-plaintiff filed a lawsuit against both the family physician and the general surgeon contending that earlier diagnosis would have resulted in less extensive treatment and a prognosis of survival from the cancer. The

defense argued that both the family practitioner and the general surgeon acted appropriately and that an earlier diagnosis would have made no difference in the treatment or the outcome. Fifteen medical and surgical experts were used in the case. The pre-suit demand of \$2.75 million had been met with an offer of \$125,000. At trial the plaintiff asked the jury to award \$7 million. The defendants requested a defense verdict. The jury found in favor of the defendants and awarded no money.<sup>1</sup>

The elements that must be proved by a plaintiff to prevail in a medical malpractice case are determined by the laws of the various states. Thus, in this case, the verdict was governed by Washington state law. In general, medical malpractice is established when it is proved, by a preponderance of the evidence, that a patient sustained an injury as a result of an act or omission of a physician or surgeon that would not have occurred had the physician or surgeon exercised ordinary skill, care, and diligence.<sup>2</sup> What a “physician or surgeon of ordinary skill, care, and diligence would or would not have done under like or similar conditions or circumstances” is called the standard of care. Family practitioners and surgical specialists, as in the Washington case described above, are usually held to different standards of care, depending on variations in state law. The standard of care for a physician or surgeon in the practice of a board-certified medical or surgical specialty should be that level of care expected of a reasonable specialist practicing medicine or surgery in that same specialty, regardless of geographical considerations or circumstances.<sup>3</sup> Negligence occurs when the care falls below the standard of care. A case can include single or multiple allegations of negligence.

When negligence is proved in the courtroom, the departure from the standard of care must also be a proximate cause of the injury to the patient for the plaintiff to prevail. Thus, there must be a cause and effect relationship between the care and the harm. For there to be a plaintiff's verdict, the jury must believe that 1) there was a departure from the standard of care, and 2) that the departure from the standard of care was a cause of the patient's injury. For the defense to prevail, the jury must

believe that either 1) or 2) above were *not* proved by a preponderance of the evidence—or that neither were proved.

Both of these issues were actively debated in the Washington case. 1) The recommendations, treatment, and decision to defer a hemorrhoidectomy were contested by both sides; 2) whether the cancer had metastasized before the critical involvement of the doctors was also argued. (If the cancer had metastasized before physician mismanagement, if any, then even a timely hemorrhoidectomy would not have changed the outcome or treatment—so physician mismanagement could not have logically been the *cause* of the patient's injuries).

In some cases, the defense attorneys will concede on item 1 above—negligence, if they think they cannot prevail on item 1 but if they think they can prevail on item 2—causation. Such a strategy may be challenging. Consider the following case tried to a Savannah, Georgia, jury in November 2001 in which defense attorneys conceded negligence and tried to convince a jury that the plaintiff was entitled to receive an award, but that the amount sought by the plaintiff exceeded that to which he should be entitled. The plaintiff had suffered a rectal tear when thrown from his vehicle during an automobile accident. The trauma surgeons who tried to repair the tear negligently closed the proximal end of his colon and matured the distal end as the stoma. As a result, he suffered a complete obstruction of his digestive tract for 7 days and developed a massive infection, causing the loss of approximately 70% of his abdominal wall. He was left with massive scarring, no abdominal muscles, only a thin layer of skin covering his intestines, and the prospect of constant diarrhea for the remainder of his life. The defendants conceded that the stapling procedure was improperly performed, but they disputed the extent of the patient's injuries that was alleged by the plaintiff's attorney, including more than \$1.2 million arguably representing the present cash value of the patient's future lost income. The jury was not asked whether the trauma surgeons had committed negligence, but rather whether all of the injuries complained of were caused by the negligence (whether too much money was being claimed for the injury). Ultimately, the jury awarded the plaintiff \$6.25 million.<sup>4</sup>

### Recurring Malpractice Themes

A study of medical malpractice cases involving colon and rectal disease involved a retrospective review of all cases tried in the federal and state civil court system over a 21-year period from 1971 through 1991<sup>5</sup> remains instructive today. The study identified 98 malpractice cases over that period of time from a computerized legal database. The 98 cases included 103 allegations of negligence. The nature and frequency of allegations were as follows:

- 43%: Failure to timely diagnose disease (principally cancer and appendicitis)
- 24%: Iatrogenic colon injury

- 15%: Iatrogenic medical complications during diagnosis or treatment
- 10%: Sphincter injury with fecal incontinence from anorectal surgery or midline episiotomy
- 8%: Lack of informed consent (usually regarding extent of procedures or endoscopy)

Recent commentators have cautioned about patients who present with fully developed cancers within 4 years of colonoscopies that apparently cleared the colon of neoplasia. The concern expressed is that the presenting patients may assume their colonoscopies were negligently performed, despite legitimate alternative explanations.<sup>6</sup>

A study reviewing 38 malpractice claims against radiologists performing contrast examinations of the colon between 1985 and 1994 revealed the following major allegations: failure to diagnose resulting in delay in treatment and death, and colon perforation attributed to improper performance.<sup>7</sup>

Risk management suggestions relevant to colon cancer screening include using authoritative screening guidelines, documenting informed consent and refusals, assessing family histories, recommending that family members of at-risk patients be contacted, repeating sigmoidoscopies and colonoscopies when the preparation is inadequate, and documenting both cecal intubation and careful withdrawal techniques.<sup>8</sup>

### Lawsuit Stress

Most physicians experience stress when their professional care and judgment are criticized in a public lawsuit. The initial stressor typically occurs when the claim letter, legal complaint, or insurance company notice arrives in the mail. The simple reality is that your chosen profession frequently lends itself to the frustrations and anxiety of litigation. Anger, uncertainty, and even depression are common symptoms among physician defendants. These emotions can be especially intense in those individuals sued for the first time.

Communications with your attorney are confidential and are protected by a privilege similar to the physician–patient privilege. Attorneys representing physicians usually advise their clients not to discuss the case with others for fear of losing the protections available through the attorney–client privilege. The tension and vulnerability that you may feel about being sued may be exacerbated by this inability to seek emotional comfort by discussing the case with colleagues and others. It is common to feel isolated—to assume that colleagues and even subordinates are talking about you and your lawsuit. It is important to place your predicament in perspective; many of your colleagues have been in the same situation before you and others will be in the future.

If you are involved in a claim or lawsuit and are experiencing any of these normal reactions to litigation or the threat of litigation, you should have a candid conversation with your attorney, risk manager, and/or insurance company claims representative. Many insurance companies and

medical institutions provide resources for defendant physicians that enable them to discuss their lawsuit and their feelings of uncertainty and isolation with counselors or colleagues in a protected manner. Conversations with psychotherapists are generally privileged and not admissible in the courtroom as evidence in the case. Remember that your emotional stability is critical to the successful defense of the litigation. You serve yourself best by sharing your feelings with your attorney and asking him or her for a way to receive emotional coaching throughout the stress of the lawsuit and afterward as well.

## Informed Consent

Informed consent is a patient's agreement to a medical procedure or other treatment after the person has been informed of the likely benefits, significant risks, and the alternatives of the treatment. The failure of a physician to obtain proper informed consent is often cited as a major component of medical malpractice litigation. In reality, few cases are prosecuted exclusively on the issue of informed consent, and juries do not customarily award damages solely for a lack of informed consent. Most malpractice lawsuits, however, contain a supplementary allegation that informed consent was not obtained. The informed consent discussion is at the heart of physician-patient communication and is usually an important component in the defense of the main medical or surgical issues in every case. You do not have to wait until the day of or the day before the procedure to obtain informed consent. A study involving 60 patients who underwent either colonoscopies or esophagogastroduodenoscopies revealed that patients remember essentially the same information whether consent is obtained immediately before a procedure or several days earlier.<sup>9</sup> The physician should discuss the procedure or treatment with the patient and obtain and document informed consent as close to the date of the procedure or treatment as reasonably possible, e.g., within days to several weeks. Allowing the patient some time to reflect on the risks, benefits, and alternatives before consenting is an ideal practice, depending on the urgency of the proposed treatment and the complexity of the patient's decision.

### Obtaining Informed Consent

Obtaining informed consent is primarily a physician obligation. Nurses and other nonphysicians are not normally responsible for failing to obtain informed consent,<sup>10</sup> because they lack the requisite legal capacity to fully inform patients of issues on which only a physician is licensed to advise. Hospitals, the typical employers of such professionals, do have an obligation to maintain an effective informed consent process within their institutions. Lack of informed consent claims may be successful if hospitals breach hospital standards and other duties imposed by law, e.g., whereby a patient

is injured by an experimental procedure without being advised of the experimental study.<sup>11</sup>

Obtaining a patient's informed consent involves more than securing a patient's name on a form. It is a communication process in which the physician should discuss the following information with the patient<sup>12</sup>:

- The patient's diagnosis, if known
- The nature and purpose of the proposed treatment or procedure
- The risks and benefits of a proposed treatment or procedure
- Alternatives (regardless of cost or insurance coverage)
- The risks and benefits of the alternatives
- The risks and benefits of not receiving or undergoing the treatment or procedure

Patients should be given the opportunity to ask questions and have their questions answered.

### Proving a Case of Lack of Informed Consent

Depending on variations in state laws, plaintiff attorneys typically must prove the following elements to establish a prima facie case of lack of informed consent by a physician:

- The physician failed to disclose to the patient and discuss the material risks and dangers inherently and potentially involved with respect to the proposed therapy, if any.
- The unrevealed risks and dangers which should have been disclosed by the physician actually materialize and were the proximate cause of injury to the patient, and
- A reasonable person in the position of the patient would have decided against the therapy had the material risks and dangers inherent and incidental to the treatment been disclosed to him or her before the therapy.<sup>13</sup>

Whether risks are material is normally an issue decided by a jury.<sup>14</sup> Juries are often instructed that risks are normally considered to be material if a reasonably prudent person would attach significance to the risk in deciding whether or not to accept the treatment. A risk that is either *severe*, such as death, or *frequent* are usually risks that are considered material. Some states regulate the specific information that must be conveyed to patients. Other states leave the determination of materiality to judges and expert witnesses. You should become familiar with the informed consent laws in the state where you practice. Withholding material risks from patients for cultural, ethnic, or paternalistic reasons is not acceptable.

### Documentation of Informed Consent

Informed consent is usually documented with formal consent forms requiring the patient's signature. Nearly all hospitals require the use of consent forms for inpatient procedures to comply with applicable law. This is done to abide by the standards of the Joint Commission on Accreditation of Health Care Organization,<sup>15</sup> and to facilitate patient education of the

treatment information. Proper informed consent is a process and not just a form. Forms can be challenged and criticized in the courtroom. A form containing errors, or one that is incomplete, can distract a jury from the real issues involving informed consent.

Claims of lack of informed consent are most successfully defended when a jury is persuaded that the physician had a meaningful conversation with the patient. In addition to a consent form, a chart notation made by the doctor, in the doctor's own words or handwriting, is usually very helpful. A jury that believes that the physician never saw the patient, or had a brief or cursory discussion with the patient, may become more inclined to decide that a surgeon departed from the standard of care in performing the procedure. Producing a diagram that was drawn for the patient to explain the procedure can be persuasive for jurors. Similarly, patient information sheets or pamphlets are effective communication devices and serve well in the litigation defense.

Listen carefully to your patients' questions. Answer questions in a friendly but candid manner. Note in the chart the presence of any family members who are present for the informed consent discussion.

Patients who are minors—usually those less than 18 years of age—may not normally consent for themselves. There are limited exceptions to that rule, e.g., patients who are living apart from their parents, or patients who are sufficiently mature to provide consent. Regardless of a minor's emancipation or maturity, it is wise to always obtain parental or custodial consent for elective procedures performed on minors. In addition to creating potential liability, the lack of parental or custodial consent for elective procedures involving a minor may result in the lack of a binding contract enabling you or the hospital to receive payment for services.

## Documentation

A patient's medical record is often the star witness in any medical malpractice lawsuit. The medical record is the one witness whose memory never fades. When you are involved in a lawsuit alleging medical malpractice, it can be your best friend, or it can be your worst enemy. Make it your best friend.

## Defensive Charting

"If it's not documented, it didn't happen." This adage serves as a good rule of thumb for all caregivers. Professional comprehensive charting conveys the appearance of professional and comprehensive care—not only to a jury but also to a plaintiff's attorney who is reviewing records and deciding whether or not to pursue a claim.

Chart notations need not contain overwhelming details to be helpful in the courtroom. A good defensive chart notation contains information that can deflect practical and obvious criticisms that may be made of the healthcare team or the

writer of the note. Examples of concepts to consider inserting, when applicable, include the following:

- Descriptions of bedside visits, especially when the physician has been paged multiple times
- When you were with the patient and what you did
- Your thought process and differential diagnosis
- Presence of family members
- "Patient states that she understands a change in bowel habits should be reported"
- "Patient refuses colonoscopy because . . ."
- "Patient not able to perform fecal occult blood test because . . ."

## Etiology Speculation

The charting of speculative opinions can be as damaging as charting too little information. Not uncommonly, one member of the medical team speculates as to the etiology of an adverse event, and the speculated etiology is adopted as fact by other members of the healthcare team.

Example: Physician undertakes a second-look laparotomy to rule out recurrence of cancer. During the procedure, the bladder and bowel are perforated, but the perforations are identified and repaired intraoperatively. A bowel leak, however, is detected 3 days later. A second-year resident records in the medical chart, "Iatrogenic perforation resulting in sepsis." This reference is repeated by two attendings on other services.

The perforation may have been iatrogenic or spontaneous. The unconfirmed presumption in the medical chart that the bowel leak occurred during the procedure, when repeated by others in the medical record, often becomes a "reality." That "reality" may become insurmountable in the courtroom, even when expert review leads to the opinion that the perforation, in retrospect, was clearly spontaneous.

Everything written in the medical chart is critical. Key phrasing and excerpts are often highlighted and/or enlarged onto exhibit boards for juries to see. Remember that causation is one of the four elements of medical malpractice, and it is frequently the most difficult of the four elements for the plaintiff to prove.

- **ALERT!**—*Iatrogenic* means "caused by manner or action of physician, not by medical treatment." Use this word only when you are sure it is applicable.

The law does not require that physicians always be correct in their decisions and treatment of patients. Rather, it requires reasonable and prudent care. A good chart notation will reflect a physician's attention and thought process, even if the diagnosis turns out to be incorrect.

## Plaintiff's Preclaim Review

Plaintiffs' attorneys are usually paid on a contingency fee basis, i.e., they receive a percentage of the amount recovered. Experienced plaintiffs' attorneys conduct a review of a

potential client's medical records before agreeing to file a lawsuit. Because most medical malpractice cases are tried before juries (as opposed to judges), attorneys representing patients look for flaws in medical record documentation that can be exploited at trial. For example, a physician's criticism of a colleague in a medical record is more desirable to showcase before a jury than complicated medical facts. Although differences of opinion are expected to occur occasionally, conflicts with colleagues that appear in the medical records are best limited to honest disagreements that are relevant to a patient's course of care.

Other items that attorneys and their reviewing physicians look for are missing laboratory reports, missing radiology interpretations, or the results of any tests or procedures that were ordered but not present in the chart. Multiple page attempts by the nursing staff that go unanswered are also fertile ground for review and focus.

Example: Elderly male patient with debilitating back pain underwent spinal surgery. He was taking anticoagulation medications because of a mechanical heart valve. Postoperatively he developed a hematoma at the base of the spine. In response to complaints of pain, he was seen three times by a house officer who did perform appropriate examinations but who neither stopped the patient's heparin nor ordered a magnetic resonance imaging. Permanent paralysis and urinary and sexual loss ensued.

A plaintiff's lawyer would be immediately drawn to nursing notes stating that multiple page attempts were made and that no corresponding notes were made by any physician responding to the pages. The attorney may immediately assume that he or she can prove in the courtroom one of the following potential scenarios: 1) no physician ever responded to the pages; 2) a physician did respond but the response was not timely; or 3) a physician responded but did not conduct a proper examination.

In this example, a comprehensive chart notation by the house officer, reflecting the thought processes and the extent of the examinations, may obviate a claim, a verdict, and tens of thousands of dollars in legal fees.

## Record Tampering and Deception

Improper alteration of the medical record is grounds for punitive damages and may result in loss of licensure. It should *never* be done. Postevent recording in a medical record should be done with proper disclosure of the timing and reason for the entry. Consider seeking the advice of risk-management personnel or legal counsel before making such an entry. Remember that your medical records are copied for multiple reasons, including insurance, compliance, and quality-review issues. Copies of any given patient's medical records may exist elsewhere, even at other healthcare facilities.

Plaintiffs' attorneys routinely request copies of the same medical records from multiple sources. This is done to ensure that all records are gathered, and to determine whether discrepancies exist among the various copies, e.g., a late entry on

one copy that does not appear on another copy. Color copying and expert document and handwriting analysis are techniques used to detect late or inappropriate entries. Evidence that a physician intentionally altered a medical record to lessen his or her own liability in a malpractice case is devastating and can rarely be overcome.

Similarly, evidence that a surgical error was known to the physician but concealed from the patient would almost certainly flame juror anger and result in a significant adverse verdict. Sponges, needles, and other "foreign objects" inadvertently left behind in the patient during surgery and later discovered by X-ray should be immediately disclosed to patients. The following 2003 Maryland case<sup>16</sup> illustrates this point.

The plaintiff, a 49-year-old married grocer, with a long history of uncontrolled diarrhea and stomach pain diagnosed as ulcerous colitis, presented to a colorectal surgeon for a total proctocolectomy with a temporary ileostomy. The surgeon performed ileostomy closure 90 days later, but the patient experienced a return of her uncontrolled diarrhea and stomach pain. She sought the advice of another physician, who discovered via colonoscopy that half of her rectum remained after the proctocolectomy. A new surgeon performed a second proctocolectomy and removed the remaining portion of the rectum, after which the patient made a full recovery. The plaintiff's attorney asserted that, although the first surgeon's medical notes indicated that he had incorrectly performed the procedure, the surgeon failed to so inform his patient. The defendant surgeon contended that it was an acceptable practice to leave half of the rectum. Plaintiff's medical expenses were \$51,438. After experts testified for both plaintiff and defendant, the jury deliberated for only 1.5 hours before returning a verdict for the woman and her husband in the amount of \$591,438. The award of such a significant sum on these facts in such a short time suggests that the jury was angered by the facts.

## Computerized Medical Records

Electronic medical records offer efficiencies and improved medical quality for the healthcare delivery system. All patient records, whether paper or electronic, are discoverable and admissible in medical malpractice lawsuits. Physicians who record entries in computerized medical records must become familiar with the use of electronic medical systems and should understand some dangers inherent in these computerized systems. For example:

- BEWARE drop-down menus and checklists
- BEWARE prefabricated medical descriptors
- BEWARE prefabricated informed consent notations
- BEWARE easy click-on techniques

Not all patient evaluations and regimens can be preformatted. There may be a natural tendency for caregivers to pick the "closest" option in a menu of options as opposed to creating their own text. Physicians should use "free text" whenever necessary and appropriate. It is easier to explain and defend

“your own words” in describing the care of a patient than the words of a computer programmer who has written a menu of typical patient diagnoses in drop-down menus or other coded formats.

## Communication

### Adverse Events, Bad News, and Apologies

When an untoward and/or unexpected event occurs involving a patient, communication is critical for quality care and for responding to later claims of malpractice. First and foremost, the patient’s medical needs must be promptly addressed. Coordination of ongoing care, including consultation and appropriate follow-up, is a critical first step.

As soon as practicable after the event, the patient and family should be informed of the event and its potential consequences to the patient. This communication should be respectful and sympathetic. The discussion should be preliminary to a more detailed conversation that should occur after more facts are available. Without assigning blame or criticizing other practitioners, the patient and family should be informed that the event occurred, the current and future consequences of the event to the patient, and what steps have been taken to address the patient’s medical condition. If the underlying causes for the event are not yet known, care should be taken not to speculate about those causes. The conversation is best handled by a physician well known to the patient and family, although circumstances may warrant placing others in that role. Questions should be honestly and factually answered. The patient and family should be told that additional information will be conveyed to them as it becomes known, and that a more thorough discussion will occur within a set period of time, ideally 24 hours.

It is usually advisable to contact a risk manager or in-house legal counsel, if applicable, when the critical incident occurs in an institution where such personnel are available. Depending on institutional policy, risk managers or quality management personnel frequently assist in the interactions with patients and family. They will also begin any appropriate administrative activity, such as initiating a sentinel event analysis, notifying an insurance carrier, sequestering medical devices or equipment, initiating an equipment analysis, and reporting device failures to the United States Food and Drug Administration (FDA). The administrative staff may also wish to convene a risk management and/or quality management review. Such reviews are typically protected from discovery in a lawsuit under applicable state privilege statutes. It is advisable for one member of the institutional team to be designated as the liaison with the patient and family so that consistent information is being delivered.

When additional facts are gathered and a better understanding of the event is known, a family meeting is advisable. Ideally the meeting should occur within 24 hours of the initial

discussion with the family. The spokesperson should lead the discussion. The patient’s attending physician, if not the spokesperson, should be present. The information known about the event, the anticipated medical consequences, and the prognosis for the patient should be discussed.

Physicians and institutions should be willing to express sympathy. An apology expressing sorrow that the patient experienced the event may be appropriate but should be carefully worded, e.g., “We are sorry you have experienced this complication.” In recent years, a number of prominent institutions have urged their physicians to say they are sorry for a patient mishap. One reason is that such apologies may deflect lawsuits. States such as Colorado, Oregon, and Ohio have even enacted legislation immunizing various forms of apologies from courtroom use.<sup>17</sup> Advice should be sought from institutional or local legal counsel regarding the wording of any apologetic statements.

At family meetings, the family members should have an opportunity to ask all of their questions. They should be provided with the name and contact information of someone to address additional questions that may arise later. The healthcare team should anticipate questions about reducing or eliminating medical bills and statements suggesting the possibility of a malpractice claim. Any questions about malpractice can be deferred at that point with the explanation that institutional legal counsel or an insurance representative will contact the family if desired. Keeping in touch with the patient and family spokesperson is critical during the next several days and weeks.

A senior member of the medical team, perhaps with the assistance of risk management and/or legal counsel, should be consulted in reviewing the chart and recording the events involving the untoward incident. Details of the event and the identity of personnel should be completely and accurately recorded. All discussions with the patient and family members after the incident should also be clearly described, including the identity of persons present at the family meetings and what was said.

Many patients and family members at this juncture are considering whether to seek the advice of a lawyer, and they may be urged to do so by friends and other family members. Care should be taken by all members of the healthcare team to provide a courteous, qualitative, and sympathetic continuity of care and interaction with family members. Physicians and other members of the healthcare team serve themselves and their patients well by using this time to provide as positive and supportive of an experience as possible for patients and family members.

### Electronic Mail

Because of the efficiencies associated with electronic mail (email) communication, many physicians communicate with both patients and other healthcare providers by using email. Special care should be taken when using email that contains patient-identifiable information.

Clinicians may communicate with other clinicians and patients by email. The Federal Health Insurance Portability and Accountability Act (HIPAA) of 1996<sup>18</sup> (discussed later) provides regulation for electronic transmission containing protected health information such as confidential medical information. HIPAA provides that healthcare providers have in place appropriate administrative, technical, and physical safeguards to protect the privacy of protected health information (PHI).<sup>19</sup> The HIPAA regulations do not provide a specific regulatory scheme for email communication, but they do require that providers have procedures that limit disclosures of PHI to the amount reasonably necessary to achieve the purposes of PHI disclosures.<sup>20</sup>

The Notice of Privacy Practices that providers give to their patients must explain in a separate statement that the provider may contact the patient to provide appointment reminders or information about treatment alternatives or other health-related benefits or services that may be of interest to the individual.<sup>21</sup> If this will be done by email, it is advisable to state that in the Notice of Privacy Practices.

You may wish to inform your patients that email transmission involves privacy and security issues that may be of interest to them. Patients may even be asked whether they wish you to communicate with them by email or not. Email that is sent to a patient's business may be intercepted by the patient's business colleagues, and emails can be inadvertently transmitted to unintended addressees. The Internet is not considered a secure medium for transmitting confidential data unless both parties use encryption technology. These types of warnings can be provided to patients who wish to communicate with their physicians by email.

It is advisable for physicians to keep either paper or electronic copies of emails to and from patients that are relevant to patient treatment. These email copies should be maintained in the patient's medical records just as traditional paper correspondence would be.

Physicians may wish to include a Confidentiality Notice that is preprinted at the bottom of email transmissions. A sample Confidentiality Notice appears below:

Confidentiality Notice: This email message including attachments, if any, is intended only for the person or entity to which it is addressed and may contain confidential and/or privileged material. Any unauthorized review, use, disclosure, or distribution is prohibited. If you are not the intended recipient, please contact the sender by reply email and destroy all copies of the original message. If you are the intended recipient, but do not wish to receive communications through this medium, please so advise the sender immediately.

## Health Insurance Portability and Accountability Act

HIPAA provides national privacy protection for patients. Administrative Regulations, encompassed in the Federal Privacy Rule<sup>22</sup> have been promulgated by the United States Department of Health and Human Services pursuant to

HIPAA. The Federal Privacy Rule establishes minimum privacy standards for healthcare providers, health plans, and healthcare clearing houses (referred to in HIPAA as "covered entities") to follow when using and disclosing patient-identifiable PHI that they create or maintain. Generally speaking, PHI is any information that is created (or received) and maintained by a covered entity related to the health or health care of a patient (or payment related to the health care) that directly or indirectly identifies the patient.<sup>23</sup>

The Federal Privacy Rule also requires compliance with state laws that afford greater privacy protections than HIPAA. Compliance with the Federal Privacy Rule was required on and after April 14, 2003. All covered entities must have policies and procedures in place that demonstrate compliance with the Federal Privacy Rule.

HIPAA provides that healthcare providers must make a good faith effort to give each patient a Notice of Privacy Practices that describes the privacy practices of the healthcare provider. Patients must be asked to acknowledge in writing that they have received this notice. Once a provider makes a good faith effort to provide a Notice of Privacy Practices to a patient and gets the patient's written acknowledgement of receipt of the notice, the healthcare provider may use and disclose PHI for reasons related to treatment of the patient, payment for the patient's health care, and the healthcare operations of the provider (TPO). Generally, physicians who are independent practitioners of the hospitals of which they practice are part of those hospitals' "organized health care arrangements," enabling the disclosure of PHI between the hospital personnel and the independently practicing physicians. To use or disclose PHI for reasons other than TPO or as otherwise permitted by law, a physician must obtain an additional written permission from the patient called an "authorization."<sup>24</sup> Clinical research, for example, is not considered "treatment" and usually must be separately approved by research subjects by signing an authorization. In many medical centers, authorizations for clinical research are integrated into the consent form approved by the institutional review board (IRB). The Federal Privacy Rule requires that authorizations contain certain elements.<sup>25</sup>

HIPAA permits treating physicians to disclose to a patient's family members, other relatives, close personal friends, and others identified by the patient any PHI that is directly relevant to such person's involvement with the patient's care or healthcare payments. Before making any of these disclosures, a physician should either obtain the patient's agreement to the disclosure or reasonably infer from the circumstances that the patient does not object.<sup>26</sup>

## Research and Innovative Surgery

### Research Versus Innovative practice

The emergence of evidence-based medicine has brought new challenges to the academic medical community. Surgeons and other physicians who serve as investigators in clinical trials

are very familiar with the review and approval process of IRBs—ethics committees established under federal law to oversee the conduct of research. Many disciplines, especially surgery, have evolved historically in an environment of unregulated innovation. It is often not clear when innovative therapy crosses the line into the research arena.

The Belmont Report<sup>27</sup> states that the distinction between research and practice is blurred and that both often occur together. Research is usually described in a formal protocol, and departures from standard practice are not necessarily “research.” The Belmont Report also states:

The fact that a procedure is “experimental,” in the sense of new, untested, or different, does not automatically place it in the category of research. Radically new procedures of this description should, however, be made the object of formal research at an early stage in order to determine whether they are safe and effective. Thus, it is the responsibility of medical practice committees, for example, to insist that a major innovation be incorporated into a formal research project.

Regulation of the practice of medicine has historically been the exclusive province of the state medical boards and other state regulatory authorities. When medical practice crosses the line into “research” involving “human subjects” or investigational drugs, devices, or other test articles, however, the activity becomes subject to the regulation of the federal Office for Human Research Protection (OHRP)<sup>28</sup> or the FDA.<sup>29</sup> “Research,” as regulated, is a systematic investigation, including research development, testing and evaluation, designed to develop or contribute to generalizable knowledge.<sup>30</sup> “Human subjects” are living individuals about whom an investigator conducting research obtains data through intervention or interaction with the individual or identifiable private information.<sup>31</sup> Traditional examples of research studies include prospective industry-sponsored files.

### Database Registries

In theory, physicians who engage in innovative treatment that does not involve a systematic design, a research protocol, a prospective intent to publish, or an investigational item are not regulated by either OHRP or FDA. Over the past decade, however, OHRP has expressed its view that the systematic collections of data performed off-chart, especially if published, may carry an implicit prospective intent and are considered research. These may include ongoing patient registries, including outcomes data; tissue banks; static databases, including ad hoc research from closed trials; and even retrospective studies, including chart reviews, if a prospective intent to publish was present.

In recent years, the OHRP has investigated a variety of innovative techniques to determine whether or not the activities should have been prospectively reviewed by an IRB as research. Examples are: 14 patients treated with fractionated stereotactic radiosurgery for treatment of large arteriovenous

malformations before IRB approval<sup>32</sup>; publication of a retrospective chart review that was conducted without IRB approval<sup>33</sup>; publication describing partial left ventriculectomies performed in the management of patients with dilated cardiomyopathy without IRB approval<sup>34</sup>; and fetal surgery procedures.<sup>35</sup> Many if not all of these scenarios involved publications that used research jargon and implied that a prospective research trial had been conducted (without IRB review and approval). In each of these investigations, OHRP suggested that the applicable institution consider the development of “innovative practice committees” or similar institutional vehicles to evaluate major innovative therapies. Physicians, especially surgeons experimenting with minor surgical modifications to accepted techniques, should use care when authoring articles about clinical experiences that did not involve “research” as defined above. When in doubt, physicians are encouraged to consult with their local IRBs for guidance.

### Promotional Prohibitions

Physicians who conduct FDA-regulated research are prohibited from representing in a promotional context that an investigational new drug, device, or other test article is safe or effective (or otherwise beneficial) before it has received regulatory approval.<sup>36</sup> Physicians should carefully review press releases and other promotional disclosures prepared by commercial sponsors or manufacturers before permitting their names to be associated with such test articles before approval.

### Insider Trading

If you are involved in clinical trials for pharmaceutical companies or biotechnology companies whose securities are publicly traded, you may have certain obligations to protect the confidentiality of sensitive information that you acquire. Your duties may stem from not only being a company officer or holding another fiduciary position, but also from being an investigator or from serving on company advisory committees such as scientific advisory boards, clinical trial steering committees, clinical trial executive committees, or data safety monitoring boards. The securities laws widely prohibit fraudulent activities of any kind in connection with the offer, purchase, or sale of securities.<sup>37</sup> The securities laws are the basis for different types of government enforcement activities, including investigation involving illegal insider trading. Insider trading is illegal when a person trades a security while in possession of material, nonpublic information, possibly including information from medical research trials, in violation of a duty to withhold the information or refrain from trading in that security. “Tipping” other traders of such information who then trade a security affected by the tip is also illegal. So is acting on an illegal tip.

## Conclusion

In recent years, the demands and pressures on physicians and surgeons have grown dramatically. Lawyer advertising and malpractice awards and settlements are greater than ever before. Web-based consumer awareness has increased the knowledge base of patients. Government regulation and enforcement activities have become more focused. Greater understanding and awareness of legal and risk management concerns is critical for healthcare practitioners facing these challenges.
